Abstract: Finger range of motion (ROM) is the amount of finger movement a person has, and is therefore a vital component of hand functionality. Therefore, assessing improvement in finger-ROM is valuable when evaluating the effectiveness of neurorehabilitation treatments in patients with hand paralysis. The goal of this study was to evaluate the accuracy and precision of a new, custom-built electrogoniometer compared to that of a standard goniometer. The custom-built electrogoniometer attaches to a finger and has three magnets and three Hall-effect sensors, each magnet-sensor pair positioned near each of the three finger joints. The Hall-effect sensors measure changes in magnetic fields as the finger extends and flexes. The changing magnetic fields are converted to changing voltage outputs, which are converted by software to joint angle values for the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints. To measure the accuracy and precision of the electrogoniometer, a hinged wooden dowel was set at a fixed angle, and the three sensors of the electrogoniometer were used to measure the angle 10 times, with removal and repositioning between measurements. The mean of the measured angles was within 0.2% (MCP), 4.3% (PIP), and 2.1% (DIP) of the set angle value, each less than the 5% typically considered the threshold for acceptance as accurate. The range of angles measured with the electrogoniometer was 3.7° (MCP), 3.6° (PIP), and 1.2° (DIP), all lower than those reported for the standard goniometer. The coefficients of variation of 2.3% (MCP), 2.1% (PIP), and 1.0% (DIP) were also less than the 2.4% (MCP), 2.9% (PIP), and 6.2% (DIP) measured with the standard goniometer. These data suggest that the custom-built electrogoniometer is accurate and has greater precision than a

standard goniometer. An additional advantage is that, unlike standard goniometers, the electrogoniometer can measure all three joint angles simultaneously and dynamically. Widespread availability of this device could improve assessment of finger range of motion in patients receiving neurorehabilitation for hand paralysis. Currently, we are creating procedures for manufacturing more electrogoniometers via 3D printing and determining their calibration arrays. After completion of this project, human studies to validate the reliability of the electrogoniometer is a next step.

Title: Somatosensory cortical excitability changes earlier in human motor learning than motor cortex excitability

Authors: *H. OHASHI[1], P. L. GRIBBLE[2], D. J. OSTRY[3];
[1]Haskins Labs. Inc, New Haven, CT; [2]Brain and Mind Inst., Western University, Canada, London, ON, Canada; [3]McGill Univ., Montreal, QC, Canada

Abstract: Motor learning is associated with plasticity of primary motor and somatosensory cortex. It is known from animal studies that tetanic stimulation to each of these areas individually induces long-term potentiation in the counterpart. In this context it is possible that changes in motor cortex play a causal role in somatosensory change and that changes in somatosensory cortex determine changes in motor areas of the brain. To better understand the relative contribution of motor cortical and somatosensory plasticity in humans, here we assess the time course of changes in primary somatosensory and motor cortex during a motor skill learning task. If motor learning is driven by motor cortical plasticity, changes in motor excitability should be seen early in learning, and those changes should predict behavioral improvement. In contrast, if somatosensory plasticity plays a predominant role in learning, then somatosensory excitability changes should be seen early in learning and should be related behavioral measures of skill acquisition. In the present study, learning was assessed using a force production task. The excitability of primary somatosensory cortex was measured using somatosensory evoked potentials in response to median nerve stimulation. The excitability of primary motor cortex was measured using motor evoked potentials elicited by single-pulse transcranial magnetic stimulation. These two measures were interleaved with blocks of motor learning trials. We found

that the earliest changes in cortical excitability during learning occurred in somatosensory cortical responses and these changes preceded changes in motor cortical excitability. Changes in somatosensory evoked potentials were correlated with behavioral measures of learning whereas changes in motor evoked potentials were not. These findings are consistent with the possibility that plasticity in somatosensory cortex drives early stages of motor learning.

Title: Transient and tonic grasp force signals in motor cortex

Authors: *B. DEKLEVA[1], K. M. QUICK[1], J. M. WEISS[1], J. E. DOWNEY[3], N. G. HATSOPOULOS[4], M. BONINGER[1], J. L. COLLINGER[2];

Abstract: The fundamental purpose of upper limb control is to interact with and manipulate objects. Integral to that function is the ability to generate and modulate the strength of grasp. As we develop brain-computer interfaces to restore arm and hand function lost due to spinal cord injury, amputation, or other neuromotor impairment, we must find ways to robustly decode grasp force. Simple, linear decoding methods have proven successful in allowing control of kinematic variables like reach velocity. However, decoding static sustained grasp force is difficult because many cortical signals are transient in nature. In order to obtain a reliable, consistent cortical signal that can be used to control grasp, we must understand the various types of transient and tonic cortical signals underlying grasp force control. We investigated these components by recording population activity from primary motor cortex (using microelectrode arrays) as a participant with tetraplegia observed and mimicked a variety of object interaction tasks in a virtual environment. While grasping a stationary object, cortical signals showed strong correlation with the attempted grasp force at all times (from pre-contact until object release). In tasks involving object carry, we observed signals related to force at grasp onset, but could not reliably distinguish grasp force throughout the remainder of the grasp. The only features consistent across all types of tasks were transient signals at the onset of grasp and at the time of object release. Based on these observations, we developed a novel, Kalman-filter-inspired grasp

force decoder that relies on transient neural activity. This architecture allows for maintained force output even if tonic signals related to grasp force are lost or diminished. During an online brain-computer interface grasp-and-carry task, the transient-based decoder significantly improved the participant's ability to: (1) achieve initial target grasp forces, and (2) maintain those forces throughout object transfer, compared to a standard Kalman filter approach. This improved decoder functionality demonstrates how an understanding of physiological phenomena can inform and improve BCI decoding.

Title: Interactions between hand force steadiness, tactile acuity, and perceived function in children with upper limb peripheral nerve injury

Authors: *R. N. LOGUE[1], R. E. BIALEK[1], C. S. MEYERSON[1], L. J.-S. YANG[2], S. H. BROWN[1];
[1]Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Neurosurg., Michigan Med., Ann Arbor, MI

Abstract: Hand force steadiness is a critical aspect when holding and manipulating objects, particularly at low force levels. However, standard clinical assessments of hand function typically involve measures of maximum grip and pinch force that are rarely used in everyday activities. While age-related impairments in force steadiness have been well documented (Ranganathan et al., 2001; Marmon et al., 2011), little is known regarding this aspect of hand function in clinical populations due, in part, to the lack of appropriate assessment techniques. This study aimed to determine the relationship between hand steadiness, tactile ability and activities of daily living in older children with conservatively treated upper limb peripheral nerve injury. Eight children with neonatal brachial plexus palsy (NBPP) (mean age: 12.25 y) and 11 age-matched controls (mean age: 12.0 y) participated in the study. Despite significant upper limb muscle weakness, all NBPP participants attended school and participated in community activities. Participants produced unilateral grasp forces equivalent to 5% of each individual's maximum voluntary force by squeezing a force transducer. Target and matching forces were displayed on a computer screen and participants were instructed to reach the target zone and

maintain the force for 3-4 sec. The task was repeated 4 times using the affected and the unaffected hands. Monofilament testing was used to measure tactile registration. A custom-designed spatial pattern device was used to assess tactile perception. Self-reported hand function was measured using the ABILHAND questionnaire. Affected hand steadiness was significantly worse in the NBPP compared to their unaffected hand ($p<0.01$) and the nondominant hand in the control group as evidenced by higher variability (coefficient of variation) scores ($p<0.01$). No between hand differences were observed in tactile registration. In contrast, the amount of processing time required to correctly identify tactile patterns was significantly greater in the affected hand compared to control values ($p<0.05$) despite similar levels of accuracy in both groups. Hand steadiness was predictive of self-reported hand function ($p<0.05$) and also correlated with the amount of time required to perceive tactile patterns ($p<0.05$). These findings of impaired force control in NBPP may reflect deficits in the central processing of hand-related sensory feedback that, in turn, impact self-reported function. Further, measures of hand steadiness may predict hand use in children with NBPP and underscore the need for more objective measures of motor and sensory function in upper limb peripheral nerve injury conditions.

Title: Functional cortical activation deficits during manual tasks in older adults with type II diabetes

Authors: *S. L. GORNIAK, A. HERNANDEZ, L. POLLONINI;
Univ. of Houston, Houston, TX

Abstract: The overall aim of this project was to evaluate the relationship between outcomes in manual sensorimotor behavior and cortical activation in older adults with Type II Diabetes (T2D). Our recent studies have shown that adults with T2D experience declines manual sensorimotor function that are not associated with a diagnosis of diabetic peripheral neuropathy; however, it is not clear if cortical deficits are responsible. Currently, no specific consistent structural deficits have been identified as a cause to motor deficits in persons with T2D. Twenty-one (21) community-dwelling T2D patients (age = 65 ± 6 years, A1c = 7.5 ± 1.1) and twenty-one

(21) age- and sex-matched healthy controls (age = 66 ± 6 years, A1c = 5.4 ± 0.3) were recruited and evaluated in this cross-sectional study (all females). Tactile detection and motor performance were evaluated while study participants donned cortical functional near-infrared spectroscopy devices (fNIRS) in one testing session. Tactile detection was evaluated via fingertip vibration; motor performance was evaluated by isometric pinch force production at two force levels using the thumb and index finger of the right hand. Bilateral cortical regions of interest (ROIs) included: PFC, SMA, M1, S1, and Brodmann area 40. Health state, metabolic (eg. glycated hemoglobin values, A_{1c}), and menopausal status data were collected. No differences in tactile function were found between the two groups. No between group ROI activation differences were found in the tactile stimulation task. Deficits in fine motor performance were found in the T2D group in both motor tasks ($p < 0.01$). Reduced HbO responses were found across all ROIs in the T2D group ($p < 0.05$) during performance of the lower force level motor task. Group-based ROI activations did not show significant differences during the high force production task. Performance and ROI activation differences in the T2D group in the low force motor task were not impacted by metabolic health state measures ($p > 0.2$). These data are the first to indicate functional cortical deficits in older adults with T2D, particularly in the performance of fine motor tasks. This suggests a potential combination of central and peripheral deficits leading to functional declines in older adults with T2D.

Title: Integrative properties and connectivity of brain sensory motor pathways in humans

Authors: *S. HSSAIN-KHALLADI[1], A. GIRON[2], C. HUNEAU[3], C. GITTON[4], D. SCHWARTZ[4], N. GEORGES[4], M. LE VAN QUYEN[2], G. MARRELEC[2], V. MARCHAND-PAUVERT[2];

Abstract: SEPs are used to evaluate the transmission in the sensory pathway at cortical level. In EEG and MEG, it is possible to collect SEP early (N20-P35) and late potentials (N60, P100). The aim of this project was to characterize the different components of SEP by characterizing the activation of brain areas based on source location and studying the relationship between sensory inputs and EEG/MEG signals (outputs), and by studying the connectivity of the cortical network. In this study, we were particularly interested in late SEP components because it has been hypothesized that they are less dependent on sensory inputs while they have been studied to a much lesser extent than early components. We collected SEPs in 19 healthy subjects by coupling multichannel EEG and MEG (74 channels for both) and we stimulated the median nerve at the wrist level at 4 intensities normalized to the intensity for perceptual threshold. Eye blinks artifact on the EEG time series were corrected using ICA. MEG time series were filtered from external noise and identified artefacts were corrected using PCA. Source reconstruction was calculated using the distributed model. We averaged the signals of all the subjects over 3 time windows corresponding to N20, N60 and P100, and for the 4 stimulation intensities. Then, we studied the link between the size of the 3 components and the stimulus intensity in different ROIs (S1, S2, M1, PM, SMA, PPC, areas 39-40, temporal and occipital lobes). For studying the functional connectivity, we used a Morlet wavelet analysis of the inter-region synchronization method to study the fast oscillation (500-1000 Hz) and those less than 200 Hz. Whatever the ROIs, the early component N20 increased with the stimulus intensity but not the late components. However, the spatial resolution was not good enough to evaluate the connectivity based on averaged SEPs only. Slow and fast oscillations were observed at the latency of both early and late components. The next step is to study the synchronization of these oscillations between the different ROIs for a better discrimination of the neural networks involved in sensory, cognitive and motor integrations at the cerebral level, underlying early and late SEP components, respectively dependent and independent of sensory inputs.

Title: A mixture of deafferented and intact digits' enrollment reveals motor inefficiency during moment-compensatory grasping tasks

Authors: *W. ZHANG[1], A. CARTERON[1], C. BENSON[2], B. HAHN[2];
[1]City Univ. of New York / CSI, Staten Island, NY; [2]Staten Island Univ. Hosp., Staten Island, NY

Abstract: Somatosensory feedback is essential in assisting human motor execution. Disturbed peripheral sensory inputs would interfere with the process of descending motor commands in both behavioral and synergetic control aspects. These observations in hand movement control lead to force control deficits, including reduced maximal force, altered force sharing patterns, weakened force covariation, and disturbed force synchronization. However, the question of how the disturbed and intact sensory inputs integrate and interact with each other to assist the motor program execution in moment control has not been studied. We recently developed a deafferentated hand model by using anesthesia on selective (not all) digits of the hand in order to simulate a redundant system with mixed-sensory motor elements.
The current study investigated the effects of selective digital deafferentation on moment control produced in grasp tasks as a function of object centers of mass (CM). Subjects performed same experimental tasks in two sessions: 1) anesthesia session, when somatosensory inputs were blocked via digital anesthesia in index, middle and the thumb of subject's right hand; and 2) control session, when digital sensation remained intact. Fourteen (7M, 7F) healthy, right handed, young adults participated in this study. Subjects were asked to lift and hold for 4 seconds a customized invert-T-shape device by using five digits while minimizing the object tilt. Object CM could be altered to: 1) the thumb's side (CM_T); 2) the center (CM_C); and 3) the fingers' side (CM_F). Subjects performed seventeen consecutive trials in each CM block, without pre-knowledge of the CM change. Five force/torque sensors (ATI nano) on sides and one position/orientation sensor (Polhemus) on the top of the device to record individual digit's kinetics and object kinematics.
After selective digital anesthesia, subject were capable to produce proper task-required compensatory moment to remain object orientation in anticipatory control phase (at object lift onset), but not in motor adaptation phase (during object hold). Despite subjects' strategic modulation on force and force sharing as a function of object CM, the removal of sensory feedback evoked significant moment production in both against and antagonist components that cancelled out each other. These findings indicate the mixture of sensory-blocked and -intact digits' enrollment post a larger challenge for the central nervous system when dealing with mixed sensory feedback inputs in a motor task adaptation. Given selective digital sensory deprivation, the resultant motor performance may be achieved with the cost of significant motor inefficiency.

Title: Combined brain and hand stimulation to improve hand movement after stroke, a pilot randomized trial

Authors: *A. SETHI[1], E. SANTARNECCHI[2], A. PASCUAL-LEONE[3];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Berenson-Allen Ctr. for Noninvasive Brain Stimulation, Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Ctr. Noninvasive Brain Stimulation, Beth Israel Deaconess Med. Cente, Boston, MA

Abstract: Eighty five percent of stroke survivors experience weakness of one upper extremity, which limits their ability to perform daily tasks. Currently there are no effective interventions to improve hand function in moderate-to-severe chronic stroke. Using the principles of neuroplasticity, we developed a novel intervention, which combines non-invasive brain stimulation with functional electrical hand stimulation for individuals with moderate-to-severe impairments. The purpose of this study was to investigate the feasibility of this intervention in individuals with chronic stroke. We assessed the preliminary efficacy of the intervention in 16 participants. All participants received a total of 18 treatment sessions three times a week for 6 weeks. Each treatment session lasted for 1.5 hours where participants practiced grasping and releasing meaningful objects with the functional electrical stimulation of the weak hand. Simultaneously, participants received 30 minutes of non-invasive brain stimulation via weak random noise currents to the affected primary motor cortex. Eight participants received real brain stimulation, while the rest received sham-brain stimulation. We assessed the preliminary efficacy of the intervention on Fugl Meyer Upper Extremity Subscale, which assess the voluntary control of the affected hand after stroke. The participants who received real brain stimulation showed significantly greater improvement in hand movement ($t = 1.9$; $p = .04$). Combined transcranial random-noise stimulation and functional electrical hand stimulation is feasible to administer in individuals with moderate-to-severe impairments after chronic stroke. The combined transcranial random-noise stimulation and functional electrical hand stimulation shows promise in improving affected hand movement in this population. Future studies are warranted to examine the efficacy of this intervention.

Title: Motor planning assessment during intraoperative functional mapping in glioma surgery

Authors: *J. J. SÁNCHEZ-DUEÑAS[1], A. B. SANDOVAL-BONILLA[2], F. DELGADO[3]; [1]Doctorado en Neurociencias de la Conducta, Univ. Nacional Autónoma De México UNAM, Ciudad de México, Mexico; [2]Unidad de Neurocirugía, Hosp. de Especialidades, CMN Siglo XXI, [3]Unidad de Resonancia Magnética, Hosp. de Oncología, CMN Siglo XXI, Inst. Mexicano del Seguro Social, Ciudad de México, Mexico

Abstract: The goal of the present study was to describe the assessment of complex motor processing in an intraoperative continuous task during awake surgery.
We report the case of an 18-years-old male patient with left low-grade glioma, who is a student of dance and scenic arts, he didn't experience cognitive and motor disturbance previous to surgery. MRI demonstrated a lesion that invades the primary motor cortex, supplementary motor cortex and white-matter fasciculi (pyramidal tract, superior longitudinal fasciculus and superior segment of arcuate fasciculus). Preoperative fMRI BOLD (finger-tapping task and foot ballet positions) and tractography were performed pre and post-surgically. Various motor areas were identified and confirmed by electrical cortical mapping during awake surgery. Were a hundred percent correspondence between localization of motor tasks fMRI BOLD signal and electrical cortical stimulation of inferior precentral gyrus (primary motor cortex), during monopolar electric stimulation in tumour exeresis were identified the pyramidal tract, superior longitudinal fasciculus and superior segment of the arcuate fasciculus. When motor or language performance exhibited a sudden interruption, aggressive motor contraction or language disorder were discontinued the extraction of tissue. Weren´t observed motor disorders or aphasia in the post-surgical outcome. We conclude that the implementation of functional techniques of neuroimaging and neuropsychological assessment for surgical planning, in addition to continuous task during awake surgery improve the long-term functional and cognitive outcome of patients with low-grade gliomas in the primary and supplementary motor cortex and white-matter bundles and contribute to a higher resection of the tumour.

Title: Touchpoints directed at 2D objects reveal medial axis sensitivity despite gross deficits in forced-choice shape discrimination: Evidence from visual form agnosia and cortical blindness

Authors: *R. L. WHITWELL, J. K. DUNKLE, J. T. ENNS;
Psychology, The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Object shape guides object recognition and object-directed actions like reaching and grasping. Classic work has shown that the in-flight kinematics of reach-to-grasp movements and their touchpoints express object shape information in individuals with compromised shape perception that followed damage to ventral-stream structures (e.g., Goodale et al. 1991). These studies constitute a cornerstone of the two visual systems hypothesis (Goodale & Milner, 1992) and its multi-visual-system descendants. Recent work with normally-sighted populations has shown that the freely chosen end points from point-to-touch movements directed at targets reveal the target-shape's medial axis, which is a metric that is specific to object shape. Here we ask whether or not this medial-axis phenomenon extends to exclusively dorsal-stream representations of shape, by testing DF, who has visual form agnosia resulting from lesions that encompass the shape-sensitive ventrolateral cortical area (LOC) bilaterally, and MC, who is cortically-blind following lesions that also encompass much of her occipital cortex bilaterally, including LOC. Each patient touched pebble-like shapes shown on a touchscreen in random positions and orientations. DF and MC could not reliably discriminate amongst the shapes in same/different, oddball, and 1-back tasks, confirming their deficits in visual shape perception. Nevertheless, both DF's and MC's touchpoints each fell significantly closer to the centre-of-mass and the medial axis than would be expected by chance alone. Moreover, the increase in their performance moving from forced-choice shape-discrimination to touchpoint selection fell significantly-beyond the distribution of differences expected from a sample of normally-sighted controls. In a second investigation in normally-sighted individuals, we show that reducing the duration of the shapes to 300ms significantly and dramatically reduces oddball-discrimination, yet only minimally influences touchpoint sensitivity to the medial axes of the shapes. Taken together, these findings strongly indicate that, in addition to centre-of-mass, other shape metrics such as the medial axis inform dorsal-stream mediated visually-guided movements.

Title: Assessing hand dexterity after stroke in 3D

Authors: *J. XU[1], S. KUMAR[1], K. OLDS[2], J. BROWN[3], J. CARDUCCI[3], A. FORRENCE[2], K. W. JOHN[2];
[1]The Malone Ctr. of Engin. in Healthcare, [2]Neurol., [3]Dept. of Mechanical Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: The dexterous hand control is the hallmark of human skill and intelligence. Among most stroke patients with hemiparesis, the loss of fine finger control and dexterity is often permanent, even after regaining a substantial amount of grip strength. In a recent longitudinal acute stroke recovery study, we found that hand dexterous control, measured by finger individuation in the direction of finger flexion, and its recovery are supported by a separate system than strength (Xu et al., 2017). However, traditional clinical assessments of dexterous hand function provide only holistic qualitative measures, and are often contaminated by strength and other behavioral compensation strategies. Here we assessed dexterous finger function in healthy participants and chronic stroke patients using a novel device that can sensitively tract isometric forces produced at all five fingertips simultaneously in 3D. Finger-joint individuation was measured for the metacarpophalangeal (MCP) and the proximal interphalangeal (PIP) joints for each finger with extension, flexion, abduction, and adduction. Two hand postures were tested: wrist pronation and neutral postures. Each participant's natural force trajectories were first assessed at all 6 directions in the 3D space. Participants were then instructed to isolate each individual finger-joint by pushing towards four different target force levels along their natural force paths, while keeping all the other fingers and joints immobile. Four target-force levels based on each subject's strength level up to 10 Newtons were tested. Our preliminary results showed superior independence of the thumb than the four fingers, flexion/extension than ab/adduction. In chronic stroke patients, thumb appears to be the most independent finger, and ab/adduction are the most impaired dimension. In addition, our data also show a compression of workspace for each finger after stroke, manifested as within-effector joint enslaving. In summary, our device and paradigm shows promise for assessing hand dexterity and its impairment in 3D, using fine-grained isometric force data.

Title: Forced-use therapy improves recovery of hand motor function after sensorimotor cortex lesions in macaca mulatta

Authors: *W. G. DARLING[1], M. A. PIZZIMENTI[2], D. L. ROTELLA[1], J. GE[3], K. S. STILWELL-MORECRAFT[4], R. J. MORECRAFT[5];
[1]Hlth. and Human Physiol., [2]Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA; [3]Basic Biomed. Sci., Univ. of Iowa, Vermillion, SD; [4]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD; [5]Basic Biomed. Sci., Univ. South Dakota Schl Med., Vermillion, SD

Abstract: Previously we showed that motor function of the preferred hand (contralesional/more affected hand) recovers to variable levels depending on lesion volume after unilateral injury to the arm/hand area of sensorimotor (frontoparietal) cortex (Darling et al. 2016 Exp Neurol 281:37). Following the injury, recovery was considered spontaneous as there was very limited motor testing of the preferred/contralesional hand weekly for 8 weeks, and then biweekly thereafter. Notably, this recovery occurred despite reductions in strength of the corticospinal projection from spared ipsilesional supplementary motor cortex (M2) (Morecraft et al. 2015 J Comp Neurol 523:669). We now test the hypothesis that forced-use therapy of the preferred hand can further improve recovery of hand fine motor function following sensorimotor cortex injury. Eight monkeys received unilateral lesions of arm/hand areas of M1, lateral premotor cortex, S1 and the rostral part of superior parietal lobule. Four monkeys recovered spontaneously and four monkeys received forced-use therapy of the preferred/contralesional hand beginning two weeks after the lesion. Therapy was provided three days/week using a device that allowed only the preferred/contralesional hand to successfully acquire small food objects without any constraint of the ipsilesional limb. On average, each animal successfully grasped and retrieved 400-450 small food treats during each rehabilitation session. Two motor skill testing devices were used in both groups that allowed testing of both hands for the duration of the post-lesion survival period (Morecraft et al. 2015). In addition, post-recovery hand preference was also computed based on 3 post-lesion learned nonuse (LNU) tests done near the end of the survival period and using a hand preference test in the cases receiving therapy. After recovery, in all spontaneous cases hand preference switched from the contralesional to the ipsilesional hand, whereas all forced-use therapy cases returned to the original (contralesional) hand preference. Furthermore, recovery of reach and manipulation skill was better in the forced-use therapy group but was quite variable in both groups perhaps due to variations in lesion size. These data show that spontaneous recovery after sensorimotor cortex lesions is variable, with the ipsilesional hand becoming preferred in tasks where the monkey could choose which hand to use. In contrast, forced-use therapy in monkeys with similar lesions produces good-excellent recovery and, notably, with return to the contralesional (more affected) hand being preferred in a fine motor task that allows the monkey choice of which hand to use.

Title: Assessment of hand motor function in a cynomolgus monkey model of ischemic stroke using endovascular transient middle cerebral artery occlusion

Authors: C.-Y. JEON[1], **J. WON**[1], K. KIM[1], J. SEO[1], H.-G. YEO[1], J. PARK[1], Y.-J. AHN[1], S.-R. LEE[1], K. YI[2], C.-H. CHOI[2], S.-H. CHA[2], *Y. LEE[1];

Abstract: Ischemic stroke occurs as a result of arterial occlusion and leads to irreversible brain injury. Upper extremity disability after stroke is the primary factor affecting activities of daily living in stroke patients. The aim of this study was to evaluate hand motor function in a non-human primate model of ischemic stroke.
A female cynomolgus macaques was used in this study. We performed magnetic resonance imaging (MRI) and evaluated hand motor performance using the hand dexterity task (HDT) to examine the pathophysiological and neurobehavioral alterations before and after middle cerebral artery occlusion (MCAO) to induce cerebral ischemia.
We found that the ischemic infarct expansion was progressively inhibited, which was consistent with the enhanced functional recovery of the affected hand over the course of 12 weeks after MCAO. We also observed that the total performance time decreased significantly with increasing success rate for both hands on the HDT. Interestingly, compensatory strategies and retrieval failure were improved in the acute post-stroke phase.
These results indicated that deficits in fine motor skills following ischemic stroke could be improved during the post-stroke period. Taken together, these finding provide a basis for the evaluation of hand motor function after ischemic stroke.

Title: Slow-conducting pyramidal tract neurons in macaque and rat

Authors: *A. KRASKOV[1], D. S. SOTEROPOULOS[3], I. S. GLOVER[3], R. N. LEMON[2], S. N. BAKER[3];
[1]Dept. of Clin. and Movement Neurosciences, [2]UCL Queen Square Inst. of Neurol., London, United Kingdom; [3]Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Anatomical and electrophysiological approaches to study the distribution of conduction velocities within the primate corticospinal tract have produced very contrasting accounts, known as the “corticospinal discrepancy”. While anatomical studies have emphasized the huge preponderance of fine fibres with diameters of 0.5-3 µm, recordings of antidromic responses evoked in pyramidal tract neurons (PTNs) by stimulation of the pyramidal tract (PT) are dominated by responses of neurons with short antidromic latencies (ADLs), indicating large, fast conducting axons. Slow conducting PTNs are likely to have thin axons and small cell bodies which suggests a number of possible explanations for the ‘corticospinal discrepancy’: (i) failure of PT stimuli to excite the finer PT axons; (ii) well-known bias of extracellular recording methods towards large neurons; (iii) failure to invade the soma-dendritic membrane; and (iv) recurrent synaptic inhibition of slow PTNs resulting from stimulation of fast corticospinal axons. We investigated these factors in the motor cortex of anaesthetised macaque monkeys (n=3) and rats (n=2), by searching for PTNs with long antidromic latencies, using a recording electrode with 32 closely-spaced contacts. We identified 21 rat PTNs with antidromic latencies of 2.6 to 14.6 ms, and 67 macaque PTNs ranging from 3.9 ms to 7.2 ms. Most PTNs had antidromic thresholds less than 300 µA; they had small spikes and were present on less than half of the recording contacts. In contrast, spikes from the largest, fastest-conducting PTNs were large and appeared on all contacts. Most slow PTNs showed no signs of failure of antidromic invasion. The impact of recurrent inhibition was tested using a number of approaches, including (i) changing anaesthetic depth, (ii) high intensity PT stimulation and (iii) cortical microinjection of bicuculline, a $GABA_A$ antagonist, to block inhibition pharmacologically. In no case did we find evidence that recurrent inhibition prevented antidromic invasion of slow PTNs.
Our results demonstrate that modern high-density silicon probes allow successful recordings

from slow PTNs, and suggest that electrode recording bias is the main reason why previous studies have been dominated by large, fast PTNs.

Title: Descending cortical pathways bidirectionally modulate forelimb tactile feedback in the cuneate nucleus

Authors: J. M. CONNER, ***A. S. BOHANNON**, D. J. BUTLER, E. AZIM;
Mol. Neurobio. Lab., Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: A critical challenge for the mammalian motor system is managing the intricate coordination of muscles in the arms and hands to interact with the world. Coordinated movement depends on constant interaction between feedforward neural circuits that produce motor output and feedback systems that report sensory consequences and external perturbations. Fundamental to this process are mechanisms for controlling how sensory information influences motor systems in a task-dependent manner - for example, attenuating feedback signals when disruptive and augmenting them when advantageous. While the precise mechanisms for modulating somatosensory feedback during voluntary movement remain largely unknown, it has been proposed that descending cortical systems play a central role in adjusting the strength of sensory signals, thereby regulating their influence on motor output. We are exploring how peripheral feedback is regulated at the level of the main cuneate, a brainstem nucleus that serves as a major conduit of ascending sensory information arising from the forelimbs and upper body. Leveraging viral and genetic tools in mice, we find that direct peripheral projections to cuneolemniscal neurons, which convey sensory signals to the neocortex via the thalamus, are primarily composed of tactile, as opposed to proprioceptive, afferents. Moreover, through a combination of anatomical and electrophysiological studies, we identify two discrete descending cortical pathways that target distinct components of cuneate circuitry - one consisting of corticospinal

collaterals that directly target cuneolemniscal neurons; and a second unique set of corticofugal collaterals that innervate inhibitory circuits in the cuneate shell, suppressing cuneolemniscal activity via feedforward inhibition. *In vivo* electrophysiology and behavioral studies are revealing the functional implications of descending modulation of tactile feedback for dexterous forelimb movement. Together, these findings identify distinct corticofugal pathways that exert bidirectional modulation of forelimb sensory gains, providing a potential circuit basis for filtering disruptive feedback while simultaneously enhancing the transmission of salient sensory signals during limb movement.

Title: Skill acquisition increases myelination and strengthens functional connectivity in the sensorimotor circuit of the adult rat

Authors: *C. SAMPAIO-BAPTISTA[1], A. DE WEIJER[1], A. VAN DER TOORN[2], W. M. OTTE[2], A. WINKLER[1], A. LAZARI[1], P. SALVAN[1], D. BANNERMAN[1], R. M. DIJKHUIZEN[2], H. JOHANSEN-BERG[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Utrecht Univ., Utrecht, Netherlands

Abstract: The effects of skill learning on whole-brain structure and functional networks has been extensively investigated in humans but has yet to be explored in rodents. Forelimb reaching training in rodents results in well-established focal functional and structural reorganization within the motor cortex and cerebellum, indicating distributed alterations in both structure and function. Here we trained adult rats in skilled reaching and used multimodal whole-brain *in vivo* MRI to assess both structural and functional plasticity over time. This approach allows us to interpret and integrate our results with both animal and human literature.
Adult rats (4 months old) were randomly assigned and trained either in the skilled reaching task (n=12) or in the unskilled version of the task (n=12) for 11 days. Caged controls were also used for comparison (n=12). All rats underwent *in vivo* MRI scanning on a 4.7 T system at baseline and after training. Magnetization transfer ratio (MTR), diffusion weighted and resting-state fMRI

were acquired. The FSL package (www.fmrib.ox.ac.uk/fsl) was used for data analysis. Voxel-wise analysis statistics were performed with non-parametric permutation testing, with a cluster-forming threshold of $t > 2$, and 5000 permutations were used to determine corrected p-values. Following motor learning, we found significant increases in MTR ($p < 0.05$, fully corrected), an indirect assessment of myelin content, in white matter tracts that primarily connect sensory and motor regions (Fig. 1A, B), as well as, within sensory cortical areas and to a lesser extent in the cerebellum (Fig. 1D, E). A trend towards increases in functional connectivity between motor cortex and cerebellum were also detected ($p = 0.09$, fully corrected, Fig. 1F). Both structural (Fig. 1C) and functional brain changes (Fig. 1G) correlated with task performance ($p < 0.05$, fully corrected). Skilled training therefore leads to myelin increases in pathways that connect sensorimotor regions, and in functional connectivity increases between areas involved in motor learning.

Title: Changes in neural population activity underlying the learning of novel arm dynamics

Authors: ***X. SUN**[1], D. J. O'SHEA[1], E. M. TRAUTMANN[1], M. D. GOLUB[2], S. VYAS[3], T. G. FISHER[1], S. RYU[4], K. V. SHENOY[5];

Abstract: The motor system can flexibly learn to produce skilled movements and may implement distinct strategies in different learning contexts. Changes in neural population activity that parallel behavioral learning have been studied under various learning contexts, such as visuomotor rotation, brain-computer interface learning, etc. However, most of these learning contexts do not necessitate generating novel patterns of muscle forces, and little is known about how neural population activity changes to facilitate learning when novel movement dynamics are required. Here, using a curl force field learning paradigm, we investigated neural population mechanisms for learning new movement dynamics and their relationship with behavioral generalization.
We trained rhesus monkeys to first reach to one of 12 targets, and then adapt to a curl field active only for one target. After monkeys adapted to the force field, reaches to untrained targets using an "error clamp" were interleaved with the adaptation trials. Monkeys displayed gradual behavioral adaptation to the force field, and this learning was generalized to adjacent targets, following a bell-shaped curve: newly learned hand forces were transferred to nearby untrained reaches. We recorded neural activity in PMd and M1 when monkeys performed the task using Utah arrays and Neuropixels probes. We found that preparatory and peri-movement neural activity displayed distinct and systematic changes to implement learning of new hand forces. During adaptation, preparatory neural states gradually shifted away from the "baseline repertoire" (the set of neural states for reaching to all targets pre-learning). The "after-learning repertoire" (the set of neural states for reaching to all targets in error clamp trials) was separated

from baseline repertoire. Surprisingly, this shift in preparatory states was observed preceeding reaches to both the trained and untrained targets, and therefore was a global change correlated with learning but not specific to the trained target. During learning, peri-movement neural states also shifted away from the baseline repertoire. In contrast with preparatory states, the shift in peri-movement neural states occurred immediately during learning and reflected the online feedback control of compensatory hand force. Peri-movement state shifts were local, and paralleled the bell-shaped behavioral generalization.
These findings begin to illustrate how systematic changes in neural population activity facilitate learning novel movement dynamics and how neural circuits learn to adapt activity patterns to changing task demands.

Title: Coordination between local and distributed population dynamics drives skilled motor behaviors

Authors: *K. DEROSIER[1,3], T. VEUTHEY[1,3], K. GANGULY[2,3];
[1]Neurosci. Grad. Program, [2]Neurol., Univ. of California San Francisco, San Francisco, CA;

Abstract: The connectivity pattern of mammalian cortex, characterized by dense local and sparse cross-area connections, suggests an important role for interactions between local population dynamics and population dynamics that coordinate across areas. Analysis of population dynamics in cortex has generally used methods that maximize variance within a single region before comparing these local dynamics to each other. However, such methods may

not be appropriate for analyzing coordination between regions. These methods may dismiss as noise fluctuations that represent cross-area population dynamics. Importantly, recent work shows that population activity in visual cortex contains a 'communication subspace' which captures variance distributed across areas (Semedo et al. 2019 Neuron). However, it is unknown whether such communication subspaces are relevant for behavior and learning. Here, we address this question in the motor cortical network, where local population dynamics are known to change with learning but cross-area population dynamics remain uncharacterized. This study aims to measure interactions between cross-area population dynamics and local population dynamics in primary motor (M1) and premotor (M2) cortex, and to assess the behavioral relevance of cross-area population dynamics during motor skill learning. We used multisite recordings in M1 and M2, along with computational modeling, to analyze how local and cross-area population dynamics interact during skilled reach learning (n=4 rats). We found that local activity patterns in each region were distinct from cross-area activity patterns throughout learning. Surprisingly, we found the correlation of cross-area dynamics did not change with learning, suggesting that changes in functional connectivity do not drive learning. However, emergence of high amplitude cross-area dynamics time-locked to behavior did coincide with learning, and cross-area activity amplitude was predictive of single-trial behavior. This supports a model where changes in the amplitude drive learning. Consistent with this, M2 inactivation via muscimol (n=3 animals) disrupted behavior and dampened M1 cross-area dynamics while maintaining the fundamental relationship between M1 population activity and behavior. Together, our results indicate that cross-area M1-M2 population dynamics are important for driving skilled movements, in part through their influence on local dynamics.

Title: Neuronal ensemble encoding bimanual motor coordination in mice

Authors: ***M. JEONG**[1], H. LEE[1], E. WANG[2], D. JANG[1], B. LIM[3], S.-B. PAIK[1], D. KIM[1]; [1]KAIST, Daejeon, Korea, Republic of; [2]UCSD, La jolla, CA; [3]Biol. Sci., UCSD, La Jolla, CA

Abstract: The use of forelimbs to manipulate objects is a behavioral trait widespread among many mammals. Though it is well known that each hemisphere of motor-related brain regions control movements of each side of forelimbs, how neurons are encoding action sequences to

move both forelimbs in a precise order remains still elusive. Here, we developed a bimanual press paradigm where mice learn to press left and right pedals via different forelimbs in a specific sequence for a reward. We confirmed that success rates continuously increased and the mice successfully learned the task during three weeks training. We expect to find out neural mechanisms of sequential bimanual coordination using this rodent behavioral model with calcium imaging, single unit recording, and optogenetics.

Title: Error signals in the red nucleus that drive adaptation in reaching: Comparison with errors in the cerebral cortices

Authors: *M. INOUE[1], S. KITAZAWA[2,3,4];
[1]Dept. of Neurolog. Diagnosis and Restoration, Grad. Sch. of Med., [2]Dynamic Brain Network Laboratoryu, Grad. Sch. of Frontier Biosci., [3]Dept. of Brain Physiology, Grad. Sch. of Med., Osaka Univ., Suita, Japan; [4]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technology, and Osaka Univ., Suita, Japan

Abstract: Errors in reaching could result from imperfect motor commands (motor error) or from target movements (target error). We have recently shown that motor error in the primary motor and the premotor cortices as well as in area 5 drives adaptation to compensate for the motor error, whereas target error in area 7 drives adaptation to compensate for the target error (Inoue et al., 2016; Inoue & Kitazawa 2018). The red nucleus (RN) receives inputs from many regions in the cerebral cortex and sends output to the climbing fibers of the cerebellar cortex via the inferior olivary nucleus. We thus aimed at testing whether the RN encodes motor and/or target errors and whether the errors are causally related to adaptation in reaching.To test this hypothesis, we recorded neuronal activities of RN while two monkeys made rapid reaching movement toward a visual target that appeared at a random location on a tangent screen. In one condition (prism condition) the motor error was augmented in a random direction by using a motor-driven prism device. In another (target-jump condition), the target jumped in a random direction to introduce

target errors. Of the 81 RN neurons we recorded, 12 RN neurons encoded motor error alone, 10 neurons encoded target error alone, and 13 neurons encoded both. Repetitive pairing of reaching movements with microstimulation to each recording site revealed that motor errors were compensated when the neuron of the stimulation site encoded motor error (n = 14). By contrast, target errors were compensated when the neuron of the stimulation encoded target error (n = 15). These results suggest that the RN provides signals for adapting to the target errors in addition to those for adapting to the motor errors.

Title: Investigating flexion synergies post-CST lesion in a NHP

Authors: *A. J. GOTT[1], S. N. BAKER[1], R. SHADMEHR[2], S. T. ALBERT[3], J. W. KRAKAUER[4];
[1]Newcastle Univ., Newcastle, United Kingdom; [2]Dept Biomed. Eng, Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD; [3]Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD; [4]Johns Hopkins Univ., Baltimore, MD

Abstract: Investigating changes in motor pathways following a motor cortical lesion (such as after a stroke) are important for understanding recovery post-injury. Whilst partial recovery of normal movement is commonly seen in stroke patients over time, some develop spasticity or synergies (an obligate co-contraction of muscles which are not agonists). The flexion synergy of the upper limb involves inappropriate elbow flexion produced during shoulder abduction; this has considerable impact on reach extent and range of movement. It is not clear why synergies develop, and to date no primate model of this phenomenon has been reported. In this preliminary study, we made objective measurements capable of detecting synergies in a monkey before and after a cortical ischaemic lesion. The single female rhesus macaque monkey was trained to perform a simple reach task with movement originating from 4 set positions for a small food reward. EMG activity from 11 muscles located in the arm and shoulder were recorded during performance of this task. Three synchronised video cameras captured the full range of movement at high frame rate, allowing subsequent kinematic analysis. After a period of capturing baseline data, an ischaemic lesion of the primary motor cortex was produced using injections of endothelial-1 over a period of 2 hours. The size and location of the lesion were confirmed using

MRI 7 days later. Beginning 2 days post-lesion, further recordings during reach task performance were made, and EMG and kinematic data were compared with the pre-lesion recordings. We found significant changes to EMG activity in many of the muscles beginning a week post-lesion, in patterns that were broadly consistent with post-stroke synergies seen in human patients. These preliminary data demonstrate the feasibility of generating a monkey model for the development of post-stroke synergies.

Title: A wireless operant behavior system for fine motor assessments in standard rack-mounted home cages

Authors: *A. M. SLOAN[1], C. A. SANCHEZ[2], D. K. BORN[1], C. A. THORN[3];
[1]Vulintus, Inc., Louisville, CO; [2]Dept. of Bioengineering, [3]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Current methods for longitudinally assessing skilled motor function in aging rodent models are labor intensive and time-consuming to administer frequently over long timescales. The proliferation of new rodent genetic models for motor diseases in which age is a primary risk factor adds new urgency to the need to develop more efficient methods for phenotyping motor function. We report the development of 'OmniHome', a wireless, battery-powered operant behavior system designed for unsupervised administration of skilled motor testing in standard, unmodified rack-mount home cages. Initial validation testing of 'OmniHome' tracked behavioral performance of PARK/DJ-1 knockout rats and aged-matched wild-type controls on an isometric pull task conducted semi-continuously in the animals' home cages over 4+ months.

Title: A 3 dof pneumatically-actuated robotic system for complex reaching tasks in rodents compatible with electrophysiology

Authors: *B. J. GEREKE[1], B. R. NELSON[3], K. E. BOUCHARD[2];
[2]Biol. Systems and Engin., [1]Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Neurosci., Univ. of California Berkeley, Berkeley, CA

Abstract: Reaching and interacting with objects are complex behaviors that require precise coordination of effectors comprised of many degrees of freedom (i.e., shoulder, elbow, wrist and finger joints). How broadly distributed brain circuits organize such precisely coordinated behaviors is poorly understood. The use of complex tasks (e.g., center-out reaching) in non-human primates (NHPs) has led to important advancements in identifying the neural correlates of sensorimotor planning, execution, and adaptation. Despite these successes, NHPs have limitations in terms of data throughput and amenability to many neuroscientific tools. Thus, there has been a movement in recent years to develop behavioral tasks for rodents comparable to those studied in NHPs. Most current rodent forelimb motor tasks are limited to simple pushing/pulling of levers/joysticks, or to reaching for food pellets. Such tasks lack either directionality or the option to dynamically perturb movements, require excessive training or experimenter intervention, and/or are incompatible with electrophysiological and imaging tools. Here, we describe a novel directional reaching task for rodents which overcomes many of these limitations. We developed a three dof pneumatically-actuated robot that is able to precisely position handles of various shapes and sizes in front of either freely-moving, or head-restrained rats. We demonstrate that rats rapidly learn to reach toward, grasp, and pull the handle to their mouths for liquid reward. The task is fully automated, and rats are able to learn the behavior and perform a large number of trials even within a single session. Reaches are detected in real-time and selectively recorded by multiple synchronized high-speed cameras. This allows for the potential to track joint kinematics using multiview markerless 3D pose estimation approaches. Licking is detected by IR beam break which ensures compatibility with electrophysiology. The use of pneumatics allows the stiffness of the system to be controlled and enables fast perturbations of variable magnitude/duration to be applied to the handle in different directions and points along the reach trajectory. The entire system is cheap, built from off-the-shelf and 3D

printed parts, and multiple systems can be housed in a single room. These features combine the richness of a primate behavioral task with the methodological amenability and high-throughput advantages of rodents. It is anticipated that this combination will enable questions related to sensorimotor processing, planning, adaptation and decision-making to be studied at a new level of detail that is currently more difficult to achieve in primates.

Title: Exploring the necessity of dopamine in vagus nerve stimulation induced motor map expansion

Authors: *J. BROUGHER, C. A. THORN;
Univ. of Texas At Dallas, Richardson, TX

Abstract: Vagus Nerve Stimulation (VNS) is capable of inducing plasticity in the motor cortex (M1), which can be measured through increased cortical map representation of specific motor movements. VNS's pro-plasticity mechanisms are not well understood, though it is known to require the release of neuromodulators, including norepinephrine and acetylcholine. Dopaminergic enervation of M1 has been shown to be necessary for skill acquisition at the behavioral level and dendritic spine growth at the molecular level, suggesting that dopamine (DA) may be also be critical for many forms of M1 plasticity. We therefore wished to determine whether DA is required for VNS-induced map expansion to occur. To do so we selectively eliminated DA projections to M1 using 6-OHDA lesions to the forelimb motor area. Animals subsequently underwent a VNS-paired training paradigm known to result in motor map expansion. Male and female adult Long-Evans rats were trained to stable proficiency on a lever-pressing task requiring skilled forelimb reaching. Rats were then implanted with a vagus nerve cuff electrode around the left vagus nerve in the neck and received 6-OHDA (or vehicle) infusions in M1 to lesion M1-projecting DA cells. Following recovery from surgery, rats received 10 additional behavioral training sessions in which VNS (or sham stimulation) was paired with correct lever press performance (4 groups; n = 12 per group). Animals were excluded if they failed to reach at least 700 total stimulations across all 10 sessions. After the final behavioral session, animals were anesthetized and intracranial microstimulation was performed to quantify the motor map representations in M1. Experiments were performed blinded to drug

treatment condition. Histological analysis was performed to verify DA lesions. Data were analyzed for sex differences. Preliminary data from these studies suggests that DA may not be required for VNS-induced map expansion to occur. If confirmed, these results could indicate that VNS may engage a different set of pro-plasticity mechanisms in M1 than natural skill learning. These studies provide insight into the role of neuromodulator signaling in multiple forms of cortical plasticty.

Title: Noradrenergic alpha-2 receptor antagonism inhibits vagus nerve stimulation dependent enhancement of motor cortical plasticity

Authors: *C.-T. TSENG, S. J. GAULDING, C. A. THORN;
Cognition and Neurosci., Univ. of Texas At Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) paired with rehabilitation training can induce specific plasticity in motor cortex (M1) and restore the motor functions following stroke. In rats, it is known that VNS paired with skilled forelimb training results in the expansion of motor representations of the trained limb in M1; however, the mechanisms underlying VNS-induced cortical plasticity remain unclear. Previous studies demonstrate that VNS drives phasic firing of the locus coeruleus, and selective lesions to the noradrenergic neurons enervating M1 block VNS-induced map expansion. These previous studies suggest that local noradrenergic neuromodulation may be required for VNS-dependent plasticity. In particular, alpha-2 noradrenergic receptor (α2-AR) activation has been shown to inhibit HCN channels in rat prefrontal pyramidal cells, leading to enhanced dendritic integration and synaptic plasticity. In this study, we test the hypothesis that α2-AR activation is required for VNS dependent reorganization of rat motor cortex by locally infusing yohimbine (YOH), a selective α2-AR antagonist, into M1 while rats receive VNS paired with training. We further ask whether direct blockade of HCN channels with ZD7288 can rescue VNS-dependent plasticity in M1 in the presence of α2-AR antagonism. In these experiments, 35 male and 35 female Sprague Dawley rats were trained to perform a lever pressing task that requires skilled forelimb reaching. Once stable proficiency on the task was reached rats were implanted with VNS cuff electrodes and intracranial cannula targeting the forelimb area of M1. After recovery from surgery, rats

underwent 10 sessions of training in which VNS, or sham stimulation, was paired with each correct lever press. YOH, ZD7288, or vehicle, were locally infused into M1 30 minutes prior to each training session. After the final session, intracortical microstimulation was used to quantify motor map representations in M1. All experiments were performed by personnel blinded to the treatment conditions, and data were analyzed for sex differences. Preliminary results from these studies indicate that inactivation of α2-AR with YOH prevents VNS-induced motor map expansion in both male and female rats. Data from ongoing experiments in which ZD7288 was co-administered with YOH are suggestive of a trend toward the ability of HCN channel blockade to partially restore VNS-dependent plasticity. By investigating the involvement of α2-AR-mediated inhibition of HCN channel signaling during VNS dependent motor map expansion, the results of these studies provide novel insight into the neuromodulatory mechanisms underlying VNS-mediated cortical plasticity.

Title: Selective gating of dynamical modes in a thalamo-cortical system

Authors: *J. JARAMILLO[1], K. SVOBODA[2], X.-J. WANG[1,3];
[1]New York Univ. Ctr. for Neural Sci., New York, NY; [2]HHMI / Janelia Farm Res. Campus, Ashburn, VA; [3]Shanghai Res. Ctr. for Brain Sci. and Brain-Inspired Intelligence, Shanghai, China

Abstract: The brain is often portrayed as a complex system of discrete interacting components, but it is not known how the brain exploits such a distributed and dynamic architecture. For example, there is mounting evidence for the involvement of subcortical structures in cognitive processes that were typically attributed to the cortex alone, but whether and how subcortical structures modulate cortical computations relevant for cognitive processes remains unclear. A notable function of several thalamic nuclei is to convey information to the cortex from subcortical structures such as the cerebellum and basal ganglia. In this modeling study we propose a circuit mechanism by which these subcortical structures, indirectly via the thalamus, modulate cortical dynamics. We put forward a circuit model of thalamo-cortical interactions that is constrained structurally by tracing and *in vitro* studies and functionally by multisite recordings in the mouse during a two-alternative forced choice task. In our model, a cortical area consists of

a set of coupled excitatory and inhibitory neural populations that exhibit low-dimensional dynamics, here referred to as “dynamical modes”. In the context of delayed two-alternative forced choice tasks, some of these cortical modes are functionally relevant: a ramping mode is related to winner-take-all processes involved in decision making while a stimulus-absent persistent mode is related to short-term memory maintenance. We contend that thalamo-cortical projections induce a reconfiguration of the cortical network, effectively changing its dynamical landscape. As a consequence, some cortical dynamical modes will be amplified or modified while others will be suppressed, a dynamical process we refer to as ‘thalamic gating of dynamical modes’. We explored how thalamo-cortical connectivity and the input current to the thalamus - corresponding to external stimulation or to salient subcortical structures such as the cerebellum and basal ganglia - influence such thalamic gating. Our simulation results suggest a distributed dynamical organization whereby subcortical nodes induce a reconfiguration of the cortical network that allows distinct cortical output modes to flexibly control behavior.

Title: Analysis of neural representations of movement and internal states by video-based prediction in a short-term memory task

Authors: Z. WANG[1], D. LIU[2], S. CHEN[3], K. SVOBODA[4], N. LI[5], *S. DRUCKMANN[1]; [1]Stanford Univ., Stanford, CA; [2]Janelia Res. Campus, Ashburn, VA; [3]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [4]HHMI / Janelia Farm Res. Campus, Ashburn, VA; [5]Baylor Col. of Med., Houston, TX

Abstract: A key question in systems neuroscience is understanding neural representations in cognitive tasks. These tasks are typically considered in terms of abstract cognitive performance, yet it is known that animals may associate particular postures or movements with different task features such as different choices in an alternative-choice-task. More generally, cognitive and emotional states are associated with typical movements, e.g., pacing when nervous, creating a difficulty in assignment of neural representation to the internal state or the movement. Understanding the neural representations underlying internal states stands to benefit from a richer understanding of how posture and movements during cognitive tasks relate to neural representations.

We trained artificial neural networks to predict animal behavior and single-neuron spike rates in multiple brain areas from videos of mice performing a short-term memory task. Mice were trained to discriminate a sensory stimulus into one of two categories, hold this discrimination in memory for a few seconds and then report its identity by two different actions (lick-left or lick-right). High-speed (300 Hz) multi-view video of the face and paws of the mouse was acquired together with extracellular recordings using 2-4 Neuropixels probes. We were able to accurately (90 %) predict upcoming actions from videos taken during the stimulus presentation epoch or memory epoch. Generalization to mice not present in the dataset was also possible, though accuracy was improved by adding a session of data from the mouse to be predicted into the dataset. We were also able to predict a substantial proportion of variability in single-trial spike rate from videos, well beyond what is predictable from trial-averaged activity (PSTHs). Predictability varied considerably across neurons, from no predictability to above 90 %. Areas more associated with motor control (e.g. the medulla for facial movements), had higher single-trial explained variance than areas related to motor preparation (e.g. Anterior Lateral Motor cortex). We compare the performance from video-based prediction to prediction from static images and from tracked facial features (using DeepLabCut), and found that prediction based on raw video was more accurate.
Finally, the main disadvantage of using artificial neuron networks are the well-known difficulties in interpreting the source of the information they use to solve the task they were trained to perform. We employed multiple visualization techniques to understand the factors driving behavioral and neural predictability.

Title: Mesoscale analysis of motor planning and movement initiation across multiple brain regions

Authors: ***L. D. LIU**[1,2], S. CHEN[2,3], A. WANG[4], M. N. ECONOMO[2,5], T. WANG[2], X.-J. WANG[6], S. DRUCKMANN[4], K. SVOBODA[2], N. LI[1];

Abstract: Movement planning is reflected in neuronal activity across multiple brain regions seconds before movements occur (Svoboda & Li, CONB 2018). The dynamics of multi-regional circuits gives insight into the mechanisms of motor planning and the initiation of movement. Recent advances in large-scale electrophysiology (e.g. Neuropixels probes) provide the opportunity for simultaneous recordings of neuronal activity across multiple brain regions. We used two to four Neuropixels probes to record from up to a dozen brain areas simultaneously. Our goal is to produce comprehensive, whole brain 'activity maps' for mice during decision-making, motor planning and movement initiation.

Head-restrained mice performed a delayed-response task. Mice make a sensory discrimination, followed by a delay epoch during which they plan a directional lick movement, and then followed by a response epoch during which they execute the movement. We have previously identified the anterior lateral motor cortex (ALM) as a region critical for motor planning and movement initiation. Based on anatomy, we targeted brain areas that form multi-regional networks with ALM for electrophysiological recordings. Each electrode track was recovered and imaged in three dimensions. Individual electrode sites were mapped into a standardized brain atlas based on the imaging data and electrophysiological measurements.

We present data from ALM and connected areas in the thalamus, basal ganglia, superior colliculus, cerebellum, and medulla. Neural activity in ALM encodes the behavioral choice long before movements, whereas activity in the medulla in addition correlates with jaw, tongue and other facial movements with millisecond time-scale precision. Encoding models based on facial movements could explain variance in neural activity (see also accompanying poster by Wang et al), but the encoding is much more precise for medulla activity compared to ALM activity. During the delay epoch, a subpopulation of medulla neurons showed rhythmic activity in phase with future tongue movements at 7-10 Hz; other neurons exhibited ramping activity that collapsed just before tongue movement onset. These measurements suggest that medulla orofacial central pattern generators are already engaged during the delay epoch and under active inhibition (similar to a mechanical clutch). These experiments reveal detailed multi-regional neuronal dynamics underlying movement planning and initiation.

Title: Attractor dynamics gate cortical information flow during decision-making

Authors: *A. FINKELSTEIN[1], L. FONTOLAN[1], M. N. ECONOMO[1], N. LI[1,2], S. ROMANI[1], K. SVOBODA[1];
[1]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [2]Deparment of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Perceptual decision-making involves information flow from sensory to motor areas. When sensation and action are separated in time, the chosen course of action should be robustly represented in memory until movement execution, while also being flexible in case additional relevant sensory information becomes available. If and how communication between sensory and motor areas is dynamically gated remains unknown. We trained mice to report detection of stimuli with directional licking, following a brief delay epoch separating sensation and action. To precisely control activity in the sensory cortex, we used direct photostimulation of genetically defined neurons in the vibrissal somatosensory cortex (vS1) as a 'sensory stimulus'. We found that stimuli biased future actions only when presented during early, but not late, stages of decision-making - suggesting temporal gating of incoming information from the sensory cortex. Neurons in the anterior lateral motor cortex (ALM) - a crucial node in the decision-making circuit that controls directional-licking - showed preparatory activity that predicted the upcoming movement, similar to behaviors with natural sensory stimuli (Svoboda, Li 2018). Stimuli caused similar transient neural responses throughout the sample and delay epochs in both vS1 and ALM, implying that sensory information was not gated in vS1 or on its way to ALM. Instead, gating occurred at the level of ALM dynamics: Preparatory activity in ALM became progressively more robust to incoming stimuli, and this robustness increased with additional behavioral training. To investigate how robustness of preparatory activity results in gating we trained recurrent neural networks (RNNs) to reproduce the heterogeneous neuronal activity patterns recorded in ALM (Rajan et al 2016). Remarkably, RNN dynamics predicted the temporal gating observed in the data, even though the network was trained only with early stimuli. Analysis of RNN dynamics revealed that our results are consistent with a discrete attractor model. In this model a non-selective external ramping input gradually separates the two basins of attraction corresponding to alternative motor plans, resulting in increase of robustness of the selected motor plan. Taken together our results demonstrate a mechanism for temporal gating of cortical information flow during decision-making that allows early flexibility and late robustness of the motor plan.

Title: A new interpretation of visual cortical areas in mice

Authors: *M. HU[1], R. V. RIKHYE[2], M. GOARD[3], M. G. M. KUMAR[4], H. MURTHY[4], M. SUR[1];
[1]Picower Inst. for Learning and Memory, Cambridge, MA; [2]Vicarious AI, San Francisco, CA; [3]Molecular, Cell. and Developmental Biol. / Psychological & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA; [4]Indian Inst. of Technol., Madras, India

Abstract: Much like other mammals, mouse visual cortex is composed of multiple areas, each containing a separate representation of the visual field. Early studies (Caviness, 1975; Drager, 1975; Wagor, Mangini and Pearlman, 1980) found that the region lateral to V1 contains at least two complete representations, labeled V2 and V3, whereas the region medial to V1 contains two partial representations, labeled Vm-r (medial rostral region) and Vm-c (medial caudal region) respectively. Subsequent work (Kalatsky and Stryker, 2003; Wang and Burkhalter, 2007; Marshel et al., 2011; Garrett et al., 2014; Zhuang et al., 2017; Waters et al., 2019) reported a number of extrastriate areas lateral and medial to V1. The sizes of these extrastriate areas are much smaller and more variable than V1. In an attempt to reconcile these studies, we used wide-field and single-cell calcium imaging from awake, head-fixed mice, which transgenically expressed GCaMP6f, to functionally segment the entire visual cortex. We further characterized the responses of neurons within each segmented area to drifting gratings and natural scene movies. Our key observations are two-fold. First, the lateral regions align closely with consistent features of extrastriate visual cortex in other species. Specifically, RL and LM together constitute a single and complete representation, consistent with its potential function as a second tier representation along the extrastriate pathway (V2), whereas AL functions as a third tier representation (V3). The regions within AL, RL/LM and V1 that represent the central visual field are organized closely next to each other in a narrow band which resembles the ‘foveal confluence’ (Zeki 1969; Newsome et al., 1986; Maunsell and van Essen, 1987; Gattass et al., 1988, 2005; Tootell et al., 1998; Schira et al., 2009, 2010) described in other species. These interpretations are strongly supported by the shared vertical meridian border between V1 and RL+LM, and the split representation of the horizontal meridian at the lateral border of RL+LM, including with AL. Second, the two medial areas (AM, PM) align closely with distal visual cortex (prostriata) recently described in marmosets (Yu et al., 2012) and humans (Mikellidou et

al., 2017; Tamietto & Leopold, 2018), and they similarly share a peripheral visual field border with V1. We propose a framework of mouse visual cortex organization that follows the same global principles of visual cortex maps in other species, with variations in local layout that possibly reflect the ecological adaption of vision in these species.

Title: Involvement of the locus coeruleus network in an attention-demanding sensory discrimination task

Authors: *V. BRETON-PROVENCHER, M. SUR;
Brain and Cognitive Sciences, Picower Inst. For Learning and Memory, MIT, Cambridge, MA

Abstract: Speed and accuracy on tasks involving high levels of uncertainty depend on arousal and attention. For example, driving during a downpour requires heightened attention compared to driving during a sunny day. Recent human and theoretical studies have described a link between uncertainty, arousal, and locus coeruleus (LC) activity. However, due to limitations of causal interrogation of brain function in these studies, how behavioral uncertainty may recruit the LC neuronal network remains unclear. Furthermore, while this recruitment implies regulation of noradrenaline (NA), the neuronal substrates of such a process are unknown. Here we used an attention-demanding task in head-fixed awake mice to assess the role of LC circuits in decisions during high uncertainty. We have used a go/no-go auditory discrimination task in which the mouse must quickly decide to enact or withhold a lever press after hearing a tone to obtain a reward or avoid a punishment. To introduce uncertainty and increase attentional demand, we vary the intensity and the timing of the auditory cues. Direct recordings of LC-NA neurons using phototagging display a high level of modulation of LC-NA spiking activity to specific task epochs. NA activity increases rapidly following the presentation of the tone during correct responses on ‘go’ trials, or after the delivery of reinforcements for both ‘go’ and ‘no-go’ trials. The level of uncertainty, with respect to the identity of the auditory stimulus, scales this response of NA neurons. We are now investigating the involvement of inhibitory neurons of the LC network, the LC-GABA neurons, in the behavior using phototagging. We are also silencing the

activity of LC-NA or LC-GABA neurons using archaerhodopsin targeted at each population, to evaluate the causal contribution of the different components of the LC network for task execution. Collectively, our results indicate that decision-making during high levels of uncertainty recruits NA activity.

Title: Prefrontal cortex-superior colliculus interactions during visually guided decision-making

Authors: R. HUDA, ***K. G. CRUZ**, A. SULLINS, M. SUR;
Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Perceptual decision-making requires mechanisms for promoting and inhibiting specific choices in accordance with task goals. The prefrontal cortex has long been implicated in guiding goal-oriented choices by generating control signals and selectively modulating the activity of downstream target structures. A similarly large body of work also ascribes an important role for midbrain circuits in choice selection and execution. Yet, how prefrontal and midbrain circuits interact to facilitate goal-oriented choices remains unresolved.
To address this question, we developed a two-alternative forced choice visual decision making task in which head-fixed mice report the spatial location of a target stimulus while suppressing responses to simultaneously presented distractor cues. Mice learn this task well and perform hundreds of trials per session, allowing us to construct high-quality psychometric functions. Our previous work, in combination with other recent studies, suggests that a subdivision of the mouse prefrontal cortex, the anterior cingulate cortex (ACC), is a crucial anatomical node for coordinating visually-guided behavior. Our anatomical studies show that the ACC provides direct top-down inputs to the superior colliculus (SC). We are defining the function of ACC-superior colliculus interactions using a combination of areal and projection-specific optogenetic manipulations during behavior. Results to date suggest that the ACC and SC play opposing, but complementary functional roles in the task. Targeted projection-specific inactivations suggest that the ACC exerts top-down inhibitory control over the SC. We are currently using two-photon calcium imaging to assess the physiological responses of ACC neurons that target the SC and

determine their specific role in the decision-making process. Overall, our work suggests that the prefrontal cortex exerts top-down inhibitory control over midbrain circuits to facilitate goal-oriented choices.

Title: Dynamic control of visually-guided locomotion through cortico-subthalamic projections

Authors: *E. M. ADAM, T. JOHNS, M. SUR;
Picower Inst. For Learning and Memory, MIT, Cambridge, MA

Abstract: Voluntary movement is fundamental as our means to act upon the world. We are interested in how the brain controls actions aligned with an organism's behavioral goals. We developed a behavioral task where mice run on a treadmill through a virtual runway and stop at visual landmarks to collect reward. The task enables a voluntary on-off visually guided locomotion pattern, constructed of sudden initiations and sudden halts. Where do control signals enabling such a pattern emanate from and how are they processed to control locomotion? Extracellular recordings in the mesencephalic locomotor region (MLR) reveal neural activity tuned to that locomotion pattern. The visually guided nature of the task further implicates cortical control, hypothesized to be over MLR. Such a control can however only be indirect, as there are no significant projections from cortex to MLR. We find that prefrontal cortex (PFC) projections to subthalamic regions (specifically the subthalamic nucleus and zona incerta) mediate stop commands, thereby posing the region as a direct controller onto MLR. Through a combination of simultaneous in-vivo extracellular recordings of PFC and MLR, calcium imaging of PFC projection neurons, axonal optogenetic manipulations in subthalamic regions, and targeted recordings of identified subthalamic neurons, all in behaving animals, we are reconstructing the dynamical nature of the control mechanism and the neural circuitry by which it is implemented.

Title: Modulation of neuronal coding by astrocytes during motor learning

Authors: C. DELEPINE[1], ***K. LI**[1], V. SHAH[2], T. JOHNS[1], M. SUR[3,1];
[1]Picower Inst. for Learning and Memory, [2]Biol. Engin., [3]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Astrocytes, long thought to operate only as a support network for neurons, are now emerging as key players in the modulation of brain information processing. Astrocytes influence synaptic transmission via glutamate transporters, and respond to, as well as modulate, neuronal activity with $^{Ca2+}$ signaling. However the contribution of astrocytes *in vivo* to complex behaviors and cognition remains unresolved. During motor learning, the primary motor cortex (M1) is functionally and structurally reorganized, manifest in changes of neuronal activity and dendritic spine turnover. We hypothesize that astrocytes modulate learning-associated neuronal network reorganization by influencing synaptic strength through glutamate clearance and $^{Ca2+}$ signaling. Here we investigated the role of cortical astrocytes in a motor learning task *in vivo*, where mice were rewarded for pushing a lever following an auditory cue. Using the engineered human muscarinic G protein-coupled receptor DREADD-hM3Dq activated by low doses of clozapine-N-oxide (CNO), we found that modulation of astrocyte $^{Ca2+}$ activity perturbed task performance, causing decreased responses rate and increased delay. Using a transgenic mouse line in which the expression of the glutamate transporter GLT1 was inhibited locally in M1, we found that decreasing astrocyte glutamate clearance prevented learning of a stereotypical motor trajectory while increasing response rate. Using genetically encoded $^{Ca2+}$ indicators and high-resolution two-photon imaging, we imaged neuron activity during execution of the motor task following training with astrocyte manipulation. Perturbing $^{Ca2+}$ activity and glutamate clearance both disrupted M1 neurons' capability to encode the motor command, as in both cases neuron populations showed drastically weakened performance when decoding for lever trajectory. Perturbation of astrocyte $^{Ca2+}$ activity was found to create a higher level of correlated noise in neural activity and to hamper neurons' ability to encode for lever trajectory. In contrast, decreased glutamate clearance by astrocytes increased neuronal activity and prevented the emergence of highly motion relevant neurons in the circuit, potentially by decreasing their dynamic range. These findings demonstrate specific contributions by astrocytes to the creation of

neuronal ensembles during motor learning, and their representation and encoding of learned trajectories.

Title: Cortical contribution to lingual kinematics as the tongue reaches for, and misses, targets

Authors: *T. BOLLU[1], S. C. WHITEHEAD[2], B. KARDON[1], J. REDD[3], M. LIU[1], J. H. GOLDBERG[1];
[1]Dept. of Neurobio. and Behavior, [2]Dept. of Physics, [3]Cornell Univ., Ithaca, NY

Abstract: Many animals, including humans and rodents, have prehensile tongues that act external to the oral cavity to contact objects such as food, water and conspecifics (Kier, 1985;Hiiemae, 2003). During natural behaviors such as licking, eating and grooming, tongues must precisely contact unseen targets. Yet from the motor control perspective, it remains unknown if animals 'reach' with their tongues. For example, when a mouse licks at an unseen water spout, does its tongue, like a hand, make an initial guess and, after a miss, produce corrective submovements to zero in on the spout?
Identifying motor control principles requires precise quantification of moment-to-moment movement kinematics, but lingual kinematics are difficult to resolve because tongues are complicated, deformable effectors that move extremely fast (Kier, 1985; Hiiemae, 2003). Even in tractable model systems such as rodents, licking is usually measured as a binary register of tongue-spout contact (Guo, 2014; Komiyama, 2010; Li, 2015; Goard, 2016;Williams, 2018;Chen, 2019), with EMGs (Travers, 1997), or with single plane imaging (Welsh, 1995 ;Gaffield, 2017). Recently, neural mechanisms of movement initiation, planning, and decision making have been clarified in head-fixed mouse preparations compatible with ascendant neural recording and manipulation technologies (Guo, 2014 ;Komiyama, 2010 ;Goard, 2016 ;Li, 2015 ;Gaffield, 2017; Svoboda, 2018; Crochet, 2019). Yet precise tongue kinematics during licking remain unknown.
Here, we combine kilohertz frame-rate imaging and a deep-learning based artificial neural

network (U-Net) to resolve tongue kinematics in mice performing a cued lick task. Cue-evoked licks exhibit previously unobserved, fine-scale movements which, like a hand searching for an unseen object, were produced after misses and were directionally biased towards remembered locations. Photoinhibition of anterolateral motor cortex (ALM) abolished these fine-scale adjustments, resulting in stereotyped, hypometric licks that missed the spout. Our results show that cortical activity is required for online corrections during licking and reveal novel, limb-like dynamics of the mouse tongue as it reaches for, and misses, targets.

Title: Kinematics of the mouse tongue as it searches for a water spout

Authors: ***B. ITO**, T. BOLLU, J. GOLDBERG;
Cornell Univ., Ithaca, NY

Abstract: Reaches to unseen targets exhibit complicated trajectories, including corrective submovements that are produced after initial misses. Biasing a submovement towards a target requires an online estimate of current hand position as well as target location. However, the neural mechanisms of submovement production and aiming remain unclear. Here, we combine kilohertz frame-rate imaging and machine vision to track 3D tongue kinematics as head fixed mice perform a novel directional lick task. Mice are trained to guess the location of a water spout among three distinct positions (left, center, right) on a trial-by-trial basis. A single rule specifies spout location: it cannot be in the location most recently rewarded. On trials with a lucky guess, cue-evoked licks are immediately followed by stereotyped water-retrieval licks to the just-contacted water spout, suggesting an immediate update of the lick plan by spout contact. Yet, on trials when an initial tongue protrusion missed the spout, mice produce within-lick adjustments resembling corrective submovements previously observed in primate reach studies. The demonstration that tongue kinematics during licking can resemble hand kinematics during reaching opens up opportunities for the study of motor control in head-fixed mice, an experimentally tractable preparation.

Title: Distinct roles of primary, secondary visual cortex and posterior parietal cortex in visually-guided decision-making

Authors: ***Y. OSAKO**[1], T. OHNUKI[1], H. MANABE[4], Y. SAKURAI[2], J. HIROKAWA[3]; [1]Grad. Sch. of Brain Sci., Doshisha Univ., Kyotanabe, Japan; [2]Doshisha Univ., Kyotanabe-Shi, Japan; [3]Lab. of Neural Information, Doshisha Univ., Kyoto, Japan; [4]Grad., Sch., of Brain Science, Doshisha Univ., Kyoto, Japan

Abstract: Previous studies demonstrated that primary visual cortex (V1) and posterior parietal cortex (PPC) are involved in visually-guided decision making, including processing of visual sensory inputs, accumulation of evidences and transformation of visual sensory signals into accurate motor plans. Recent studies argued that secondary visual cortex (V2) is also involved in visually-guided decision making. However, distinct roles of these areas in visually-guided decision making remain unclear. In our previous study, we established a quantitative behavioral paradigm in rodent to evaluate subjective decision threshold for accurate visual detection performance. Here we investigated the role of V1, V2 and PPC for subjective decision threshold during our visual detection task. Electrophysiological recording revealed that V1, V2 and PPC neurons exhibited heterogeneous responses spanning stimulus and movement(response). While V1 and V2 population was predominantly selective for visual stimulus rather than visual detection performance, PPC population was selective for both visual stimulus and visual detection performance in equal proportion. Only PPC subpopulation exhibited predominantly visual response in self-initiated correct choice, while V1 and V2 subpopulation exhibited no differences between self- and forced-initiated correct choices. Interestingly, V1 subpopulation predominantly showed second peak at around 300ms after stimulus onset in detected performance, while V2 subpopulation showed it irrespective of detected performance. PPC subpopulation, which is selective for both visual and detected performance, showed motor-related response in only self-initiated movement, but not in forced movement. Our data indicated that V1 and V2 processed predominantly visual features, while PPC processed visual information and motor command. This has led a speculation that PPC is a potential candidate for

visuomotor transformation especially for self-initiated motor, suggesting that PPC subpopulation represents subjective decision threshold for self-initiated motor command.

Nacional Autonoma de Mexico., Queretaro, Mexico

Abstract: Motor cortex participates in the coordination of the activity of subcortical systems related to muscle control, playing a fundamental role in the coordination of movements and posture. In particular, layer 5 neurons connect with several subcortical structures by means of the pyramidal system contributing in various phases of the movement, such as the planning, execution and termination of movements. Pyramidal tract neurons are organized in partially segregated subgroups according to their projection site; however, it is still unknown how each subgroup participates in the information processing during voluntary movements. Here, a method has been developed to allowing us to identify and study the neuronal activity before, during and after the execution of a voluntary movement. Wistar rats (250-300 g at the time of registration) were used for the experiments. The animals were trained from postnatal day 24 until 2 and a half months, to execute a lever movement in response to a light stimulus in head-fixed conditions. Using this protocol, we recorded 63 putative neurons from layer 5 of the motor cortex (recording depths 600-1700 μm) were performed during different phases of movement. In this way, different subclasses of putative neurons of layer 5 of the motor cortex were found, which exhibit activity related to different phases of a movement and which were classified as

preparation, initiation, execution and termination. We conclude that the neurons of layer 5 related to motor control are functionally segregated.

Title: Dendritic resonance in a detailed model of pyramidal tract neuron of mouse primary motor cortex

Authors: *C. KELLEY[1], S. DURA-BERNAL[1], S. NEYMOTIN[2], W. W. LYTTON[1]; [1]SUNY Downstate Med. Ctr., Brooklyn, NY; [2]The Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: Dendritic computation, though poorly understood, presents one of the strongest candidates for distinguishing complex biological neurons from simple integrate-and-fire analogs and still simpler units of artificial neural networks. We simulated frequency responses to subthreshold sinusoidal inputs of 0.5-20 Hz distributed across M1 apical and basilar dendritic arbors of pyramidal tract (PT) type neuron from mouse primary motor cortex (M1). Voltage recordings from the stimulated dendrites yielded three distinct groups of impedance profiles: those with broad peaks at 5-6 Hz in the basal dendrites and the apical trunk (perisomatic), those with narrow resonant peaks at 1.8-2.5 Hz for apical dendrites, and those with no discernible peaks for apical obliques. However, voltage recordings from the soma during stimulation of the saturating apical tufts showed transfer impedance profiles with resonant peaks at 1.8-2.5 Hz. At the soma, stimulation from apical dendrites showed strong positive correlation between peak impedance and frequency, while the perisomatic group had a relatively weak negative correlation between the two. The two groups both showed an inverted sigmoid relationship between peak impedance and distance from the soma, with highest impedance for proximal dendrites and a drop-off between 50-100 microns. Our findings suggest that the different populations of dendritic sections act as selectivity filters with distinct frequency response characteristics. Since synapses from long and short range inputs are spatially organized across the dendritic arbor of

PT cells, we hypothesize that these differences in dendritic resonance will play an important role in the behavior of the network and intend to investigate this further in a detailed network model.

Title: Response to simultaneous long-range inputs and oscillatory inputs in a multiscale model of M1 microcircuits

Authors: *S. DURA-BERNAL[1], S. A. NEYMOTIN[2], B. A. SUTER[3], C. KELLEY[4], R. TEKIN[5], G. M. SHEPHERD[6], W. W. LYTTON[7];

Abstract: We developed a multiscale model of mouse primary motor cortex (M1) microcircuits. The model simulates a cylindrical volume of cortical tissue with over 10,000 biophysically detailed neurons and 30 million synaptic connections. Neuron densities, classes, morphology and biophysics, and connectivity at the long-range, local and dendritic scale were derived from published experimental data. Our model includes most major long-range inputs, primarily arising from posterior nucleus (PO) and ventrolateral thalamus (VL), and contralateral M1, primary somatosensory (S1), secondary somatosensory (S2), secondary motor (M2), and orbital (OC) cortices. We used the model to study the M1 circuit responses to simultaneous long-range inputs from different regions. We compared responses to short pulses from individual regions to combined pulses from two or more regions at varying time lags to investigate dynamical pathway interactions and information flow within the M1 microcircuit. Preliminary results showed M1 response to S2 and M2 inputs depends strongly on the order of, and interval between inputs, and the level of Ih current in pyramidal-tract corticospinal (PT) neurons (one important effect of neuromodulation by norepinephrine). We also studied oscillatory inputs with a variety of dominant frequencies seen in cortex. We computed frequency preference (resonance) of multiple populations and of different dendritic regions within individual neurons. Preliminary results indicated that IT5A and PT5B response to IT2/3 stimulation depends on frequency, phase and PT Ih level. Our results support the hypothesis that the brain encodes multiple parallel information pathways, multiplexing within and across frequencies, by filtering oscillatory synaptic inputs at the circuit and cellular level.For each of the conditions above, we computed and correlated measures of neural activity responses at multiple spatiotemporal scales: single-neuron voltage traces, single-neuron and population spiking activity, local field potentials (LFP), primary currents contributing to electro- and magnetoencephalogram (EEG/MEG) signals, and information transfer measures. Interactions observed within scale include synchronous firing of neuronal ensembles with LFP phase-amplitude coupling; interactions across scales included dendritic frequency resonance filtering synaptic inputs, and coupling of cell spiking with large-scale LFP/EEG/MEG oscillations. Analyzing correlations within and across scales identified mechanisms of multi-plexed neural signaling, and predicted observables that can be pursued experimentally.

Title: Single unit characterization of cortical sensorimotor transformations in a whisker detection task

Authors: *Z. ZHANG[1], B. ZAREIAN[2], E. ZAGHA[2];
[1]Neurosci. Grad. Program, [2]Dept. of Psychology, UC Riverside, Riverside, CA

Abstract: How are neuronal signals transformed across cortex to convert sensory information into decisions and motor actions? Here, we assess single unit representations in different cortical areas during a passive whisker detection task. In this task, mice learn to lick a water port in response to whisker deflections in one whisker field (target) and ignore identical stimuli in the opposite (distractor) whisker field. Concurrent studies in our lab have identified several cortical regions active during the sensorimotor transformation including whisker primary somatosensory cortex (S1), whisker primary motor cortex (wM1) and anterior lateral motor cortex (ALM). We recorded single unit activities from these cortical regions during task performance and analyzed diverse neuronal firing properties including stimulus encoding, response latency, transient versus sustained firing, sensory versus motor temporal alignment and choice probability. Most S1 neurons were transiently active, aligned to the stimulus onset at short latency, and showed low choice probability, consistent with pure sensory coding. Individual S1 neurons displayed a wide range of stimulus encoding magnitudes, with a small portion of neurons encoding stimulus probability values that approached behavioral performance. In contrast, most ALM neurons were active at long latency from stimulus onset and then remained active until the response time, aligned to response initiation, and showed high choice probability, consistent with pure motor coding. Our results suggest that S1 and ALM neurons represent two ends of the cortical sensorimotor transformation spectrum. Single units in wM1, alternatively, showed a mixture of sensory, motor and sensorimotor representation. We discuss why this mixed population may be a critical node in transforming cortical signals in our whisker detection task.

Title: Visualizing cortical sensorimotor propagation for selective detection

Authors: *K. ARULJOTHI[1], K. MARRERO[2], E. ZAGHA[1];
[1]Psychology, [2]Neurosci., Univ. of California, Riverside, Riverside, CA

Abstract: Widefield Ca^{2+} imaging enables us to observe neural activity simultaneously across multiple cortical regions. We apply this technique to mice performing a selective detection task, in which mice learn to respond to rapid stimuli in the target whisker field and ignore identical stimuli in the opposite (distractor) whisker field. Comparing activity between cortical hemispheres enables us to study both enhanced (target-aligned) and suppressed (distractor-aligned) sensorimotor transformations throughout dorsal cortex. For both hit and correct rejection trials we observe post-stimulus signals emerging first in somatosensory cortex (contralateral to the deflected whisker field). Only on hit trials do we observe subsequent propagation to frontal areas, including both the rostral portion of the whisker representation of primary motor cortex and anterior lateral motor cortex (ALM). Propagation to frontal cortex occurred prior to the response, and therefore may represent part of the motor command. During the response epoch we observe widespread Ca^{2+} signals throughout dorsal cortex. On correct rejection trials, we observe Ca^{2+} signals that did not propagate to frontal areas but remained confined to primary somatosensory cortex. Using signal detection theory, we quantify sensory representation for target and distractor stimuli. Sensory signals are comparably strong for both stimuli, suggesting that stimulus encoding is not gated out before it reaches the sensory cortex. Thus, our data illustrate a cortical correlate of sensory selection as the regulated propagation of sensory signals from primary sensory to motor regions.

Title: Optimal post-injury time window to apply activity-dependent stimulation to drive functional recovery after traumatic brain injury in the rat

Authors: *H. M. HUDSON[1], D. J. GUGGENMOS[1], N. VITALE[3], M. AZIN[3], P. MOHSENI[3], R. J. NUDO[1,2];
[1]Rehabil. Med., [2]Landon Ctr. on Aging, Univ. of Kansas Med. Ctr., Kansas City, KS; [3]Electrical Engin. and Computer Sci., Case Western Reserve Univ., Cleveland, OH

Abstract: Traumatic brain injury (TBI) is a significant contributor to death and disability worldwide. Approximately 1.7 million people in the United States sustain a TBI annually. Forty-three percent of patients discharged from acute hospitalization with TBI develop some form of long-term TBI-related disability, leading to reduced quality of life, prolonged medical

complications and significant health care expenses. Injury to the cerebral cortex, as might occur from TBI, can result in substantial cell loss and widespread disruption of the sensorimotor network, leading to chronic motor deficits. Few treatment options exist for those with chronic disabilities following acquired brain injuries. Our previous research has shown that activity-dependent stimulation (ADS), used to create an artificial communication link between spared cortical areas, is effective in restoring functional use of the forelimb when applied immediately following a cortical TBI to primary motor cortex (M1) in rats. From a clinical perspective, the immediate implementation of ADS following cortical injury may not be feasible as surgical implantation of the device in a patient would need to be delayed days to weeks allowing for the patient to become medically stable and post-TBI edema to be resolved. The goal of this study was to determine the optimal post-injury time window to apply ADS treatment and achieve functional recovery following a TBI. We hypothesized that delaying the initiation of ADS by 1, 2 or 3 weeks after an M1 injury will lead to improved skilled reaching performance compared to non-stimulated controls. In a rodent model of TBI, we used a custom wireless microdevice to create an artificial communication link between spared cortical areas (premotor cortex, PM; primary somatosensory cortex, S1), forming a closed loop brain-machine-brain interface. At the specified post-injury delay (1, 2 or 3 weeks), the closed-loop operation of the microdevice was turned on. PM neural activity was recorded, and action potentials were discriminated in real time and used to trigger stimulation pulses in S1 for 24 hours per day over a 4-week treatment period. Behavioral recovery was assessed weekly using a skilled reaching task. Preliminary results indicate that the application of ADS, regardless of treatment delay, leads to significant improvement in skilled reaching performance compared to non-stimulated controls. The results demonstrate that delaying the application of ADS does not impair the ability to bridge communication between spared cortical areas in the sensorimotor network and can drive functional behavioral recovery following a TBI.

Title: Non invasive kinesthetic feedback in a bidirectional hand system for upper limb amputees

Authors: *G. DOMINIJANNI[1], G. VALLE[2,1], E. D'ANNA[1], S. MICERA[1,2];
[1]Ctr. for Neuroprosthetics and Inst. of Bioengineering, École Polytechnique Fédérale de

Lausanne (EPFL), Lausanne, Switzerland; [2]The BioRobotics Inst., Scuola Superiore Sant'Anna, Pisa, Italy

Abstract: Rich sensory feedback restoration is proved to be the key for better and more intuitive control of current myoelectric prostheses. In light of this, a stimulation system for muscle vibration was developed to provide homologous and somatotopic kinesthetic feedback non-invasively to transradial amputees. Testing protocols were then designed to understand the capabilities of the developed device in eliciting hand related illusory movement sensations as well as to investigate the possibility of properly controlling the illusion created. The results obtained with both healthy subjects and amputees suggested that the developed vibratory stimulation system could be exploited to provide kinesthetic sensory feedback in a closed-loop configuration to improve motor control of the prosthetic hand. In this perspective, a one degree of freedom robotic hand was endowed with the vibratory stimulation system for proprioception of hand position and movement restoration. In order to evaluate the functionality of the delivered feedback in conjunction with the bidirectional hand system, a set of experiments with the system in open-loop and closed-loop configuration was carried out. Open-loop experiments were designed to quantify only the performances of the vibratory stimulation system when used to provide kinesthetic feedback, without the influence of the additional burden of robotic hand control. The closed-loop experiments instead involved the overall bidirectional hand system. Open-loop experiments showed how the amputee was able to discriminate hand closing and opening movement, as well as rest condition. In particular, overall correct movement identification percentage was as high as 88.9%. Moreover, all the movements were identified above chance level with 95% confidence interval. Object size recognition task was performed considering two cylinders of different diameters. The overall correct classification performance achieved in the object size recognition experiment was 87.5% and both objects were correctly identified above chance level. The same object recognition experiment was carried out also in closed-loop configuration and high overall performance was achieved by the patient (87.5% correct classification) with both objects classified above chance level.

Title: Neuroprosthetic stimulation optimized by learning control algorithms

Authors: *M. BONIZZATO, S. COTE, S. LAFERRIERE, S. QUESSY, G. LAJOIE, M. MARTINEZ, N. DANCAUSE;
Univ. de Montreal, Montreal, QC, Canada

Abstract: We are developing neuroprosthetic systems for motor control that are based on intracortical microstimulation (ICMS). In rats with spinal cord injury (SCI) we demonstrated that targeted and timed ICMS immediately alleviates locomotor deficits. Here, we tackled the problem of controlling multi-dimensional neurostimulation intervention.
In practice, in ICMS as other functional electrical stimulation applications, stimulus parameters are often arbitrary and the strategies for optimizing these stimulations poorly developed. Moreover, the motor cortex (M1) organization widely varies from one individual to another and even over time for the same subject. We propose that learning algorithms could be used to quickly optimize the stimulation parameters of an implant according to the specific effects evoked by its electrodes and to be able to rapidly adapt these parameters according to the changes that may occur in the brain, for example after injury. This would maximize the effectiveness and durability of motor neuroprostheses.
We implanted n=4 rats with 32-channel arrays in the hindlimb M1 and n=2 non-human primates (NHP) with 96-channel cortical arrays in the forelimb M1. Under ketamine anesthesia and in resting awake subjects, ICMS through different electrodes generates a variety of motor outputs. We used a Bayesian learning algorithm based on Gaussian processes to explore the space of stimulation parameters. In a first experiment, the algorithm was used to determine which spatial location for stimulus delivery within M1 held the strongest activation of a target muscle. Over a total of 2 to 3 muscles per subject and 10 repetitions per muscle, the algorithm over-performed random search in determining the optimal stimulation site.
We further demonstrated that the algorithm can be applied to online optimization of cortical neuroprosthetic stimulation. In n=3 rats with SCI, the learning routine optimized stimulation parameters to maximize leg clearance and alleviated leg dragging. The algorithm found optimal cortical locations for stimulus delivery in less than half a minute and during active usage of the neuroprosthesis, largely outperforming the capacity of a human operator.
The proposed algorithm optimized ICMS delivery in the space of a minute, across complex motor representations and during neuroprosthetic usage. Our framework could be extended to other neurostimulation treatments to maximize their therapeutic benefits. Furthermore, intelligent algorithmic approaches to “motor mapping” can provide new optimized tools to support studies in neural control of movement, skilled motor learning and effects of neurological damage and rehabilitation.

Title: A neural-machine interface for control of a lower-limb prosthesis

Authors: *J. A. BRANTLEY[1], J. L. CONTRERAS-VIDAL[2];
[2]Electrical and Computer Engin., [1]Univ. of Houston, Houston, TX

Abstract: Limb amputation is a major cause of physical disability that causes activities of daily living to become difficult or impossible for the amputee. Current lower-limb prostheses provide limited control and result in reduced mobility for the amputee. Recent advancements in powered lower limb prostheses allow for more intelligent control and better locomotion functions (3). The most advanced strategy employs user intent detection to combine volitional and autonomous control during locomotion. The incorporation of neural signals, specifically muscle and brain, may offer a viable method for improved volitional control by directly interpreting signals from muscle (measured through electromyography—EMG) and cortical brain activations (measured through electroencephalography—EEG). In this study, we employ a multimodal neuroimaging approach to: (1) identify neural correlates of movement during isolated limb movements and walking in the amputee population, and (2) demonstrate the feasibility of control of a powered LL prosthesis using neural signal from EEG and EMG. Transfemoral amputees were recruited to perform a series of isolated limb movements of the intact and phantom knee and ankle while undergoing a functional magnetic resonance imaging (fMRI) scans. The subjects subsequently repeated the experiment while instrumented with EEG, EMG, and motion capture. fMRI data were used to extract regions of interest during individual limb movements, and a systematic EEG processing approach was implemented to reduce artifacts (e.g., eye blinks/movements, muscle artifacts) and estimate the underlying source activity. We investigate the temporal and spectral dynamics associated with activation of the phantom limb as compared to the intact limb. Secondly, we investigate the ability to leverage EEG signals for control of a lower limb prosthesis and how this may supplement control schemes utilizing neural signals from the muscles of the residual limb. This work contributes to a greater understanding of the neural dynamics associated with phantom limb movements in lower limb amputees and presents a strategy for BMI control of powered prostheses. Title: Repetitive anodal transcranial direct current stimulation hastens isoflurane-induced emergence and recovery and enhances memory in healthy rats

Authors: M. T. MANSOURI, *P. S. GARCIA;
Anesthesiol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Introduction: Rapid and smooth recovery from general anesthesia is a goal for clinical anesthesiologists. Recently intense research interest has focused on the neural mechanisms involved in emergence from unconsciousness. Thus far, there has been no effective clinical strategy proven to hasten recovery from surgical anesthesia. One promising approach is the use of non-invasive brain stimulation techniques such as transcranial direct current stimulation (tDCS) to stabilize neural activity around a physiologic setpoint. To date, use of this technique for the relief of symptoms caused by neuropsychiatric disorders and the enhancement of cognitive performance has led to promising results. **Objective:** In this study, we hypothesized that repetitive anodal tDCS can hasten post-anesthesia emergence and recovery behaviors. **Methods:** Age-matched, adult male rats (n=15; 450-525 g) were divided into two groups; the anodal tDCS and sham groups. Four days after the tDCS socket implantation over the right motor cortex (AP: +1.5mm, ML: +2mm), repetitive anodal direct electrical current of 0.2 mA intensity applied for 20 min/day for 10 consecutive days in tDCS group, while sham stimulation was applied to sham group. Minimum alveolar concentration (MAC) to prevent movement, as well as emergence and recovery behaviors following 2-hour isoflurane anesthesia were evaluated 24 hours after the last tDCS session. Cognitive performance was assessed by novel object recognition and spontaneous alternation Y-maze tests 48 h after the last tDCS session. Locomotion was also measured using Oxymax indirect calorimetry system. **Results:** The concentration of isoflurane necessary to suppress movement to tail-pinch was not affected by tDCS, although tDCS-treated animals righted themselves after anesthesia sooner than sham-treated group. Recovery behaviors such as attempts to remove adhesive tape affixed to the forepaw (sticky-dot test) were also hastened in tDCS-treated rats as compared to sham. Treatment with tDCS also exhibited positive effects on both novel object recognition and Y-maze tests, without affecting locomotor performance, indicating a potential benefit on working memory from the intervention. **Conclusions:** Taken together, our findings propose that anodal

tDCS over the motor cortex might be useful to hasten recovery from the anesthesia in patients who take the isoflurane during the surgery.

Title: Dose and montage effects of transcranial direct current stimulation on motor sequence learning

Authors: *G. SCHLAUG[1], A. B. SHINDE[2];
[1]Neurol., Beth Israel Deaconess Med. Center/HMS, Boston, MA; [2]Neurol., Beth Israel Deaconess Med. Center/Harvard Med., Boston, MA

Abstract: Research investigating the use of noninvasive electrical stimulation has provided compelling evidence that such stimulation can modulate behavior and cognition, and even facilitate recovery of function after a focal brain injury. Our understanding of stimulation variables such as *current strength* and *electrode montage* has to be further explored. We are conducting a series of studies to characterize brain and behavioral responses to tDCS varying dose and electrode montage. In this study, we used three different dose levels (Sham-0.1mA, 2mA and 4mA (Corresponding current densities under Anodal electrode: 0.007 mA/cm^2, 0.156 mA/cm^2, and 0.318 mA/cm^2) and two different electrode montages (unihemispheric or bihemispheric) to examine effects on a finger sequencing task. Anodal electrode diameter was 4 cm placed over the right motor region (C4) while the cathodal electrode was 5 cm diameter and it was either placed over the left supraorbital region (unihemispheric montage) or over the left motor region (C3; bihemispheric montage). C3 and C4 correspond to the precentral gyrus hand motor knob region. Each stimulation study was of 10 min duration including initial ramp up and final ramp down signal. 20 healthy Right-Handed subjects participated in the study. Each visit was separated by at least 24 hours and subjects performed a finger sequence learning task consisting of a randomly chosen sequence of 7 digits with each hand separately before and immediately after the stimulation. Subjects performed finger sequence learning task for 30 sec at a time, the task was performed five times with each hand with 30 sec rest between two tasks. Repeated measure ANOVA for unihemispheric electrode montage with all three stimulation conditions showed significant difference in left hand pre-post performance. There was no significant effect on the performance of the right hand with unihemispheric stimulation. Post

unihemispheric stimulation, both left and right hand showed improvement in the task performance with a clear trend between the stimulation dose and percentage change. Bi-hemispheric 2mA and 4 mA stimulation showed improvement in performance for left as well as right hand; improvement in performance of left hand was more than the improvement of right-hand performance. Pairwise comparisons confirmed the causal relationship between the anodal stimulation of the peri-rolandic region during the motor learning consolidation phase and the improved motor sequence performance after stimulation.

Title: Transcranial direct current stimulation increases regional cerebral blood flow in targeted and network brain regions

Authors: *A. B. SHINDE, F. MUNSCH, D. ALSOP, G. SCHLAUG;
Neurol., Beth Israel Deaconess Med. Ctr. and Harvard M, Boston, MA

Abstract: Noninvasive transcranial direct current stimulation(tDCS) of targeted brain regions leads to an increase or decrease in cortical excitability in the stimulated region. How tDCS drives these physiological and associated behavioral effects remains speculative at this point. In the current experimental setup, we investigate local and network relationships between tDCS stimulation and cerebral blood flow(CBF) change. This is achieved with two intertwined sets of experiments. First, increasing stimulation current to study dose effects (sham, 2mA, and 4mA) and second, varying placement of the cathodal electrode (Unihemispheric-FP1and Bihemispheric -C3) to study montage effects with Anodal electrode fixed on the right primary motor area(C4). Each stimulation session was of 10 min duration with initial ramp up and final ramp down over 30s. A 3T GE MRI scanner, acquiring non-invasive blood flow images using ASL fMRI, and an MR compatible NeuroConn DCMC stimulator allowed us to simultaneously perform brain

stimulation and MR acquisitions. The ASL sequence lasted 24 min (resulting in 160 acquisitions) while tDCS was delivered in the middle of the scanning session. Fifteen healthy Right-Handed subjects participated in the study so far undergoing 6 imaging and 6 behavioral assessments. The resulting MR images were analyzed with SPM12 and its toolbox CAT12. A significant change ($p < 0.05$ unc) in cerebral blood flow between ON and OFF conditions was seen for the group under the anodal electrode for unihemispheric tDCS of 2mA. In contrast, the 4mA unihemispheric condition showed blood flow changes in the precentral gyrus in both hemispheres. Bihemispheric stimulations caused significant changes ($p<0.05$ unc) in blood flow changes under both anode and cathode electrode for the 2mA and 4mA condition, with the 4mA condition driving blood flow changes in larger brain areas including frontomesial regions compared to changes in the 2mA condition. In conclusion, ASL-CBF changes, induced by tDCS can be used as a surrogate marker of regional and remote (network) neuronal effect, with differential effects caused by varying parameters of the stimulation.

Title: Brain computer interface operation of a commercial augmentative and alternative communication device

Authors: ***J. E. HUGGINS**[1], R. T. CROSS[2], M. A. GARCIA VERDUGO[1], C. G. WOODWORTH[3], K. HILL[3];
[1]Physical Med. and Rehabil., Univ. of Michigan, Ann Arbor, MI; [2]Prentke Romich Co., Wooster, OH; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Brain-computer interfaces (BCIs) are often intended for use as augmentative and alternative communication (AAC) devices. But to be successful, BCIs must incorporate the linguistically robust AAC user interfaces resulting from 50 years of AAC research. BCIs can thus most efficiently serve people with complex communication needs by interfacing to commercial AAC technology instead of trying to recreate an AAC user interface in the BCI. This NIH-funded project was intended to provide a BCI input accessory to a commercial AAC product line.
A non-invasive P300-based BCI design [1] was configured as an input device to the AAC system of an industry partner. Using the Microsoft User Interface Adaptation framework, the AAC

system publishes the size and location of every key on its on-screen keyboard. The BCI then matches stimuli to the size and shape of the AAC system keys to provide BCI access to on-screen keyboards and icon displays of up to 144 locations. The stimuli update after each selection to match the selections on the AAC user interface.
The AAC-BCI was tested with 8 people with cerebral palsy who use an AAC device for everyday communication. Participants (2 female; 6 male) were aged 13 to 61 years. The custom user interface from each participant's own communication device was loaded into the AAC-BCI prototype to provide familiar screens and content. These interfaces included single-hit and multiple-hit stored vocabulary using icons and spelling/word prediction.
The AAC-BCI was calibrated for 7 of the 8 participants. For the remaining user, the study was interrupted when the gel-based EEG cap twisted under the weight of the head-mounted typing stick typically used for communication. The participants found the communication potential exciting, but wanted improved interface responsiveness. BCI accuracy did not vary based on the number of active locations on the AAC display. However, issues were identified with the gel electrode caps, which were slow to set up and catch on user headrests.
Future work will include using dry electrodes and testing a P300-certainty algorithm, both for accuracy of typing and to provide an automatic pause feature.

Title: Neurofeedback (NFB) using brain computer interface (BCI) software for training reading-related attention in mild Alzheimer's disease (AD)

Authors: D. KLEE, D. MCLAUGHLIN, T. MEMMOTT, M. FRIED-OKEN, *B. S. OKEN; Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Prior BCI research has suggested NFB may improve performance. The goal of this study was to develop NFB to improve reading-related cognitive processes in people with AD. In addition to memory deficits, AD is usually associated with functional impairments in language and reading. This abstract describes the outcome measures and the generation of BCI NFB signals in a group of healthy younger and older adults.

NFB training used a P300 speller and rapid serial visual presentation (RSVP) of letters developed with BciPy software and a dry-electrode cap. Calibration consisted of 100 trials. Each trial presented a target letter and then 10 letters serially including the target letter at a rate of 4 Hz. Machine learning was trained on 500 ms of EEG data following target and non-target letters using a regularized discriminant classifier following dimension reduction using a principal components analysis. The best parameters for the classification were obtained using a 10-fold leave-one-out cross-validation. The session AUC is used as a BCI outcome measure.

Currently, NFB uses steady state VEP amplitudes for attentional feedback. NFB was presented after each trial based on estimated SSVEP amplitude using 3.4 - 4.6 Hz power for each trial. The feedback was presented as 5 horizontally oriented rectangles ranging from red to green. The trial feedback was presented for 2 s as a highlighted border around 1 rectangle. SSVEP amplitude thresholds for the 5 levels were individualized for each subject based on a prior calibration. We provided more positive than negative feedback and selected category 1 as the lowest 15^{th} percentile up to category 5 as the top 30^{th} percentile. Primary cognitive outcome measures assessed reading processing speed, attention (letter cancellation task), and working memory skills (letter span task; WAIS digit span).

Four healthy participants (age range 23-71 years) signed informed consent, completed cognitive outcomes measures, and completed the RSVP BCI task with neurofeedback. Participants completed 2 letter cancellation tasks: harder condition in 32.5 ± 3.7 s and easier condition in 27.3 ± 4.0 s. Participants responded to an average of 78.5 ± 14.5 items correctly on the sentence fluency task. Participants' letter spans averaged 5.85 ± 1.5 letters in the forward condition and 4 ± 1.8 letters in length in the backward condition. On the BCI task, participants achieved a mean correct classification rate (AUC) of 0.71 $\pm$ 0.09. For individualized neurofeedback, we were able to successfully deliver feedback at the 5 levels in approximate target distributions. Following development of the NFB, we have begun the 6-week NFB implementation phase of the experiment.

Title: Artificial somatosensory kinaesthetic feedback of arm movements

Authors: *L. HEHENBERGER, A. I. SBURLEA, R. J. KOBLER, G. R. MUELLER-PUTZ; Inst. of Neural Engin., Graz Univ. of Technol., Graz, Austria

Abstract: Afflictions like spinal cord injury potentially interrupt both efferent and afferent pathways. The main focus of neuroprosthesis research naturally lies on restoring the forward part of the feedback loop, i.e. control, while the loop is usually closed via visual feedback. In pursuit of making neuroprostheses increasingly intuitive to use, artificial somatosensory feedback should be a prominently featured topic.

We are exploring non-invasive vibrotactile stimulation to give artificial kinaesthetic feedback to a person controlling a robotic arm. In the current setup, tactors driven by a custom device are arranged in a sparse grid attached to a custom shirt in the area of the shoulder blade, and their intensities are modulated such that the stimulation is perceived as a smoothly moving sensation. This perception is based on tactile illusions arising due to the low spatial resolution of the tactile sense. We have performed tests to identify correct settings for a number of parameters to produce such moving sensations with our custom setup. Most importantly, we conducted a behavioural experiment to identify how to correctly manipulate tactor intensities in order to evoke specific apparent movement sequences across the grid, and found that a power relation between the intensities and the desired stimulation location (relative to the active tactors) at any time point leads to the best result.

Subsequently, we conducted a study to investigate the impact of vibrotactile feedback on movement parameters in electroencephalography. Participants performed unidirectional arm movements in 3 different directions on a planar surface with either real-time vibrotactile feedback of the movement, static vibrotactile stimulation or no vibrotactile input. Average peak amplitudes of motor-related cortical potentials were found to be higher in the feedback condition, and lowest in the condition with static stimulation. We present classification results with respect to the movement directions and conditions.

Abstract: Half of spinal cord injuries (SCI) result in reduced mobility in both the upper limbs and lower limbs. In particular, loss of upper limb functions can dramatically impair the social and professional lives of patients, making recovery of these functions a top priority. Several studies employing functional electrical stimulation of the arm muscles have been able to produce grasping gestures in people with tetraplegia. However, this strategy is insufficient to generate the forces necessary to produce three-dimensional natural reaching movements, thus hindering its application in real-life scenarios. Epidural electrical stimulation (EES) applied over the dorsal spinal cord engages motoneurons through the recruitment of large sensory afferents, thus producing large forces while concurrently improving functional muscle control. Here, we detail the technological framework allowing the restoration of reaching and grasping movements in a nonhuman primate model of incomplete SCI by delivering brain-controlled EES to the cervical spinal cord. We designed and validated a soft spinal implant that targets the posterior roots of cervical segments in macaque monkeys. After training to perform a three-dimensional reaching and grasping tasks, the spinal implant was inserted together with intramuscular electrodes into selected arm muscles to record electromyographic (EMG) activity and intracortical multi-electrode arrays to record the spiking activity of neurons in the primary moor cortex, dorsal premotor cortex and somatosensory cortex. We evaluated the chronic stability, efficacy and selectivity of our spinal implant to elicit activation of synergistic muscles. We then implemented

a real-time control framework that extracted movement-related intentions from intra-cortical recordings of primary motor and dorsal pre-motor cortex and linked them to the delivery of electrical stimulation at different spinal locations. Finally, we performed a partial hemisection of the spinal cord at the C6 level and evaluated the effects of alternated EES bursts timed with reaching (arm extension) and grasp (hand flexion) on arm/hand kinematics.

Title: Dynamical encoding of swing and stance phases as orthogonal states in hindlimb motor cortex

Authors: *L. S. URBAN, I. SEÁÑEZ, S. ANIL, C. HITZ, S. SUN, N. MACELLARI, G. COURTINE;
EPFL, Geneve, Switzerland

Abstract: While the forelimb region of primary motor cortex has been extensively studied, less is known about the neural dynamics of the hindlimb region. This is a problem, first, because these brain regions likely share functional characteristics, since both interact with distant spinal circuits to control the major limbs of the body. Basic functional properties may be obscured by

the sophistication of forelimb movements, and may be better observed with the limited repertoire of hindlimb movements. Second, hindlimb motor cortex activity could serve as a control signal in a brain-spine interface for adjusting stimulation parameters in real-time throughout the gait cycle to assist in the recovery of walking for paraplegic patients.
Here we apply dynamical system analysis to show that hindlimb motor cortex encodes the swing and stance phases of the gait cycle as two distinct states. Neural activity was recorded during walking from chronic implanted arrays (Utah) in the nonhuman primate. These neural signals were projected onto a dynamical system space optimized for a harmonic oscillator. These dynamics were chosen to match the oscillatory patterns of leg movements during walking and to mimic physical models used in bipedal robotics. Our results were derived from continuous recording sessions with many gait cycles and rest periods.
Our work shows that the dominant oscillating patterns in the hindlimb motor cortex strongly correlate with movement during walking. The 3D structure of the dynamics shows two orthogonal brain states that correlate with the swing and stance phases respectively. This means swing and stance are encoded by two distinct patterns of neural activity that do not overlap in time. Each pattern fades in and out before transitioning to the next, as opposed to smoothly transitioning between the two. Therefore the brain enters a unique state during the swing phase, then switches states during the stance phase. Results also show that the swing phase is encoded in a localized region of hindlimb primary motor cortex, while the stance phase is more distributed.
These results show that although walking is an oscillatory movement, the brain encodes swing and stance as independent states, and suggests that their neural properties should be studied separately. The robustness of this signal suggests this is an important property of the hindlimb motor cortex, and has potential for decoding in the brain-spine interface.

Title: Experimental framework for the assessment of the efficacy of spinal cord stimulation to restore voluntary arm movement in monkeys after spinal cord injury

Authors: *S. CONTI[1], B. BARRA[1], M. G. PERICH[2], K. Z. ZHUANG[1], G. SCHIAVONE[3], N. GREINER[3], M. KAESER[1], E. ROUILLER[1], S. P. LACOUR[3], T. MILEKOVIC[2], J. BLOCH[4], G. COURTINE[3], M. CAPOGROSSO[1];

Abstract: Recovery of arm and hand movement is a high priority for people with cervical spinal cord injury (SCI). Several studies employing electrical stimulation of hand muscles showed promising results in restoring grasping abilities in paralyzed people. However, direct muscle stimulation induces rapid muscle fatigue, limiting the applicability for functional three-dimensional arm reaching movements that are critical for activities of daily living. In contrast, epidural electrical stimulation (EES) of the spinal cord can elicit large muscle forces with reduced fatigue by recruiting motoneurons pre-synaptically through the activation of proprioceptive afferents. Indeed, this technology has already shown remarkable results in improving voluntary motor control of the legs in people with incomplete and complete spinal cord injuries. Here we present an experimental framework for the investigation of the behavioural effects and the therapeutic potential of cervical spinal EES on the restoration of voluntary arm function after unilateral SCI in monkeys. We designed and implemented a robotic framework allowing the evaluation of natural three-dimensional arm reaching performances in macaque monkeys. We then trained macaque monkeys to perform a reach, grasp and pull task using our set up. We simultaneously recorded full-limb kinematics, neural activity along with EMG signals from proximal and distal arm muscles. The monkeys were then implanted with an epidural spinal implant tailored to the C6 to T1 dorsal roots. We then performed a partial hemisection of the spinal cord at the C6 level that led to incomplete paralysis of the left arm. Specifically, while forearm and elbow extensors muscles were compromised, the macaques were able to voluntarily activate proximal shoulder and biceps muscles. We then tested the efficacy of targeted spatiotemporal EES protocols to restore movements of the arm as well as control of the paralyzed muscles as early as 6 days after injury. Similarly to what has been shown in locomotion, our preliminary results seem to indicate the critical role of voluntary motor intention in the recovery of arm motor function using EES.

Title: Exploring the neural basis underlying locomotor activities and leg reaching in macaque motor, premotor, and sensory cortex

Authors: *I. SEÁÑEZ[1], S. BORGOGNON[2,1], N. MACELLARI[1], A. HICKEY[1], C. HITZ[1], R. ORNELAS KOBAYASHI[1], L. S. URBAN[1], H. LORACH[1], M. G. PERICH[3], T. MILEKOVIC[4], M. CAPOGROSSO[2], E. ROUILLER[2], J. BLOCH[5], G. COURTINE[1];

Abstract: Cortical activity is believed to coordinate the adjustment of leg movements associated with volitional modifications of gait, such as walking along ladders, avoiding obstacles, or climbing up staircases. However, previous studies have primarily been conducted over motorized treadmills, a relatively simple and automated locomotor task. Consequently, cortical dynamics underlying the production of basic and skilled locomotion remains unclear. To address this question, we trained *Macaca fascicularis* monkeys to walk on a moving treadmill at different speeds, along corridors, uneven ladders, obstacles, and stairs. We also trained them to perform a center-out reach and grasp task with the leg. Finally, we introduced a novel, untrained task requiring object avoidance during stepping. Three animals were implanted with 48-channel intracortical arrays in the leg motor (M1) and premotor (PMd) cortices to record multi-unit activity, in conjunction with 14 pairs of electrodes in leg muscles to record electromyographic (EMG) activity. One animal was additionally implanted with a 64-channel array in the leg sensory (S1) cortex. Neural and EMG signals were transmitted wirelessly. Kinematics of the hindlimb were recorded using a high-definition video camera system and tracked via transfer

learning with DeepLabCut. In this work, we document the neural dynamics of motor, premotor, and sensory cortex activity during rhythmic and volitional control of locomotion. We describe the neural correlates of these sensorimotor areas during specific tasks and how these generalize to the other tasks by using a neural decoder to predict kinematic events from neural recordings within and across tasks. Finally, we study the neural population mechanisms of these areas during the learning of a novel locomotor task. These results will guide the design of additional experiments that aim to link cortical activity to the execution of leg movements.

Title: The music box: A steady-state visual evoked potentials (SSVEP)-based brain-computer interface (BCI) for people with complex communication disorders

Authors: O. ZHOU[1], J. J. S. NORTON[1,2], C. S. CARMACK[1], J. CARTER[1], *K. GOSMANOVA[1], J. R. WOLPAW[1,2], T. M. VAUGHAN[1,2];

Abstract: Nearly 4 million children and adults in the US with complex communication disorders (CCD) experience life-long educational, vocational, medical, and social challenges (Light and McNaughton, AAC 2015). Visual scene displays (VSDs) allow users with CCDs to make selections within a broader context, (e.g., selecting the image of a TV in a living room scene to activate an actual TV). VSDs can be an effective communication tool for people who have never learned to speak or control a computer, and for those with acquired apraxia or aphasia (Beukelman et.al, AAC 2007). Here, we describe Music Box, a VSD interface controlled using steady-state visual evoked potentials (SSVEPs). The Music Box elicits an SSVEP by alternating between light and dark grey squares at 7.5 Hz (PsychToolBox), and recording EEG signals from 8 scalp locations using BCI2000. The amplitude of the SSVEP elicited by the stimulus is analyzed in real time by canonical correlation analysis. The participant receives visual feedback via a semi-transparent overlay. The size of the overlay is proportional to the SSVEP amplitude.

When the amplitude of the SSVEP exceeds a predetermined threshold, the overlay turns from red to green and music plays. The overlay remains green and the music continues to play as long as the amplitude of the participants' SSVEP is above threshold. Thresholds are adjusted manually to challenge individuals to do better. Four healthy participants each performed sixty 30-sec trials during a 90-min session. SSVEP amplitude exceeded the threshold (i.e., music played) in 88.1(0.1SD)% of the trials; time to reach threshold averaged 1.5(1.1SD) seconds. The spectral power of EEG in the 7.5 Hz band (and its harmonics) increased the longer the participant gazed at the screen. These initial results show that SSVEP-based BCIs can be used to control VSDs. Ongoing studies in our laboratory are examining the impact of stimulus contrast, threshold value, and trial length on participants' performance. We then plan to test the system with people who have CCDs; the goal is to enhance their ability to interact with and control their environments.

Title: Brain Storm: A gamified steady-state visual evoked potential (SSVEP)-based brain-computer interface (BCI) for children

Authors: J. MULLINS[1], ***J. J. S. NORTON**[2,3], T. BRETL[1];
[1]Univ. of Illinois, Urbana, IL; [2]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NY State Dept. of Hlth., Albany, NY; [3]Stratton VA Med. Ctr., Albany, NY

Abstract: There is very little previous research on the development of BCIs for children. Some of that research suggests that children are not able to control SSVEP-based BCIs. A lack of adequate engagement is one possible explanation for these results. Motivated by previous research that uses gamification as an engagement tool, we incorporated gaming elements—narrative, improved graphics and audio, scoring, and prize selection—into Brain Storm, a gamified SSVEP-based BCI. Twenty-two children (9-11 years old) completed experiments with three phases: a calibration phase (CP) and two experimental phases (EPs). During the CP, participants were asked to attend to one of three targets (each flashing at a unique frequency) for five seconds. The CP data from 15 trials were then used to set parameters of an online SSVEP classifier. During the EPs, participants were asked to use two different SSVEP-based BCIs—Brain Storm and a control interface (previously reported in Norton et al., J Neuroeng, Vol 15,

2018)—to select targets (nearly identical to those used in the CP) as quickly and accurately as possible. Half of the participants used Brain Storm first; the other half used the control interface first. For each interface, there were four rounds of target selection with 15 targets/round. At the end of the four rounds, the participants were allowed to select as many targets as they wanted during a bonus round. We compared the two interfaces based on participants' performance (accuracy, latency, and bitrate) and engagement (number of targets selected in the bonus round). The children selected targets with a similar accuracy (78% versus 83%), latency (2.13 versus 2.17 seconds), and bitrate (0.53 versus 0.51 bits/second) when using Brain Storm as compared to the control interface. During the bonus round, however, children voluntarily selected more targets with Brain Storm (56.18 targets) than with the control interface (19.18 targets). Our data show that 9-11-year-old children can use both of the SSVEP-based BCIs tested here for target selection. Furthermore, gamification increased the engagement of children with these systems.

Title: Investigating modularity and functional outcomes of rehabilitation of rats with complete T9/10 SCI through viral brain-derived neurotrophic factor, epidural stimulation and pelvic-based robot training

Authors: *A. P. BORISYUK, S. F. GISZTER;
Dept Neurobiol & Anat, Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: It is believed that some interneuronal circuits in the spinal cord that synapse directly onto motor neurons may be organized so as to control muscles modularly, i.e., as groups, rather than individually. Electromyogram (EMG) recordings can serve as a proxy for detecting the modular structure of these interneuronal circuits and their firing patterns as premotor drives, allowing inferences of modular spinal circuit changes after a spinal cord injury (SCI) and rehabilitation. Previous research in our lab demonstrated enhancement in functional outcomes in rats with complete T9/10 SCI after a combined rehabilitation of viral brain-derived neurotrophic factor (BDNF) and passive ankle-based robot training. Combining epidural stimulation (ES) with the ankle-based rehabilitation further enhanced functional outcomes. Interestingly, the combined rehabilitation at the ankle didn't result in improvement in functional outcomes to levels as high as did viral BDNF treatment with pelvic-based weight-supported treadmill training alone (i.e.,

without ES). Further, relative to the viral BDNF effects, our prior work has demonstrated the possibility of a critical period in the initial two weeks of training where ES likely has its effects on preventing some spasticity viral side effects on motor function in the experiments using pelvic centered rehab. Modularity analysis of the hindlimb muscles in the ankle based and in pelvic-based training combined with viral treatments is unexplored. The current study aims to measure the changes in modularity and improvement in functional outcomes in rats with complete SCI though rehabilitation combining viral BDNF, ES and the pelvic-based training - a combination which so far generates the best outcomes. We hypothesize that modularity analysis of the hindlimb muscles should help reveal the patterns of change during an initial period of reorganization of spinal circuit and then a subsequent stabilization. Improvement in weight-supported stepping is expected throughout therapy in most of these rats.

Title: Magnification of visual feedback alters modulation of motor neuron pool in older adults

Authors: *S. PARK[1], M. KWON[3], E. A. CHRISTOU[2];
[2]Applied Physiol. & Kinesiology, [1]Univ. of Florida, Gainesville, FL; [3]Physical Therapy, Marquette Univ., Milwaukee, WI

Abstract: Magnification of visual feedback impairs force control in older adults by increasing the power in low-frequency oscillations in force. However, it is unclear how the impaired visual information processing in older adults alters the modulation of the motor neuron pool that increases the low-frequency oscillations in the force output with magnified visual feedback. To address this, eleven healthy young adults (21.82 ± 3.52 years, 6 females) and 11 healthy older adults (78.27 ± 5.59 years, 7 females) performed an isometric ankle dorsiflexion task at 15% maximal voluntary contraction with magnified visual feedback (1.2°). We recorded the force output and multiple motor unit activity from the tibialis anterior muscle and quantified the following outcomes: 1) force variability using the standard deviation (SD) and coefficient variation (CV) of force and 2) power spectrum of force and multiple motor unit activity. Older adults exhibited greater force variability compared with young adults (SD: $P = 0.045$; CV: $P = 0.01$). The greater force variability was associated with greater power in the <0.3 Hz oscillations in force (SD: $R^2 = 0.30$; CV: $R^2 = 0.36$). The power in the <0.3 Hz oscillations in force were

positively related to power <0.3 Hz in multiple motor unit activity ($R^2 = 0.42$). These results provide novel evidence that magnification of visual feedback alters the modulation of the motor neuron pool with detrimental consequences to force control in older adults.

Abstract: Brain-machine interfaces (BMIs) offer the promise of new therapeutic approaches for millions of people worldwide who suffer from a range of neurological disorders. Here, we describe two non-invasive BMI control strategies, aimed at restoring locomotion in paraplegic patients suffering from chronic spinal cord injuries (SCI) but used for different needs: 1) We suggest the hybrid state machine (HSM) protocol, to maximize the decoding robustness for assistive devices and 2) The single legs control (SLC) method to promote control intuitiveness using lower-limb motor imagery for rehabilitation purposes.
We validated the two paradigms with 12 motor-complete SCI patients (11 AIS A, 1 AIS B) in a setup where the BMI signal was used to control the locomotion of a virtual avatar or a robotic-gait training device.
For the HSM protocol, subjects used arms motor imageries (captured via 16 channel EEG recording) to select specific actions in a state machine (walk, stop, etc.), followed by EMG

activation to confirm the selection. For the SLC paradigm, they used leg motor imageries to trigger the stepping of the corresponding limb.
We report patients' performance for 498 BMI blocks (a block was 6 minutes long) with the HSM protocol for 8 patients and 147 BMI blocks with the SLC method for 4 patients. Control performance was significantly above chance level (t-test, $p < .05$), for all patients trained with the HSM and 3 out the 4 patients using the SLC protocol. Notably, two patients, trained with the HSM reached above 95% accuracy and a cumulated 83 BMI blocks (> 1000 consecutive BMI instructions) without a single mistake.
We also compared for 8 patients, the BMI training performance for 154 blocks of leg motor imagery (LMI) and 295 blocks of arm motor imagery (AMI). In both cases, patients were randomly instructed to imaging move their left or right limb for 3 seconds, 40 times per block. Patients were significantly better than chance level for both paradigms, with significantly higher scores for AMI (75.8 +- 7.3 %, mean +- SEM) compared to LMI (74.1+- 4.9 %) (t-test, $p = .012$). The ability to perform the LMI was independent of both the lesion height and the time since the lesion (coefficient of correlation, $r < 0.02$, $p > .1$), suggesting that our protocol is not restricted to a subset of patients with SCI.
We propose that the two strategies could target different contexts of the rehabilitation process and yet being complementary; the HSM for assistive devices in real-world activities where high levels of accuracy are demanded, whereas the SLC for clinical environments to promote neurological recovery with SCI patient by stimulating cortical plasticity and engaging patients in performing leg motor imagery.

Title: Effects of a vibri-tactile brain-computer interface paradigm on the coma recovery scale-revised in patients with disorders of consciousness

Authors: N. MUROVEC[1], A. HEILINGER[1], R. XU[2], R. SPATARO[3], V. LA BELLA[4], Y. MIAO[5], J. JIN[5], *G. EDLINGER[6], **C. GUGER**[6];

Ctr., Palermo, Italy; [5]East China Univ. of Sci. and Technol., Shanghai, China; [6]g.tec neurotechnology GmbH, Schiedlberg, Austria

Abstract: Persons diagnosed with disorders of consciousness (DOC) typically suffer from motor disabilities, and although their cognitive abilities might be intact, they are difficult to assess. Recent research has shown that the non-invasive brain-computer interface (BCI) technology can help to assess these patients' cognitive abilities and command following. In the study presented here, twenty DOC patients participated and performed 10 vibro-tactile P300 BCI sessions over 10 days with 8-12 runs on each day. Patients were in a stable chronic stage, 11 were diagnosed with a minimally conscious state (MCS) and 9 with unresponsive wakefulness syndrome (UWS) based on the Coma Recovery Scale-Revised (CRS-R). Changes of the BCI classification accuracy were investigated over the 10 days, and the changes of the CRS-R score before and after 10 vibro-tactile P300 sessions. Patients had vibro-tactile stimulators fixed on both writs and one foot, and were instructed to mentally count either the stimuli on the left or right wrist, which induces the P300 for the target wrist only. The grand average accuracy of the BCI paradigm in the first session for all patients was 40 %, in the best session the grand average accuracy was 88 % and the median accuracy of all sessions was 21 %. In the first run 10 patients had a classification accuracy above chance level (>23 %). In the best run every patient reached an accuracy ≥ 60 %. Twelve out of twenty patients showed an improvement of 1 to 7 points in the CRS-R score after the VT3 BCI sessions. 6 patients did not show change in the CRS-R score and 2 patients showed a decline in the score for 1 point. This study shows the importance of repeating the EEG measures when DOC patients are assessed to increase the chance of detecting the abilities of the command-following. The improvement of the CRS-R score after the 10 vibro-tactile sessions is an important fact for future studies to test the training effects and the signs of motor recovery with DOC patients with a larger group of patients and the vibro-tactile BCI setup.

Title: Brain plasticity following intensive robotic 'Third Thumb' usage for hand augmentation

Authors: P. KIELIBA, D. CLODE, ***T. R. MAKIN**;
Univ. Col. London, London, United Kingdom

Abstract: Interest is growing in augmentative technologies that extend the physical and cognitive abilities of able-bodied individuals. These new devices introduce various theoretical and practical challenges for how the brain should adapt to representing a new robotic body-part. Supernumerary robotic fingers, such as the 'Third Thumb', allow the user to single-handedly perform normally bimanual tasks. Strapped to the ulnar side of the right hand, the Third Thumb is controlled via pressure sensors under the users' big toes, providing two degrees of freedom for operating a 2nd opposable thumb. Here, using the human somatosensory cortex as a model, we investigate neural correlates of Third Thumb usage. We trained 18 healthy able-bodied participants to use the Third Thumb over the course of five days, including spontaneous usage (tracked using pressure signals, used to operate the device) and customised daily training sessions. During training, participants completed a set of typical bimanual daily life tasks, using their (right) augmented hand. A separate control group (n=10) wore the Third Thumb and underwent daily training sessions, but did not operate the Third Thumb. Multiple measures of Third Thumb dexterity and hand-robot coordination showed significant improvement in motor control over the five days of usage. We used pre- to post- comparison measures to assess brain and behavioural outcomes of Third Thumb usage on body representation. Questionnaires for explicit sense of body ownership revealed increased embodiment over the Third Thumb specifically in the users' group. fMRI neuroimaging (focusing on multivoxel representational similarity across the biological digits) revealed increased similarity after Third Thumb usage, both for the augmented hand digits, and between the toes and the augmented hand digits. Preliminary results for hand-digit individuation revealed trends towards increased enslavement following Third Thumb usage. By studying the neural correlates of hand augmentation, we introduce a novel model for examining the adult brain's ability to dynamically update body representations based on new experiences with technology. We conclude that even short experience with wearable motor augmentation impacts fundamental aspect of hand and body representation.

Title: Efficacy and long-term stability of a high-density intramuscular electrode system for functional electrical stimulation

Authors: N. L. HOLLY[1], B. A. HASSE[1], L. COX[2], D. M. MARGOLIS[3], K. M. GOTHARD[4], *A. J. FUGLEVAND[1];
[1]Physiol., [2]Univ. of Arizona, Tucson, AZ; [3]Orthopedic Surgery, Col. of Medicine, Univ. of Arizona, Tucson, AZ; [4]Univ. Arizona, Col. Med., Tucson, AZ

Abstract: Functional electrical stimulation (FES) involves artificial electrical stimulation of muscles to elicit movement in paralyzed limbs. We are developing a method that uses electromyographic and kinematic signals recorded in able-bodied subjects to train machine-learning algorithms to control FES in paralyzed individuals. For this system to work, we need access to most of the muscles controlling a limb with implanted intramuscular electrodes. As such, we require an electrode system that: 1) minimizes electrode migration, 2) is biocompatible, 3) has small leads needed to accommodate large numbers of electrodes, and 4) is efficient to implant within one surgical session. With such requirements in mind, we developed an electrode system and tested it in a chronic implant of 60 electrodes in 30 upper-limb muscles of a rhesus macaque. Electrode leads were made of Teflon-coated multi-stranded stainless steel wire (0.3 mm outside diameter). During surgery, the color-coded leads were tunneled below the skin from a skull-mounted connector to incisions made over target muscles. Leads were then cut to length, insulation from the tip of the leads was removed with a thermal wire stripper, and gold anchors (~ 1 x 4 mm) were crimped onto the leads. The anchor was loaded into a 14-guage needle with the lead exiting the needle in a slot cut along its shaft. The needle was inserted into the muscle and stimulation was delivered through the tip of the needle that was otherwise insulated. The position of the needle was adjusted until strong contractions were evoked. The anchor was then deployed with a plunger and the needle removed. Anchor placement was then verified by stimulating through the lead and the threshold current was determined visually. The entire surgery lasted 9 hours. There were no post-operative complications and no electrode rejection. All 60 electrodes were functional at 8 weeks. At 5 and 8 weeks post surgery, the animal was anesthetized, secured upright in an infant car seat, and the hand fixed to a 6 degree-of-freedom force/torque transducer. Contractile responses to 1-s pulse trains, incrementing in 1 mA steps,

were measured for each electrode. Average (± SD) thresholds were 3.0 ± 2.2 mA and 2.8 ± 2.3 mA at 5 and 8 weeks, respectively. These values were slightly higher than that measured visually during surgery (1.5 ± 0.7 mA). While preliminary, these results indicate that such anchor electrodes might provide a long-lasting implant that could be used in future FES systems.

Title: The effect of dry needling therapy on gene expression in a model of muscle spasticity

Authors: *E. E. GARCIA-VENCES[1], J. CEBALLOS ZAVALA[1], J. FIGUEROA VARELO[1], E. DE LA CRUZ CASTILLO[1], S. CALVO CARRION[2], P. HERRERO GALLEGO[2], A. IBARRA[1];
[1]Facultad de Ciencias de la Salud, Univ. Anahuac Mexico Norte, México, Mexico; [2]Univ. de San Jorge, Zaragoza, Spain

Abstract: The spinal cord injury (SCI) is an adverse condition that involve different consequences like muscle spasticity with many repercussions in patients as muscle atrophy and pain. These signs and symptoms are triggered by the activation of molecular mechanisms that promotes the release of acetylcholine into neuromuscular end-plate as a consequence of denervation after SCI, that leads to increasing calcium levels and therefore the depolarization of cell membrane that result in the myofibrillar destruction and the activation of inflammatory molecules as inducible nitric oxide synthase (iNOS), cyclooxygenase-2 (COX-2), interleukin-1 beta (IL-1β), tumor necrosis factor alpha (TNFα) and decrease the acetylcholinesterase (AChS) The dry needling (DN) is an innovative strategy that promotes the reduction of the sustained muscle contraction; however, the molecular mechanisms hadn´t been studied yet. For this reason, our goal was to analyze the motor and molecular changes that induce DN inside spastic gastrocnemius muscle in a chronic SCI model. Adult female Sprague-Dawley rats (13-14 weeks old, 200-220 g) were anesthetized and its spinal cords were exposed by laminectomy at T9. Rats were subjected to spinal cord transection (SCT) (n=20). Twenty days after SCT the animals were randomly allocated into five groups: 1. Sham surgery, n=4, 2. SCT without DN, n=10; 3. SCT + DN, 3 days n=5 and 4. SCT + DN 7 days n=5 and the DN was applied in gastrocnemius muscles with previous localization of the trigger points at 3 hr and 7 days after (28 days after SCT). We

perform motor recovery test with BBB scale from SCT until 28 days. We assessed the gene expression of iNOS, COX-2, IL-1β, TNFα and AChS in gastrocnemius to 3 hr and 7 days after DN. Seven days after DN the animals showed a significant increased motor recovery comparing with the other groups (5.6+/- SD vs 2.1 +/- SD, U de Mann Whitney p≤0.05). In relation to gene expression at 3 hr iNOS, COX-2 and AChS were down-regulated (U de Mann Whitney p ≤0.05); however, at 7 days shift up-regulated (U de Mann Withney p ≤0.05). The other genes didn´t show a significant difference. The DN induce the up-regulation of AChS, iNOS y COX-2 at 7 days that promotes the reduction of the sustained muscle contraction, vasodilatation and protection of the muscle fiber, data support the trend to motor recovery at this time. The DN set up a focal inflammatory response that promote the decreased of chronic inflammation of trigger points in spastic muscles.

Title: Preservation of Ia afferent synaptic inputs on regenerated motoneurons after nerve injury does not result in restoration of function

Authors: *T. M. ROTTERMAN[1], P. NARDELLI[2], V. GARCIA[3], F. J. ALVAREZ[5], T. C. COPE[4];
[1]Biol. Sci., [2]Sch. of Biol. Sci., [4]Applied Physiol. and Engin., [3]Georgia Inst. of Technol., Atlanta, GA; [5]Physiol., Emory Univ., Atlanta, GA

Abstract: Peripheral nerve injury (PNI) results in the permanent reorganization of essential motor circuits within the spinal cord even after peripheral axon regeneration is complete. One example of this is the loss of the proprioceptor Ia afferent input from axotomized motoneurons (MNs) which ultimately results in the complete absence of the stretch reflex. Recent work from our labs has shown that this loss is due to a central neuroinflammatory response. We hypothesized that administration of the broad-spectrum antibiotic with known anti-inflammatory properties, Minocycline, would dampen overall inflammation resulting in the preservation of Ia afferent boutons and restoration of the stretch reflex. To investigate this, we completely transected the medial gastrocnemius (MG) nerve in adult rats followed by an immediate repair using fibrin glue. Rats were treated with minocycline (49mg 1x daily) or vehicle food cubes for two weeks post injury. Sham control rats treated with minocycline were also prepared. Three

months post injury, well after peripheral regeneration has occurred, we quantified the somatic and linear dendritic density of Ia synapses on retrogradely labeled MG MNs. Rats who had undergone injury with no drug showed, as expected, an 81% decrease in Ia input on the soma and a 58% drop on the proximal dendritic arbor. However, treatment with minocycline rescued this synaptic loss resulting in a 5% increase on the soma and a mild 17% loss on the dendrites compared to controls. To investigate the function of these preserved synapses we measured the stretch reflex in regenerated and control rats. Rats who had undergone a nerve injury with no drug showed absolutely no stretch reflex in response to both vibration and to a ramp-hold-release paradigm compared to sham controls. Rats who had undergone injury with drug, in which synapses were preserved, surprisingly also showed no response to muscle stretch. To investigate these findings further we performed *in vivo* intracellular recordings of MG MNs in all conditions. In injured rats with vehicle there was a significant drop in stretch evoked synaptic potentials (SSPs) compared to controls, while majority of all MG MNs in drug treated rats evoked an SSP but still did not produce a reflex. Based on current evidence the preservation of Ia afferent inputs on regenerated MNs in necessary but not sufficient to restore stretch-evoked reflexes even though SSPs can be detected in essentially all MG MNs with drug treatment. This lack of functional recovery is under further investigation to explain the discrepancy between structural synaptic preservation and presence of SSPs but no reflex.

Title: Exercise improves contractile force and kinematical movement of paralyzed hindlimb after brain damage of mice

Authors: *A. YOSHIKAWA[1], H. OHTAKI[2], M. IZUMIZAKI[1];
[1]Physiol., Showa University, Sch. of Med., Tokyo, Japan; [2]Anat., Showa Univ. Sch. of Med., Tokyo, Japan

Abstract: Rehabilitation is one of the therapies for recovery of lost function after neural damage. Exercise such as movement of the extremities in the patients promotes the recovery of motor function. In rodents, although several behavior experiments such as ladder waking and footprint

test are performed to assess the motor function, there are no objective measurement for the motor evaluation. In present study, we induced brain damage in mice and evaluated the effect of exercise on the motor function in a quantitative fashion using motion-capture technology. Male 8 weeks old mice were subjected to brain damage. The brain damage was produced by aspiration of left sensorimotor cortical region. Then the mice divided into exercise (Ex) and non-exercise (Non-Ex) group. Rehabilitation program was a running exercise. Mice were run on treadmill (30 min/day, 5 days/week) for 4 weeks. After the exercise, the mice were recorded the steps on the treadmill by synchronized four cameras and were analyzed three-dimensional motor functions by using kinematical analysis including motion-capture technology. The mice then were removed soleus muscle in the side of paralyzed and the contractile force was measured by the Magnus method under the KCl stimulation. There were no significant differences in gait parameters (time of gait cycle, stance phase and swing phase) and in the mass of muscles in the limbs between Ex and Non-Ex group. However, the contractile force of paralyzed soleus muscles in Ex group was shown significantly stronger than that in Non-Ex group. The soleus muscle is responsible for the ankle movable of the dorsal-plantar flexion. Therefore, the mice were further evaluated the ankle movement on the paralyzed side during the steps by using kinematically analysis. No significant difference in the range of joint movement during the steps was observed in the ankle of paralyzed side. However, the angular velocity and acceleration of the paralyzed side in Ex mice was increased shortly before takeoff the floor. From this study, hindlimb movement was evaluated quantitatively by using kinematical method. Our results suggest that exercise therapy after brain damage improve paralyzed muscles activity participate as joint movement.

Title: The duration and frequency of vibration modulate the recovery time of the post-vibration depression of monosynaptic Ia facilitation in humans

Authors: *M. NITO, T. YOSHIMOTO, M. JIMENJI, W. HASHIZUME, A. NAITO;
Dept. of Anat. and Structural Sci., Yamagata Univ. Sch. of Med., Yamagata, Japan

Abstract: Effects of the tonic vibration stimulation (TVS) to a muscle on the monosynaptic Ia facilitation to the homonymous and heteronymous muscles were examined using the Hoffmann(H)-waves of the flexor carpi radialis (FCR) and the tendon(T)-waves of the biceps

brachii (BB), respectively, in fifteen healthy human volunteers. The H-wave of FCR were provoked by electrical stimulation to the median nerve trunk at the elbow. The T-wave of BB were induced by a mechanical quick tap applied to the distal tendon of BB (test T-wave) and the amplitude of the T-waves was increased significantly by electrical stimulation to the median nerve trunk (conditioned T-waves). TVS (frequency: 57, 77 and 100 Hz; duration: 2, 4, 6, 8, 10 and 20 minutes) was delivered manually to the FCR muscle belly. As a result, the amplitudes of the H-waves and the conditioned T-waves were suppressed by TVS, and the suppression lasted after removal of TVS in all the subjects. In both the H- and conditioned T-waves, the longer the duration and the higher the frequency of TVS, the longer the recovery time of the suppression. Since the amplitude of the test T-waves did not change throughout the experiment, TVS should not have affected the excitability of motoneurons. It therefore seems that the duration and frequency of TVS affect the transmission of group Ia afferent terminals mediating the facilitation to the homonymous and heteronymous motoneurons.

Title: Loss of NAMPT alters function and structure of the neuromuscular junction (NMJ)

Authors: *S. LUNDT, N. ZHANG, X. WANG, L. POLO-PARADA, S. DING;
Univ. of Missouri, Columbia, MO

Abstract: Nicotinamide adenine dinucleotide (NAD^+) is one of the most abundant metabolites in the human body. The majority of NAD^+ in cells is synthesized via the NAD^+ salvage pathway, where nicotinamide phosphoribosyltransferase (NAMPT) functions as the rate-limiting enzyme. NAMPT converts nicotinamide into nicotinamide mononucleotide (NMN). In mice, conditional knockout of NAMPT in projection neurons has been shown to produce broad physiological deficits and, eventually, death. The impact of the knockout of NAMPT on the neuromuscular junction (NMJ), specifically vesicle cycling in the motor neuron or end-plate structure and contractile responses of skeletal muscles, has yet to be characterized. We found that loss of NAMPT significantly disrupts endocytosis and exocytosis of synaptic vesicles in motor neurons,

possibly impairing movement of the vesicles intracellularly. The end-plate morphology of the NMJ was significantly altered, having reduced area and thickness. When treated with NMN, the mice showed improved vesicle endocytosis and exocytosis with end-plate structure more resembling the structure observed in control mice. At low frequencies of stimulation, knockout of NAMPT produced responses of similar strength but quicker end of contraction. At moderate frequencies, Nampt$^{-/-}$ cKO mice had exaggerated contraction strength but showed no response to the highest frequency. NMN-treated Nampt$^{-/-}$ cKO mice were similar to Nampt$^{-/-}$ cKO at low frequencies, displayed reduced contraction strength at moderate frequencies but remained responsive to the highest stimulation frequency. Our results indicate that neuronal NAMPT is important for the proper function of the NMJ and that loss of NAMPT leads to both presynaptic and postsynaptic deficits.

Title: No influence of the menstrual cycle on ankle joint position sense and inhibitory function of primary somatosensory cortex

Authors: *K. IKARASHI[1], D. SATO[2], K. IGUCHI[1], Y. YAMAZAKI[1], K. YAMASHIRO[1]; [1]Niigata Univ. of Hlth. and Welfare, Niigata, Japan; [2]Niigata Univ. of Hlth. and Welfare, Niigata City, Japan

Abstract: Previous studies have reported that the menstrual cycle may affect sensorimotor performance, and that sex hormones, such as estradiol and progesterone, modulate cortical excitability. Accordingly, it is considered that the menstrual cycle may affect joint position sense and somatosensory cortical activity. We aimed to clarify the influence of the menstrual cycle on the ankle joint position sense and the inhibitory function of the primary somatosensory cortex. Fourteen women with regular menstrual cycle participated in the present study. Based on the basal body temperature measured during two months prior to the main experiment, we predicted the follicular, ovulation and luteal phase in the menstrual cycle of each participant. In the main experiment, in each menstrual cycle phase, we evaluated the ankle joint position sense using a joint angle modulation task, and the somatosensory inhibitory function using somatosensory paired pulse inhibition (somato-PPI) measurement. The absolute error angle, response time of the joint angle modulation task, and somato-PPI ratio were compared between each menstrual cycle

phase. The results of repeated measures ANOVA revealed no significant difference in either joint angle modulation performance or somato-PPI ratio between each menstrual cycle phase. Correlation analysis revealed a significant negative correlation between the absolute angle error in the early follicular phase and the ratio of absolute angle error in the luteal phase to that in the early follicular phase. Contrary to our hypothesis, the results of our study demonstrated that the menstrual cycle did not affect ankle joint position sense or the inhibitory function of the primary somatosensory cortex. However, the results of the correlation analysis might indicate that the change in sex hormones concentration modulates joint angle sense in the luteal phase. In conclusion, our results demonstrated that the menstrual cycle has no influence on the ankle joint position sense or inhibitory function in primary somatosensory cortex.

Title: Influence of focal muscle fatigue on paired associative stimulation induced plasticity in the primary motor cortex

Authors: *K. KURIHARA[1], D. SATO[2], K. YAMASHIRO[1], Y. YAMAZAKI[1], A. MARUYAMA[3];
[1]Niigata Univ. of Hlth. and Welfare, Niigata, Japan; [2]Niigata Univ. of Hlth. and Welfare, Niigata City, Japan; [3]Kagoshima Univ., Kagoshima-Shi, Japan

Abstract: Previous studies have reported that muscle fatigue changes the balance between excitability and inhibitory neural activity of the primary motor cortex. Our research group and others have previously shown decreased inhibitory neural activity of the primary motor cortex (M1) during and after focal muscle fatigue. However, the effect of focal muscle fatigue on neural plasticity has remained unclear. We examined the effects of changes in M1 excitability induced by focal muscle fatigue on spike timing-dependent plasticity (STDP) using paired associative stimulation 25 (PAS 25), which induces long-term potentiation (LTP)-like effect.Ten right-handed, healthy adults participated in the present study. We measured the motor evoked potentials (MEPs) induced by transcranial magnetic stimulation (TMS) to evaluate the M1 excitability before and after PAS 25 in three experimental trials: PAS25 without fatigue, PAS25 immediately after muscle fatigue, and PAS25 after recovery. TMS was applied over the M1

hotspot of the right first dorsal interosseous muscle at the intensity required to induce MEPs with an amplitude of 1 mV. Electrical stimulation (ES) was applied to the ulnar nerve at the right wrist at the intensity of three times the sensory threshold. For the PAS protocol, paired stimulation with TMS and ES was conducted in 25-ms intervals at 0.2 Hz for a period of 20 min. We observed slightly increased MEP amplitude after PAS 25 without muscle fatigue. In addition, significantly decreased MEP amplitude was observed after focal muscle fatigue, similar to findings of previous studies. The results of repeated measures ANOVA revealed no significant change in MEP amplitude after PAS 25 after focal muscle fatigue compared to that at baseline measurement. These results indicate that muscle fatigue abolished PAS 25-induced plasticity due to homeostatic meta-plasticity, as has been previously reported. Notably, a new finding based on the results of this study is that this metaplastic effect lasts at least 30 min after muscle fatigue, as PAS 25 did not increase the MEP amplitude even when the MEP amplitude returned to baseline levels. In conclusion, focal muscle fatigue might abolish the STDP effect induced by PAS 25 irrespective of recovery of decreased MEP amplitude.

Title: Orexin modulates electrophysiological properties of Phox2b neurons located around trigeminal motor nucleus

Authors: *K. NAGOYA[1,2], S. NAKAMURA[2], T. TSUJIMURA[1], M. INOUE[1], T. INOUE[2]; [1]Niigata Univ., Niigata city, Japan; [2]Showa Univ., Tokyo, Japan

Abstract: Phox2b is a member of transcription factors and essential for the development of the autonomic nervous system. Previous study indicated that Phox2b-expressing neurons were located at the reticular formation dorsal to the trigeminal motor nucleus (RdV) in the rat brainstem. We recently reported that Phox2b-expressing and -nonexpressing neurons in the RdV have different physiological properties, and about half of both neurons were send their axons to the trigeminal motor nucleus. This result suggests that these neurons are also involved in the control of coordinated jaw-movements such as chewing and swallowing.
Orexin is one of the neuropeptides that are mainly derived from orexin-containing neurons in the lateral hypothalamus, and are widely distributed throughout the central and peripheral nervous

systems. Orexin have an essential role to regulate physiological functions such as feeding and wake/sleep stabilities. However, the effect of orexin on Phox2b-expressing or -nonexpressing neurons and its functional role remain unknown. In the present study, we investigated physiological changes of Phox2b-expressing neurons located at RdV by the administration of orexin.
Using brainstem slices including RdV were prepared from P2-14 Phox2b-EYFP rats, whole-cell recording were performed in Phox2b-expressing and -nonexpressing RdV neurons. We analyzed neuronal activity with the presence of orexin-A (200 nM) or orexin-B (200 nM). Furthermore, we examined effects of an orexin 1 receptor antagonist,
SB-334867, and orexin 2 receptor antagonist TCS OX2 29, on orexin-A- induced depolarization of Phox2b-expressing neurons.
The majority of Phox2b-expressing neurons (15/18) were produced membrane depolarization sometimes accompanied by spontaneous firing, whereas most of Phox2b-nonexpressing neurons (9/12) showed no depolarization changing during the application of orexin-A. Orexin-B induced depolarization in most Phox2b-expressing neurons (6/7) as well as the effect of orexin-A. Orexin-A or orexin-B- induced depolarization ranged from 5 to 20 mV. However, orexin A-induced membrane depolarization were prominently reduced with the presence of SB-334867 or TCZ OX2 29. On the other hand, all Phox2b-expressing and -nonexpressing neurons exhibited reduction of firing rate by the administration of orexin-A. Mean reduction of Phox2b-expressing and -nonexpressing neurons with the presence of orexin-A were 5.8 and 5.2 Hz, respectively. Taken together, present study suggests that orexin modulate passive membrane and firing properties of Phox2b-expressing neurons, which may affect the regulation of the jaw-movement during feeding behavior and bruxism.

Title: Stimulation of a reinnervating laryngeal muscle with low frequency inhibits foreign reinnervation and promotes selective reinnervation by native motoneurons and restores function

Authors: *D. L. ZEALEAR, Y. LI, M. E. POWELL, S. HUANG;
Otolaryngology, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Electrical stimulation of a denervated canine laryngeal muscle was shown to promote reinnervation by original over foreign motoneurons. An implantable nerve stimulation-EMG system was used to index the appropriateness of reinnervation of the vocal fold abductor (posterior cricoarytenoid, PCA) muscle by inspiratory versus foreign reflex glottal closure (RGC) motoneurons following recurrent laryngeal nerve section and repair. In the present study in 11 canines, a clinical model was used, where both nerves were sectioned and ventilation compromised due to loss of vocal fold abduction. The EMG system and a pulse generator were implanted, the latter for electrical conditioning of PCA muscles. After nerve section, animals were randomly assigned to four groups to assess the effect of different muscle stimulus paradigms on reinnervation quality and degree of functional recovery: 1)40 pps train, 2)20 pps train 3)10 pps train and 4)control-no stimulation. One msec pulses were applied with 4 sec on/4 sec off duty cycle during the post neurorrhaphy regeneration period. In bimonthly sessions, spontaneous vocal fold movement was measured endoscopically during induced hypercapnea in the anesthetized animal. Rectified integrated EMG potentials were recorded from abductor muscles and adductor (thyroarytenoid, TA) muscles. Recordings were obtained during hypercapnic respiration to index reinnervation by inspiratory motoneurons, and during superior laryngeal nerve stimulation to index reinnervation by RGC motoneurons. Exercise tolerance was measured on a treadmill in the awake animal using pulse oximetry. Results demonstrated that all stimulated groups tended to have better results (i.e. higher rank order) in all outcome measures compared to the non-stimulated control group. The rank order stayed fairly consistent across all outcome measures: 10pps > 20pps > 40pps > non-stimulated. It would appear that electrical stimulation of the denervated PCA muscle inhibited synkinetic reinnervation by RGC motoneurons and promoted selective reinnervation by its original inspiratory motoneurons. In addition, stimulation with low frequency, characteristic of the intrinsic activity of PCA inspiratory motoneurons, was more effective than high frequency in inducing correct reinnervation and improving functional recovery.

Title: Hypoexcitability and hyperexcitability in sacral motorneurons of SOD1G93A high copy ALS mice: Disease versus compensation

Authors: *C. S. I. DRAPER[1], A. A. MAHROUS[2], S. M. ELBASIOUNY[2,3];
[1]Biomed. Sci. PhD Program, [2]Neuroscience, Cell Biology, and Physiol., [3]Biomedical, Industrial, and Human Factors Engin., Wright State Univ., Dayton, OH

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease characterized by the selective and progressive loss of motorneurons in the motor cortex, brain stem, and spinal cord. To date, many hypotheses to explain the pathogenesis of ALS has been explored, but abnormalities in motorneurons and glutamate excitotoxicity remain predominant. The current excitotoxicity theory predicts that motorneurons in ALS are excessively activated by glutamate, leading to increasing amounts of calcium entering these cells and eventually cell death. However, the current literature regarding the excitability state of motorneurons in ALS is inconsistent in which some studies have reported hyperexcitability (Pieri et al.,2003, Kuo et al., 2005, and Martin et. al., 2013) others reported hypoexcitability (Bories et. al.,2007, Delestree et al.,2014, and Martinez-Silva et al.,2018) or some reported no excitability changes (Pambo-Pambo et al. 2009 and Quinlan et al.,2011). This conflicting data on motor neuron excitability in ALS probably reflects the dynamic interaction between the underlying disease and compensatory mechanisms. Therefore, the purpose of this study was to examine spinal motorneurons' excitability in $SOD1^{G93A\text{-}High}$ mice at the time of symptom onset (i.e., postnatal day 90, P90); a stage when disease and compensatory mechanisms are at peak interaction. Interestingly, intracellular recordings from spinal motorneurons in the in-vitro whole cord preparation exhibited *concurrent* signs of hypoexcitability and hyperexcitability. Specifically, SOD motor neurons exhibited increased rheobase and input conductance (signs of hypoexcitability) but reduced afterhyperpolarization amplitude (a sign of hyperexcitability). Our study is the first to report both excitability abnormalities in the same motorneurons in ALS. Accordingly, our results indicate that hyper- and hypoexcitability are both present and interact dynamically during ALS pathogenesis.

Abstract: The proprioceptive sensory inputs from neurons in the mesencephalic trigeminal nucleus (MesV) to masseter motoneurons (MMNs) play an important role in regulating masseter muscle activity during mastication. Several histological studies have shown that serotonin (5-HT) fibers densely innervate both the MesV and the trigeminal motor nucleus. However, the functional roles of 5-HT in the regulation of the excitatory synaptic inputs from MesV afferents to MMNs remain to be clarified. Thus, using the whole-cell recording technique in brainstem slice preparations from juvenile Wistar rats aged between postnatal days 8 and 12, we examined the effects of 5-HT on the excitatory synaptic inputs from MesV afferents to MMNs. Bath application of 5-HT (0.1-100 μM) reduced the peak amplitude of excitatory postsynaptic potentials evoked in MMNs by electrical stimulation of the MesV afferents (eEPSPs) in a dose-dependent manner. This inhibitory effect of 5-HT on eEPSPs was replicated with the 5-HT_{1B} receptor agonist CP-93129 (0.1 μM) but not by the 5-HT_{1A} receptor agonist 8-OH-DPAT (1 μM). Moreover, the 5-HT_{1B} receptor antagonist SB-224289 (10 μM) but not the 5-HT_{1A} receptor antagonist WAY-100635 (1 μM) antagonized the inhibitory effect of 5-HT on eEPSPs. CP-93129 increased the paired-pulse ratio and decreased the frequency of miniature excitatory postsynaptic currents (mEPSCs), while it did not alter the mEPSC amplitude. These results suggest that presynaptic 5-HT_{1B} receptors are involved in the inhibition of the excitatory synaptic inputs from MesV afferents to MMNs. Such inhibition may regulate MesV afferent activity during mastication.

Title: Quadriceps muscle motor unit activity after anterior cruciate ligament reconstruction

Authors: *A. MCPHERSON[1], N. BATES[1], C. HAIDER[1], T. HEWETT[2], N. SCHILATY[1];
[1]Mayo Clin., Rochester, MN; [2]Univ. of Kentucky, Lexington, KY

Abstract: Introduction
Quadriceps strength deficits exist after anterior cruciate ligament (ACL) injury and reconstruction (ACLR) despite rehabilitation. The mechanism for persistent strength deficits remains unclear, although reduced alpha motor neuron (α-MN) output has been suggested to reduce voluntary strength after ACLR. Therefore, the purpose of this exploratory study was to determine α-MN is different after ACLR compared to healthy controls.
Methods
Subjects (29F/24M) completed isometric knee extension tasks while surface electromyography (EMG) signals were recorded from the vastus medialis (VM) and vastus lateralis (VL). Three maximum voluntary isometric contractions (MVIC) determined peak force for 10, 25, 35, and 50% MVIC trials. After data acquisition, EMG decomposition was performed. Motor unit (MU) (de)recruitment and average firing rates (FR) were compared between groups with mixed model analyses and post-hoc Tukey all pairwise comparisons.
Results
Group, trial, and muscle were all significant effects in the mixed model for average FR and (de)recruitment thresholds ($p<0.001$). Significant differences were observed between groups for average FR, except 6 months post-ACLR and controls ($p=0.47$), and between all groups for recruitment thresholds. All trials were significantly different for average FR and recruitment thresholds, except 10% vs 25% MVIC, 10% vs 50% MVIC, and 25% vs 50% MVIC average FR. VM average FR was greater than VL, but VL recruitment was greater than VM. All groups and trials were significantly different for derecruitment threshold except controls and 12 month post-ACLR.
Conclusion
MU (de)recruitment was lowest at 6 months post-ACLR concomitant with higher average FR. This inverse relationship between average FR and MU recruitment thresholds has previously been demonstrated in healthy subjects and is now demonstrated here after ACL injury and ACLR. ACL injury and ACLR appears to have variable effects on VM and VL α-MN activity, as VM decreased (de)recruitment thresholds and increased FR whereas VL exhibited the opposite pattern. These findings suggest that quadriceps α-MN activity changes throughout rehabilitation up to 12 months post-ACLR compared to controls.

Title: Behavioral recovery and spinal motoneuron remodeling after polyethylene glycol fusion repair of singly cut and ablated sciatic nerves

Authors: E. A. HIBBARD[1], C. GHERGHEREHCHI[2], M. MIKESH[2], G. BITTNER[2], ***D. R. SENGELAUB**[3];
[1]Indiana Univ., Bloomington, IN; [2]Univ. of Texas, Austin, TX; [3]Indiana Univ. Bloomington, Bloomington, IN

Abstract: Peripheral nerve injuries lead to the immediate loss of motor and sensory function, rapid degeneration of the distal nerve segment, neuromuscular junction loss, and muscle atrophy. Behavioral recovery is typically poor. Peripheral nerve injuries also have consequences centrally for the affected motoneurons, including somal shrinkage and retraction of dendritic arbors. The current standard of treatment for peripheral nerve injury involves microsuturing of the severed nerve segments. However, this treatment leaves axonal membranes unrepaired, and therefore Wallerian degeneration is not prevented and recovery is not improved. We have developed a novel strategy that uses a plasmalemmal fusogen, polyethylene glycol (PEG), to nonspecifically re-fuse the membranes of severed axons. This treatment allows for the immediate re-innervation of the distal muscles, prevents Wallerian degeneration, maintains muscle innervation, and improves behavioral recovery. In this study, we determined the effects of PEG-fusion repair on the central consequences of peripheral nerve injury by examining motoneurons contributing to the sciatic nerve after non-specific PEG-repair of their peripheral axons. At 2-112 days after either a single-cut or allograft repair of the sciatic nerve with PEG, the number and size of motoneurons contributing to the sciatic nerve was assessed stereologically. The location and morphology of motoneurons projecting to the anterior tibialis muscle was also assessed after retrograde labeling. Following peripheral axotomy and PEG-repair, the number and size of sciatic motoneurons was unaffected. Retrograde labeling of motoneurons revealed that following non-specific axonal fusing with PEG, retrograde transport was re-established within 2-17 days, depending on repair type. Labeled motoneurons were found not only in the appropriate L3 spinal segment, but also in the L4-L6 segments, indicating mis-pairings of proximal and distal motor axons. The morphology of PEG-repaired motoneurons was also affected, with changes in dendritic distribution from patterns typically displayed by these motor populations. Together, these findings indicate that PEG-repair after axotomy preserves spinal motoneurons, and a substantial reorganization of motoneuron morphology is induced by the non-specific repair of the severed nerve. This central reorganization may contribute to the improved behavioral recovery seen after PEG-repair, supporting the use of this novel repair methodology over currently available treatments.

Title: Estimate of persistent inward currents in humans during varying muscle contraction speeds

Authors: *E. H. KIM[1], R. K. POWERS[3], C. HECKMAN[2];
[2]Dept. of Physiol., [1]Northwestern Univ., Chicago, IL; [3]Dept Physiol & Biophysics, Univ. Washington, Seattle, WA

Abstract: Persistent Inward Currents (PICs) amply the spinal motoneuron outputs by prolonging their firing and it has been postulated that PICs might play an important role in balance and postural control. Unlike in animals, the level of PICs cannot be directly measured in humans. Delta-F (ΔF) is a pair-wise comparison of motor unit discharge patterns that is widely used as an indirect estimate of PICs in humans. However, a simulation study has shown that increasing muscle contraction speed decreases ΔF because of spike-threshold accommodation. Therefore, we hypothesized that as the rate of rise increases, ΔF will decrease. In this study, ΔF of the soleus and tibialis anterior (TA) were measured from young and healthy subjects while they performed voluntary isometric contractions over varying rates of rise (1-5% MVC per second) at varying %MVC levels (10-50% MVC). EMG signals were collected through High-density surface array electrodes (HD-sEMG) and were decomposed into discharge patterns of individual motor units for ΔF calculation. The results showed that in both muscles, as the effort level increases, the ΔF did not change if the rate of rise stayed constant. However, unlike the hypothesis, ΔF increased in the TA as the rate of rise increased. On the other hand, ΔF did not significantly change in the soleus, as the rate of rise increased. Our simulation experiment also showed that as the contraction speed increased, ΔF increased as well.

Title: Fatigue induced modulation of human soleus H reflex in conditions of ipsilateral common peroneal nerve stimulation

Authors: *E. V. KOLOSOVA;
Natl. Univ. of Physical Educ. and Sports of Ukraine, Kyiv, Ukraine

Abstract: It was reported that after fatiguing calf triceps muscle contraction the soleus H (Hoffmann) reflex is inhibited, probably due to the activation of the groups III and IV afferent nerves under the influence of mechanical and metabolic changes in the fatigued muscle. Other authors described soleus H-reflex depression which was caused by conditioning common peroneal nerve stimulation at rest. We supposed that investigation of inhibition, connected with conditioning peroneal nerve stimulation before and after fatiguing contraction (FC) might help to assess peculiar patterns of inhibition processes in intrasegmental systems. Ten healthy people (4 men and 6 women, 18-34 years of age, M_{age}=25.8, SD=4.9) took part in this EMG-study. The method of H-reflex of soleus muscle with tibial nerve stimulation (test H-reflex, THR) and conditioning peroneal nerve stimulation with 15 ms peroneal-tibial interstimulus interval (conditioned H-reflex, CHR) were performed using neurodiagnostic complex Nicolet Biomedical Viking Select (Viasys Healthcare, USA). Fatigue was caused by voluntary static contraction of calf triceps muscle lasting 6-9 min with the force egual to 75 % of the maximal voluntary contraction. Two-factor analysis of variance with repeated measures considering two within-subjects factors (fatigue and conditioning) was carried out in the SPSS 17.0. It was found that the fatigue factor had significant inhibitory effect on the H-reflex (F=15.634, P=0.000). The conditioning factor had similar effect (F=306.586, P=0.000). The interaction of fatigue and conditioning factors was also found (F=2.237, P=0.016). A significant result of the study was that decrease of the CHR amplitude immediately after FC was proportional to THR amplitude reduction for mean group value as well as for individual ones. This might be the evidence of existence of certain percentage (about 35 % in average) of fatigue-inhibited motoneurons; this part does not essentially depend on H-reflex amplitude before FC. Besides, predicted summarized inhibitory influence of fatigue and conditioning was calculated as 34,6 % (THR amplitude difference before and immediately after FC) adding 24,4 % (THR and CHR amplitudes difference before FC) and equaled 59,0 %. On the other hand, total inhibitory influence calculated as difference between THR amplitude before FC and CHR amplitude immediately after FC was 51,8 %. Obtained data demonstrate that two types of soleus H-reflex inhibition, namely connected with conditioning peroneal nerve stimulation and fatiguing

contraction, proceed mainly through different nervous pathways, although partial convergence of inhibition influences is possible.

Title: An investigation into the differential effects on somatosensory functions during deafferentation

Authors: *W. CAI, F. G. HEPWORTH LLOYD, P. SARAI, S. HUGHES, P. H. STRUTTON; Dept. of Surgery and Cancer, Imperial Col. London, London, United Kingdom

Abstract: Deafferentation is the severance of sensory inputs to the central nervous system and is associated with increased motor cortical excitability to the proximal muscles of the deafferented limb and homotopic contralateral muscles. Previous work has demonstrated that partial deafferentation is sufficient to induce alterations in cortical excitability, evidenced by an increase in proximal and contralateral motor evoked potentials (MEP) accompanied by a reduction (rather than loss) of somatosensory evoked potentials during an ischaemic nerve block (INB). However, the extent to which the INB differentially affects sensory nerve function has not been investigated. In order to explore this, we performed a low-pressure INB on the right forearm in healthy volunteers for 30 mins. Transcranial magnetic stimulation was used to induce MEPs from adductor pollicis brevis and brachioradialis muscles bilaterally, whilst a truncated quantitative sensory testing paradigm was used to interrogate the sensory function distal to the INB (brush stroke for Aβ, pinprick for Aδ and heat pain for C-fibre). We observed a significant decrease in MEP amplitudes of right APB towards the end of the ischaemic period, accompanied by a significant increase in MEP amplitudes of left APB MEPs from BR bilaterally tended to increase. A significant loss of brush stroke sensation was observed in the late occlusion period. Heat pain sensation was maintained throughout the experiment. Most participants lost pinprick sensation just before cuff release. However, a minority reported an increase in pinprick sensitivity. These results suggest that selective Aβ and Aδ sensory loss may underlie the changes in cortical excitability. In participants where an exaggerated response was found to pinprick, it is possible that the preserved C-fibre transmission facilitates pinprick sensation via mechanisms such as central sensitization, resulting in the development of secondary hyperalgesia. As pain is implicated in cortical reorganization, this may be key to how cortical plasticity is shaped by somatosensory function. These results may provide insight into the development of pathological pain conditions, especially following nerve injury.

Title: Cerebellar influence on the H-reflex of soleus muscle during acquisition of sexual experience in male rats

Authors: *J. R. GUTIERREZ[1], R. ZEMPOALTECA[2], P. CARRILLO[3], A. J. CHACON[3], R. TOLEDO-CARDENAS[4], J. FISHER[4], G. A. CORIA-AVILA[4], J. MANZO[4], L. I. GARCIA[4]; [1]Doctorado en Investigaciones Cerebrales, Xalapa, Mexico; [2]Ctr. Tlaxcala de Biología de la Conducta, Tlaxcala, Mexico; [3]Inst. de Neuroetología, Xalapa, Mexico; [4]Ctr. de Investigaciones Cerebrales, Xalapa, Mexico

Abstract: The cerebellum receives afferents signals through ascending spinal pathways that convey information about posture, balance and muscle tone. Hence, the cerebellum integrates a complex circuit underlying the neural basis of sexual behavior (SB). This wiring serves not only for the expression of SB but also for the learning of skills needed for appropriate behavioral displays during copulation. Descending signals from cerebellum modulate spinal reflex response, and studies have shown that the cerebellum is necessary for the maintenance of a motor skill, and alterations in the cerebellum or descending pathways modify spinal cord reflexes. The H-reflex (HR) as the electrical analog of the spinal stretch reflex, changes during skill acquisition. These observations support the hypothesis that the cerebellum could modify the HR response due to SB experience in male rats. In the present study, we analyzed the effect of cerebellar circuit activity (states) over the properties of soleus HR in male Wistar rats (250 and 300 gr). We used two different paradigms, sexual behavior training (4 sessions, one every two days interrupted at ejaculation) to make an efficient cerebellar circuit, and electrolyte lesion of L6a at the vermis (3.5 mA/20 s), to remove cerebellar control over the HR. Rats were divided into two groups, Naïve and Sexual experts. In each of these groups two subgroups were organized, the Control and Lesion groups, the latter with an electrolyte lesion in the cortex of L6a of the cerebellar vermis. The aim was to analyze and determine the effect of cerebellum changes on the amplitude of HR. For each animal, we did the assessment of the umbral intensity stimuli and we recorded H-waves while intensity of stimulation increases until muscular contraction begins. Results show that in both Control and Lesion groups the amplitude of the HR is higher in experts compared to naïve rats. The latency and duration of the H-wave, as well as the amplitude, duration, and

latency of the M-wave, showed no differences between groups. Our results indicate that sexual behavior experience has a disinhibitory effect on H reflex amplitude. However, further studies are needed to determine the effect of electrolyte lesion of cerebellum on the soleus HR.

Title: Non uniform denervation of muscle fibers in botulinum toxin injected spastic muscle

Authors: S. CHANDRA[1,3], B. AFSHARIPOUR[2], W. Z. RYMER[1,3], *N. L. SURESH[1,3]; [2]Sensory Motor Performance Program, [1]Shirley Ryan Ability Lab., Chicago, IL; [3]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL

Abstract: Intramuscular botulinum toxin (BT) injections are often used to mediate spasticity in post-stroke survivors, The mode of action of the toxin is via chemo denervation at the neuromuscular junction of the motor neuron from the respective fibers. We hypothesize that BT works non uniformly and selectively on different motor units among the whole motor unit population of a targeted muscle. We have recorded joint contraction force and surface electromyography (sEMG) from BT injected biceps brachii muscle during sustained isometric contractions allowing us to analyze the electromechanical delay (EMD) and (peak) amplitude distribution of the recorded sEMG, and compare them to understand the effect of BT on different size of motor units. Recordings of participants who were chronic stroke survivors was moded in both their impaired and contralateral sides 2-12 weeks after their scheduled BT injection (part of their clinical care plan)with an additional pre-injection session as reference. The force and sEMG signals were recorded during multiple isometric, non-fatiguing elbow flexion with trapezoidal force trajectory at various force ranges. EMG data were recorded using special Sensor Arrays (SA) and Single Differential (SD) electrodes from Delsys Inc. A pair of SA and SD electrodes recorded signals from long and short heads of the biceps brachii muscle. Additional electrodes were used to monitor brachioradialis and triceps brachii activity. All the data were normalized with a Maximal Voluntary Contraction (MVC) before computation of the peaks and the electromechanical delay. The (EMG) was computed as the onset of the EMG signal - onset of the force signal during the rising phase of the isometric contraction and the peaks were calculated

during the steady state contraction phase. We have found that the EMD increases by a significant amount (3x) in the BT injected side for all the subject two/four weeks after the BT injection, we have also found only larger peaks were present during this session while mean steady state contraction force (as a %MVC) and the root mean square SEMG becomes significantly low. Moreover, the higher EMD values were found during the higher contraction levels. Increased EMD value and presence of larger peaks indicate the existence of active larger motor units in the injected muscle. From 4^{th} week onward the EMD falls down and also smaller sEMG peaks starts appearing becomes comparable by the end of 12 weeks to its pre-injection recording. Any such changes were not observed in the contralateral side of the subjects. In summary, botulinum toxin may selectively affect smaller motor units subsequent to the injection in muscles that exhibit spasticity.

Title: Sex differences in fatigue of ankle plantar flexor muscles

Authors: *M. BILODEAU, A. DUGAS, F. DUQUETTE, C. GIROUX, K. GUERTIN;
Sch. of Rehabil. Sci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: AIM: The aim of this study was to investigate differences in exercise-induced fatigue features of the plantar flexor muscles between men and women. METHODS: Seven men and eight women, all healthy and aged between 20 and 28 years, participated in the study which was approved by the relevant local research ethics boards. Measures of maximal voluntary isometric contraction (MVIC) torque, isometric twitch and doublet electrically-elicited torque and voluntary activation were taken before and immediately after fatigue, as well as at 1, 2, 5 and 10 minutes of recovery. Fatigue was induced by having participants hold a 50% MVIC torque until exhaustion. Mixed-model ANOVAs and t-tests were used to test the effects of sex and fatigue on the variables of interest. RESULTS: Time to fatigue was not different between men (142.4 ± 27.2 s) and women (124.5 ± 26.5 s; $t = 1.29$, $p = 0.22$). Also, fatigue-related changes in MVIC torque, doublet torque, twitch torque and voluntary activation show similar trends between men and women (non-significant sex X fatigue interaction ($p > 0.05$)).

DISCUSSION/CONCLUSION: In contrast to other muscle groups, fatigue-related features of the plantar flexor muscles do not appear to be influenced by sex.

Title: Exercise to the rescue: Effects of aging and long-term exercise on structural plasticity of motor neurons and GDNF expression in spinal cord

Authors: *A. F. CINTRÓN-COLÓN, J. SPITSBERGEN;
Biol. Sci., Western Michigan Univ., Kalamazoo, MI

Abstract: As age progresses the neuromuscular system weakens. A possible reason for this weakening is the loss of connectivity between motor neuron and muscle. Physical exercise has been shown to be beneficial for both nervous and muscle tissue by contributing to neuroprotection and modulation of inflammation. A possible way to achieve neuroprotection is by the production and release of target-derived neurotrophic factors like glial cell line-derived neurotrophic factor (GDNF). GDNF is a potent survival/differentiation factor for somatic motor neurons. Results from previous studies have demonstrated a decline in skeletal muscle GDNF content with increased age and an increase in GDNF content with exercise. The goal of this study was to examine changes in motor neuron size that occur with age and exercise. Our hypothesis is that the size of motor neuron cell bodies will decline with age and that exercise will result in an increase in the size of motor neurons. Spinal tissues were taken from sedentary and exercised Sprague-Dawley rats between 4 weeks and 24 months of age. Sedentary groups consisted of 4-week-old, 14-week-old, 12-month-old, 18-month-old, and 24-month-old rats, while exercised groups consisted of 14-week-old rats that had access to running wheels for 10 weeks; and 12-month-old, 18-month-old, and 24-month-old rats that had access to running wheels for 24 weeks. In sedentary and exercised rats the lumbar region of the spinal cord was removed and processed for immunohistochemical analysis. Antibodies against choline acetyltransferase (ChAT) were used for detection of motor neurons, anti-GDNF was used for GDNF localization, and DAPI was used for nuclear staining. The results show that motor neuron cell body size increased from 4 weeks of age (958.4$\mu m^2 \pm$ 552μm^2) to 14 weeks (1070$\mu m^2 \pm$

505.8μm^2) and 6 months of age (2331.24μm^2±1607.4μm^2) and then decreased at 12 (969.21μm^2 ± 837.5μm^2), 18 (694.15μm^2 ± 542.2μm^2) and 24 months of age (395.5μm^2 ±101μm^2) in sedentary, aging rats. Exercise in age-matched groups caused an increase in motor neuron cell body size at 14 weeks (1180μm^2 ± 638.9μm^2), 12 months (1659μm^2 ± 1295.1μm^2) and 18 months of age (898.9μm^2 ± 697μm^2). Motor neurons in the spinal cord were found to contain GDNF co-localized at the cell body at all ages. These findings suggest that exercise plays a role in the structural plasticity of ChAT-positive cells. Understanding the role that neurotrophic factors play in regulating neural plasticity may help in identifying novel targets for pharmacological development.

Title: Trans-cranial direct current stimulation changes fore paw dominance in mice

Authors: A. GORIN[1], O. ELWANY[1], B. ABDELRAHMAN[1], A. ELCHARFA[1], M. ARNOS[1], ***Z. AHMED**[2];
[1]Col. of Staten island, Staten Island, NY; [2]Col. of Staten Island, Staten Island, NY

Abstract: Handedness is a strong preference to use either the right or the left hand when performing skilled manual actions. In recent studies, MRI-based methodology has linked this ability to underlying functional and structural motor control. TDCS is a well-known clinical neuromodulation technique which has proved to be of growing interest for applications in neurorehabilitation. The aim of the current study is to examine the effect of applying a subthreshold transcranial direct current (TDCS) on one hemisphere on paw dominance in mice. Animals were placed in a pyrex cylinder and filmed when rearing to explore the environment. The instances in which the mouse uses each paw to touch the cylinder was assessed to determine paw dominance. Baseline testing of paw dominance showed that all animals used in the present study have the right paw dominance. Therefore, we stimulated the left hemisphere (sensorimotor cortex). The results showed that during cathodal-TDCS paw dominance was changed from right forepaw to left forepaw. Moreover, anodal-TDCS diminished paw dominance, the mice used the two forepaws equally. These findings indicate that TDCS could modulate forepaw dominance in mice. Since TDCS is known to modulate neuronal excitability and activity, the present results suggest that laterality in hemispheric excitability is the underlying mechanism of paw dominance and maybe handedness.

Title: Synaptic inputs terminating on alpha motor neurons undergo age-related changes in mice

Authors: *R. W. CASTRO[1], K. VANCE[2], G. VALDEZ[2];
[1]Neurosci., Brown Univ., Providence, RI; [2]Fralin Biomed. Res. Inst., Roanoke, VA

Abstract: The impact of aging on α-motor neurons and their connections in the spinal cord remains largely unexplored despite the central function these cells play in relaying voluntary motor commands. Previous work in our lab revealed that both cholinergic and glutamatergic excitatory synaptic inputs originating from local interneurons and sensory neurons degenerate in the ventral horn of the spinal cord of aged mice and rhesus monkeys. We have now examined the fate of glutamatergic synaptic inputs originating from the cortical and brain stem regions in the ventral horn of aged mice. We also examined the impact of aging on GABAergic and glycinergic inputs. Using light microscopy, we found that aging alters the distribution and number of these additional synaptic inputs and their postsynaptic sites throughout the ventral horn of the spinal cord, and specifically terminating on the soma of alpha-motor neurons. Further, we have determined that microglia become increasingly activated during aging, and may play a role in the age-related loss of α-motor neurons' synaptic connections. These ongoing analyses are necessary to uncover the initial sites in the spinal cord disrupted with advancing age, and that contribute to motor deficits.

Title: A high-density electrode array for mapping corticospinal recruitment of upper-limb muscles after stroke

Authors: *E. H. BEDOY[1], M. URBIN[1], G. F. WITTENBERG[2], G. SHARMA[4], D. J. WEBER[3]; [2]Neurol., [3]Bioengineering, [1]Univ. of Pittsburgh, Pittsburgh, PA; [4]Battelle Mem. Inst., Columbus, OH

Abstract: Nearly 800,000 Americans per year experience a stroke and more than half of survivors are left with disability due to muscle weakness (i.e., hemiparesis) in the arm and hand. Stroke-induced damage to the corticospinal system can result in abnormal muscle synergies, reducing the ability to recruit agonist muscles and increasing co-contraction of agonist and antagonist muscles. The severity of impairments in humans with stroke is also associated with higher thresholds to elicit motor-evoked potentials (MEPs) from transcranial magnetic stimulation (TMS) of primary motor cortex. Previous work has shown that MEPs in paretic muscles are lower in amplitude, delayed in latency and prolonged in duration after stroke, but the spatial distribution of MEPs across different muscles of a limb has not been well characterized. Understanding patterns of corticospinal recruitment may provide unique insights into physiology and function after stroke. Therefore, our group has developed a high-density electromyographic (HD-EMG) array to record MEPs from the entire forearm. The array consists of 150 surface disc electrodes embedded in fabric spanning the length and circumference of the dominant (neurologically-intact) or paretic (stroke) forearm of human subjects. Single-pulse TMS was delivered at multiple increments of resting threshold over the optimal scalp location for eliciting MEPs in the extensor digitorum communis (EDC) muscle. MEPs were recorded in resting forearm muscles, as well as during precision and power grasps at a fixed level of maximum voluntary contraction. Our results show that the spatial extent of corticospinal recruitment is modulated by stimulation intensity and muscle state. Differences in the pattern and timing of recruitment were also noted between intact controls and stroke. Our results show that the HD-EMG array allows high-resolution mapping of corticospinal recruitment across the upper limb. The ability to map recruitment may provide a diagnostic tool capable of evaluating impairments due to stroke and in response to rehabilitation. Our team is also exploring the HD-EMG array as an assistive technology that drives recruitment of weak muscles on an as-needed basis.

Title: The potassium-chloride cotransporter KCC2 is regulated by muscle innervation, but not exercise, in spinal motoneurons following peripheral axotomy

Authors: *E. T. AKHTER[1], S. SARIN[1], A. W. ENGLISH[3], F. J. ALVAREZ[2];
[2]Physiol., [1]Emory Univ., Atlanta, GA; [3]Dept Cell Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Following various types of neuronal injury, the potassium-chloride cotransporter (KCC2) becomes dysregulated in multiple cell types. KCC2 is responsible for maintaining the low intracellular chloride levels typical of most adult neurons, and decreases in KCC2 can induce hyperexcitability. After peripheral nerve injuries (PNIs), loss of KCC2 in the dorsal horn contributes to neuropathic pain; after spinal cord injury, KCC2 decreases in motoneurons and induces spasticity. In both of these cases, exercise can attenuate KCC2 loss and ameliorate the symptoms. Additionally, exercise enhances motoneuron regeneration after PNI, and KCC2 is downregulated on these neurons axotomized during nerve injury. However, whether exercise may protect motoneurons from KCC2 loss after PNI is unknown. We tested here whether there is a relationship between exercise and motoneuron KCC2 levels following peripheral axotomy. To investigate this relationship we injured the sciatic nerve by performing complete nerve transections followed by repair in wild-type female mice. We then put the mice through an exercise paradigm that is known to enhance axon regeneration and sacrificed mice prior to any muscle reinnervation (14 days) and as differences in muscle reinnervation between groups (exercised vs non-exercised) were expected to become significant (28 and 35 days). We then compared the degree of KCC2 depletion on injured motoneuron cell bodies between groups and checked for correlations with successful muscle reinnervation by looking for successful neuromuscular junction (NMJ) reinnervation of the muscle as well as maximal muscle response using electromyography. We observed that exercise alone does not upregulate KCC2 in spinal motoneurons after PNI. Instead, KCC2 levels appear to be regulated by peripheral signals; more reinnervation in the periphery is correlated with higher KCC2 levels. Current experiments are blocking signaling at the NMJ using alpha bungarotoxin to determine whether signaling at the

muscle is responsible for maintenance of KCC2 protein in motoneuron somatic membranes. Our results illustrate that KCC2 regulation on axotomized motoneurons occurs via a different mechanism than previously established in other cell types or injury paradigms.

Abstract: Understanding how nervous systems generate motor behavior requires investigating both neural activity and muscle properties, inasmuch as it is the latter that transform neural activity into movement. Stick insect (*Carausius morosus*) walking is a very well-studied locomotory model system that has provided much information about how the basic walking pattern is produced and controlled, e.g., changes in speed and direction. Stick insect central and peripheral nervous systems are richly endowed with neuropeptides, but relatively little is known about the role these potential neuromodulatory substances play in stick insect behavior and in particular locomotion.
Transcriptomic and neuropeptidomic techniques have been used in prior work to define the neuropeptidome of the stick insect CNS. Here, we report on data obtained from MALDI-TOF single cell profiling of motor neurons to restrict this analysis to putative neuropeptide candidates involved in locomotion. Our analysis revealed the processing of myoinhibitory peptide (MIP) in dorsal unpaired median neurons (DUM) and common inhibitor motor neurons (CI). CIs have been long known to inhibit slow leg muscle fibers via the inhibitory transmitter GABA, and thereby contribute to the generation of fast movements. We then used immunocytochemistry to show that MIP is expressed in DUMs and CIs, and transported to, and released on, *extensor tibiae* muscle fibers. We confirmed the presence of the MIP-receptor in leg muscles by

transcriptomic analysis and are currently defining its localization with *in situ* hybridization. We also investigated the physiological effects of MIP on tibial extensor muscle contractions. MIP application decreased slow muscle fiber isometric force production and isotonic muscle shortening amplitude.
We have thus shown that stick insect common inhibitor neurons contain MIP, that the muscles the CIs innervate contain the MIP receptor, and that these muscles respond to MIP. Given that the CIs also modulate the muscles by GABA release, we conclude that insect CIs affect muscle fibers both via fast synaptic transmission and by neuromodulation. The common effects of GABA and MIP (slow muscle fiber inhibition in both cases) supports the belief that the CIs function to alter muscle temporal response properties, and in particular, to increase the ability of these muscles to produce fast motor patterns.

Title: Trkb activation is required for 17beta-estradiol induced enhancement of hippocampal memory consolidation

Authors: *K. S. GROSS[1], R. ALF[1], T. R. POLZIN[2], K. M. FRICK[1];
[1]Psychology, Univ. of Wisconsin Milwaukee, Milwaukee, WI; [2]Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The potent estrogen 17β-estradiol (E_2) is known to enhance memory consolidation in object placement (OP) and object recognition (OR) tasks, however the molecular mechanisms underlying these effects are not fully understood. Brain derived neurotrophic factor (BDNF) is an important regulator of hippocampal memory and is also known to interact with E_2, however whether BDNF plays a mechanistic role in E_2-induced enhancement of memory consolidation remains unknown. Previously, we demonstrated that infusion of E_2 into the dorsal hippocampus (DH) leads to increases in BDNF and pro-BDNF proteins via epigenetic modification of *Bdnf* gene promoters. Here, we examined the role that BDNF signaling with its receptor TrkB may

play in the effects of E_2 on hippocampal memory consolidation. To determine whether TrkB activity is required for the memory enhancing effects of E_2, female C57BL/6 mice were ovariectomized and cannulated in the DH and dorsal third ventricle. Immediately following object training, mice were infused with vehicle or a non-memory impairing dose of ANA-12, a TrkB antagonist, into the DH and vehicle or E_2 into the dorsal third ventricle. Object placement or object recognition memory was then tested 24 or 48 hours later, respectively. We found that ANA-12 blocked the memory-enhancing effects of E_2, suggesting that BDNF/TrkB signaling is necessary for E_2-induced memory enhancement. Current work is examining the molecular mechanisms that couple E_2 to TrkB activation in the DH and the influence of TrkB on estradiol-mediated dendritic spine plasticity. In sum, this work will provide new insight into how E_2 exerts its effects on hippocampal memory consolidation.

Title: Maintenance of hippocampal estrogen receptor α protein levels following continuous and previous estradiol treatment in aging ovariectomized rats

Authors: *N. E. BAUMGARTNER[1,2], S. M. MCQUILLEN[1,2], M. J. MAROTEAUX[3,1], D. D. HUTSON[3,1], J. M. DANIEL[1,2,3];
[1]Tulane Brain Inst., [2]Neurosci. Program, [3]Psychology Dept., Tulane Univ., New Orleans, LA

Abstract: Work from our lab has demonstrated that previous midlife estradiol treatment enhances memory and results in lasting increases in levels of estrogen receptor (ER) α in the hippocampus of aging ovariectomized rats months after hormone exposure has ended. We have recently shown that both ongoing and previous exposure to estradiol in midlife increases protein levels of ERα in the nuclear compartment of hippocampal cells. The goal of the current project is to determine how these protein levels are maintained following continuous or previous estradiol treatment. Previous work from our lab demonstrated that short-term exposure to estradiol in midlife decreases protein interactions between ERα and the ubiquitin ligase C-terminus of Hsc-70 interacting protein (CHIP), suggesting the sustained ERα protein levels are maintained via decreased degradation through the proteasome. However, it is unknown if continuous or previous exposure to estradiol in midlife also impacts transcription of *Esr1*, the gene that encodes for ERα. In the current project, middle-aged rats were ovariectomized and implanted with capsules

containing either estradiol or vehicle. Forty days later, all capsules were replaced. Rats initially receiving vehicle capsules received another vehicle capsule (ovariectomized controls), and rats initially receiving estradiol capsules received either another estradiol capsule (continuous estradiol) or a vehicle capsule (previous estradiol). One month later, hippocampi were dissected and processed for RNA extraction and RT-PCR with primers for *Esr1* and *Gapdh*. Results show no effect of hormone treatment on *Esr1* RNA levels in the hippocampus. These data support the idea that the elevated ERα protein levels in the hippocampus following continuous or previous estradiol exposure in midlife is maintained through decreased degradation of the protein, rather than through increased transcription of *Esr1*. Ongoing work is further investigating the impacts of hormone treatment on degradation of ERα in the hippocampus.

Title: The interplay of the rapid activation of the G-protein coupled estrogen receptor and/or estrogen receptor beta and the oxytocin receptor on social recognition

Authors: *P. PALETTA[1], I. GREWAL[2], A. CLARKE[1], E. CHOLERIS[1];
[1]Psychology, [2]Biol. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Both estrogens and oxytocin (OT) can influence social recognition (SR). Knocking out the genes for the estrogen receptors, OT, or the OT receptor (OTR) impairs SR, whereas the administration of 17β-estradiol (E2) or the agonists for the estrogen receptors either systemically or intracranially can facilitate SR. An interplay between estrogens and OT in the mediation of SR has been suggested. A model for this interplay was developed that proposes that estrogens binding to their receptors in the paraventricular nucleus (PVN) of the hypothalamus, where most of the OT is produced in the brain, leads to the release of OT into the medial amygdala (MeA), an important region for SR as the olfactory information of individuals being encountered is sent to this region. The OT will then bind to the OTR in the MeA to facilitate SR. We have previously tested this model for estrogens' rapid mechanisms of action and found that E2 in the PVN rapidly facilitated SR and that this facilitation was blocked when a subeffective dose of an OTR antagonist (OTRA) was infused into the MeA, supporting estrogens' rapid mechanism interacting with OT to effect SR as the model describes. In the present study we investigated the

specific estrogen receptors mediating the rapid facilitation of SR by E2 in the PVN. We used agonists for the G-protein coupled estrogen receptor (GPER) and estrogen receptor beta (ERβ) since both estrogen receptors are highly expressed in the PVN. We found that the infusion of the GPER agonist G1, at 50, 100, and 200nM, or the ERβ agonist DPN at 100 and 150nM, were able to rapidly facilitate SR. The next step is to determine whether the same subeffective OTRA dose used in the E2 experiment, a dose that by itself does not block SR, infused into the MeA can prevent the SR facilitating effects of the GPER and ERβ agonists in the PVN. A rapid SR paradigm is used that takes advantage of the natural tendency of mice to prefer novelty, where in 2 sample phases 2 stimulus mice are presented to the experimental mouse followed by a test phase where one of the stimulus mice is replaced with a novel mouse. If the novel mouse is investigated more, it suggests that the other mouse if familiar and SR occurred. This paradigm occurs within 40 minutes to test the rapid effects of estrogens. If the OTRA blocks the facilitation of SR by the agonist, it would suggest that that estrogen receptor is mediating the interplay between estrogens and OT on SR.

Title: Motherhood has short and long term effects on hippocampal neurogenesis, inflammation, and gene expression

Authors: *P. DUARTE-GUTERMAN[1], S. E. LIEBLICH[1], R. S. EID[1], D. A. SKANDALIS[2], M. IBRAHIM[1], L. A. M. GALEA[1];
[1]Djavad Mowafaghian Ctr. for Brain Health, Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Whitney Lab. for Marine Bioscience, Univ. of Florida, St. Augustine, FL

Abstract: Women are more likely to be diagnosed with Alzheimer’s disease (AD) and show greater AD neuropathology and cognitive decline than men. Pregnancy and motherhood (parity) have dramatic effects on physiology, including the endocrine system, and can modulate brain function in women and animal models in the short and in the long term. Increasing parity is associated with a greater risk of dementia, AD neuropathology, and an earlier age of AD onset. Work from our laboratory suggests that parity influences hippocampal neuroplasticity,

circulating immune markers, and cognition into middle-age in rats. The goals of this study were to determine how parity interacts with aging to influence levels of hippocampal inflammation and adult neurogenesis in female rats and to explore unknown mechanisms of parity through transcriptomics. Female rats were bred once (primiparous), twice (biparous), or not at all (nulliparous). Brain and plasma were collected at 30 days (7 months old; adults) and 240 days postpartum (13 months old; middle-aged). We measured adult neurogenesis through the expression of the immature marker doublecortin (DCX), neuroinflammation through a multiplex system of nine cytokines (IFN-γ, IL-1β, IL-4, IL-5, IL-6, IL-10, IL-13, CXCL1, and TNF-α), and global gene expression through RNA sequencing. In young adults, we found that motherhood decreased the number of DCX-expressing cells relative to nulliparous females. Hippocampal neurogenesis decreased with aging, but more so in nulliparous than parous females. We found that in the hippocampus, interleukin-6 (IL-6) increases in biparous females regardless of age, while plasma IL-6 decreases with age in nulliparous but not parous females. Levels of individual cytokines may result from covariation with other cytokines as well as responses to treatments. We used principal components analysis to group cytokines with similar expression patterns and then constructed classification trees based on these groups. Parity predicted levels of cytokines in the hippocampus, whereas age predicted levels of plasma cytokines. Our work suggests that motherhood has consequences on neurogenesis and neuroinflammation that persists into middle age and that peripheral immune changes do not reflect immune changes occurring in the brain of aging female rats. Finally, RNA sequencing results indicate that in young primiparous and biparous females there is a decrease in the expression of genes related to oxygen transport and metabolism. We are currently analysing middle aged brain samples for changes in gene expression. These data will aid in elucidating how reproductive experience influences brain aging.

Title: Effects of hot flash induction and estrogen receptor beta activation on hippocampus-dependent memory consolidation in ovariectomized mice

Authors: *A. W. FLEISCHER, K. M. FRICK;
Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The loss of cycling estrogens underlying the menopausal transition is often associated with problematic symptoms, such as hot flashes, mood disorders, and dementia. Additionally, these symptoms have the capacity to exacerbate one another. For example, disruption of sleep due to hot flashes can prevent proper memory consolidation and result in memory loss. Several of these symptoms have been attenuated via estrogen-based hormone therapies (HT). However, these HTs have been linked to health concerns, such as increased rates of several forms of cancer and heart disease, which have been associated with the activation of estrogen receptor isoform alpha (ERα), but not isoform beta (ERβ). Therefore, development of ERβ-selective treatments are crucial avenues to explore for attenuation of menopause-associated symptoms. Mouse models of hot flashes and learning and memory are found readily throughout the literature, though to our knowledge, no studies have been conducted specifically on the effects of hot flash induction on memory consolidation processes. Here, 10-week-old female C57BL/6 mice were bilaterally ovariectomized. After recovery, they were placed in a large white box with two identical objects placed near the corners and required to spend 30 sec exploring the objects. During testing, one of the objects was replaced with a novel object (object recognition, OR) or moved to a new location (object placement, OP). OR and OP testing occurred 24 or 4 hours later, respectively, time points at which we have shown memory to be intact for these tasks in ovariectomized mice following vehicle administration. To test whether an acute hot flash can disrupt memory consolidation, mice were injected immediately after training with vehicle, 17β-estradiol (E_2), or the ERβ agonist diarylpriopionitrile (DPN) intraperitoneally (IP), and then subsequently injected subcutaneously (SC) with vehicle or senktide, a tachykinin receptor type 3 agonist known to induce hot flash symptoms in humans and rodents. Rodents shed heat through tail skin vasodilation, so tail skin temperature changes from baseline were measured via FLIR camera as a proxy for hot flash-like symptoms. Preliminary data demonstrate that post-training IP injection of E_2 and DPN facilitate memory consolidation in these tasks, and that senktide induces hot flash-like tail vasodilation. Ongoing studies are examining the effects of E_2 and DPN on senktide-induced hot flashes, as well as the effects of hot flash induction and attenuation on memory consolidation.

Title: Quantifying rapid effects of 17β-estradiol on cell signaling pathways in the dorsal and ventral hippocampus

Authors: *T. PURI, P. A. S. SHEPPARD, S. E. LIEBLICH, L. A. M. GALEA;
Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: 17β-Estradiol (E2) can modulate memory consolidation in the hippocampus *in vivo* through the cell signaling cascades that activate in 5-30 minutes following E2 treatment in male and female mice, and rapidly enhances cell proliferation and long-term potentiation (LTP) in the dentate gyrus of female rats. E2 can have neuroprotective effects that are mediated through mitogen-activated protein kinase (MAPK) pathways, and MAPK cascades in the dorsal hippocampus are necessary for long-term spatial memory. However, E2 has dose-dependent effects on hippocampus-dependent learning, with low physiological levels of E2 enhancing and high levels of E2 impairing performance in spatial working memory and contextual fear conditioning in female rats. Repeated administration (3 days) of E2 has been shown to increase Akt signaling cascade activity in the hippocampus, but rapid effects remain unknown.
This experiment aims to determine whether changes in cell signaling cascades occur in a dose-dependent manner following E2 administration in ovariectomized female rats. We treated adult ovariectomized female rats with high E2 (10µg/0.1mL oil), low E2 (0.3µg/0.1mL oil), or vehicle (sesame oil), and dorsal and ventral hippocampi were extracted and flash frozen either 30 min or 24 hours following E2 administration. Dorsal and ventral hippocampal tissue was homogenized and subsequently analyzed for cell signaling markers using multi-array electro-chemiluminescent detection assays. Preliminary data show a significant interaction of dose and time since E2 administration in the levels of cell signaling proteins pAkt and p70S6K in the dorsal, but not ventral, hippocampus. Both pAkt and p70S6K show increased levels at 30 minutes (compared to 24 hours) following a high dose of E2. However, pAkt and p70S6K levels are higher at 24 hours than 30 minutes for low-level E2 and vehicle administration. These data show that Akt cell signaling is activated in a dose-dependent manner both rapidly and over longer timeframes. Given the ability of 17β-estradiol to rapidly improve memory consolidation, cell proliferation, and LTP, it is important to establish which cell signaling proteins may be activated in the short- and long-term after E2 exposure.

Title: Intrahippocampal infusion of a G-protein coupled estrogen receptor (GPER) agonist increases CA1 spine density and enhances memory consolidation in female mice

Authors: *J. C. SCHALK, J. KIM, W. A. KOSS, K. M. FRICK;
Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Little is known about the role of G-protein-coupled estrogen receptor (GPER) in hippocampal synaptic plasticity and memory consolidation. G-1 is a GPER agonist that mimics the memory-enhancing effects of 17β-estradiol (E2), a potent estrogen. However, the mechanisms through which G-1 enhances memory remain unclear. Here, we examined the effects of dorsal hippocampal infusion of G-1 on memory consolidation and CA1 dendritic spine density. In Experiment 1, ovariectomized mice received bilateral dorsal hippocampal infusion of G-1 (4 µg/hemisphere) or vehicle immediately after training in the object recognition and object placement tasks. Compared to vehicle, G-1 significantly increased the time spent with the novel or moved objects, indicating an enhancement of hippocampal-dependent object recognition and spatial memory. In Experiment 2, ovariectomized mice received bilateral dorsal hippocampal infusion of vehicle or G-1, and then brain tissue was collected 40 minutes later for Golgi staining and dendritic spine analysis. Compared to vehicle, G-1 significantly increased apical dendritic spine density on pyramidal neurons in the CA1 region of the hippocampus. Further analysis showed that G-1 specifically increased the number of mushroom spines, but not thin or stubby spines. These findings suggest that G-1 may enhance hippocampal-dependent memory by increasing mature apical dendritic spines in CA1.

Title: 17β-estradiol rapidly induces activity-regulated cytoskeleton-associated protein (arc) expression

Authors: *Y. RIZWAN[1], J. LALONDE[2], E. CHOLERIS[3];
[1]Dept. of Psychology; Dept. of Mol. and Cell. Biol., [2]Dept. of Mol. and Cell. Biol., [3]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Administration of estrogens to the mouse dorsal hippocampus produces rapid facilitation of learning and memory, as well as the growth of new dendritic spines in pyramidal neurons. Recently, we found that blocking protein synthesis with anisomycin but not gene transcription with actinomycin D can prevent these rapid estrogenic effects on cognition and structural plasticity of neurons. These results therefore suggest a central role for localized protein synthesis events in the rapid facilitation of learning and spinogenesis by estrogens; however, which specific transcripts may be regulated in this manner to act as intermediary effectors remain unknown. Here, we present efforts to answer this question.
Activity-Regulated Cytoskeleton-associated protein (Arc) is an immediate-early gene that has been implicated in many facets of neuroplasticity, including trafficking of AMPA receptors and morphogenesis of dendritic spines. Notably, *Arc* mRNA transcripts can be transported along dendrites where they will accumulate at the base of postsynaptic structures. There, *Arc* transcripts can then be rapidly translated upon synaptic activity to affect neuron biology. Because of these unique features, we hypothesized that Arc may play a central role in rapid estrogenic effects.
First, using mouse primary cortical neurons we present clear evidence for rapid induction of Arc in response to exogenous application of 17β-estradiol. Specifically, our results show Arc being expressed in a dose-dependent manner within 15 to 40 minutes of acute application of 17β-estradiol (50nM and 100nM). Second, we extended this finding by showing that *in-vivo* administration of 17β-estradiol (100nM) directly into the dorsal hippocampus of ovariectomized adult, female CD1 mice also induces Arc expression within 15 to 40 minutes. Finally, to directly investigate Arc's potential downstream role in 17β-estradiol's rapid facilitation of learning and memory, we used a collection of short-hairpin RNA constructs packaged into lentiviruses. Together, our results strongly support the role for Arc in the positive effects of estrogens on cognition and dendritic spine changes.

Title: Impaired BDNF signaling disrupts modulation of cognition and behavior by estrogens in female rats

Authors: *A. V. PRAKAPENKA[1], M. M. CAMPANICO[2], R. ELMAN[3], A. BERLIN[4], N. RAMIREZ-ESTEVEZ[1], C. E. SORTWELL[5], T. J. COLLIER[5], K. STEECE-COLLIER[5], D. L. KOROL[1];

Abstract: 17β-estradiol (E2), the predominant estrogen in reproductive females, improves hippocampus-sensitive learning and memory yet impairs striatum-sensitive learning and memory. E2 also promotes the transcription and release of brain-derived neurotrophic factor (BDNF), known for its role in neural plasticity and cognition. The single nucleotide polymorphism in humans (SNP, rs6265) with a Val66Met substitution in the prodomain region of *BDNF* is thought to impair BDNF release. If BDNF signaling mediates the cognitive effects of E2 as reported, then modulation of learning and memory in female Met carriers will be blunted compared to the wildtype Val/Val variant. We tested the effects of E2 on hippocampal and striatal learning in a CRISPR/cas9 rat model of the human BDNF Val66Met gene variant (Val68Met in rats). Three weeks after ovariectomy, female homozygous Val or Met rats were treated with vehicle or E2-benzoate (EB, s.c.) 48 and 24 hrs prior to training on a hippocampus-sensitive place or a striatum-sensitive response learning task. In general, Met rats were impaired in learning compared to age-matched Val rats. Moreover, EB-treated Val rats exhibited improved place learning and impaired response learning compared to vehicle-treated Val rats as expected from previous work. EB in Met rats, however, failed to enhance or impair learning in either task, supporting a key role for BDNF release in modulation of learning by estrogens. Findings from a separate study using ovary-intact Val and Met rats showed that typical fluctuations in locomotor activity seen across the estrous cycle in Val rats were blunted in Met rats. Together, our findings suggest that dysfunctional BDNF signaling interferes with estrogen modulation of learning, memory, and other behaviors. Because menopause and its accompanying decline in circulating hormones are associated with increased risk for certain neurological disorders and diseases, ongoing work tests the interaction of age and E2 in these CRISPR rats on various behaviors. Elucidating the role of hormones, and ultimately downstream neural targets, on cognition across the adult lifespan using the Val68Met BDNF rat model could lead to the development of novel or individualized strategies to promote healthy aging in women.

Title: Let's talk about sex (hormones): Cognitive characterization and evaluation of gonadal hormone deprivation in a rat model of Alzheimer's disease

Authors: *H. L. BULEN[1,3], V. L. PEÑA[1,3], S. N. NORTHUP-SMITH[1,3], C. BARKER[1,3], V. E. WONER[1,3], A. V. PRAKAPENKA[4,3], S. ODDO[2,3], H. A. BIMONTE-NELSON[1,3];
[1]Psychology, [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Tempe, AZ; [4]Biol., Syracuse Univ., Syracuse, NY

Abstract: As of 2019, the Alzheimer's Association estimates that in the United States alone, 5.8 million individuals are living with Alzheimer's disease (AD), with two thirds of those individuals women. As the population continues to age, it is increasingly imperative to make advancements in our understanding of AD progression and treatment, while additionally focusing on why women have an increased risk of developing the disease. Recently, the TgF344-AD transgenic rat model of AD expressing mutant human amyloid precursor protein (APP_{SW}) and presenilin 1 (PS1ΔE9) genes has been developed. This model exhibits amyloid β (Aβ) plaque-like pathology, tau-like pathology leading to neurofibrillary tangles, and neuronal loss. Although it has been less studied, the TgF344-AD rat also exhibits some behavioral impairment. The goal of this experiment was to delineate the role of hormone deprivation in the TgF344-AD model to elucidate whether gonadectomy (Gdx) impacts behavior- and AD- like pathology. Eight treatment groups were included in this study: male wild type (WT) Sham (n=10), female WT Sham (n=10), male WT Gdx (n=10), female WT Gdx (n=10), male transgenic (TG) Sham (n=10), female TG Sham (n=10), male TG Gdx (n=10), and female TG Gdx (n=10). All animals underwent a behavioral battery consisting of the Water Radial Arm Maze (WRAM) to assess spatial working and reference memory, the Morris Water Maze (MWM) to assess spatial reference memory, the Open Field Task (OFT) to assess locomotor activity and anxiolytic behavior, and the Visible Platform Task to evaluate procedural components of solving a water-escape task. For the WRAM, both sexes with the TG genotype were impaired during learning compared to their respective WT counterparts. Additionally, TG Gdx males demonstrated impaired working memory compared to WT rats during the WRAM learning phase. During

memory retention, both sexes showed improvements in handling an increasing working memory load with Gdx. TG rats also showed reference memory detriments on the MWM compared to WT rats. These data indicate that TG animals of both sexes exhibit learning impairments compared to their respective WT counterparts, and that hormone loss can impact behavioral outcomes. Further behavioral analyses and pathology assessments are ongoing in these behaviorally-tested animals to allow further characterization of the relation between pathology and behavioral outcomes. This work will allow a better understanding of the interactions between sex, hormones, and AD-associated behavior and pathology.

Title: Sex and subregion differences in the rapid effects of 17β-estradiol on cell signaling cascades in the dentate gyrus of male and female rats

Authors: *P. A. S. SHEPPARD[1], T. PURI[2], L. A. M. GALEA[1];
[1]Djavad Mowafaghian Ctr. for Brain Health, Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Rapid effects of estrogens within the hippocampus of rodents have been found to be dependent upon cell signaling cascades (Sheppard et al., 2018; Frick et al., 2018). Whether these pathways are rapidly activated within the dentate gyrus by estrogens has yet to be determined. Exogenous 17β-estradiol (E2) or estradiol benzoate increases cell proliferation in the dentate gyrus of ovariectomized (OVX) rats 2 or 4h (Tanapat et al., 1999; Ormerod et al., 2003; Barha et al., 2009; Mazzucco et al., 2006), but not 48h (Ormerod et al., 2003), following systemic administration. Cell proliferation within the dentate gyrus is also increased 30min following systemic E2 administration in ovariectomized (OVX) female rats, suggesting that rapid, likely non-genomic mechanisms may underlie these effects. Whether these E2-mediated increases also occur in males remains to be determined. Importantly, sex differences exist in the rapid activation of hippocampal cell signaling cascades in response to estrogens (Koss et al., 2018). Here, gonadally intact female rats (estrous phase determined *via* lavage) and OVX female rats were given a subcutaneous injection of either 0.3 (low E2) or 10μg (high E2) of E2 (in 0.1mL

oil) or vehicle (oil); whereas gonadally intact male rats were given 0.525 (low E2) or 17.5µg (high E2) of E2 (in 0.175mL oil) or vehicle – 75% more than females due to larger size. Thirty minutes later, rats were euthanized, and their brains were flash frozen for protein analyses. Using a multiplex electrochemiluminescent reader, we measured levels of phosphorylated extracellular signal-regulated protein kinase (ERK), c-Jun N-terminal kinase (JNK), p38, Akt, glycogen synthase kinase 3 beta (GSK-3β), and ribosomal protein S6 kinase (p70S6K) in the dentate gyrus. OVX females have increased ERK and JNK activation in the ventral DG when compared to males. Phospho-p38 is increased in the ventral DG in males given low E2. Males also show a trend towards an increase in pJNK in the dorsal DG, whereas OVX females show a trend towards an increase in pERK in the same region. ERK, JNK, and p38 analyses are ongoing in intact females, as are analyses of Akt, GSK-3β, and p70S6K in all animals. We are also examining rapid effects of these treatments on cell proliferation in the DG of intact males and females, as these have yet to be explored, with the aim to determine the necessity of these cascades to rapid effects of E2 on cell proliferation.

Title: A sex-specific role of the basolateral amygdala in fear-based cognitive bias in adult rats

Authors: *T. E. HODGES, L. A. M. GALEA;
Djavad Mowafaghian Ctr. from Brain Health, Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Negative cognitive bias, an increased perception of neutral situations or objects as negative, is a cognitive symptom of depression and has been found to predict the onset of future depressive episodes. However, the underlying neural mechanisms of cognitive bias have seldom been investigated. Here, adult male and female Sprague-Dawley rats underwent a fear-based cognitive bias task and brains were collected after the task for analysis. Rats were trained for 15 days to distinguish between two situations: one foot-shock-paired situation and a situation paired with no foot-shock. Two days after training (day 17), rats were tested on optimistic (low freezing, positive cognitive bias) or pessimistic (high freezing, negative cognitive bias) behaviours in response to an ambiguous situation. Females displayed less freezing in response to the ambiguous situation compared to their behaviour in the foot-shock-paired situation ($p=0.045$)

and compared to males in the ambiguous situation ($p<0.001$). Males treated the ambiguous situation like the foot-shock-paired situation (a negative cognitive bias). In response to the ambiguous situation, females had greater activation of the basolateral amygdala (as measured by high Fos immunoreactive cell counts) than did males ($p=0.009$). Further, time spent freezing in the ambiguous situation and neural activity in the basolateral amygdala were positively correlated in females ($r=0.812$) and negatively correlated in males ($r=-0.692$). Neural activation was also measured in the prefrontal cortex and hippocampus. Moreover, the impact of hippocampal newborn neurons on cognitive bias was examined. Our data suggest a more positive cognitive bias in females than in males in response to a fear-based cognitive bias task, and a sex-specific role of the basolateral amygdala in these responses.

Title: Sex differences in the brain expression of steroidogenic molecules under basal conditions and after gonadectomy

Authors: *R. C. MELCANGI[1], S. DIVICCARO[1], L. M. GARCIA-SEGURA[2], S. GIATTI[1]; [1]Pharmacol. and Biomolecular Sci., Univ. degli Studi di Milano, Milano, Italy; [2]Inst. Cajal-CSIC, Madrid, Spain

Abstract: The brain is a steroidogenic tissue. It expresses key molecules involved in the synthesis and metabolism of neuroactive steroids, such as steroidogenic acute regulatory protein (StAR), translocator protein 18kDa (TSPO), cytochrome P450 cholesterol side-chain cleavage enzyme (P450scc), 3β-hydroxysteroid dehydrogenases (3β-HSD), 5α-reductases (5α-R) and 3α-hydroxysteroid oxidoreductases (3α-HSOR). Previous studies have shown that the levels of brain steroids are different in male and female rats under basal conditions and after gonadectomy (Caruso et al., *J Neuroendocrinol*. 2010, 22: 1137-47; Caruso et al., *Psychoneuroendocrinology* 2013, 38: 2278-90). In the present study we have assessed gene expression of key

neurosteroidogenic molecules in the cerebral cortex and cerebellum of gonadally intact and gonadectomized adult male and female rats. In the cerebellum, the basal mRNA levels of StAR and 3α-HSOR were significantly higher in females (at the proestrus day) than in males. On the contrary the mRNA levels of TSPO and 5α-R were significantly higher in males. In the cerebral cortex, all neurosteroidogenic molecules analyzed showed similar mRNA levels in males and females. Four months of gonadectomy increased the expression of 5α-R in the cerebral cortex of both sexes. In addition, ovariectomy decreased the expression of 3β-HSD and increased that of P450scc and TSPO in the cerebral cortex. Furthermore, ovariectomy increased the expression of StAR and decreased that of 3α-HSOR in the cerebellum but not in the cerebral cortex. Similar regional differences were observed for the effect of castration on the mRNA levels of TSPO and 5α-R in males. These findings indicate that the expression of steroidogenic molecules in the adult rat brain is sexually dimorphic and presents regional specificity, both under basal conditions and after gonadectomy. Thus, local steroidogenesis may contribute to the reported sex and regional differences in the levels of brain neuroactive steroids (Caruso et al., *J Neuroendocrinol*. 2010, 22: 1137-47; Caruso et al., *Psychoneuroendocrinology* 2013, 38: 2278-90) and may be involved in the generation of sex differences in the adult brain function.

Title: An assessment of the transition to menopause in the rat in the TgF344-AD model of Alzheimer's disease

Authors: *V. L. PEÑA[1,3], S. N. NORTHUP-SMITH[1,3], V. E. WONER[1,3], H. L. BULEN[1,3], C. A. DYER[4], L. P. MAYER[4], S. ODDO[2,3], H. A. BIMONTE-NELSON[1,3];
[1]Psychology, [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Tempe, AZ; [4]Senestech, Inc., Flagstaff, AZ

Abstract: In the United States, Alzheimer's disease (AD) is the sixth leading cause of death with over 5.8 million Americans currently diagnosed; of those diagnosed, roughly two-thirds are

women. One possible factor is that women undergo a transition to reproductive senescence, known as menopause, which involves the dysregulation of ovarian hormones as ovarian follicle reserves become deplete. Previous preclinical assessments of menopause and AD have been primarily limited to evaluations of surgical menopause, usually via ovariectomy (the surgical removal of the ovaries). The current project utilized 4-vinylcyclohexene diepoxide (VCD) to model follicular depletion and transitional menopause in the ovary-intact TgF344-AD transgenic rat model of AD expressing two human genes: human amyloid precursor protein (APP_{SW}) and presenilin 1 (PS1ΔE9). This model displays Aβ plaque-like and neurofibrillary tangle-like pathology, neuronal loss, as well as some less-characterized behavioral impairments. The overall goal of this experiment was to investigate the relationship between transitional menopause, behavior, and AD-like pathology. Young adult female rats received either Sham or VCD injections, resulting in four experimental groups: wild type (WT) Sham (n=10), WT VCD (n=10), transgenic (TG) Sham (n=10), and TG VCD (n=10). After the completion of injections, rats underwent a behavioral battery that included the Water Radial Arm Maze (WRAM) to assess spatial working and reference memory, the Morris Water Maze (MWM) to assess spatial reference memory, the Open Field Task to assess locomotor activity and anxiety-like behavior, as well as the Visible Platform control task. Results indicated that TG rats were impaired compared to WT rats during learning on the WRAM. Menopause induction had a negative cognitive impact on the WT rats, but not the TG rats, for WRAM performance. TG rats were also impaired compared to WT rats on the MWM. Overall, initial data analyses suggest that the TG animals are impaired while learning a complex working and reference memory task in the TgF344-AD model, and that whether transitional menopause influences these outcomes might depend on TG status. Further analysis of open field data, AD-like pathology, ovarian histology, and hormone levels are underway to better understand the relationships between transitional menopause status, behavioral outcomes, and AD-like pathology.

Title: APOE genotype, sex, and 17beta-estradiol influence memory and the hippocampus in a mouse model of Alzheimer's disease

Authors: *L. R. TAXIER[1], S. M. PHILIPPI[2], J. M. YORK[3], M. LADU[4], K. M. FRICK[1]; [1]Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Univ. of Wisconsin Milwaukee, Milwaukee, WI; [3]Dept. of Anat. and Cell Biol., Univ. of Illinois at Chicago Dept. of Anat. and Cell Biol., Chicago, IL; [4]Anat. and Cell Biol., Univ. of Illinois, Chicago, Chicago, IL

Abstract: Loss of circulating estrogens at menopause is correlated with increased risk of Alzheimer's disease (AD) in women relative to men. Women carriers of the *APOE4* genotype, which is the leading genetic risk factor for late-onset AD, are more likely than women of the *APOE2* or *APOE3* genotypes, and men of any *APOE* genotype to develop AD. Moreover, interactions among *APOE* genotype, sex, and 17β-estradiol (E_2) are not well characterized. Gonadally-intact male and female mice expressing 5 familial AD mutations (5xFAD-Tg) and human *APOE3* (E3FAD) or *APOE4* (E4FAD) were trained on object recognition (OR) and object placement (OP) tasks to test object recognition and spatial memory formation. Two weeks after testing, mice were trained with novel objects, and brains were removed and hemisected 5 minutes later. The dorsal hippocampus (DH) was dissected from one hemisphere for Western blot analysis, and the other hemisphere taken for dendritic spine analyses. To determine whether E_2 mediates memory consolidation in EFAD females, ovariectomized E3FADs and E4FADs were trained in the OR and OP tasks, received an immediate post-training infusion of E_2 into the DH, and memory was tested 4 or 24 hours later. Male E3FAD mice exhibited intact OR and OP memory, whereas E3FAD females and E4FADs of either sex did not, suggesting preserved memory function in E3FAD males relative to females, and impaired memory in E4FAD mice of both sexes. E_2 enhanced OR and OP memory in E3FAD, but not E4FAD, females. Data indicate that levels of PSD95 were reduced in E4FADs compared to E3FADs, and levels of synaptophysin were lower in E4FAD females than every other group. ERα levels were lower in E3FADs relative to E4FADs, and in E3FAD males compared to E3FAD females. Levels of astrocytic and microglial proteins were increased in female EFADs compared to male EFADs, with highest levels in E4FAD females. Spine analysis is ongoing. These data suggest that *APOE* genotype and sex influence memory formation and the ability of E_2 to enhance memory consolidation in the EFAD model, and that alterations in synaptic proteins, glial proteins, and ERα may play a role. The results also suggest sex differences among *APOE3* carriers that could provide insights into neurobiological mechanisms underlying sex differences in AD risk.

Title: The cognitive effects of the highly selective progestin segesterone acetate in a rat model of surgical menopause

Authors: *V. E. WONER[1,2], S. V. KOEBELE[1,2], S. N. NORTHUP-SMITH[1,2], M. N. WILLEMAN[1,2,3], C. BARKER[1,2], A. SCHATZKI-LUMPKIN[1,2], M. VALENZUELA SANCHEZ[1,2], H. A. BIMONTE-NELSON[1,2];

Abstract: Progestogens, including natural progesterone and progestins (synthetic hormones that mimic some effects of endogenous progesterone) are prescribed for a myriad of health reasons to women across their reproductive and menopausal years. Administration of several different progestogens has been shown to be detrimental to cognition. Parent molecules from which progestins are derived are known to yield biological activities and affinities beyond the progesterone receptor (PR), and could modulate cognitive outcomes. These findings, along with research demonstrating the role of some progestogens with strong affinities for the PR in neurogenesis and neuroprotection, suggest that a 'purely-progestational' molecule that maximizes PR affinity and minimizes affinities to other receptors may be cognitively beneficial. We evaluated the cognitive effects of segesterone acetate (registered trade name: Nestorone™; ST-1435), a 19-norprogesterone derivative with a strong PR affinity and no androgenic or estrogenic receptor affinity, in a rat model of surgical menopause. Middle aged female Fischer-344 rats were given Sham surgery or Ovariectomy (Ovx) followed by daily administration of either medroxyprogesterone acetate (MPA; previously shown by our laboratory to induce cognitive deficits), ST-1435, given at a low or high dose, or Vehicle (administered to the Sham group and one Ovx group). Rats were tested on a behavioral battery involving spatial working and reference memory, including the Water-Radial Arm Maze (WRAM), Morris Maze (MM), Visible Platform control task, and the Open Field Test to measure locomotor activity and anxiety-like behaviors. WRAM results indicated that Ovx rats given the low dose of ST-1435 demonstrated impaired spatial working memory compared to Ovx rats given vehicle, and Ovx rats treated with the high dose of ST-1435 exhibited memory retention deficits. We also found memory retention impairments for MPA-treated Ovx rats on the WRAM, replicating our previous findings. Additionally, Ovx rats given MPA or the high dose ST-1435 were impaired relative to Ovx rats given vehicle on the MM. The cognitive effects and underlying neurobiological mechanisms of ST-1435 merit further study, as the memory deficits with long term administration at both low and high doses reported here are in contrast with other literature suggesting neuroprotective effects of ST-1435. Thus, we seek to characterize the relationship between the biological activity of ST-1435 and subsequent behavioral outcomes in future studies in order to identify a progestin that promotes positive health outcomes for women across the lifespan.

Title: Investigating long-term cognitive effects of variations in gynecological surgery during adulthood in a rat model

Authors: *S. V. KOEBELE[1,3], V. E. WONER[1,3], S. N. NORTHUP-SMITH[1,3], M. N. WILLEMAN[1,3,4], I. M. STROUSE[1,3], H. L. BULEN[1,3], A. R. SCHRIER[1,3], D. F. DENARDO[2], L. P. MAYER[5], C. A. DYER[5], H. A. BIMONTE-NELSON[1,3];
[1]Psychology, [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ; [4]The Translational Genomics Res. Inst., Phoenix, AZ; [5]Senestech Inc., Flagstaff, AZ

Abstract: It is currently estimated that by age 60, about a third of US women will have experienced hysterectomy, or the surgical removal of the uterus. This surgery is often performed in adulthood, prior to the final menstrual period. Although some women undergo a complete ovariohysterectomy in adulthood, the ovaries are retained in about half of hysterectomy cases to avoid premature or abrupt surgical menopause. Research has suggested that hysterectomy, with and without ovarian conservation, can increase the relative risk of developing dementia compared to age-matched reproductive-tract-intact women. This association has piqued interest into how the non-pregnant uterus, which is typically considered to be an endocrine target but otherwise a dormant organ, may influence non-reproductive functions including cognitive processes. Our laboratory recently reported that hysterectomy with ovarian conservation resulted in detrimental effects on spatial working memory in adult Fischer-344-CDF rats six weeks after surgery. The current study aimed to extend these findings and investigate the longitudinal cognitive effects of hysterectomy in adulthood in order to elucidate whether the cognitive effects observed six weeks post-surgery were transient and reversed with time or the observed cognitive changes were the beginning of a long-term, more global cognitive impairment. Adult female rats received either sham, ovariectomy, hysterectomy, or ovariectomy-hysterectomy surgeries. Rats

were then tested on a battery of cognitive tasks evaluating spatial working and reference memory either six weeks, seven months, or twelve months after surgery. Preliminary results indicate that the working memory impairment observed in hysterectomy rats six weeks after surgery persisted in both the middle-aged and aged time points. These behavioral findings will be discussed in the context of serum hormone levels and ovarian follicle profiles for each time point. Understanding the cognitive effects of variations in gynecological surgery is a critical avenue of research to explore with the goal of enhancing quality of life and women's health throughout aging.

Title: Altered methylation pattern of the SRD5A2 gene in cerebrospinal fluid of post-finasteride patients

Authors: ***S. DIVICCARO**[1], L. CASARINI[2], M. MARINO[2], D. SANTI[2], S. SPERDUTI[2], S. GIATTI[1], M. GRIMOLDI[3], D. CARUSO[1], G. CAVALETTI[4], M. SIMONI[2], R. C. MELCANGI[1];
[1]Univ. Degli Studi Di Milano, Milano, Italy; [2]Dept. of Biomedical, Metabolic and Neural Sci., Univ. of Modena and Reggio Emilia, Modena, Italy; [3]Neurol. Div., Papa Giovanni XXIII Hosp., Bergamo, Italy; [4]Exptl. Neurol. Unit and Milan Ctr. for Neurosci., Univ. of Milano Bicocca, Monza, Italy

Abstract: Finasteride is an inhibitor of 5alpha-reductase type 1 and 2 enzymes, encoded by the *SRD5A1* and *SRD5A2* gene, respectively. This enzyme converts neuroactive steroids, such as testosterone and progesterone into dihydrotestosterone and dihydroprogesterone respectively (Melcangi R.C. et al., *Cellular and Molecular Life Sciences* 2008, 65:777-797). Post-finasteride syndrome (PFS) occurs in patients with androgenic alopecia after suspension of the treatment with finasteride, leading to a large variety of persistent side effects, including impairment of sexual behavior, depression, reduction in self-confidence, decreased initiative and difficulty in concentration, forgetfulness or loss of short-term memory, irritability, suicidal thoughts, anxiety, panic attack, sleep problems, muscular stiffness and cramps, tremors, chronic fatigue, joint pain

and muscular ache (Traish AM et al., *Reviews in Endocrine and Metabolic Disorders* 2015, 16:177-198; Giatti S. et al., *Endocrine* 2018, 61: 180-193). Despite the severity of the clinical picture, the mechanism underlying the PFS symptoms onset and persistence is still unclear. We have here studied whether epigenetic modifications may occur in PFS patients. In particular, the methylation pattern of *SRD5A1* and *SRD5A2* promoters was analysed in blood and cerebrospinal fluid (CSF) of 16 PFS patients recruited through the Italian network of finasteride side effects and in 20 blood and 13 CSF samples of age-matched healthy men. Data obtained indicate that the *SRD5A2* promoter was more frequently methylated in CSF of PFS patients compared to controls (56.3 *versus* 7.7%). No promoter methylation was detected in blood samples in both groups. No methylation occurred in the *SRD5A1* promoter of both groups. In conclusion, we demonstrated, for the first time, a tissue-specific methylation pattern of *SRD5A2* promoter in PFS patients. Animal models might be useful to elucidate the link between the use of finasteride, epigenetic changes, neuroactive steroid levels and behavioural disturbances described previously in PFS patients.

Title: Sex dimorphism of pregnenolone synthesis in the rat spinal cord of a multiple sclerosis experimental model

Authors: *S. GIATTI[1], R. RIGOLIO[2], S. DIVICCARO[1], D. CARUSO[1], G. CAVALETTI[2], R. C. MELCANGI[1];
[1]Dept. of Pharmacol. and Biomolecular Sci., Univ. degli Studi di Milano, Milano, Italy; [2]Surgery and Translational Med., Univ. of Milano-Bicocca, Monza, Italy

Abstract: The incidence of multiple sclerosis (MS) is higher in females than in males (ratio of 2:1). The course of the disease is more benign in women than in men, that develop a more severe pathology (Darlington C., Curr Opin Investig Drugs, 2002, 3:911-14). Neuroactive steroids (NA) are important physiological regulators of the nervous functions and their levels were altered in MS patients as well as in experimental models (Caruso D. et al., J of Neurochem 2014, 130:591-

97; Giatti S. et al., J Neuroimmune Pharmacol 2013 8:238-50). However, whether the synthesis of NA in the nervous system (i.e., neurosteroidogenesis) is affected by the pathology and differently in the two sexes has been poorly investigated. To this aim, using a common MS paradigm, the experimental autoimmune encephalomyelitis (EAE) Dark Agouti rat model, the levels of the first NA produced from cholesterol (i.e., pregnenolone, PREG) were evaluated at acute (i.e., 14 days post EAE induction, DPI), and chronic phase (i.e., 40 DPI), in the spinal cord of male and female (i.e., at diestrous day) animals. We reported that male EAE vs control animals, showed a decrease of PREG levels at acute and chronic phase, while in female EAE animals the levels were decreased only at chronic phase. In agreement, the gene expression of CYP11A1 (i.e., the gene coding the enzyme P450 side chain cleavage responsible for the synthesis of PREG from cholesterol) was decreased at 14 and 40 DPI in males, and only at 40 DPI in females. Decreased PREG levels in males, at least at 40DPI, were also associated with decreased levels of its precursor (i.e., the free cholesterol) in the spinal cord. The effect on the free cholesterol levels was a consequence of a reduction in cholesterol synthesis, since the gene expression of the rate liming step in cholesterol production (i.e., HMG CoA-R) was significantly decreased, as well as to an increase in its metabolism. Indeed, the levels of a cholesterol metabolite, such as the 25OH-cholesterol, were significantly increased at 40DPI. In conclusion, PREG levels present in spinal cord decreased in male at both phases while in female only at the chronic phase. In both sexes, this decrease was associated with an impairment of CYP11A1. Interestingly, altered levels of free cholesterol, possibly due to a decrease in its synthesis and an increase its metabolism, were observed in the male spinal cord at chronic phase.

Title: The effects of ovarian hormones on the nuclear progesterone receptor in the female rat hippocampus

Authors: *C. GAGNE, S. PATEL, A. GHEZZO, W. G. BRAKE;
Concordia Univ., Montreal, QC, Canada

Abstract: Estrogens and progesterone are implicated in a wide array of cognition and behaviors, including learning and memory. Classically thought to act exclusively on nuclear receptors, it is

now evident that both hormones act on membrane-bound receptors in the brain as well. While the distribution of estrogen receptors (ERs) across brain areas is relatively well characterized, less is known about the distribution of both nuclear and membrane-bound progesterone receptors (PRs). Furthermore, it is not known whether fluctuating levels of these ovarian hormones influence the density of PRs. This research investigated the effect of 17β-estradiol (E2) and progesterone (P) on the percent volume of nuclear PRs via epifluorescent microscopy. Here, 18 OVX Sprague-Dawley female rats were assigned to one of three hormonal conditions: low E2, high E2, and high E2 + P. While nuclear PR immunoreactivity was found throughout the hippocampus, there appears to be no effect of hormonal manipulation. Western blot analysis indicates that the antibody used may be detecting a novel isoform of the rat nuclear PR migrating at a similar molecular weight to those observed in humans.

Title: The effects of ovarian hormones on the membrane-bound progesterone receptor β in the female rat hippocampus

Authors: *S. PATEL, C. GAGNE, A. LESTAGE, W. G. BRAKE;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Ovarian hormones play a widespread role in female brain and cognition beyond reproductive functions. For example, estrogens play a role in memory system bias in female rodents and women. However, less is known about progesterone (P) which also has been implicated in the bias to use either place or response memory. Two subclasses of progesterone receptors (PR) have been identified: membrane-bound PR (mPR) and nuclear PR (nPR). The recent discovery of mPRs in the female mouse brain provides a potential rapid, nongenomic mechanism in which progesterone may influence nerve cell function. The localization of these novel mPR subtypes in the female rat brain remains unexplored. Thus, the purpose of this study was to determine if mPRβ, the most abundant of these receptors, is localized to the hippocampus, and if its expression is regulated by ovarian hormones. Eighteen ovariectomized, female rats received either high 17β-estradiol (E2) + P, high E2 alone, or low E2 alone. The mPRβ immunoreactivity volume was calculated based on the proportion of receptor volume from epifluorencent images to total volume of a 3D images. High E2 increased the density mPRβ

immunoreactivity relative to low E2 alone. On the other hand, it appears that P down regulates these receptors as the high E2+ P group had low mPRβ immunoreactivity relative to the high E2 alone. These findings provide a potential mechanism for the rapid effects of P on memory bias.

Title: Training-induced neurosteroids enhance remote spatial memory in mice

Authors: *K. SHIMIZU[1], K. MAEHATA[1], T. IKENO[1], Q. WANG[2], T. TAKAO[2], Y. FUKADA[1];

Abstract: Neurosteroids are neuroactive steroids that are synthesized in the brain and they regulate a variety of biological functions including cognition and behavior. These neurosteroids are synthesized from cholesterol by a series of cytochrome P450 enzymes, among which a new member of P450 hydroxylase, cytochrome P450-7b1 (CYP7B1), has been shown to catalyze formation of 7-hydroxylated neurosteroids, 7α-hydroxypregnenolone (7α-OH-Preg) and 7α-hydroxydehydroepiandrosterone (7α-OH-DHEA). Here we found that the mRNAs encoding the enzymes required for the synthesis of 7α-OH-Preg and 7α-OH-DHEA from cholesterol were detected in all the brain regions we examined. Higher level of *Cyp7b1* mRNA expression were determined in the mouse hippocampus among various brain regions. We identified 7α-OH-Preg and 7α-OH-DHEA in the mouse hippocampal extract by using liquid chromatography coupled with *electrospray* ionization tandem mass spectrometry. In the Morris's water maze test, we found a dawn-dusk change in remote spatial memory in WT mice, the memory performance at ZT1 (dawn) was significantly higher than that at ZT11.5 (dusk). The remote memory performance at ZT1 was impaired by *Cyp7b1* deficiency. In *Cyp7b1*-deficient mice, chronic intracerebroventricular administration of 7α-OH-Preg and 7α-OH-DHEA improved remote spatial memory performance. Furthermore, the administration of mixture of these neurosteroids was more effective than the single administrations. We conclude that 7α-OH-Preg and 7α-OH-DHEA play a cooperative role for the long-term maintenance of remote spatial memory in mice.

Title: Effects of developmental and acute exposure to environmental estrogenic compounds on anxiety and memory in male and female rats

Authors: M. VOGT[1], J. ASBERRY[1], ***J. WILLING**[2];
[2]Psychology, [1]Bowling Green State Univ., Bowling Green, OH

Abstract: There are a variety of different ways to humanely house laboratory rodents in animal research facilities. As such, animal facilities at universities and other organizations utilize a vast number of different environmental/housing protocols, which are often unreported in scientific literature. However, recent research shows that many elements of these environments, including bedding, diet, water bottles, and cage material, inadvertently expose laboratory rodents to natural and synthetic substances that can affect the development of the body, brain and behavior. Notably, these environmental variations can expose rodents to increased levels of estrogen and endocrine-disrupting compounds. Exogenous estrogens have been shown to induce developmental and acute changes in neural functioning that can have long-term effects on anxiety and learning/memory. Here, we compare male and female rats raised from birth in an environment high in estrogen (standard rodent chow, plastic cages, plastic water bottles, corn cob bedding) to rats raised in a relatively low-estrogen environment (phytoestrogen-free chow, polyethylene cages, glass water bottles and wood-chip bedding) on several behavioral, developmental and reproductive endpoints. Additionally, we examine the acute effects of these housing conditions in littermates whose environmental condition was switched in adulthood. Specifically, we report the effects of environment on anxiety-like behavior in the elevated plus maze and long-term memory in the object recognition task. These results provide further evidence for the role of environmental endocrine compounds in development and behavior, and may provide insight into issues of reproducibility in animal sciences stemming from environmental context-dependent results.

Title: Anabolic-androgenic steroids impair biconditional task performance in male rats

Authors: *R. I. WOOD[1], R. O. SERPA[2];
[1]Integrative Anatom. Sci., Keck Sch. Med. USC, Los Angeles, CA; [2]Integrative Anatom. Sci., Keck Sch. of Med. of USC, Los Angeles, CA

Abstract: Our goal is to understand the consequences of anabolic-androgenic steroid (AAS) abuse on cognitive function, using rats as a model. Although AAS abuse is now widespread, there has been relatively little research on how steroid abuse impacts cognition. In the present study, rats were tested for their ability to use contextual information to guide decision-making in biconditional discrimination. The Stroop task is a classic human test for contextual decision-making. Subjects are asked to read a color word (e.g. "green", "orange") and name the ink color in which the word is printed (green or orange). Subjects respond faster when the word and ink are congruent ("green" printed in green ink), than when they are incongruent ("green" printed in orange ink). In rodents, biconditional discrimination challenges subjects to use contextual cues in the operant chamber to resolve the correct lever response when auditory and visual cues are incongruent. The hypothesis is that chronic high-dose testosterone impairs biconditional discrimination. Rats were trained in 24 trials/day over 14 days, in alternating sessions with each environment On a flat floor with the houselight illuminated, auditory cues (clicker vs tone) signified the active lever. On a barred floor with no light, rats used visual cues from 2 stimulus lights (constant vs blinking) to identify the active lever. Rats treated chronically with testosterone (7.5 mg/kg) were unimpaired in initial task acquisition, and all rats learned to select the correct lever in response to auditory or visual cues. During extinction, vehicle controls made significantly more correct than incorrect responses in congruent trials ($p<0.05$ by paired t-test), but testosterone-treated rats failed to show a similar preference. This was reflected by a significant effect of testosterone ($F_{1,76}=5.875$, $p<0.05$), as well as a significant interaction of drug, cue agreement, and response accuracy ($F_{1,76}=8.076$, $p<0.05$). These results suggest that testosterone impairs cognitive flexibility, and demonstrates the potential for AAS abuse to impair cognitive function in humans.

Title: Hippocampal estrogen and androgen modulate dendritic spines and LTP in non-genomic manner

Authors: *S. KAWATO[1,2], M. SOMA[2], M. OGIUE-IKEDA[2], Y. KOMATSUZAKI[3];
[1]Univ. of Tokyo, Tokyo, Japan; [2]Teikyo Univ., Tokyo, Japan; [3]Nihon Univ., Tokyo, Japan

Abstract: We demonstrated (1) hippocampal synthesis of estrogen and androgen, and (2) non-genomic synaptic modulation by these sex-steroids. [Synthesis] We showed expression as well as neuronal/synaptic localization of essential enzymes (mRNA and protein) in the adult male rat hippocampus. Mass-spectrometric analysis demonstrated that exact levels of estradiol (E2), testosterone (T), dihydrotestosterone (DHT) were 8 nM, 18 nM and 7 nM, respectively, which are much higher than their levels in plasma. Castration significantly decreased T and DHT in the hippocampus, indicating that plasma-derived T is efficiently converted to DHT within the hippocampus. Even after castration to deplete circulating T, the male hippocampal E2 level was not decreased, indicating that E2 is mainly synthesized from hippocampal T. Female hippocampal levels of E2 (0.5-4 nM), and T (1 nM) were less than those of male, but much higher than those in female plasma. [Synaptic Modulation] E2-induced rapid non-genomic modulation (1- 2 h) was demonstrated by analysis of spinogenesis and LTP of adult male rat hippocampal ‘acute’ slices (steroid-depleted slices). Spine analysis was performed for pyramidal neurons in hippocampal slices. The density of spines and their head diameters were obtained by mathematical and automated software Spiso-3D which identifies spines by calculating geometrical parameters. E2 at 1 nM rapidly increased the density of small-head spines, in CA1 pyramidal neurons. T and DHT at 10 nM increased the density of small-head spines and large-head spines, respectively. Signaling pathways are: synaptic ERalpha or AR→LIMK, MAPK, Src, PKA, PKC →cofilin or cortactin → actin polymerization→ new spines. LTP analysis showed that 1 nM E2 induced full-LTP (E2-LTP) upon weak sub-threshold stimulation, although without E2 the weak sub-threshold stimulation did not induce full-LTP. Kinase inhibitors against MAPK, PKA, PKC blocked E2-LTP. Only 20 min application of letrozole (aromatase inhibitor) suppressed full-LTP upon full teta-burst stimulation, indicating that rapid E2 synthesis is necessary for LTP in hippocampal slices. Title: The impact of the estrous cycle and novelty on female rat behavior in the open field test

Authors: *C. K. MILLER, H. B. PATISAUL, J. MEITZEN;
North Carolina State Univ., Raleigh, NC

Abstract: Many natural factors impact animal behavior. In females, one important consideration is hormone status due to cyclic hormone changes such as in the menstrual cycle in humans and the estrous cycle in rats. These behaviors include those related to anxiety, locomotion, depression, and motivation, which are often assessed in rodents using the open field test. In female rats, exploratory behaviors such as locomotion and propensity to enter areas perceived as dangerous fluctuate naturally across the estrous cycle. However, it is not well-explored as to how behavioral differences induced by hormone cycles interact with other factors such as exploration in a novel environment. Thus, hormone-induced behavioral differences may be masked by novelty-induced behavioral changes. Here, we aim to disassociate differences in exploratory behaviors in the context of the estrous cycle from differences resulting from a novelty effect. We hypothesized that behaviors in the open field such as total distance traveled and time spent in the center would be increased both during initial exposure to the open field as well as in the estrus stage compared to diestrus stage, when hormone effects are limited. We found that both the estrous cycle stage and day of exposure to the open field influenced exploratory behavior. This is important to note in the context of the open field test, as hormone-induced behavioral differences may not be detected as robustly due to the presence of the novelty effect. This approach to open field testing should be considered when exploring hormone-induced behavioral changes across the natural cycle.

Title: Hibiscus is a source of phytoestrogens that modulates spatial memory and hippocampal BDNF expression: A behavioral and molecular study

Authors: *G. LORENZANA[1], A. SANTERRE[1], I. ANDRADE-GONZALEZ[2], J. BAÑUELOS-PINEDA[1];
[1]Univ. of Guadalajara, Zapopan, Mexico; [2]Inst. Tecnológico de Tlajomulco, Tlajomulco, Mexico

Abstract: INTRODUCTION Ovaric hipofunction (OH) is characterized by decay in brain derived neurotrophic factor (BDNF), a neurotrophin critical for neuron survival and function, associated with cognitive and memory decline. Hormone replacement therapy (HRT) is the most common treatment against OH, however this therapy may increase odds of endometrial cancer, blood clots, stroke and breast cancer. Phytoestrogens may offer a safer natural alternative to the synthetic estrogen used in HRT. *Hibiscus sabdariffa* L. (Malvaceae) is known to present health benefits related with its high content of anthocyanins which present structures similar to other compounds, known for their phytoestrogenic activity. In the present study an ovarectomarized rat model was used to assess the phytoestrogenic effect of an anthocyanin extract of *H. sabdariffa*, through BDNF expression and spatial memory evaluation. **MATERIALS** Preparation of the *H. sabdariffa* anthocyanin extract (HSAE) was according to Gonzalez-Palomares et al., 2009. Adult female Wistar rats (90 days old) were randomly separated in six groups. Rats from four groups were ovariectomized (OVX) and injected physiological dose of estradiol (E2), or given HSAE in drinking water at 50 or 100 mg/kg of body weight (bw), for six weeks. Two control groups were included (intact and sham). At day 52 of treatment the Barnes maze tasks were performed to assess short and long term memory (STM, LTM); then hippocampal BDNF expression was evaluated by RT-qPCR and western blot (day 62). **STATISTICAL ANALYSIS** Data for multiple variable comparisons were analyzed by one-way analysis of variance (ANOVA). For the comparison of significance between groups, Tukey's post hoc test was used; $p<0.05$ was considered significant. **RESULTS AND DISCUSSION** The analysis of Barnes´ tests data showed that the administration of HSAE reversed the negative effect of ovariectomy on STM and LTM parameters. A stronger effect was observed in animals administered the lower dose of the anthocyanin extracts (50 mg/kg bw) compared to the higher dose (100 mg/kg bw), probably due to the better acceptation of the extract. The administration of HSAE restored BDNF protein expression. In particular, BDNF protein expression was higher in hippocampus of rats that received 50 mg/kg bw compared to all other study groups. Moreover, the animals that received HSAE presented a significant increase in BDNF transcriptional expression (mRNA) compared to

the rest of the groups. In conclusion HSAE acted as a phytoestrogen, improving hippocampal BDNF expression and spatial memory performances. Further work is now needed to determine if this effect involves ERα, ERβ, as well as GPR30 estrogen receptors.

Title: Postnatal progesterone receptor activity influences adult episodic-like memory in the rat

Authors: *A. J. N. NEWELL, C. K. WAGNER;
Univ. at Albany, Albany, NY

Abstract: The transcription factor progesterone receptor (PR) is expressed in Cajal-Retzius (CR) cells of the hippocampal dentate gyrus during the postnatal period. CR cells are critical for dentate gyrus morphogenesis and establishing hippocampal connectivity with the entorhinal cortex via the perforant path. Therefore, postnatal PR activity in CR cells may influence the development of these connections and in turn, affect the behaviors dependent on this pathway, such as episodic memory. To test this hypothesis, Sprague-Dawley rats were treated for the first postnatal week with the PR antagonist, RU486 (20 mg/kg s.c. daily injections) or the vehicle alone. In adulthood, animals were assessed on the Episodic-Like Memory (ELM) task, a test of entorhinal and hippocampal connectivity. In the ELM task, animals are required to integrate functional components of episodic memory, ‘what’, ‘when’, and ‘where’, into a conjoined representation. Results indicate that vehicle treated rats were able to distinguish a stationary object from one which had been displaced when the objects were encountered at a distant time point rather than more recently, but showed no difference in exploration time for recent objects regardless of their position. This suggests integrated memory for the ‘what’, ‘where’ and ‘when’ components of ELM. In contrast, rats treated with the PR antagonist, RU486, spent equal time with objects, regardless of when or where the objects were experienced. This suggests a disruption in the ability of RU486 treated rats to recall episodic specifics and a disruption of an integrated memory for the ‘what’, ‘where’ and ‘when’ components of ELM. However, when the ‘what’ and ‘when’ components were tested separately in a different task, both oil treated and RU486 treated rats were able to distinguish objects and their relative order of presentation, indicating that both groups can recall these components individually in a task that does not

require the integration of the what, when, and where components of ELM. Taken together, these observations suggest that PR activity in CR cells during the postnatal period is critical for fully integrated episodic-like memory in adulthood and generates the hypothesis that PR is involved in the development of the lateral perforant path.

Title: Luteinizing hormone fluctuations across the estrous cycle impacts synaptic markers in the cingulate and hippocampus

Authors: *M. E. MEY[1], G. CASADESUS SMITH[2], S. BHATTA[1], N. MULLINS[3], K. SRACIC[3];
[1]Biomed. Sci., [2]Biol. Sci., [3]Kent State Univ., Kent, OH

Abstract: The hypothalamic-pituitary-gonadal (HPG) axis has long been associated with changes in behavior and neuronal morphology. Over the course of the estrous cycle, the HPG axis steroid hormones fluctuate and these fluctuations have been associated with estrous-cycle related variations in learning and memory and underlying neuronal plasticity. Recently, luteinizing hormone (LH) has also emerged as another potential regulator of cognition. However, whether LH fluctuation over the course of the estrous cycle is a player in the regulation of synaptic markers is unknown. To address this, cingulate and hippocampal levels of synaptic plasticity markers (synaptophysin, spinophilin, PSD95, BDNF) were measured from animals at different stages of the estrous cycle. Our results thus far indicate a differential and inverse relationship between levels of peripheral LH and the plasticity markers mentioned above. Together, these findings support emerging data demonstrating a CNS role for LH signaling, particularly in neuronal communication and synaptic plasticity.

Title: Long term ovariectomy in a nonhuman primate model of menopause reduces hippocampal volume and shifts microglial morphology toward an inflammatory profile; conjugated equine estrogens are not protective

Authors: A. MAFI[1], E. BLAGINYKH[2], S. MISTRY[1], P. MIRJALILI[1], A. BESSKEN[1], E. HOPKINS[1], G. HOWE[1], ***G. P. TINKLER**[1];
[1]Biol. Sci., [2]Col. of Publ. Hlth., Kent State Univ., Kent, OH

Abstract: Loss of circulating ovarian hormones that accompanies menopause may increase the risk of dementia with aging. Inflammation is a key component to many diseases of brain aging, and administering ovarian hormones (estrogen therapy, ET) can quell inflammatory responses. Nonhuman primates are an excellent animal model with which to study menopause, given their similarities to humans. We hypothesized that ovarian hormone loss (ovariectomy, OVX) would increase inflammation in the hippocampus, an area relevant for cognitive processes such as learning and memory, as measured by microglial proliferation and morphology. We further hypothesized that conjugated equine estrogens (CEE) would prevent inflammation in this area. Our study employed the brains from 25 perimenopausal monkeys (age approximately 20 years). These animals were previously ovariectomized and treated for either six or 24 months with placebo (OVX) or estrogens (OVX+CEE). A separate group of animals were available as intact, cycling controls (INT). Using stereological methods, we assessed brain inflammation by quantifying the numbers of microglia in the hippocampus. Compared to INT, the hippocampus of both 24 month OVX and OVX+CEE animals was reduced in volume, while microglia densities were increased in both groups. Interestingly, animals that were OVX or OVX+CEE for only 6 months were not statistically different from INT control animals. Morphological analysis of hippocampal microglia indicated that in the 24 month OVX condition, there was a shift away from the ramified (resting) phenotype toward the amoeboid (activated) morphology. CEE was not effective at preventing this shift. Our results suggest that there may be long term neurobiological consequences to OVX which do not manifest in shorter time frames, and that CEE may not be effective at mitigating chronic inflammatory events that accompany OVX.

Title: Social instability in adolescence alters dendritic morphology in medial prefrontal cortex and its response to stress in adult rats

Authors: *M. R. BREACH, K. M. MOENCH, C. L. WELLMAN;
Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Women are more susceptible to many stress-linked psychological disorders, including depression and posttraumatic stress disorder. Dysfunction of prefrontal cortex is implicated in many stress-linked disorders. Thus, understanding how stress may differentially influence prefrontal cortex in males and females may shed light on the neurobiological underpinnings of these sex-biased stress-linked disorders. Chronic restraint stress (CRS) induces sex-specific changes in pyramidal neurons in rodent medial prefrontal cortex (mPFC). For example, apical dendrites of adult male rats retract after 10 days of CRS, which is followed by outgrowth after 7 days of rest. Conversely, apical dendrites of stressed female rats exhibit minimal changes throughout the post-stress period. As adolescence is an important period for HPA axis development and synapse maturation, stress during this time could produce long-lasting changes in stress-sensitive brain regions and alter later stress-induced changes in the adult brain. However, little is known about how stress in adolescence affects these sex-dependent stress-induced changes in adulthood. We investigated the effects of adolescent social instability stress (SIS) on adult dendritic morphology in mPFC of male and female rats. We then examined dendritic reorganization following chronic restraint stress with and without a rest period in adolescently-stressed rats. Golgi-Cox stained pyramidal neurons in mPFC were reconstructed. Dendritic length and spine density analyses revealed that adolescent SIS confers long-term alterations in PL of males and females, whereby females show reduced apical length and basilar thin spine density and males show reduced basilar length. In addition, CRS does not induce dendritic or spine changes immediately after the cessation of CRS. However, CRS reduces apical dendritic length and increases mushroom spine density in adolescently-stressed male rats given a rest period. Conversely, CRS produces outgrowth and decreases mushroom spine density in adolescently-stressed females given a rest period. Both sexes experienced an increase in thin spine density following a rest period after chronic stress. These results corroborate previous evidence of sex-dependent stress-induced changes in mPFC and suggest that stress during

adolescence alters development of the prefrontal cortex and may modulate stress-induced dendritic changes in adulthood.

Title: Stress during puberty decreases sexual motivation and affects the correlation testosterone-electroencephalographic activity in adult male rats

Authors: *E. HERNANDEZ-ARTEAGA[1], M. L. RAMÍREZ-RENTERÍA[2], M. HERNÁNDEZ-GONZÁLEZ[2], M. A. GUEVARA[3], H. BONILLA-JAIME[4], A. AGMO[5]; [1]Inst. Autónoma Metropolitana, Mexico city, Mexico; [5]Univ. of Tromsø, Tromsø, Norway

Abstract: Puberty is a critical period of development during which occur neurophysiological changes that allow the manifestation of sexual behavior in the adulthood. This behavior requires adequate levels of testosterone, which affects the functionality of the brain structures such as the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA). A prevalence of electroencephalographic (EEG) theta band (4-13 Hz) has been reported during sexually motivated states. Several studies have reported the deleterious effects that stress exerts on sexual behavior. Considering the above, the aim of this study was to evaluate the effect of stress by social isolation during puberty on sexual motivation and on the association between testosterone levels and the theta band in the mPFC and BLA of male rats. 60 male rats were classified into two groups (n=30), as follows: a stressed group (SG, each male was maintained in social isolation from day 25 to 50 postnatal), and a control group (CG, 4 males housed per cage). At 90 days of age, all rats were subjected to three copulatory tests to select the sexually-experienced individuals, which were implanted bilaterally in the mPFC and BLA to record the EEG activity during the awake-quiet state in a subgroup without sexual motivation (n=15, stimulated with a non-receptive female) and in a subgroup with sexual motivation (n=15 stimulated with a receptive-female). Immediately afterward, blood samples were obtained for quantifying testosterone levels. Pearson correlations (r) were then calculated between the absolute power values of the theta band and the testosterone levels for each of the 4 sub-groups, obtaining one correlation for each brain structure. Subsequently, these r values were compared between groups. All the males of the stressed subgroups spent less time in the incentive zone of the receptive female than those of the control subgroups. The control males without sexual motivation showed

a positive r while those with sexual motivation showed a negative r. In the stressed subgroups, no correlation between testosterone levels and absolute power was observed. These data show that stress during puberty affects the association between testosterone levels and brain function and so has an impact on sexual motivation in male rats.

Title: Effects of social stress exposure during adolescence on impulsivity

Authors: *L. F. GONZALEZ MARTINEZ, K. MORAN, G. GRAY, C. MALONE, Y. DELVILLE;
Psychology, The Univ. of Texas at Austin, Austin, TX

Abstract: Adolescent male hamsters exposed to chronic social stress become themselves aggressive adults, characterized by increased attack frequency and shorter latencies to engage opponents. Perhaps, this enhanced aggression is associated with a lack of impulse control, particularly the ability to inhibit responses (i.e. action inhibition) and waiting to respond (i.e. waiting impulsivity). Male golden hamsters were exposed daily to aggressive adults from postnatal day 28 to 42. Later, the animals were trained in conditioning chambers and tested in a Go-NoGo task to evaluate action inhibition. Overall, previously stressed hamsters were less likely to inhibit a conditioned lever pressing response during NoGo trials, showing a decreased ability to withhold responses, consistent with higher attack frequencies. To test waiting impulsivity, animals learned to respond to a main house-light by nose-poking in any of two, adjacent illuminated ports in a modified version of a 5-choice-serial-reaction-time task. During testing, random and varying delays were introduced between the main house-light presentation and illumination of the ports, and premature nose-poking responses were considered an indicator of waiting impulsivity. As delays grew longer, animals performed more premature responses. However, previously stressed animals were 25% less likely to perform such actions by the longest delay. These studies show that early stress exposure enhanced the capacity to wait to perform a response, which is unrelated to aggression. Aspects of perseverance also were tested in additional studies. Previously stressed animals were intolerant to delays in reward in specific conditions. In summary, exposure to chronic social stress in early adolescence causes a variety of

behavioral changes including enhanced aggression, decreased action inhibition and improved waiting impulsivity. This ambiguous relation between aggressive and impulsive behaviors shows that there are multiple types of impulsive-aggressive profiles likely related to different brain mechanisms. We propose that the concept of aggression should be reconsidered as a multidimensional construct mediating multiple aspects of personality.

Title: Effects of prolonged social isolation in adolescence: Sex differences in anxiety and sociability behavior in rats

Authors: *E. MRACKOVA, J. ROSENKRANZ;
Dept. of Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Early life stress such as prolonged social isolation is regarded as a risk factor for the development of depression and anxiety in adulthood. Extensive research has found that sex differences in anxiety-like behaviors emerge during adolescence, with females more at risk than males. Despite the rising social isolation and loneliness across the world, the causes and effects of social isolation in adolescence remain still poorly understood. The purpose of this study was to determine whether the housing condition of rats (social isolation vs group housing), social isolation duration (1-week vs 4-week continuous isolation), or sex (male vs. female) would affect sociability behavior as well as the development of anxiety-like behaviors. Four behavior tests (open field, conditioned place preference, social interaction, and appetitive operant conditioning) were administered at postnatal days 53-69 to determine the effects of social isolation on hyperactivity, thigmotaxic behavior, social behavior, and reward seeking. Overall, we found that 4 wk social isolation in both males and females increased thigmotaxic behavior and in female rats decreased social interaction. Furthermore, 1 wk social isolation in male rats resulted in an increased social place preference compared to a novel object. Lastly, while 4 wk social isolation did not significantly impact conditioned appetitive sucrose seeking behaviors, it increased sensitivity of conditioned seeking to a bright light anxiogenic stimulus. Overall, this research adds new insight into the understanding of sex differences associated with prolonged social isolation and subsequent anxiety-like behaviors. Future research will focus on immunohistochemistry staining of brain areas implicated in anxiety.

Abstract: Epidemiological and clinical studies have shown that early life experiences could be involved in the development of emotional and affective disorders, such as depression and anxiety in adulthood (1,2). There is also a general consensus, emerging from epidemiological studies, that the activation of the immune system in response to inflammatory agents, plays an important role in the pathophysiology of stress and depressive states (2).We are trying to link early inflammatory events with depressive-like behavior *in vivo* and we have established a model of maternal separation (MS, postnatal day 2 to 14, 3 h per day). Our preliminary results show robust microglial activation in the brain just after the MS at P15 (24 h after the last MS session) as well as significant alteration peripheral and hippocampal inflammatory response. Furthermore, at 6 weeks old (considered the adolescence period in mice (3)), the exposure to MS leads to several changes in the brain, including down-regulation of synaptic plasticity genes and growth factors as well as cognitive impairment and anxiety- and depressive-like behavior, in a sex-dependent manner.Our results will try to answer how priming events of microglial reaction can participate in the manifestation of depressive and anxiety-like behavior in the adolescence, in a sex-specific manner.References:(1) Nugent et al., 2011.(2) Reus et al., 2017.(3) Brust et al., 2015.

Abstract: Chronic stress increases the risk for stress-related disorders including anxiety and depression. A major form of chronic stress in humans is social in nature. Sex based differences exist in the resilience and susceptibility to develop stress-related disorders. Most basic research using models of chronic stress focus on using males only. Our main objective was to develop a model of chronic social stress that could be applied in both male and female mice. We examined a 7-week model of chronic social crowding and instability (CSCI) stress in mice. We also tested a 30-day model of CSCI stress in the presence and absence of paper nesting material, Enviro-dri and nestlets. Eight same sex mice were placed in a standard sized mouse cage with or without Enviro-dri and nestlets. Every 2-5 days the group composition of the cages was changed in an unpredictable manner using a randomized schedule. The control mice were housed in same sex pairs in a standard sized mouse cage with or without nesting material and handled when the CSCI stress mice were rotated cages. A battery of behavioral tests to measure depression and anxiety-like behavior were given at the end of the CSCI stress protocol. We found that 7-week CSCI stress without Enviro-dri significantly increased the latency to feed in a novelty suppressed feeding test in males but not females, compared to the control groups. Thirty days of CSCI stress without Enviro-dri did not have an effect on any behavioral tests measuring anxiety and depression-like behavior. However, thirty days of CSCI stress with Enviro-dri (10g) significantly increased the latency to feed in a novelty suppressed feeding test in both males and females. CSCI stress also increased immobility time in a forced swimming test in males but not females, and increased plasma corticosterone levels in females. The results suggest that CSCI stress with

Enviro-dri is a novel and practical animal model to measure anxiety/depression-like behavior that can be applied in both sexes.

Title: The effect of maternal deprivation on behavior in a mouse model

Authors: *M. D. THOMPSON, S. L. P. LIPPI, C. M. KREITLER;
Psychology and Sociology, Angelo State Univ., San Angelo, TX

Abstract: Foster care is a growing concern in Texas and in the United States. According to the U.S. Department of Health and Human Services (2016), the number of children in the foster care system has been increasing by approximately 10,000 children every year since 2012. The emotional deprivation experienced by a foster child leads to a form of brain trauma that has lasting effects through adulthood. There is a dearth of research investigating the long-term effects of maternal deprivation. The current research sought to investigate behavioral outcomes in a mouse model of maternal deprivation and highlight those behavioral changes through adulthood. In this study, we sought to explore the short-term and long-term behavioral effects. The study used four timed-pregnant C57BL/6J mice, two of which were randomly assigned to the maternal deprivation condition and were separated from their pups for 24 hours on postnatal day 4. The pups did not have access to food or water during these 24 hours (Kentrop, 2018). Pups were then returned to their home cages, until weaning at 3 weeks. At 4 weeks the pups began behavioral testing including the open field test, elevated zero maze, Morris water maze, and activities of daily living. Behavioral testing was repeated at 10 weeks of age; this was done to assess longer changes. Repeated measures ANOVAs were conducted for each behavioral test. Significant differences of age were found in the open field, elevated zero maze, and burrowing. There was a significant difference in the open field at 4 weeks between the two groups. Brain tissue will be assessed for markers related to learning and inflammation. The purpose of this project was to examine early life stress experiences in a mouse model on behavior both in short and long-term timeframes. Results showcase the impact of maternal deprivation as was found by the open field at 4 weeks of age, with maternally deprived mice spending significantly more time in the surround ($F(1,17) = 11.435$, $p < .01$). Indeed, we hope to raise awareness of foster care needs in the country and highlight the far-reaching impact on children's cognition and behavior.

Title: Chronic mild unpredictable stress and high-fat diet given during adolescence impact both cognitive and noncognitive behaviors in young adult mice

Authors: ***S. L. P. LIPPI**, M. D. THOMPSON, L. C. VOTH, A. M. FLORES;
Psychology & Sociology, Angelo State Univ., San Angelo, TX

Abstract: Stress and diet are intricately linked and often interact in a negative fashion. Increases in stress can lead to poor food choices; adolescence is a period that is often accompanied by increased levels of stress. Adolescents are noted to engage in emotional eating behaviors, which often involve poor food choices. The period of adolescence has shown a high prevalence of obesity (Bibiloni et al., 2013) and adolescent mice given diets high in fat have shown impairments in memory. Given that both stress and poor dietary choices can affect learning and memory, it is important to understand their combined effects when encountered during crucial developmental periods. Few studies have examined both chronic stress and intake of high-fat diet on behavior; in those that have, often only one sex has been used and diet administration starts at varying time points (Yang et al., 2016). The current experiment explored how chronic mild unpredictable stress (CMUS) and high-fat diet (HFD) affect animal memory and behavior when given during the period of adolescence (starting at PND 28). C57BL/6J mice received *ad libitum* access to either a control diet (D12450J – 10 kcal% fat) or a high-fat diet (D12492 – 60 kcal% fat) starting at four weeks of age and experienced either no stress or four weeks of CMUS (4 – 8 weeks). Behavioral tests run included: open field, elevated-zero maze (EZM), and Morris Water Maze (MWM). Non-cognitive tests were also run; these included burrowing and nesting assays. Both male and female mice were used in this study. Mice experiencing CMUS exhibited behavioral disinhibition; spending significantly more time in the open arms of the EZM, $p < .05$ and significantly less time in the center of the open field, $p = .01$. In MWM, there were significant effects of training day for latency to find the hidden platform and thigmotaxicity ($p < .001$). Mice that underwent CMUS made significantly fewer crosses on the final 24-hour probe trial compared to those with no stress, $p < .05$. Additionally, a significant diet x stress interaction was noted in time spent in the target quadrant on the final 24-hour probe trial, $p < .05$. Mice given a HFD with no stress spent significantly longer in the target quadrant than the HFD mice with CMUS, $p < .01$. CMUS mice burrowed significantly more peagravel after 2 hours in the burrowing assay, $p < .05$ and had higher rated nest scores than non-stressed mice, $p < .05$. High-

fat diet mice built significantly poorer nests compared to those on a control diet, $p < .05$. These results show that CMUS and HFD administration given during adolescence have the ability to affect both cognitive and non-cognitive behaviors in early adulthood.

Title: Alternative splicing of glucocorticoid receptor (GR) increases in the brain following acute and chronic stress

Authors: *J. CHANG, A. ASIMES, T. PAK;
Loyola Univ. Chicago, Maywood, IL

Abstract: Alternative splicing increases the diversity of proteins that arise from a single pre-mRNA transcript. The brain has a high incidence of alternative splicing, which can be modulated under a variety of pathological conditions. For instance, alcohol abuse causes dramatic changes in gene alternative splicing, leading to neuroadaptive changes in the brain. In addition, our lab and others have shown that adolescent “binge pattern” alcohol abuse caused dysregulation of the physiological stress response mediated by the hypothalamo-pituitary-adrenal (HPA) axis. The hypothalamic glucocorticoid receptor (GR) mediates the negative feedback effects of cortisol on the HPA axis and dysregulation of this negative feedback pattern causes increased anxiety-like behaviors, which leads to the development of mood disorders. Previously, our lab showed that binge pattern alcohol (ETOH) exposure in adolescent rats caused disruptions in GR negative feedback in the hypothalamus. Therefore, we hypothesized that the observed dysregulation could be due to increased alternative splicing of GR to the dominant negative isoform, GRβ, which does not have ligand-binding ability. To test this hypothesis, we used a binge model of ETOH exposure in rat hypothalamic-derived cell lines. Briefly, cells were treated with 50 or 100 mM ethanol for two hours once/day for 3 consecutive days. The cells were collected every 24 hours and we measured GRβ expression using RT-qPCR. Our results showed an initial increase of GRβ expression, which decreased following subsequent ETOH exposures. Next, we tested whether the increased expression of GRβ was specific to ETOH or generalized stressors by

subjecting the cells to heterotypic stressors. Consistent with ETOH exposure, GRβ expression was also increased following heterotypic stress exposure. We then assessed GRβ expression in a rat model of adolescent "binge" ETOH exposure and in a chronic stress model. Similar to our *in vitro* data, GRβ was increased in both of these *in vivo* paradigms. Together, these results demonstrate prolonged changes in GR splicing following a stressor, which can impact HPA axis regulation leading to the development of mood disorders in later life.

Title: Mechanisms of resilience after adolescent chronic stress: Implications for PTSD

Authors: *E. M. COTELLA[1], R. D. MOLONEY[1], P. MAHBOD[1], J. NIBLACK[1], M. FITZGERALD[1], J. B. CHAMBERS[2], J. P. HERMAN[1];
[1]Pharmacol. and Systems Physiol., [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Posttraumatic stress disorder (PTSD) is a psychiatric condition that can develop after exposure to traumatic experience. Not everybody that experiences trauma develops the disorder, suggesting that mechanisms exist to confer resilience to some individuals but not others. Chronic stress during development is generally associated with later emergence of psychopathology, particularly under conditions of severe stress. However, mild to moderate stress during this period can also promote an adaptive response to stressful situations later in life, contributing to stress resilience. We recently demonstrated that chronic variable stress (CVS) during adolescence attenuates the impact of single prolonged stress (SPS), a potent rodent model of PTSD, on extinction and reinstatement of fear conditioning. These results suggest that stress during adolescence can evoke a resilient phenotype. In the present study, we analyzed the neuronal recruitment in the cortico-amygdalar circuitry after SPS and reinstatement in animals exposed to CVS in late adolescence. To identify possible molecular candidates mediating resilience to SPS, we then assayed expression of stress-related mRNAs using low-density PCR arrays, immediately and after 5 weeks of adolescent CVS. Our results suggest that the infralimbic division (IL) of the prefrontal cortex is involved in SPS resilience. We observed a

reduction of IL neuronal activation in SPS animals after reinstatement of fear ($p<0.05$) and this was prevented by CVS in adolescence (adol CVS). This was not accompanied by changes altered Fos activation basolateral (BLA) and central nuclei (CeA) of the amygdala, although we cannot discard differences regarding activation of principal neurons versus interneurons. Notably, at the level of the amygdala, adol CVS reduced the expression of the pituitary adenylate cyclase-activating polypeptide (PACAP) ($p<0.05$). PACAP is a neuromodulator associated with enhancement of fear conditioning. Therefore, based on our results, we propose a prefrontal cortex-amygdala circuit mechanism whereby previous adolescent stress buffers the effects of SPS during adulthood through 1) maintenance of top-down control onto the amygdala by the infralimbic cortex and 2) reducing intrinsic excitability of the amygdala mediated by PACAP.

Title: Previous studies have shown that though the outward symptoms of these disorders are similar between adults and adolescents, some physiological and psychological differences between the two groups are apparent. It is likely that the underlying mechanisms by which anxiety disorders develop differ between the two age groups

Authors: M. A. CORTES[1], K. M. CORDER[2], *L. E. DOBRUNZ[1];
[1]Neurobio., [2]Biol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Anxiety disorders are the most common family of neuropsychiatric disorders diagnosed in adolescence and adulthood. Previous studies have shown that though the outward symptoms of these disorders are similar between adults and adolescents, some physiological and psychological differences between the two groups are apparent. It is likely that the underlying mechanisms by which anxiety disorders develop differ between the two age groups. To investigate the underlying mechanisms of stress-induced anxiety, a variety of rodent stress models have been used that vary in exposure times, nature of the stressor, and predictability of the onset of the stressor. Most studies have looked at the consequence of stress in adult rodents, whereas much less work has been done studying anxiety behaviors in adolescents. Footshock is a physical stressor that has been shown to cause anxiety and fear responses in adult rodents,

although the effects in adolescents are unclear. Here we used a 30-minute footshock protocol to investigate the differences in anxiety between adolescent (6 weeks old) and adult (3 months old) male C57Bl6/J mice. This protocol consists of a 2-minute habituation period, followed by 15 footshocks over the course of 26 minutes (1 mA, 2 s duration, randomized time intervals between shocks), and ending with a 2-minute recovery period. Anxiety phenotypes were assessed on the elevated plus maze and open field after stress exposure. One week after footshock exposure, the adults showed reduced open arm time and entries on the elevated plus maze, indicative of typical anxiety-like behavior. In contrast, the adolescents displayed no change in open arm time or entries, both one week and one day after footshock, suggesting no increase in anxiety-like behavior. Both age groups displayed reduced activity levels in the elevated plus maze and open field at one week after the stressor. The hypolocomotion did not relate to motor deficits, as there were no differences between footshock and control groups using rotarod. It is possible that the reduced activity levels in adolescents are due to generalized fear (increased freezing), as has been documented in the literature for adults. To investigate this, we will measure elevations of corticosterone in blood plasma and fecal pellets, c-fos staining in the amygdala, and levels of the anti-anxiety molecule Neuropeptide Y in regions associated with anxiety behaviors. In summary, we find that the behavioral consequence of a 30-minute session of randomized footshocks is different between adolescent and adult mice, indicating that there are differences in fear expression and anxiety-like behaviors to a physical stressor.

Title: Acute traumatic stress during adolescence alters myelination in the rodent prefrontal cortex

Authors: *J. BRETON, M. BARRAZA, A. VADHRI, N. GALOUSTIAN, D. KAUFER; Univ. of California Berkeley, Berkeley, CA

Abstract: Myelination is altered in patients suffering from post-traumatic stress disorder (PTSD), depression, and other psychiatric illnesses. For example, PTSD patients have increased myelin content in the hippocampus compared to trauma-exposed individuals, and this altered hippocampal myelin is correlated with PTSD symptom severity. Previous work from our lab

established that a single acute traumatic stress similarly increases myelin in the hippocampus of rats. However, it is unknown whether these stress-induced changes in myelination generalize to other regions of the brain. In particular, dysfunction of the prefrontal cortex (PFC) is implicated in these same disorders; yet the effect of traumatic stress on PFC myelination remains unknown. Furthermore, an important remaining question is whether there are critical time periods during development when stress is especially harmful. During adolescence, myelination of the PFC is still ongoing. Therefore, adolescence may be a time period when the developing brain is particularly vulnerable to the effects of stressors. In the current study, we used a rodent model to test how exposure to an acute, traumatic stressor during adolescence affects myelination in the PFC. Male and female adolescent Sprague Dawley rats (p26) were exposed to three hours of severe stress (restraint stress with exposure to a predator odor). Subsequent fear and anxiety-like behavior was assayed either one-week later, or in adulthood (p90), to test for short or long term effects respectively. Brains were then analyzed for oligodendrocyte and myelin markers using immunohistochemistry and fluorescent microscopy. We found that acute traumatic stress increased myelination in PFC regions one week later ($F(1,116) = 11.31$, $p=0.0010$). Interestingly, the long term effects of traumatic stress interacted with sex; female animals showed reduced myelination in PFC regions, while male animals had no change ($F(1,100) = 10.70$, $p=0.0015$). In both short and long term conditions, the number of oligodendrocytes remained unchanged. Our findings suggest that the PFC is vulnerable to a single traumatic stressor, and that there are both immediate and long-term effects on myelination. Stress during adolescence may provoke early maturation of the PFC, and also lead to sex-specific long-term changes. Overall, our data indicate that stress-induced changes in myelination may be a novel and underappreciated mechanism by which psychopathologies such as PTSD and anxiety emerge. Findings in rodents will inform our knowledge of how traumatic stressors may impact human prefrontal cortex development and mental health.

Title: miR-137 drives anxiety-like behavior and epigenetic remodeling in the adult amygdala after adolescent alcohol exposure

Authors: *E. J. KYZAR, J. P. BOHNSACK, H. ZHANG, S. C. PANDEY;
Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Adolescent binge drinking is a major risk factor for alcohol use disorder (AUD) and comorbid psychiatric disorders including anxiety in adulthood, and epigenetic mechanisms likely play a role in the lasting deleterious effects of early life alcohol exposure. We thus investigated miR-137, which is a crucial microRNA for normal neurodevelopment, in the amygdala in adolescent intermittent ethanol (AIE) exposure-induced epigenetic reprogramming, anxiety, and alcohol intake in adulthood. Sprague-Dawley rats were exposed to 2g/kg ethanol (AIE) or intermittent n-saline (AIS) on a 2 days on-2 days off schedule via intraperitoneal injection (i.p.) during postnatal days (PND) 28-41 and allowed to grow to adulthood for analysis of behavior, miRNA expression, and epigenetic measures in the amygdala. miR-137 was increased and the miR-137 target genes lysine-specific demethylase 1 (*Lsd1*) and *Lsd1+8a*, which are histone demethylases known to be involved in epigenetic regulation and alcohol exposure, were decreased in the AIE adult amygdala. LSD1 occupancy was decreased on the chromatin at the *Bdnf* exon *IV* promoter region in the amygdala of AIE adult rats, correlating with decreased *Bdnf IV* mRNA expression in AIE-exposed adult rats. Interestingly, miR-137 was increased in the postmortem amygdala of human subjects with AUD, indicating that these results translate across species. Infusion of a locked nucleic acid antagonist to miR-137 (miR-137 antagomir) directly into the central nucleus of the amygdala (CeA) rescues AIE-induced alcohol drinking and anxiety-like behaviors, and also normalizes the decreased *Lsd1* expression, decreased LSD1 chromatin occupancy, and decreased *Bdnf IV* expression due to increased repressive H3K9 dimethylation (H3K9me2) occupancy in AIE adult rats. Further, concomitant *Lsd1* siRNA infusion into the CeA prevents the miR-137-mediated reversal of AIE-induced adult anxiety, gene expression changes, and chromatin remodeling at the *Bdnf IV* promoter. These results indicate that AIE causes an enduring increase in amygdala miR-137 leading to *Lsd1* downregulation and epigenetic reprogramming, anxiety, and higher alcohol intake in adulthood. Our results highlight miR-137 and the targeting of LSD1 as a potential therapeutic avenue for treatment of anxiety and AUD susceptibility after adolescent alcohol exposure.

Abstract: Fatty acid amide hydrolase (FAAH) is an integral membrane enzyme that hydrolyzes the endocannabinoid anandamide and related amidated signaling lipids. Converging evidence suggests that the endocannabinoid system is an important constituent of neuronal substrates involved in brain reward processes and emotional responses to stress. We investigated the effects of fatty-acids amylase inhibitor (URB597) in (a) eliciting anxiolytic responses (b) enhancing depression behavior (c) changes in TRPV1 and CB1 receptors expression within the mesocorticolimbic structures. To evaluate anxiety and locomotor behavior, male Sprague Dawley rats were exposed to the locomotor activity chambers after receiving systemic intraperitoneal injections of (saline 0.9%) 0.3mg/kg/ip or 1mg/kg/ip during five consecutive days. On the testing session (D7), separate groups of male rats received: 0, 0.3, 1 mg/kg/ip of URB597 prior being exposed to the associated environment followed by the Elevate Plus Maze (EPM). In addition, separate groups of animals were exposed to the Forced Swim Test (FST) in order to examine the effects of URB597 on depression-like behaviors. One group of animals received a single dose of 0.1mg/kg URB597 and another group were treated for 4 days with either vehicle or URB597 dose before testing in the FST. Our results suggest that fatty acid amide hydrolase inhibitor significantly decreased locomotor behaviors and tend to decrease anxiety at dose 0.3mg/kg/ip. In addition, URB597 tended to decrease floating and increase mobility behaviors in the FST. Ongoing biochemical analysis of the changes in expression of TRPV1 and CB1 receptors following treatment with URB597 will support mechanistic explanations for the present behavioral results. These findings suggest that URB597 might be an innovative therapeutic approach for treating anxiety and depression via the endocannabinoid system.

Title: The memory engram for trauma and its implications for vulnerability to PTSD

Authors: *B. C. J. DIRVEN[1,2], J. R. HOMBERG[2], T. L. KOZICZ[3,1], M. J. A. G. HENCKENS[2];

Abstract: A great deal of experimental investment is directed towards understanding the mechanisms of memory storage and the neuronal ensembles and circuits that hold specific memories. This search has become increasingly urgent, as we now understand that some memories can become the nucleus of later psychopathology, like anxiety disorders or post-traumatic stress disorder (PTSD). While previous studies have mainly addressed the *capacity* for memory storage, recent advances in technology have allowed us to identify and study the engrams for specific *individual* experiences. Memory engram technology, which is based on the experimental coupling of immediate early gene expression (e.g. *c-fos* and *arc*) to fluorescent molecular labels, enables the labeling of neurons that are active during a given learning experience.
By employing this new technology in an established mouse model of PTSD - where we phenotypically subdivide animals in vulnerable and resilient subgroups, based on their scores on a battery of PTSD-related behavioral tasks after trauma exposure - we study the neuronal populations involved in creating the memory engram for a traumatic experience. Immunohistochemical data from our lab show that the basolateral amygdala is more active both during the encoding and recollection of traumatic memory in PTSD-vulnerable vs. PTSD-resilient animals. The CA1 area of the ventral hippocampus in these animals, on the other hand, shows reduced activation during trauma recollection, but not encoding. This reduced hippocampal activity is accompanied by an increase in parvalbumin-positive neuronal density, suggesting that structural differences might also be involved. Collectively, these data suggest that vulnerability to PTSD psychopathology might be underlain by subtle changes in activity of specific neuronal populations during exposure to and recovery from trauma.
By employing a novel technique to clear, immunolabel and 3D image whole brain tissue,

iDISCO+, we are now investigating neuronal activation during trauma exposure at the neural network level, going beyond the subareas of the hippocampus and amygdala. These experiments are essential towards a finer understanding of the distinct processing of traumatic memory that distinguishes the PTSD-resilient from the PTSD-vulnerable brain.

Abstract: Damage of vestibular function bilaterally produces difficulty in maintaining balance, especially when walking at night, and a reduction in the patient's capability to see clearly during head movements. Because of these difficulties, patients with HBV may limit their activities and socially isolate themselves. The neural mechanisms involved in the maintenance of postural stability are not yet well understood. However, non-invasive treatment options for bilateral vestibular hypofunction (BVH) patients are very limited. Therefore, in this study, we use noisy galvanic vestibular stimulation (nGVS) method that non-invasively excites the brain of BVH patients. The aim of this study is to investigate the EEG brain dynamics before nGVS and after

nGVS in the vestibular cortex of BVH patients. We utilized higher temporal resolution electroencephalography (EEG) method with 32 channels to acquire the EEG signals from ten healthy subjects and seven BVH patients in walking and standing conditions. The terms of behavioral results we observed that the center of pressure (COP) sway decreased after nGVS during standing in both groups of subjects. In walking, both groups revealed the improvement in 2Hz head yaw movements after nGVS. However, in EEG results we investigated that the EEG activity in theta, alpha, beta and gamma bands increased in the vestibular cortex after nGVS during walking and standing in both groups. These results displayed a novel non-invasive therapeutic method to improve postural stability in BVH patients through nGVS.

Title: Prefrontal cortical Rap1 expression regulates synaptic morphogenesis, *in vivo* neuronal engagement, and cognition

Authors: *B. A. KERMATH, A. M. VANDERPLOW, A. M. NOVAK, M. E. CAHILL; The Univ. of Wisconsin-Madison, Madison, WI

Abstract: The complex mechanisms underlying cognitive deficits in neuropsychiatric disorders remain unclear. Protein expression of the Rap1 small GTPase is decreased in the prefrontal cortex of subjects with schizophrenia and major depressive disorder. Surprisingly, we found that in a model of acute stress, a risk factor for the etiology of neuropsychiatric disorders, Rap1 levels are increased in synaptic fractions of the mouse prefrontal cortex (PFC). As this stress protocol also results in impaired cognitive function in mice, we were interested in determining how PFC-specific manipulation of Rap1 impact cognitive endophenotypes. To this end, we used viral-mediated gene transfer to augment Rap1 levels in the PFC, and assessed neuronal structure, cognitive behavior, and neuronal engagement during cognitive processing. We found that Rap1 overexpression impaired performance in a spontaneous alternation test of spatial working memory and resulted in deficits in object location associative memory. Preliminary studies further indicate that impairments in object location memory upon Rap1 overexpression in the PFC are likely due to a reduced engagement of PFC neurons, as measured by immediate early gene expression profiles, during object exploratory behavior. Current studies are aimed at

assessing dendritic spine density and morphology in PFC pyramidal neurons following *in vivo* manipulation of Rap1 levels. Overall, these data support the hypothesis that changes in Rap1b expression in the prefrontal cortex are sufficient to alter cognitive function and may underlie some of the cognitive deficits seen in stress-based disorders.

Title: Inhibition of GABA-ergic parvalbumin interneurons during chronic stress prevents stress mediated behavioral and physiological phenotypes

Authors: *N. NAWREEN[1], R. MORANO[2], P. MAHBOD[1], E. M. COTELLA[1], K. DALAL[1], M. FITZGERALD[1], S. MARTELLE[1], B. PACKARD[1], R. D. MOLONEY[3], J. P. HERMAN[4]; [2]Psychiatry, [3]Psychiatry and Behavioral Neurosci., [4]Dept Pharmacol. and Systems Physiol., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: Hypofunction of the prefrontal cortex (PFC) is thought to underlie neuropsychiatric illnesses such as post-traumatic stress disorder (PTSD) and depression. However, little is known about the mechanisms leading to reduced PFC functional activity in the context of stress-related mood disorders. Several lines of evidence suggest that enhanced activity of parvalbumin (PV) expressing GABA-ergic interneurons (IN) in the PFC might play a crucial role in chronic stress related pathologies. These studies test the ability of PV IN inhibition during chronic variable stress (CVS) to rescue chronic stress associated phenotypes in male mice. PV-cre C57/Bl6 mice were bilaterally injected with Cre-inducible AAV2 (hM4Di) designer receptors exclusively activated by designer drugs (DREADDs) or control virus into the infralimbic (IL) PFC. The first stressor in the CVS paradigm was a tail suspension test (TST) to determine effects of acute PV IN inhibition on stress coping. Animals then underwent 2 weeks of CVS, during which PV INs were inhibited prior to each stressor exposure. Acute PV IN inhibition reduced struggling behavior and increased in immobility in the TST. Following CVS, coping strategy was measured in the forced swim test (FST), followed by collection of brain for assessment of Fos expression in the IL and IL targets. Our results indicate that chronic inhibition of PV IN during stress increases active and reduces passive coping behaviors in FST. Furthermore, PV IN inhibition

during CVS prevents stress mediated adrenal hypertrophy and Fos activation in key limbic regions after FST (prelimbic cortex, basolateral amygdala and ventrolateral periaqueductal gray). Our results indicate that inhibition of PV activity in the mPFC can prevent some of the chronic stress mediated phenotypes suggesting an important role of PV neurons in driving stress pathologies. Our results also show differential actions of PV INs in acute vs chronic stress conditions. Together, our results highlight modulation of PV IN activity in the IL PFC as a possible therapeutic target in preventing chronic stress related neuropsychiatric illnesses.

Title: Acute stress transiently regulates DUSP6 in murine hippocampal neurons

Authors: *E. CRAIG[1], K. NICHOLSON[1], W. NG[1], N. J. MACLUSKY[2];
[2]Biomed. Sci., [1]Univ. of Guelph, Guelph, ON, Canada

Abstract: Physiological stress modulates neuronal growth, differentiation and survival in the hippocampus. Stress released glucocorticoids (GCs) induce shrinkage of dendrites in the hippocampus, and rapidly inhibit the ability of estradiol (E_2) to induce increases in spine density. The mechanism underlying GC potency remains unknown. One possible explanation is that GCs interfere with extracellular signal-regulated kinases 1 and 2 (ERK 1/2), potentially through modulation of the ERK 1/2 specific regulator dual-specificity phosphatase 6 (DUSP6). Long term stress and the development of depression is associated with DUSP6 downregulation in a sex-specific manner (Labonte et al Nat Med, 23 (2017) 1102-1111). Given the fine tuning involved in ERK 1/2 phosphorylation and signaling, we sought to determine the effects of acute GC exposure on DUSP6. Immortalized hippocampal neurons derived from a female murine embryo (mHippoE-14; Gingerich et al Neuroscience, 170 (2010) 54-66) were allowed to grow to 60-80% confluency and subsequently transferred to medium containing 1% charcoal stripped fetal bovine serum for 18 hours. Cells were treated with 10 nM of the synthetic glucocorticoid dexamethasone or vehicle control and collected 1, 10, or 24 hours afterwards. DUSP6 protein levels were assessed through western blotting. Significant change was detected between treatment groups [n=4, two-way ANOVA; $F(3,24)=3.375$, $p=0.0349$], without significant differences between DUSP6 isoforms [$F(1,24)=1.081$, $p=0.3089$] or a significant interaction

effect between the treatment and isoform factors [F(3,24)=0.05406, p=0.9830]. Cells exposed to dexamethasone for 1 hour had elevated DUSP6 levels compared to the vehicle control, suggesting rapid activation of DUSP6 in response to acute stress. DUSP6 levels also appear to be sensitive to medium and confluency conditions in this model. Our findings, combined with those previous reported by Labonte et al. (2017), suggest biphasic regulation of DUSP6 levels in response to dexamethasone. Understanding the effects of stress hormones on DUSP6 regulation may enhance our understanding of how stress contributes to neurological disease.

Title: Chemogenetic inhibition of the infralimbic division of the medial prefrontal cortex blocks acquisition of social familiarity-induced anxiolysis (SoFiA)

Authors: *A. R. BURKE[1], S. MAJUMDAR[2], A. R. ABREU[2], E. A. LUNGWITZ[2], A. DIETRICH[1], K. D. ANDREWS[2], W. A. TRUITT[1];
[1]Anat. and Cell Biol., [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Familiar social support attenuates anxiety and facilitates the success of exposure-based therapy for anxiety disorders. The neural circuitry underlying this effect, termed social familiarity-induced anxiolysis (SoFiA), remains elusive. SoFiA is modeled in rats by employing the social interaction habituation (SI-hab) protocol. Using SI-hab protocol it has been determined that SoFiA represents social safety learning, which requires both anxiogenic stimulus and social familiarity during training sessions (5-6 daily social interaction sessions), and SoFiA expression is dependent on infralimbic cortex (IL). Here, the neural mechanisms underlying acquisition of SoFiA are investigated. Inactivation of the IL with bilateral infusions of muscimol (90 pmol) 10 min prior to the SI test blocked the acquisition of SoFIA. Next, we targeted glutamatergic neurons in the IL using chemogenetics. The designer receptors exclusively activated by designer drugs (DREADDs) virus, pAAV5-CAMKIIa-hM4D(Gi)-mCherry, was infused into the IL 6 weeks prior to SI testing. Clozapine-n-oxide (CNO) or vehicle was injected (0.5 mg/kg, ip.) to stimulate the hM4D inhibitory receptor 30 mins prior to each SI test. While vehicle treated rats acquired SoFiA, defined as a sustained significant increase in SI compared to the first SI-hab session (when the SI partner rat was novel), CNO treated rats continued to show low SI times

indicative of an anxiogenic response. These CNO treated rats, continued with the SI-hab protocol for 5 more days except they were given vehicle injections in place of CNO. These rats gradually acquired SoFiA. Social interaction times of fifth vehicle SI session were significantly greater than the first vehicle SI session. Thus, inhibition of IL neurons not only blocks SoFiA expression, but also blocks safety learning such that when the inhibition is lifted, rats acquire SoFiA at the same rate as naïve rats. Experiments to determine the input to the IL that are pivotal for SoFiA acquisition are on going. Overall, learning to associate the familiar partner with a signal of safety requires activity of glutamatergic neurons in the IL, implicating the IL in the acquisition of SoFiA.

Title: Role of mineralocorticoid receptors in the development of hippocampal area CA2 and in CA2- dependent behavior

Authors: *K. E. MCCANN, D. J. LUSTBERG, E. K. SHAUGHNESSY, K. E. CARSTENS, S. FARRIS, G. M. ALEXANDER, S. M. DUDEK;
Neurobio. Lab., NIH/NIEHS, Research Triangle Park, NC

Abstract: In the brain, glucocorticoid (GR) and mineralocorticoid (MR) receptors mediate behavioral and physiological responses to stress. In the adult hippocampus, the distribution of GRs and MRs is subregion-specific, with the highest MR:GR mRNA ratio found in area CA2 in mice ($F(3,8)=40.51$, $p<0.0001$) and in humans ($F(3,20)=21.39$, $p<0.0001$). In mice, CA2 pyramidal neurons have a distinct molecular makeup resulting in a plasticity-resistant phenotype that distinguishes them from cells in CA1 and CA3. Thus, we asked whether MRs regulate CA2 neuron properties and related behaviors. Using three conditional knockout methods at different stages of development, we found a striking decrease in all tested CA2 markers. This effect was mimicked by chronic antagonism of MRs. Furthermore, embryonic deletion of MRs also enabled synaptic potentiation of the normally LTP-resistant synaptic currents in CA2 and disrupted inputs into the hippocampus from the supramammillary nucleus (SuM). Specifically, we found that staining for VGLUT2, an axon terminal marker that labels SuM inputs, was significantly reduced in CA2 of cre-positive mice, and that a neuronal tracer injected into the SuM did not

travel to CA2 to the same degree as seen in cre-negative mice. We also found that CA2-targeted MR knockout was sufficient to similarly disrupt behaviors as observed with whole brain MR deletion. MR knockout mice exhibited normal social investigation behavior; however, these mice failed to discriminate between a familiar and a novel conspecific. In addition, MR knockout mice showed hyper-reactivity in response to novel objects. Finally, we tested the mice for anxiety-like behavior in an elevated plus maze and found that mice with a CA2-targeted deletion of MRs spent more time in the open arms of the maze, suggesting an anxiolytic-like behavioral phenotype. Together, these results demonstrate a novel role for MRs in regulating CA2's molecular profile and provide insight into their role in regulating CA2-related behavior.

Title: Activation of infralimbic cortical glutamate neurons reduces cardiovascular and endocrine stress reactivity

Authors: *B. MYERS, D. SCHAEUBLE, T. WALLACE, S. A. PACE, A. J. CHICCO; Biomed. Sci., Colorado State Univ., Fort Collins, CO

Abstract: Stress, a real or perceived threat to homeostasis or well-being, has a considerable role in the pathogenesis of mood and anxiety disorders. Moreover, prolonged stress and mood disorders are significant risk factors for numerous cardiometabolic conditions that further burden health-related quality of life. The neurobiological mechanisms of stress-related health detriments remain elusive; however, we have identified a specific population of glutamate neurons in the infralimbic cortex (IL) that regulate multiple aspects of stress responding. To test the hypothesis that IL glutamate neurons reduce stress reactivity and prevent the cardiovascular consequences of chronic stress, we used optogenetics to stimulate these cells while investigating physiological stress responses. Additionally, we investigated whether increased IL neuronal activity mitigates chronic stress-induced changes in cardiac function. These hypotheses were addressed in two experiments in which male rats received intra-IL injections of adeno-associated virus containing a construct coding for the light-sensitive cation channel, channelrhodopsin-2, or a control construct expressing yellow fluorescent protein. Both constructs were expressed under the calcium/calmodulin-dependent protein kinase IIα promoter, permitting the activation of IL

glutamate neurons. In the first experiment, animals were exposed to restraint stress to measure stress-evoked plasma glucose and corticosteroid levels. For the second experiment, after rats were instrumented for optogenetics, electrocardiography-enabled radiotelemeters were implanted to examine cardiovascular stress reactivity and cardiac autonomic balance during novel environment exposure. Additionally, these animals underwent echocardiographic assessment of cardiac function during IL optic stimulation, both before and after chronic variable stress. Our results indicated that activation of IL glutamate neurons reduced endocrine stress reactivity. IL activation also decreased novel environment stress-induced effects on heart rate, arterial pressure, and sympathovagal balance. Moreover, chronic variable stress increased left ventricular fractional shortening, consistent with a chronic elevation of sympathetic tone driving cardiac contractility and load; however, this effect was prevented by IL optical stimulation. Collectively, these studies highlight IL cortical neurons as a critical component of the neural network(s) integrating physiological responses to stress. These findings also provide a neurobiological mechanism for the relationship between stress and cardiovascular health outcomes.

Title: Cell type specific impact of chronic stress in striatum neurons

Authors: *D. RODRIGUES, N. SOUSA, P. MONTEIRO;
Life and Hlth. Sci. Res. Inst. (ICVS), Minho Univ., Braga, Portugal

Abstract: In today's society, people are constantly challenged to a high level of performance, competition and perfection. As consequence of modernization, this increasing pressure in modern society leads to an insidious increase in chronic stress, which can trigger mental illnesses, such as anxiety spectrum disorders, depression and post-traumatic stress disorder, for which current therapeutic approaches are insufficient. Given the impact of chronic stress on

mental well-being, the brain alterations associated with chronic stress are being intensively studied. However, the specific neuronal circuits affected by chronic stress continue to unravel. Evidence shows that chronic stress induces atrophy of dorsomedial striatum (DMS), a brain region essential for cognitive performance and decision making. Besides the morphological alterations, nothing is known about the functional impact and the specific neuronal cell types that are affected by chronic stress within this brain region. Using bacterial artificial chromosome (BAC) transgenic mice expressing the modified DsRed fluorescence protein, tdTomato, under the control of parvalbumin (PV) promotor or D1 dopamine receptor promoter, and the fluorescence reporter protein EGFP under the control of D2 dopamine receptor promotor, we investigated the functional impact of chronic stress at cell-type specific level. Mice were subjected to a well-established protocol of chronic unpredictable stress which consists in exposing the animals once a day to one of three stressors: forced swimming, restraint and social defeat. After 21 days, whole-cell patch clamp recordings were performed from D1-MSNs, D2-MSNs and PV interneurons located in DMS. Looking at these cell populations in chronic stressed mice, we have now found that stress leads to cell type specific changes. Our electrophysiology data, together with optomanipulations, demonstrate for the first time the functional impact of chronic stress in specific neuronal populations.

Sci., Univ. of California - Collaborative Mass Spectrometry Innovation Ctr., San Diego, CA

Abstract: Commensal gut bacteria and their metabolites can impact host physiology and complex brain function. There is growing interest in discovering ways to optimize health-promoting microbial ecology and metabolic signatures. **Prebiotics are substrates that are selectively utilized by host microorganisms conferring health benefits.** Galactooligosaccharide (GOS) and polydextrose (PDX) are FDA-approved prebiotics that produce favorable changes in the gut microbiome/metabolome and promote a stress robust phenotype. Organisms that are stress robust can endure more intense and prolonged stressors before suffering negative health consequences. We have previously reported that GOS/PDX prevents the effect of uncontrollable tail shock on learned helplessness behavior (LH) and dorsal raphe-prefrontal cortex circuitry responsible for LH. It remains unknown, however, if stress robustness produced by GOS+PDX will also modulate impacts of social defeat (SD) on brain and behavior. Juvenile male rats (10/group) ate GOS+PDX enriched diet or nutrient/calorically matched control diet, and were implanted with biotelemetry devices to record *in vivo*, undisturbed EEG and core body temperature (CBT). Fecal samples were collected for microbiome (16SrRNA, metagenomics shotgun, qPCR, selective culture) and metabolite analyses (liquid chromatography, mass spectrometry). After 6 weeks, rats were either exposed to no stress or SD using the colony-intruder model. Using *in situ* hybridization, changes in serotonin receptors ($5HT1_A$, $5HT2_C$) and c-fos gene expression were assessed in stress-responsive regions of the brain. Rats ingesting GOS+PDX, compared to control diet, have divergent fecal microbiome/metabolome beta diversity and increased abundance of a consortium of probiotic microbes. GOS+PDX prevented SD-induced decreases in dorsal raphe (DRN) $5HT1_A$ receptors, decreased SD-induced increases in DRN c-fos, increased SD-induced c-fos in PFC and had no effect on 5HT2C. SD had little impact on EEG and/or CBT. Unexpectedly, however, CBT and sleep EEG diurnal rhythmicity were disrupted every day of rat handling, regardless of SD or GOS+PDX. Based on these findings and recent evidence that ingestion of GOS+PDX activates nucleus tractus solitarius (vagal afferent termination site) and prefrontal cortex (stress modulatory site), we hypothesize that metabolites released from gut microbes fueled by GOS+PDX, signal the brain via vagal afferents and modulate neural circuitry responsive to IS and SD in ways relevant to changes in behavior.

Abstract: Exposure to prolonged stress is a major risk-factor for psychiatric disorders such as anxiety and major depressive disorder (MDD). Human imaging studies have identified structural and functional abnormalities in the prefrontal cortex of MDD patients, particularly Brodmann's area 25 (BA25). Further, deep brain stimulation of BA25 successfully reduces symptoms of treatment-resistant depression. The rat homolog of BA25 is the infralimbic cortex (IL) which is critical for cognitive appraisal, stress reactivity, and mood. Previous studies indicate that the IL undergoes stress-induced changes of excitatory/inhibitory balance culminating in reduced activity of glutamate output neurons. However, the regulatory role of IL glutamate output in mood-related behaviors after chronic variable stress (CVS) is unknown. Here, we utilized a lentiviral-packaged small-interfering RNA to reduce translation of vesicular glutamate transporter 1 (vGluT1-siRNA), thereby constraining IL glutamate output. After confirming the efficacy of our viral approach, we examined the interaction of CVS and reduced IL glutamate output using behavioral assays examining coping, anxiety-like behavior, associative learning, and nociception in adult male rats. IL glutamate knockdown decreased immobility during the forced swim test compared to GFP controls, both in rats exposed to CVS as well as rats without previous stress exposure. Further, vGlut1-siRNA prevented CVS-induced reductions in exploratory behavior with no significant changes in associative learning or nociception. Next, we performed a quantitative anatomical analysis of cells expressing the stable immediate-early gene product ΔFosB, which accumulates in response to repeated neural activation. Through assessment of ΔFosB-expressing neurons across the frontal lobe, we mapped regions altered by chronic stress and determined the coordinating role of the IL in frontal cortical plasticity. Specifically, CVS-exposed rats had increased density of ΔFosB-expressing cells in the IL and decreased density in the anterior insula. The later effect was dependent on IL glutamate output. Further analysis identified ΔFosB-expressing cells as exclusively co-expressing the pyramidal cell marker calcium-calmodulin dependent protein kinase IIα. Ultimately, this study identifies the necessity of IL glutamatergic output for regulating frontal cortical neural activity and behavior following chronic stress. These findings also highlight how disruption of excitatory/inhibitory balance within specific frontal cortical cell populations may impact neurobehavioral adaptation and lead to stress-related disorders.

Title: The role of hemispheric lateralization on the mPFC-VTA pathway on stress resilience

Authors: *R. KAMALETDINOVA[1], M. SHANLEY[2], A. ONOICHENCO[1], R. KARIM[1], A. K. FRIEDMAN[1];

Abstract: Social stress is a powerful environmental factor that induces changes in brain circuitry. Individuals exhibit varying degrees of susceptibility to environmental stressors, a phenomenon which is also found in genetically identical mouse model (C57-BL/6J). Previous work has demonstrated that following stress, susceptible mice exhibit a decreased firing in ventral tegmental area (VTA) dopamine neurons that project to the medial prefrontal cortex (mPFC) as compared to stress resilient mice. However, the role of the mPFC neuronal feedback to the VTA in this context is unclear. Dynamics of mPFC neurons is highly heterogeneous and may depend on their long-range projection targets. We hypothesize that the mPFC pyramidal neurons projecting to the VTA have may have distinct cortical hemispheric roles in mediating the behavioral stress response, and that these interactions change as the result of stress exposure. Previous studies have shown that repetitive transcranial magnetic stimulation (rTMS) had a positive effect on people's mood when administered on the right prefrontal cortex, but not the left prefrontal cortex. Similarly, lateralization of optogenetic stimulation of the mPFC in mice has been shown to have opposing effects on susceptibility and resilience to social stress. To determine lateralization of the mPFC-VTA specific projection, we utilized a dual intracranial infusion strategy of two different color retrograde bead tracers into the contralateral and ipsilateral VTA. This retrograde tracer is taken up into the axons of the mPFC neurons that project to the VTA and transported into the cell bodies of the mPFC. Utilizing confocal microscopy, we have visualized the two different color retrograde tracers and have confirmed our injection site in the VTA. We found that mPFC neurons project to both ipsilateral and contralateral VTA, with the confocal visualization of both color beads in both two cortical hemispheres. We then quantified mPFC-VTA neurons to determine if there is a quantitative difference between the two hemispheres. Further, projection specific electrophysiological characterization of the lateralization of these mPFC neurons will inform our understanding of the

mechanisms of stress response, with the predication that increased plasticity of this pathway may confer resilience.

Title: Digging deeper into the molecular effects of acute stress on mouse hippocampus

Authors: *A. FLORIOU-SERVOU[1], L. VON ZIEGLER[1], R. R. DAS GUPTA[2], O. STURMAN[1], H.-Y. LIN[1], H. U. ZEILHOFER[2], J. BOHACEK[1];

Abstract: The hippocampus is a brain region implicated in memory, spatial navigation and emotion regulation, and it is particularly sensitive to the impact of stress. However, dorsal (dHC) and ventral hippocampus (vHC) vary dramatically in terms of molecular composition, connectivity and function. We previously showed that both regions respond very differently to acute stress on a transcriptomic and proteomic level. Here, we extend these analyses in three ways: 1) Since transcriptional changes are down-stream of fast acting phosphorylation cascades we investigate whether changes in protein phosphorylation can be observed immediately after acute stress. 2) Since the molecular consequences of stress unfold over time, we chase the transcriptomic stress response in dorsal and ventral hippocampus across time using RNA-sequencing. 3) To gain cell-type specificity, we employ BAC-TRAP technology to capture actively translated mRNA from inhibitory interneurons in dorsal and ventral hippocampus after stress.

Title: Chronic exposure to environmental noise differentially affects the newborn phenotypes in male rat brain

Authors: *F. CRUZ MENDOZA[1], D. FERNÁNDEZ-QUEZADA[2], S. LUQUIN[2], F. PAJARITO[2], Y. RUVALCABA-DELGADILLO[2], F. JAUREGUI[2];
[1]Univ. De Guadalajara, Guadalajara, Mexico; [2]Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Environmental noise has been described as an environmental stressor that can activate HPA axis and affect the central nervous system. Regulation of neurogenesis and differentiation has been reported to be linked to stress response. Then, environmental stressors may affect the cell fate of newborn cells, which might differentiate to neurons or glial cells. The newborn cells in adult mammals has been shown to remain mainly in two zones, the sub-ventricular zone (SVZ) and the dentate gyrus of hippocampus (DG), but there is also reports showing cytogenesis in other regions of the brain. Then, we hypothesized that environmental noise is capable to affect neurogenesis and gliogenesis in the central nervous system (SNC). We used a model of environmental noise adapted to the rat's audiogram that included traffic, airplane and machine noise. We exposed adult male wistar rats for 21 days to this model and then realized immunohistochemistry to identify proliferation (BrdU+ cells); and differentiation of these newborn cells (BrdU+/NeuN+ BrdU+/GFAP+). We found differential effects that were dependent on the examined region (DG vs SVZ) and the examined phenotype (neurons vs glia). We concluded that environmental noise, besides the well-known effects on auditory organs, might affect central nervous processes indispensable for brain regeneration and plasticity.

Title: Chronic exposure to environmental noise promote changes in dendritic arborization of male rat cortex and limbic system

Authors: *D. FERNÁNDEZ-QUEZADA, S. LUQUIN, A. GARCÍA-ZAMUDIO, Y. RUVALCABA-DELGADILLO, F. JAUREGUI-HUERTA;
Neurosciences, Univ. De Guadalajara, Guadalajara, Mexico

Abstract: Noise is an inarticulate auditive stimulus that threats health in different ways. Environmental Noise (EN) is one of the most important pollutant factors affecting cognition and mood. It is also an environmental stressor that consistently activates the HPA axis. Stress-like effects could in turn promote structural and/or functional changes in neurons. Dendritic arborization has been shown to be a hallmark of neuron plasticity. Then, measuring spine changes could evidence regional changes associated to environmental noise exposure. Here, we exposed a group of rats to environmental noise and assessed the effects of these exposure on the dendritic morphology of neurons belonging to cortical and limbic regions. We employed a rats' audiogram-fitted adaptation to mimic noisy environments and presented the noisy stimuli during 21 days. We examined neuronal dendritic morphology following the protocol of FD Rapid Golgi-Stain kit (FD NeuroTechnologies; PK401). Rats were decapitated and brains were cut with a thickness of 200 μm. Images from the distal dendrites in the hippocampus, amygdala, habenula, thalamus, hypothalamus, and auditory areas were captured with a Leica DMi8 microscope. Dendritic analysis was made using Image J, Neuronstudio, and Bonfire program. Data obtained evidenced that exposed rats diminished the length, number and branching pattern of dendrites compared with the control group. Changes were differentially evident in neurons from limbic and cortical structures. Then, our data suggest that environmental noise may elicit potent stress-like effects that change the pattern of organization of neuron dendrites belonging to regions crucial for individual adaptation.

Title: The effect of chronic stress and a post-stress rest period on the hippocampal GABAergic neurons

Authors: J. B. ORTIZ[1,2], J. M. NEWBERN[3], ***C. D. CONRAD**[2];
[1]Child Hlth., Univ. of Arizona Col. Med., Phoenix, AZ; [2]Psychology, [3]Sch. Life Sci., Arizona State Univ., Tempe, AZ

Abstract: Chronic stress leads to deficits in hippocampal mediated cognition and a retraction of hippocampal CA3 dendrites, which improve when chronic stress ends and a post-stress rest period is given. Past work found that chronic stress altered the expression of genes associated with subtypes of hippocampal inhibitory neurons, such as somatostatin (SOM) and calretinin (CR). But, whether a post-stress rest period impacts these inhibitory neuron subtypes is unknown. Moreover, some studies report that chronic stress decreases hippocampal inhibitory neuron number, while other reports fail to find effects. We utilized a transgenic mouse model that contained an indelible marker for GABAergic neurons throughout the brain to determine whether chronic stress and a post-stress rest period altered the total number of GABAergic neurons and/or the expression of different neurochemical markers for various GABAergic cell types. Mice carrying a vesicular GABA transporter (VGAT) promoter-driven Cre recombinase (VGAT:Cre$^{+/-}$) were crossed with a Cre-dependent tdTomato reporter mouse line (Ai9$^{+/+}$). *VGAT:Cre Ai9* offspring exhibit expression of the red fluorescent protein, tdTomato in all GABAergic neurons. At 3 months of age, mice were chronically stressed in wire mesh restrainers for 6h/d/21d (Str) or not (Con), and then allowed a 21d post-stress rest period (Str-Rest) or not (Str-Imm). Following the last day of the stress paradigm, mice were perfused and brains were collected and prepared for immunohistochemistry. Epifluorescent microscope images of the hippocampus were collected and the total number of tdTomato expressing GABAergic neurons and the number of SOM and CR positive neurons were quantified. Chronic stress or a post-stress rest period had no statistically significant effect on the total number of hippocampal GABAergic cells, nor did they alter the number of SOM+ neurons. Chronic stress and a post-stress rest period significantly altered CR+ interneurons. Chronic stress reduced the number of CR+ neurons in the CA3 region of the hippocampus, with marginal effects in the CA1

and DG region. This stress-induced decrease returned to levels of non-stressed controls following a rest period. These results demonstrate that the total GABAergic number does not change in response to chronic stress or the weeks following the end of chronic stress and point to CR+ as being a potential new lead to understand mechanisms facilitating the previous reported spatial memory improvements that occur in the weeks following the end of chronic stress.

Abstract: PTSD is a highly prevalent and complex psychiatric disorder that develops after exposure to a traumatic event. Rodent stress models have been extremely helpful in studying both the pathophysiology and circuitry implicated in this debilitating disease. In particular, lasting structural changes in the hippocampus, amygdala, and prefrontal cortex can occur after traumatic stress, but whether these changes are dependent on the type of stress itself is not known. Here, we examined the effects of two separate rodent stress models: underwater trauma (UWT) and acute predator exposure (APE) on dendritic morphology in three stress-sensitive regions. We performed iontophoretic microinjections of fluorescent dye into neurons in the basolateral amygdala (BLA), medial prefrontal cortex (mPFC) and ventral hippocampus (vHPC) in both stress and control animals. Raw Z-stack images of dendritic segments were acquired via confocal microscopy, and deconvolved prior to analysis for spine number and shape (thin or mushroom). This study will provide insight into the structural plasticity of these relevant regions with regards to traumatic stress, including whether different forms of trauma induce discrete patterns of plasticity.

Title: Pubertal stress reprograms inhibitory tone in the PVN at genetic and electrophysiological levels

Authors: *K. E. MORRISON[1], A. B. COLE[2], P. J. KANE[1], S. M. THOMPSON[3], T. L. BALE[4];
[2]BRB-5-017, [1]Univ. of Maryland Sch. of Med., Baltimore, MD; [4]Pharmacol., [3]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Adverse childhood experiences, specifically during the pubertal transition, are one of the greatest predictors for affective disorder presentation for women. Periods of hormonal flux in the female lifespan, including pregnancy, exacerbate the risk for affective disturbances and promote stress dysregulation, a key feature of affective disorders. We have established a translationally relevant mouse model in which pubertal adversity leads to broad stress dysregulation in adulthood that depends on hormonal status. Our previous work has shown that pubertal stress enacts lasting reprogramming in the transcriptome of the paraventricular nucleus of the hypothalamus (PVN), where corticotropin-releasing factor (CRF) neurons are a critical node in the stress response pathway. To determine whether the transcriptional reprogramming is driven by changes in chromatin accessibility, we utilized ATAC-Seq to interrogate which genes are available for transcription. Female mice exposed to chronic stress from postnatal day 21-34 were sacrificed in adulthood, either as virgins or in late pregnancy. We found that pubertal stress resulted in significant differences in open peaks in the PVN of pregnant females. Genes aligned to the significantly different open peaks clustered into biological pathways related to how cells respond to input at the synapse. These findings suggest both that there is an enduring programmatic event in the chromatin underlying the transcriptomic findings and that there should be a functional consequence of the altered transcriptome. We have previous evidence that the rise in allopregnanolone in pregnancy interacts with the GABA system to unmask the

dysregulated stress response. Using whole-cell voltage-clamp, we recorded spontaneous inhibitory postsynaptic currents (sIPSCs) from CRF neurons in the PVN of pubertally stressed or control virgin and pregnant mice. Consistent with the sequencing results, we found that only in pregnant, pubertally stressed females did CRF neurons have an elevated sIPSC frequency. These studies support the conclusion that pubertal stress results in lasting changes to the chromatin that are associated with functional changes in CRF cells in the PVN. As the PVN sequencing was performed on all cell types, these cell-specific electrophysiological findings suggest that reprogramming of the peri-PVN GABA may be responsible for the phenotype. The underlying causes of peripartum affective dysfunction are complex, and these studies provide evidence that pubertal adversity is an important factor in determining how women will respond to pregnancy and to hormone-based therapies aimed at treating affective symptoms.

Title: Kappa opioid regulation of lateral habenula neurons and response to early life stress

Authors: *S. C. SIMMONS, R. D. SHEPHERD, S. GOUTY, R. HAMMACK, L. LANGLOIS, B. M. COX, F. S. NUGENT;
Dept. Pharmacol., Uniformed Services Univ. of Heath Sci., Bethesda, MD

Abstract: The lateral habenula (LHb) is an epithalamic brain region associated with value-based decision making and stress evasion through its modulation of dopamine-mediated reward circuitry. Specifically, increased activity of the LHb is associated with drug addiction, schizophrenia and stress-related disorders such as depression, anxiety and PTSD. Previously, we have shown that maternal deprivation (MD), a severe early life stress, increases LHb intrinsic excitability while blunting LHb neuronal response to central corticotropin releasing factor (CRF) signaling suggesting an MD-induced dysregulation of the LHb. Kappa opioid receptor (KOR) signaling is an additional mediator of stress response in reward circuitry and also mediates part of central CRF stress response. Surprisingly, there has been little study of direct KOR regulation of the LHb despite its distinct role in stress, reward and aversion processing. Here, we show that maternal deprivation significantly increases immunolabeled dynorphin(DYN) fibers (endogenous KOR agonist) in LHb. Consistent with a possible MD-induced hypertrophy of

DYN signaling, we also found a significant decrease in mRNA levels of KORs in LHb tissues from MD rats compared to those from control animals. To elucidate the functional role of a DYN-KOR signaling in the LHb, we utilized ex-vivo electrophysiology combined with pharmacological tools in rat LHb slices. We found that even under non-stress control conditions, tonic KOR stimulation may contribute to basal LHb neuronal excitability which can be uncovered using KOR antagonist, norBNI. Additionally, we show that KOR agonists (U50,488, and dynorphin) have distinct effects on LHb neuronal excitability through changes in passive and active membrane properties based on the presence of an Ih current in neurons. Specifically, KOR stimulation increases neuronal excitability in LHb neurons with large Ih currents (Ih+) while decreases neuronal excitability in Ih negative (Ih-) neurons. Additionally, KOR activation alters both glutamatergic and GABAergic synaptic transmission onto LHb neurons assessed through mEPSC and mIPSC recordings. To our knowledge this is the first demonstration of existence of the DYN-KOR signaling in the LHb that can be modulated in response to severe early life stressors such as MD.

Title: Prefrontal cortical modulation and encoding of motivation, social behavior, and stress responding

Authors: *T. WALLACE, D. SCHAEUBLE, S. A. PACE, B. MYERS;
Biomed. Sci., Colorado State Univ., Fort Collins, CO

Abstract: Brodmann's Area 25 (BA25) of the medial prefrontal cortex has a pivotal role in depression. Specifically, patients experiencing depression display altered metabolic activity in BA25; further, electrical stimulation of BA25 ameliorates symptoms in patients with treatment-resistant depression. The rat BA25 homologous region, infralimbic cortex (IL), is responsive to stress in models of depression and has been implicated in aspects of social behavior. The IL is thought to regulate behavior through glutamatergic projections to a variety of limbic and forebrain structures. However, the precise neural mechanisms through which the IL may integrate motivational, social, and hedonic behaviors remain to be determined. In the current

study, we hypothesized that IL glutamatergic neural output regulates depression-relevant behaviors and that chronic stress exposure may disrupt the activity of IL projection neurons, potentially accounting for reduced motivation and sociability. To address this hypothesis, we first sought to determine how increasing IL activity may modulate affective valence and sociability. In brief, adult male rats received bilateral injections of an adeno-associated virus (AAV) in the IL to express the light-sensitive cation channel, channelrhodopsin-2 (ChR2), specifically in glutamatergic projection neurons. Following an incubation period for ChR2 expression, a fiber optic cannula was implanted into the IL to permit light delivery. In the real-time place preference assay, rats displayed a preference for optic stimulation, demonstrating IL activity has a positive motivational valence. In a 3-chambered social behavior assay, IL stimulation increased social motivation compared to YFP controls, indicating IL glutamate neurons promote sociability. In a second study, we utilized fiber photometry to monitor IL neural activity during depression-relevant behaviors. For these experiments, an AAV was injected in the IL to express the genetically-encoded calcium-indicator GCaMP6s in glutamatergic neurons, followed by fiber optic cannula implantation. Rats were then exposed to social stimuli, restraint stress, and chocolate. Analysis of GCaMP fluorescence indicated that IL glutamate neurons encode social interaction, stress responding, and hedonic food reward. Ongoing studies aim to determine how chronic variable stress exposure may alter IL activity to disrupt appropriate encoding of social, stressful, and hedonic stimuli. Taken together, our data indicate that the IL is a critical node for modulating social behavior and mood, as well as encoding depression-relevant stimuli.

Title: Corticotropin-releasing factor administration into locus coeruleus affects theta activity in medial prefrontal and orbitofrontal cortex differentially in female and male rats

Authors: *S. BATES[1], J. ARNER[1], A. L. CURTIS[2], S. BHATNAGAR[3];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Dept Anesthesiol., Children's Hosp. Philadelphia, Philadelphia, PA; [3]Dept Anesthesiol., Univ. Pennsylvania, Children's Hosp Philadelphia, Philadelphia, PA

Abstract: The locus coeruleus (LC) is part of a stress responsive system that is involved in arousal and cognitive function. This is accomplished through extensive projections to many regions, including the prefrontal cortex (PFC). The PFC is comprised of regions with distinct functions. Among these regions are the medial PFC (mPFC) and the orbitofrontal cortex (OFC). The reciprocal connection between the LC and the PFC has been shown to underlie the role of arousal in cognition. Additionally, this circuit is disrupted following chronic stress, and is thought to underlie impairment in executive function that arises during stress. Previous work in the lab has shown that the LC is activated by corticotropin-releasing factor (CRF) that is released during stress. This study examined the effects of CRF administered into the LC of adult male and female rats on mPFC and OFC network activity, measured as local field potentials (LFPs). Network activity was recorded in awake animals in the mPFC and OFC for 30 minutes before and after intra-LC infusion of aCSF, 2ng of CRF, or 20ng of CRF in adult male and female Sprague-Dawley rats. Our data show that 20ng of CRF increases high theta (7-9 Hz) activity in the mPFC in female, but not male animals. This dose did not induce any significant effects in the OFC. Conversely, 20ng of CRF decreased low theta (4-6 Hz) activity in the mPFC and OFC selectively in males. The 2ng dose of CRF did not produce any significant effects in either brain region in males or females. Theta activity in the PFC has been associated with improved working memory and attention to environmental cues. Therefore, these data suggest that a high dose of CRF may increase attention to the environment in females. These data are consistent with sex differences in the ability of CRF to alter LC activity, and provide new evidence that this alteration may affect downstream cortical regions. In ongoing studies, we are analyzing coherence between mPFC and OFC in animals that received intra-LC CRF. Additionally, we are examining if activating LC with CRF has behavioral and cognitive ramifications.

Title: Differential effects of ten-days of stress on BDNF-TrkB signaling in the hippocampus and prefrontal cortex

Authors: *A. MOGUL[1], E. TAYLOR-YEREMEEVA[2], A. KHAN[3], S. ROBINSON[2], H.-Y. WANG[3];
[1]NIH, Bethesda, MD; [2]Psychology Dept. and Neurosci. Program, Hamilton Col., Clinton, NY; [3]Dept Physiol , Pharmacol & Neurosci, CUNY Sch. of Med., New York, NY

Abstract: Brain-derived neurotrophic factor (BDNF) signaling through its cognate receptor, tropomyosin receptor kinase B (TrkB), is critical for optimal neuronal function and is altered in neurodegenerative conditions and depression. TrkB is expressed in the nervous system and immune cells, influencing cell development, maturation and survival. In the hippocampus (HC) and prefrontal cortex (PFC), TrkB signaling regulates long term potentiation (LTP) and learning in part through interaction and activation of *N*-methyl-d-aspartate receptors (NMDARs). NMDAR activity through TrkB signaling increases mRNA expression and protein levels of the immediate early gene, activity regulated cytoskeletal protein (Arc). Arc is a regulator of synaptic plasticity, heavily influencing learning and cognition.Reduced TrkB signaling contributes to defective synaptic plasticity and cognition observed in depression and dementia associated with Parkinson's and Alzheimer's diseases. Correspondingly, treatments, such as exercise and transcranial stimulation, that reduce disease symptoms also restore TrkB signaling. These disorders involve an amalgamation of different causes, making it difficult to identify a specific process or experience that may be responsible for TrkB signaling abnormalities. Because stress is a risk factor for neurodegenerative disorders, anxiety and depression, stress may be one of the causal factors that shape TrkB signaling. Data showing that Arc mRNA is disrupted by stress or cortisol treatment supports the view that reduced BDNF-TrkB and TrkB-NMDAR interactions may be involved. BDNF-TrkB signaling and TrkB-NMDAR coupling, however, have not been studied in the context of stress. To test whether stress effects these signaling pathways, we subjected rats to two different stress induction paradigms: five stressors in one day or two stressors every day for ten days. We then assessed basal and BDNF-stimulated TrkB signaling cascades, TrkB-NMDAR coupling and BDNF-induced Arc expression in the HC and PFC.Our results show that in both the HC and PFC, ten-day stress elevated basal Arc but decreased BDNF-induced Arc protein expression relative to non-stressed controls. In the HC, both stress groups had diminished BDNF-TrkB signaling and TrkB-NMDAR coupling. Like the HC, in the PFC, one day of stress reduced BDNF-TrkB and TrkB-NMDAR signaling, however ten days of stress reduced BDNF-TrkB signaling but *strengthened* TrkB-NMDAR coupling. These data indicate differential regulation of stress on TrkB signaling between the HC and PFC. The data may suggest a previously unknown early signaling alteration that could lead to sustained brain function changes.

Title: Acute restraint stress reorganizes VTA-NAc communication and affects reward processing

Authors: *D. C. LOWES[1], E. S. HOLT[1], L. YUSUFOVA[1], Z. H. BRETTON[1], A. FIRDOUS[1], J. A. GORDON[2], A. Z. HARRIS[1];

Abstract: Acute stress has been shown to inhibit reward-seeking and VTA reward activity. However, the mechanism through which acute stress impacts the VTA-NAc circuit is unclear. To determine the effect of acute stress on the VTA-NAc circuit, we simultaneously recorded single unit and local field potential (LFP) activity in the VTA and LFP activity in the NAc of mice during restraint. We found that restraint induces a low-frequency oscillation in the NAc. Lag analysis of VTA multi-unit activity revealed that VTA activity precedes this oscillation, and pharmacological inhibition of the VTA with muscimol prevents this oscillation. We used optogenetic inhibition to dissect which neuronal subtypes within the VTA contribute to this stress-induced oscillation. Conversely, we were able to use optogenetic stimulation of the VTA to recapitulate this long-range oscillation in the NAc. Moreover, stimulating at this frequency produced reward processing deficits similar to those observed after restraint stress. These data suggest that altered VTA-NAc communication may be the mechanism through which acute stress impairs reward processing.

Title: Medial prefrontal cortex-mediated control of food restriction-evoked hyperactivity differs for the pathway projecting to dorsal striatum versus dorsal raphe versus an all-inclusive corticofugal pathway

Authors: *A. N. SANTIAGO, S. GEORGE, I. HANDA, C. AOKI;
New York Univ., New York, NY

Abstract: Anorexia Nervosa (AN), defined by compulsive food restriction (FR) and excessive exercise, has the highest mortality rate of all neuropsychiatric illnesses. A mouse model, termed activity-based anorexia (ABA), restricts food availability to the first 2hrs of the dark phase (2FA) of adolescent mice with wheel access. This evokes voluntary FR during 2FA and a paradoxical FR-evoked hyperactivity (FREH), measured as wheel running, especially during the light-phase hrs preceding 2FA, termed food anticipatory activity (FAA). These behaviors precipitate rapid and potentially lethal weight loss as compared to FR without wheel access. As in AN, the extent of mouse FREH correlates with anxiety-like behavior. AN patients and ABA rodents both exhibit reduced cognitive flexibility, which requires the prefrontal cortex (PFC). FAA requires D1 receptor activity in dorsal striatum (DS). PFC-to-dorsal raphe (DR) activity is associated both with increased escape behavior and reduced food consumption. We therefore hypothesized that medial (m)PFC circuits drive maladaptive wheel running, with mPFC-DS activity controlling FAA and mPFC-DR activity controlling 2FA activity.
We tested this hypothesis with two DREADDs (Designer Receptors Exclusively Activated by Designer Drugs): hM3D(Gq), which activates cell firing upon binding to C21, and KORD, which suppresses cell firing upon binding to Salvinorin B (SalB). We used a CAMKII promotor to express both DREADDs in mPFC pyramidal cells (Part 1). We then used cre-conditional DREADD virus to test how activation vs suppression specifically of the mPFC-DS pathway (part 2) and mPFC-DR pathway (part 3) alter FREH.
Upon target of the mPFC-DS pathway, we observed an increase in FREH upon C21 activation and a decrease upon SalB suppression, specifically during the FAA hrs with no effect during the 2FA period. These effects were not recapitulated during the same hrs once mice recovered from ABA, or by general mPFC pyramidal cell activation or suppression. We will also present correlations with measures of cFos activity and results from the mPFC-DR pathway activation and suppression.
These findings reveal that mPFC provides flexible modulation of FR stress-induced escape behavior through differential recruitment of mPFC pathways, during 2FA, which demands making the decision to eat vs run and during FAA, which demands making the decision to forage vs conserve energy.

Title: Social stress alters locus coeruleus and medial prefrontal cortex network activity and coherence in adult and adolescent female rats

Authors: *J. ARNER[1], A. L. CURTIS[1], M. BATES[1], H. GUAJARDO[1], R. J. VALENTINO[2], S. BHATNAGAR[1,3];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Natl. Inst. on Drug Abuse, Washington, DC; [3]Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Incidences of stress-related psychiatric disorders tend to be higher in women as compared to men. This may be related to sexual dimorphism in network activity of brain regions that are related to stress. The locus coeruleus (LC) is a component of a stress-responsive system that is involved in arousal and cognitive function. This is accomplished through extensive projections to many regions, including the medial prefrontal cortex (mPFC). Previously, we identified age-specific responses in stress-induced LC activity in socially-defeated male rats (Zitnik et al., 2016). The present study was conducted in adolescent and adult female rats and examined the effects of social stress using the resident-intruder model (30 minutes per day) on LC and mPFC activity in awake animals. Single-unit and local field network activity were recorded in LC and mPFC before and during the 1st and 5th exposure to resident-intruder stress. Although basal LC single-unit activity was higher in adolescent than adult females prior to the 1st defeat, we found that neither group exhibited a significant change in single-unit activity as a result of the initial stressor. By the 5th defeat, LC single-unit activity during stress was increased in both adolescent and adult females. With regards to network activity, social stress decreased the power of low theta (4-6 Hz) LC activity in both ages on days 1 and 5. In the mPFC, there were no effects of the 1st exposure to social defeat. However, there was increased network activity in the mPFC within low theta during the 5th defeat in adults, but not in adolescents. In LC-mPFC coherence, stress produced similar changes in coherence in both ages on days 1 and 5 with reductions in coherence within the low theta range. In addition, on day 5, adolescents showed increased coherence in the beta (12-20 Hz) and gamma (20-40 Hz) frequency ranges, whereas the adults showed no change. In conclusion, we observed both LC single-unit and network activity as well as LC-mPFC coherence that was largely similar between adolescent and adult female rats as a result of stress. The similarity across age suggests that adolescent females are exhibiting adult-like activity in this circuit. These findings help to improve our understanding of the basis of sex differences relevant to stress-related psychiatric disorders.

Title: Association between chemotherapy induced brain structural alterations and cognitive performance in breast cancer patients revealed by GQI

Authors: *W. CHUANG[1], J.-C. WENG[1,3], V.-H. CHEN[3,2], Y.-H. TSAI[4];
[1]Dept. of Med. Imaging and Radiological Sci., [2]School of Medicine, Chang Gung Univ., Taoyuan, Taiwan; [3]Dept. of Psychiatry, [4]Dept. of Diagnos. Radiology, Chang Gung Mem. Hosp., Chiayi, Taiwan

Abstract: Breast cancer (BC) is the most common cancer and the second leading cause of cancer-related mortality in women worldwide. Approximately 11 to 35% of BC patient had cognitive impairment before treatment that may result from post-traumatic stress disorder (PTSD). In addition, chemotherapy is a widely-used treatment in BC, however, chemotherapy can induce cognitive impairment and emotional disturbance, and the change of brain is termed chemo brain. In this study, we tried to use generalized q-sampling imaging (GQI) to investigate the alteration of white matter structure, and aimed to detect the association between the GQI indices and neuropsychological scales, including Patient Health Questionnaire-9 (PHQ9) and anxiety of Hospital Anxiety and Depression Scale (HADS).
The study included 45 women with a history of BC but did not receive any treatment and 62 women who had completed their chemotherapy less than 12 months. All subjects were acquired by 3T MRI (Verio, Siemens). We used FSL (FMRIB Software) for eddy current correction, and normalized all diffusion images of participants with SPM (statistical parameter mapping). The GQI indices, including generalized fractional anisotropy (GFA) and normalized quantitative anisotropy (NQA), were calculated using DSI Studio. The multiple regression analysis was performed to obtain the relationship between the GQI indices and neuropsychological scales. Age and education year were used as covariates.
The result of multiple regression analysis with p-value less than 0.01 showed that the GQI indices of BC patient before treatment were significant negative correlated with the neuropsychological scales (i.e., PHQ9 and HADS-anxiety) in the regions of left posterior thalamic radiation, left superior longitudinal fasciculus, left anterior cingulate gyrus, left precuneus, and left temporal gyrus. The GQI indices of BC patient after chemotherapy were highly negatively correlated with the neuropsychological scales in the region of left precentral gyrus, left superior temporal gyrus, left inferior parietal gyrus, right postcentral gyrus, and right middle frontal gyrus. It indicated that people with higher depression and anxiety score had higher demyelination, which is probably due to PTSD or chemotherapy. In conclusion, our GQI study

discovered that breast cancer patients have an association between brain structure alterations and cognitive performance due to PTSD or chemotherapy.

Title: The effect of aging and ancestral stress on T2 relaxation values in the hippocampus

Authors: ***L. S. TRUICA**[1], M. AMBESKOVIC[2], J. K. MCCREARY[3], G. A. METZ[4]; [1]Canadian Ctr. For Behavioral Neurosci., Lethbridge, AB, Canada; [2]Canadian Ctr. for Behavioural Neurosci., Univ. of Lethbridge, Lethbrigde, AB, Canada; [3]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [4]Univ. Lethbridge, Lethbridge, AB, Canada

Abstract: Introduction: Adverse environments early in life reprogram brain development and behaviour with lifelong consequences. Specifically stress during pregnancy may lead to permanent morphological alterations in the offspring brain and subsequent generations. However, little is known about the effects of generational stress on the aging brain. Here, for the first time we investigate brain tissue age-related changes in the ancestral stress animal model and its implications using MRI structural and T_2 -relaxometry model. Methods: F4 generation Long-Evans male offspring were derived from a rat lineage in which their parental mothers (F0-F3) were stressed during pregnancy. A non-stress lineage served as control. To generate mutigenerationally stressed (MPS) group three consecutive generations were stressed, and only great-great grandmothers were stressed to generate transgenerationally (TPS) stress group. Adult (6 month), middle aged (12 months) and aged (18 months) offspring were imaged longitudinally using a 4.7 T Oxford magnet (Oxford, UK). Structural and T_2 relaxometry measurements was used for quantification. A region of interest (ROI) based analysis was performed for all groups and mean values were extracted from the T_2 maps with Image J (NIH, USA). Central slice HPC was used for the analysis, where ROIs corresponding to both HPC hemispheres were drawn and their average was obtained. T_2 values were calculated using Marquardt-Levenberg fitting routines from software written in our lab in IDL (ITT, USA). All images were co-registered. Quantitative Mean Grey Value (MGV) analysis was also performed on structural images corresponding to a same size ROI. Results: Aging exhibited a decrease in both MGV and T_2 value in all groups across the lifespan. Ancestral stress exacerbated aging associated decrease in MGV and T2 values with most profound reduction from young to middle age. The reduction in T_2 relaxation may arise from an increase in neuropil, such as larger dendritic complexity to compensate for the neuronal loss. These findings indicate that ancestral stress may compromise

neuronal integrity which could lead to neurodegeneration and accelerated aging. Discussion: Our study showed that ancestral stress affects the biological aging processes of the brain and our results suggest that this neuronal remodeling and possible compensation may be occurring not only in the hippocampus, but also in other brain areas as stress accumulates across generations and with aging. Taken as a whole, T2 relaxometry offers a valuable insight into the neuro-morphological changes induced by aging and stress.

Title: Evaluating blood brain barrier contribution to cortical extracellular glucose and lactate fluctuations during motor behaviour

Authors: *A. BELAND, C. MESSIER;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The relative contribution of glucose and lactate to neuroenergetics is a controversial topic. Despite this controversy, there is much evidence demonstrating the brains ability to take up and use a variety of blood-borne metabolites to meet its energetic needs. Therefore, we aimed to examine the role of metabolite availability as well as the role of BBB metabolite transport in sustaining extracellular cortical levels of glucose and lactate. The mice were subjected to glucose transporter 1 (GLUT1; WZB117) and monocarboxylate transporter 1 (MCT1; AZD3965) inhibition. Following this inhibition of the two most common transporters found on the BBB barrier, the mice received an injection of either glucose, lactate, fructose or beta-hydroxybutyrate. The mice were subjected to motor behaviors that typically elicit a rise in extracellular lactate and a decrease in extracellular glucose. Inhibition of individual transporters attended the extracellular glucose and lactate decoupling as well as decreased grip strength. Combined inhibition, however, exaggerated the observed decoupling, suggesting a large

upregulation of BBB transporters. These results will be compared to observed changes in cortical endothall levels of GLUT1 and MCT1.

Title: Baseline brain oxygen metabolism predicts fatigue in multiple sclerosis

Authors: *K. L. WEST[1], D. SIVAKOLUNDU[2], M. D. ZUPPICHINI[1], G. B. MARUTHY[1], H. LU[3], D. T. OKUDA[4], B. RYPMA[1];
[1]Behavioral and Brain Sci., [2]Dept. of Biol. Sci., Univ. of Texas at Dallas, Dallas, TX; [3]Radiology, Johns Hopkins Univ., Baltimore, MD; [4]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Fatigue is one of the most prevalent and debilitating symptoms in Multiple Sclerosis. While fatigue is thought to result from auto-immune pathogenesis, there are currently no objective techniques capable of monitoring fatigue non-invasively. Global cerebral metabolic rate of oxygen ($CMRO_2$), a measure of oxygen metabolism throughout the brain, reflects cellular activity at rest. If fatigue indeed reflects ongoing auto-immune activity, we postulate that $CMRO_2$ should also reflect this, however the relationship between $CMRO_2$ and fatigue remains unknown. Assessing relationships between $CMRO_2$ and fatigue could provide new insights into the pathophysiology of fatigue in MS and indicate a clinically-feasible biomarker.
We performed a cross-sectional study comparing 34 RRMS MSP and 14 age- and sex-matched healthy controls (HC). All MRI scans were conducted on a Philips 3T MRI system with a 32-channel head coil. T_2-Relaxation-Under-Spin-Tagging (TRUST) was acquired to assess venous oxygenation (Y_v). Phase contrast (PC) MRI was acquired to estimate whole-brain cerebral blood flow (CBF). Using Yv and CBF from the superior sagittal sinus, baseline global $CMRO_2$ was calculated. T_2-FLAIR was used to assess RRMS lesion volume. High resolution MPRAGE was acquired for co-registration and atrophy estimates. Participants also underwent neuropsychological evaluation including Modified Faitigue Index Scales (MFIS) and patients were split by MFIS <38 (non-fatigued MSP; n=18) and MFIS>38 (fatigued MSP; n=17). Associations were assessed using Pearson correlations ($p<0.05$).
Global baseline $CMRO_2$ correlated with MFIS score in MSP ($R= 0.43$, $p=0.01$) but not in HC

(R=-0.23, p=0.46). Further, $CMRO_2$ and MFIS correlated strongly in fatigued MSP (R=0.59, p=0.02) but not in non-fatigued MSP (R=0.15, p=0.567). Hierarchical regression was performed to determine if the addition of $CMRO_2$ improved the prediction of fatigue in MSP. The addition of $CMRO_2$ to the prediction of MFIS after age, gender, education, and atrophy led to a significant increase in R^2 of 0.137 (F(1,27)=5.626, p=0.025). This result supports the hypothesis that $CMRO_2$ reflects on-going sub-clinical disease activity leading to fatigue in MSP. These simple, brief (eg, 90sec) resting scans used to measure $CMRO_2$ could provide a clinically meaningful biomarker of fatigue for better monitoring and treatment in MS.

Title: Developmental changes in [2,4-$^{13}C_2$] beta-hydroxybutyrate and [1-^{13}C] glucose metabolism in rat brain

Authors: *K. SAKOGAWA, T. KANAMATSU;
Dept. of Envrn. Engin. for Symbiosis, Grad. Sch. of Engin., Soka Univ., Hachioji, Tokyo, Japan

Abstract: Glucose is the primary energy substrate for the adult brain. However, under conditions of starvation, diabetes, and hypoglycemia, lactate and ketone bodies such as beta-hydroxybutyrate (BHB) and acetoacetate support cerebral metabolism in the adult brain. It is also well known that monocarboxylic acid is the cerebral fuel for the immature brain of newborns under normal physiological conditions. The purpose of this study was to investigate the developmental changes in BHB metabolism when compared with that of glucose metabolism in the rat brain. Wistar rat pups, in day 1-, 4-, 8-, 12-, 16-, 20-, 22-, 24-, and 26-days old (the day of birth was day 0), were given an intraperitoneal bolus injection of [2,4-$^{13}C_2$]-BHB or [1-^{13}C]-glucose (0.5 g/kg-body weight, both 99% ^{13}C enriched). After 30 min, the pups were decapitated, and the blood was collected and the forebrain dissected, weighed, and frozen. Frozen tissue was ground with 75% ethanol (10:1 vol/wt) followed by extraction of amino acid fractions using a water saturated chloroform. Supernatants were clarified by centrifugation, lyophilized, and resuspended in 600 µL of a deuterium oxide containing 3-trimethylsilyl propionate (TSP) as the

external standard. Samples were subjected to proton decoupled ^{13}C-NMR spectroscopic measurement. The total amount of ^{13}C spectra intensity calculated by integrating the peaks of Glu, Gln, Asp, and GABA obtained by ^{13}C NMR spectra by measuring relative intensity for TSP. The total ^{13}C-signal intensity in Glu, Gln, Asp and GABA (total signal intensity of ^{13}C) derived from [2,4-$^{13}C_2$]-BHB increased with progressive development (from age, 1-day to 20-days), and then decreased at 26-days old. However, total signal intensity of ^{13}C derived from [1-^{13}C]-glucose weakend from 1-day to 16-days, and then sharply increased when the pups were 26-days old. In terms of the ^{13}C labeling ratio of C3 to C4 in Glu, which means the ratio of the second turn of the TCA cycle to the first turn of the TCA cycle, both BHB and glucose content increased till the pups were 20-days old, thereafter (in 26-days old pups), there was no change. These data may indicate that BHB is the preferred substrate for energy source over glucose in the brain during the early postnatal period and that the metabolic switch between the utilization of BHB and glucose in the rat brain occurs when the pups are exists 20-days old. It may be suggested that this switching is induced by stabilization of the TCA cycle.

Title: Innervation is required for apolipoprotein A-IV-induced fatty acid uptake by adipose tissues

Authors: *C. C. LO[1], H. SHI[2], Q. ZHU[2], J. WENG[1], M. SHEN[2];
[1]Biomed. Sci., Ohio Univ., Athens, OH; [2]Biol., Miami Univ., Oxford, OH

Abstract: Apolipoprotein A-IV (ApoA-IV) synthesized by the small intestine in the presence of dietary lipids regulates lipid metabolism. ApoA-IV, a well-known satiating protein, acts on vagal afferent nerves to suppress food intake. We hypothesized that ApoA-IV increased fatty acid (FA) uptake by adipose tissues via the nervous system. After 3 weeks feeding of either a low-fat diet (LFD) or a high-fat diet (HFD), mice with unilateral denervation of brown adipose tissue (BAT) received intraperitoneal administration of recombinant Apo A-IV protein and intravenous

infusion of lipid mixture with radioactive triolein. Both denervated and intact BAT were exposed to the same circulating factors, whereas the denervated BAT did not receive neural signals as their contralateral intact BAT. In LFD-fed mice, ApoA-IV administration increased FA uptake by the intact BAT. In contrast, ApoA-IV failed to elevate FA uptake by the contralateral denervated BAT. ApoA-IV had no effect on FA uptake by epididymal or inguinal white adipose tissue (EWAT and IWAT, respectively). In HFD-fed mice, ApoA-IV elevated FA uptake by EWAT, but not BAT or IWAT. The immunoblots showed that ApoA-IV increased expression of lipoprotein lipase (LPL) and tyrosine hydroxylase in both intact BAT and IWAT of the LFD-fed mice. In HFD-fed mice, ApoA-IV only elevated LPL in intact BAT. Thus, the observations suggest that ApoA-IV is dependent on intact neural signal to upregulate LPL in BAT and subsequently increase FA uptake by BAT.

Nacional Autónoma de México, Tlaxcala, Tlaxcala, Mexico

Abstract: Hypothyroidism promotes pancreatitis, insulitis, failure of β cells and insulin resistance. For its part, estrogens regulate the β cells differentiation and insulin secretion. Although there is a link between thyroid hormones and estrogens, any study has been done to analyze the impact of hypothyroidism on the estrogen receptors (ER) and local synthesis of estrogens in the pancreas. This study was aimed to analyze the impact of hypothyroidism on insulin, GLUT4, aromatase and ER (α and β), as well as GPR30 expression in islet cells of the pancreas of female rabbits. Twelve Chinchilla-breed virgin female rabbits were divided into control (n=6) and hypothyroid (n=6; methimazole 10 mg/kg for 30 days). Insulin

immunohistochemistry was used for analyzed histological characteristics of islets. Expression of insulin, GLUT4, aromatase and ERs were determined by western blot. Hypothyroidism increased the number of small and extra small islets. It also increased the expression of insulin and GLUT4, but decreased the expression of aromatase. The expression of ERα was increased, while ERβ, and GPR30 were decreased in the hypothyroid group. Interesting, hypothyroidism seems to promote the formation of new islets. These results describe for first time the impact of hypothyroidism on the expression of insulin and GLUT 4, and on the actions of estrogens in the pancreatic islet cells. Our results may be important to understand the link reported between hypothyroidism and diabetes, particularly in women.

Abstract: The Farnesoid X receptor (FXR) is a bile acid receptor belonging to the nuclear receptor superfamily of ligand-regulated transcription factors. FXR has been described to be highly expressed in the liver and intestine, where it regulates the expression of target genes to control bile acid, glucose and lipid metabolisms. While FXR has been reported to be expressed in brain, its central function remains unknown. Here, we specifically found that FXR is expressed in neurons of the arcuate nucleus of the hypothalamus, suggesting a role in the brain control of energy homeostasis. In line, sub-chronic intracerebroventricular (ICV) administration of the synthetic FXR agonist GW4064, performed in C57Bl6/J chow-fed lean mice, induced a significant decrease of energy expenditure and enhanced food efficiency along with an increased

body weight gain, suggesting a positive energy balance. Interestingly, these changes elicited by the ICV injection of the FXR agonist were associated with a decrease of Uncoupling Protein 1 (*Ucp1*) and an enlargement of adipocytes in brown adipose tissue as well as to the inability of the latter to respond to the peripheral administration of the β3 agonist CL316243. These effects were linked to a decreased TH expression in afferent BAT adrenergic neurons and a reduced activity of the sympathetic nervous system upon ICV treatment with GW4064. Effects of ICV FXR agonist were found to arise from changes in PKA-CREB signaling and TH expression in the hypothalamus and to be FXR-dependent since effects of GW4064 were found to be lost in FXR-KO animals. These findings identify a new function of brain FXR and shed new light on the complex control of energy homeostasis by bile acids through this nuclear receptor.

Title: C2 domain protein involved in MC4R trafficking and hypothalamic control of energy balance

Authors: *C. K. GAVINI, T. COOK, D. RADEMACHER, V. MANSUY-AUBERT;
Cell and Mol. Physiol., Loyola Univ. Chicago, Maywood, IL

Abstract: Rates of overweight and obesity epidemic have risen significantly in the past few decades, and 34% of adults and 15-20% of children and adolescents in the United States are now obese. Melanocortin receptor 4 (MC4R), contributes to appetite control in hypothalamic neurons and is a promising target for anti-obesity treatments or drug development. While the presence of functional MC4R is crucial for normal neural control of homeostasis and is altered in obesity and in presence of lipids, the mechanisms underlying altered MC4R trafficking are unknown. Our studies identified a novel C2-domain protein, C2CD5 that appears to contribute to the regulation of MC4R trafficking. We found that 1) the expression of C2CD5 is decreased in diet-induced obesity models compared to controls, 2) C2CD5 knock-out mice exhibit pronounced obesity partially due to an increase in food intake compared to control mice when fed a high-fat diet, 3)

C2CD5 colocalize and interacts with MC4R complex, 4) loss of functional C2CD5 alters MC4R endocytosis, and, 5) C2CD5 knock-out mice exhibit decreased acute responses to Melanotan-II injection into the paraventricular hypothalamus. Based on these, we hypothesize that hypothalamic C2CD5 is a MC4R trafficking protein that responds to metabolic cues and is involved in neural control of energy balance. These studies provide evidence for a novel pathway and targets, to develop therapeutic drugs potentially to rescue energy balance defects that contribute to the development and maintenance of obesity.

Title: The role of lateral hypothalamic area leptin receptor circuitry in behavior and metabolism

Authors: *B. A. TOTH[1], U. SINGH[1], K. C. DAVIS[1], K. SAITO[1], D. A. MORGAN[1], K. RAHMOUNI[1,2,3,4], H. CUI[1,2,3,4];

Abstract: While it has been known that heterogeneous groups of neurons in the lateral hypothalamic area (LHA) play a vital role in maintaining metabolic homeostasis, the mechanisms by which these neurons sense peripheral metabolic cues and carry out homeostatic behaviors affecting metabolic functions are incompletely understood. In the current study, we first characterize projections from lateral hypothalamic leptin receptor (LepR)-expressing neurons - a subset of LHA GABAergic neurons distinct from well-known orexin and MCH neurons. Using anterograde viral-mediated tract tracing we confirmed a broad innervation of these LepR-positive GABAergic neurons to the brain regions known to regulate feeding, locomotor activity, and autonomic function, including but not limited to paraventricular nucleus, arcuate nucleus of hypothalamus, ventral tegmental area, ventrolateral preoptic area, locus coeruleus, and ventrolateral medulla. To delineate the behavioral effects of these projections, using a viral-mediated Cre-LoxP system, we deleted LepR specifically from the LHA and observed that loss of LepR signaling in the LHA results in the reduction of both body weight and locomotor activity. Furthermore, we find that deletion of LepR signaling in LHA decreases

orexin expression levels, indicating that active LepR signaling in the LHA is crucial in maintaining orexin expression. These finding identify the LHA as a key site where adipocyte-derived metabolic hormone, leptin, acts to control homeostatic behaviors, likely through the modulation of orexin signaling.

Title: Differential regulation of glucose metabolism in the cerebrospinal fluid and peripheral circulation in wild-type mice

Authors: *T. NAKAJIMA[1], S. TAKEDA[2], A. OYAMA[1], Y. ITO[2], Y. TAKAMI[1], Y. TAKEYA[1], K. SUGIMOTO[1], K. YAMAMOTO[1], H. RAKUGI[1], R. MORISHITA[2]; [1]Dept. of Geriatric and Gen. Med., [2]Dept. of Clin. Gene Therapy, Grad. Sch. of Medicine, Osaka Univ., Suita-city, Japan

Abstract: Recent investigations have demonstrated that diabetes can be a risk factor for Alzheimer's disease. Abnormalities of cerebral glucose metabolism are indicated in the mechanism of pathologic interaction between Alzheimer’s disease and diabetes mellitus. We previously reported that decreased insulin concentration and insulin sensitivity in the brain underly the exacerbated cognitive impairment in the mouse model of diabetic Alzheimer’s disease (PNAS 2010). However, little is known about the dynamic interaction between peripheral and central glucose metabolisms. Here we assessed temporal changes in glucose levels of cerebrospinal fluid and blood using a unique method to collect cerebrospinal fluid in free-behaving mice. We also analyzed the relationship between steady-state glucose levels in blood and cerebrospinal fluid in patients with cognitive impairment. An intraperitoneal glucose tolerance test (2 g/kg) was performed in 3-month-old male C57BL/6 mice. Cerebrospinal fluid and blood glucose concentrations were measured at 30-minitue intervals. Serial collections of cerebrospinal fluid were performed via the tube fixed on the dura mater over the cisterna magna. Blood glucose levels were measured by tail-tip sampling. Cerebrospinal fluid and blood were collected from subjects with mild cognitive impairment at the same time after an overnight fast. Blood glucose levels peaked at 30 minutes after glucose loading and returned to baseline by 120 minutes. On the other hand, cerebrospinal fluid glucose levels reached a plateau within 30 minutes and were stable until 120 minutes. The cerebrospinal fluid/blood glucose ratio showed a time-dependent alteration during glucose loading test. The ratio of cerebrospinal fluid/blood

glucose levels, at steady state, was fairly consistent (0.635±0.005, mean±SEM) in subjects with cognitive impairment. We were able to measure cerebrospinal fluid glucose levels in free-behaving mice with a high-temporal resolution. The cerebrospinal fluid/blood glucose ratio was not kept constant following glucose loading in young wild-type mice, while the steady-state ratios in mice and human subjects were maintained at constant levels. These results suggest that there are distinct mechanisms regulating glucose levels in the central nervous system and peripheral circulation.

Title: Pine needle extract activates POMC neurons in the hypothalamus

Authors: E. KIM[1], E. BYUN[2], D. KANG[2], S.-G. HONG[2], J. HAN[2], *D. LEE[2];
[1]Dept. of Convergence Med. Sci., [2]Dept. of Physiol., Gyeongsang Natl. University, Sch. of Med., Jinju, Korea, Republic of

Abstract: Prolonged excessive energy intake over the energy consumption leads to obesity which is a major cause of metabolic disease such as type 2 diabetes. The Arcuate nucleus (ARC) of the hypothalamus is the most important brain area to regulate energy balance. The ARC is a major component of the melanocortin system, a regulation center of energy balance in the hypothalamus. Two distinct neuronal types of ARC are anorexigenic POMC (Pro-opiomelanocortin) and orexigenic Neuropeptide Y/Agouti related peptide neurons. Also, the POMC neurons in the ARC are known as an energy expenditure enhancing neurons. In addition, the pine needle contains strong antioxidant polyphenols and has capability of lipolysis and improve elevated blood glucose levels by obesity. However, the role of pine needle extract (PNE) onto the hypothalamic POMC neurons remain unclear. In this study, we use hot water extracted PNE to investigate the role of PNE in regulation of energy balance via hypothalamic POMC neurons. Orally injected PNE (200 mg/kg) increases c-fos expression in the ARC and the paraventricular nucleus of the hypothalamus. Also, PNE increased 20% of c-fos expression in the hypothalamic POMC neurons as compared to control group. And, direct application of PNE

(200 μM) on the brain slice with patch clamp showed that 78% of POMC were depolarized by PNE (200 μM). Moreover, body weight and food intake were decreased by 2 weeks consecutive oral injection of PNE after 12 weeks high fat fed. Simultaneously, PNE improved blood glucose levels after high fat fed as compared to control. Overall, these findings strongly suggest that PNE plays pivotal to regulate energy balance via melanocortin system.

Abstract: Environmental enrichment (EE) which contains complex combinations of various physical, cognitive, and social stimuli can induce synaptic plasticity and neurogenesis. However, the exact mechanism underlying EE-mediated changes remains unclear. Previous studies showed that physiological responses and the level of various neurotrophic factors are altered after exposure to EE. Therefore, we attempted to uncover the mechanism of EE based on ketone metabolism and BDNF signaling in various brain regions. At 6 weeks of age, CD-1 mice were randomly assigned either in EE condition or standard cages for two months. After the conditions, the mice were sacrificed and their brain regions (frontal cortex, striatum, hippocampus, and cerebellum) were extracted for molecular works. Quantitative real-time reverse transcription-polymerase chain reaction (qRT-PCR) and western blot (WB) were conducted to validate the expression of RNA and proteins associated with neurotrophic factors, G-protein regulated inducer of neurite outgrowth (GPRIN1) and ketone metabolism. The RNA expressions of enzymes associated with ketone metabolism (Monocarboxylase Transporter (MCT); MCT1, MCT2, MCT4, and Beta-hydroxybutyrate Dehydrogenase(BDH); BDH1), neurotropic factors (BDNF, Nerve Growth Factors (NGF) and Neurotrophin-3 (NT-3) were significantly increased

in EE mice compared to control mice. Moreover, the GPRIN1 expression was significantly increased in EE mice as indicated in qRT-PCR and WB analysis. In addition, GPRIN1 is colocalized with early neuronal markers (nestin, DCx, Tuj-1) but not mature neuronal marker NeuN, in the SVZ. In conclusion, the upregulation of GPRIN1 following exposure to an EE is related to neuroblast activation especially in the SVZ of adult brain The beneficial effect of EE was also shown in cognition, motor, and emotion by various behavioral tests. Altogether, the upregulation of the enzymes associated with ketone metabolism and BDNF signaling and GPRIN1 following the exposure to EE and the close interplay among beta-hydroxybutyrate, BDNF, and GPRIN1 may be responsible for the therapeutic mechanism of EE

Title: Parasympathetic nervous system directly regulate hepatic glucose metabolism

Authors: *W. SONG, C. NAMKOONG, H.-J. CHOI;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Aim: The role of the neuronal circuity and its function between the nervous system and metabolic organs in the perspective of pathogenesis of obesity and diabetes is poorly understood. To elucidate the direct role of neurons in the DMV region through the parasympathetic nervous system on hepatic both lipid and glucose homeostasis. Method: We injected the virus expressing the hM3Dq DREADD by stereotaxic surgery targeting Dorsal Motor Nucleus of the Vagus (DMV) neurons in the Phox2b-Cre mouse brain. Targeted neurons are activated by intraperitoneal injection of chemogenetic ligand, clozapine-N-oxide (CNO). To exam the effect of neuronal activation on the regulation of liver metabolism, liver tissue is collected for gene expression study and immunohistochemistry analysis. Results: We confirm that our chemogenetic virus and mouse model is working by electrophysiology of DMV neurons showing that CNO activates the neurons. Parasympathetic nervous system and liver are anatomically innervated in not only portal vein region but also hepatocytes. To further dissect the metabolic pathways in the liver by which parasympathetic nervous system controls glucose metabolism, we analyzed gene expression of key hepatic enzymes and present the expression fold change compared to each control including Glucose 6-phosphatase (G6P) and Phosphoenolpyruvate carboxykinase 1 (PCK1). Conclusion and Discussion: In this study, we

show that the parasympathetic nervous system and liver are anatomically innervated. Chemogenetic acute activation of DMV neurons regulate hepatic gene expression indicating the brain-liver neuronal axis is regulating hepatic glucose metabolism gene expression.

Title: Hyaluronan at the brain-environment interface

Authors: *D. M. THEVALINGAM[1], E. C. JENKINS[1], D. P. MCCLOSKEY[2];
[1]Biol., [2]Dept of Psychology and Program in Developmental Neurosci., City Univ. of New York, Staten Island, NY

Abstract: The brain extracellular matrix is composed a diverse set of proteoglycans and lectins with Hyaluronan (HA; Hyaluronic Acid) serving as a primary scaffolding element. The size of the HA molecule can vary across tissue types and species, and recent work has reported functional differences cell signaling and metabolism depending on the size of the HA molecule. The fossorial African naked mole-rat (Heterocephalus glaber; NM-R), a mammal which is capable of tolerating extreme hypoxia and hypercapnia, has been shown to synthesize and sustain a unique high-molecular-mass variant of hyaluronan macromolecule (HMM-HA). This variant may help the NM-R better tolerate the wide environmental excursions experienced between the densely populated underground nest and the fresh air near the burrow surface. Here, we explore the functional consequences of HA size in the NM-R brain. Under acidic and neutral pH conditions, NM-R neuronal viability is enhanced in a concentration-dependent manner when a high-molecular-weight HA species is added exogenously to primary neuron cultures. In addition, analysis of Alcian blue stained paraffin-embedded sections of mouse and NM-R brain tissue illustrates characteristic differences, including unique patterning and variations in expression density, in HA distribution between the two species across multiple brain regions. Together, these findings highlight the contribution of extracellular HA in buffering the NM-R brain against dramatic metabolic shifts, and demonstrate a novel mechanism for the brain to withstand prolonged exposure to extreme environments.

Title: Effects of hypothalamic cAMP response element binding protein (CREB1) on energy and glucose homeostasis

Authors: *B. TAIB[1], V. FONG[1], J. WEST[1], K. KAESTNER[2], R. S. AHIMA[1];
[1]Div. of Endocrinology, Diabetes and Metabolism, Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Dept. of Genet. and the Inst. for Diabetes, Obesity and Metabolism, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Type II diabetes is characterized by fasting hyperglycemia and a prolonged increase in the blood glucose level after glucose or meal ingestion. Creb1 has been linked to diabetes through activation of hepatic gluconeogenesis, which has been suggested to be the predominant factor of the fasting hyperglycemia. Studies have also shown that Creb1 is expressed in the hypothalamus and may affect metabolism. The aim of this study is to determine whether Creb1 plays a role in the paraventricular hypothalamus (PVH), a critical integrator of energy homeostasis. Using Sim1-cre mice, we performed a targeted deletion of Creb1 in PVH to generate ($Creb1^{\Delta SIM1)}$ mice and compared them to control (lox/lox) mice. Metabolic parameters were examined in the fed, fasted or refed states or following calorie chronic restriction (CR, 50% energy deficit for 4 weeks). Body composition measured with ^{1}H-MRS was similar in both groups in the fed, fasted and refed states. However, under CR, the $Creb1^{\Delta SIM1}$ mice maintained a higher lean mass. Indirect calorimetry in a Comprehensive Laboratory Animal Monitoring System (CLAMS) revealed that the respiratory exchange ratio (RER) was lower during feeding and refeeding in $Creb1^{\Delta SIM1}$ mice compared to control mice, indicating an increase in fat oxidation. During CR, the VO_2, RER and heat production were significantly lower in $Creb1^{\Delta SIM1}$ compared to control mice. Moreover, $Creb1^{\Delta SIM1}$ mice displayed lower blood glucose levels in the fed and fasted states. Insulin was significantly reduced in fed $Creb1^{\Delta SIM1}$, and the fall in insulin in response to fasting was blunted. Our results highlight novel effects of hypothalamic Creb1 on energy and glucose homeostasis, which may represent a new therapeutic strategy to improve glycemic control in the pathogenesis of Type II diabetes.

Title: The effect of intermittent hypoxia on body weight regulation in diet induced and genetically obese mice

Authors: *K. E. PROPSOM[1], S. N. FRAMNES[1], D. M. ARBLE[2];
[1]Biol. Sci., [2]Dept. of Biol. Sci., Marquette Univ., Milwaukee, WI

Abstract: Obstructive Sleep Apnea (OSA) is characterized by periodic breathing cessation which results in blood oxygen desaturation. These drops in blood oxygen can be mirrored in animal models using an intermittent hypoxia (IH) protocol. As OSA affects over 50% of the overweight and obese populations, it is hypothesized that IH leads to further impairment of body weight regulation. To determine if insensitivity to leptin, which occurs with obesity, can exacerbate obesity in the context of IH, we utilized lean wild type, diet-induced obese (DIO) wild type, and leptin-deficient *ob/ob* mice. All mice were exposed to 7 days of IH. Preliminary data demonstrate that IH leads to a negative energy balance in WT mice. IH does not alter the food intake of WT lean mice but reduces caloric intake in DIO mice, resulting in weight loss. Interestingly, *ob/ob* mice increase their food intake in response to IH. These results suggest that severe leptin insensitivity combined with IH may increase body weight and food intake homeostatic set points in mice. Clinically, these results help elucidate why an already overweight individual may be at a high risk for becoming obese after developing OSA.

Title: Chronic variable stress during adolescence alters the thyroid axis response to voluntary exercise

Authors: *M. A. PARRA-MONTES DE OCA, J.-L. CHARLI, P. JOSEPH-BRAVO;
Inst. de Biotecnologia UNAM, Cuernavaca, Mexico

Abstract: One of the principal regulators of energy balance is the hypothalamus-pituitary-thyroid (HPT) axis that is activated by energy demands like cold exposure and exercise, the cold-activation is inhibited by a previous stress. We have demonstrated that chronic stress at adulthood blunts HPT axis response to voluntary exercise in a sex dependent manner. Adolescence is considered as a critical development stage when synaptic limbic circuits mature, and is vulnerable to stress situations. We evaluated now the effect of chronic variable stress during adolescence of male and female rats in the response of HPT axis to voluntary exercise. Wistar male and female rats at PND 30 were divided in: a) control group (C) left undisturbed, b) another submitted to chronic variable stress (CVS) where rats received a different type of stress every day during adolescence period (up to PND-60 for females, PND-70 for males). Anxiety-like behavior was evaluated every week by open field test or elevated plus maze; CVS females showed anxious behavior after two weeks of stress and CVS males after four. At PND-74 (females) and PND-84 (males) C and CVS groups were divided in three groups, one placed in a cage with running wheel (Ex) for 14 nights, one sedentary group with food *ad libitum* (Sed), and one sedentary group which was pair-fed (PF) to the amount of food consumed by Ex group. Hormones and mRNA levels were quantified by ELISA, RIA and RT-PCR. Females ran 4x more than males; exercised diminished food intake by 13-17% in males, 30-33% in females, diminished body weight gain in PF compared to Sed of both sexes, but only females lost weight by exercise, more in CVS than C. Exercise reduced retroperitoneal fat mass in C and epididymal fat in CVS males, visceral and subcutaneous in C-females to a greater extent than males. CVS reduced *Trh* mRNA levels in hypothalamic paraventricular nucleus (PVN), without altered concentration of thyroid hormones in both sexes. Expression of *Crh* and *Avp* in PVN was diminished by CVS and diet restriction, more in females than males. *Trh* expression increased in both C and CVS female groups after exercise and TSH in the latter. *Dio2* and *Pgc1a* expression was measured in skeletal muscle (gastrocnemius), that of *Pgc1a* increased considerably by exercise only in C-males. These results suggest that CVS during adolescence affects more female rats than males, modifying the activity of HPT and HPA axis, and their response to voluntary exercise in adulthood.

Abstract: Kidneys achieve the elimination of toxic substances from the organism. In this process, they also have to reabsorb important molecules that include glucose. Glucose uptake can be done through up to 14 glucose transporters (GLUTs) expressed in kidneys. One member of this family is the GLUT4 that is located in a specialized tubulovesicular compartment located beneath the plasma membrane. As a response to insulin, this reservoir of GLUT4 is then available to be recruited to the cell surface to raise glucose uptake. The consumption of sugary drinks has been associated with metabolic diseases including type 2 diabetes mellitus that is linked to renal failure. The aim of our present study was to determine whether the consumption of sugared water during pregnancy and lactation alters the expression of GLUT4 in the kidney of adult male offspring. We used female rats that mated and divided in a control group fed with a standard diet and tap water, and the experimental group fed with standard diet and 5% sucrose diluted in tap water (sugared water). At weaning, the two male rats were randomly selected per litter; one of them had free access to simple water while the other had free access to the sugared water. Male rats were sacrificed at four months old and the expression of GLUT4 in the left kidney was analyzed. In contrast to the group that consumed plain water, we observed that consumption of sugared water caused a GLUT4 overexpression in males from mothers that consumed sugared water during pregnancy and lactation. Furthermore, the expression of GLUT4 was different renal cortex and medulla. Together, the consumption of sugared water, even in low concentration, modifies the renal expression of GLUT4. In doing this, we advanced in the knowledge of renal outcomes associated with the intake of sugary beverages.

Abstract: Understanding of neuron function at the sub-cellular level requires biochemical simulations and membrane architecture analysis, creating a need for highly accurate 3D membrane reconstruction meshes at a nano-meter scale. No structure better exemplifies this challenge than the mitochondria. Especially in the highly dynamic metabolic landscape of a neuron, mitochondria membrane architectures can provide critical insight into the unique energetics of the cell. Theoretical calculations of functional outputs like ATP and heat are often unreliable because mitochondria are represented simply as spheres or ellipsoids. In reality, the mitochondria are glaringly different from simple spheres. The secondary lipid bilayer is riddled with invaginations, known as cristae junctions, which generate complex cristae compartments that intersect the matrix. Cristae form functionally specialized morphologies which differentiate the mitochondria in different cell types, sections of the cell, and metabolic states. 3D tracings of dendritic and axonal mitochondria were constructed using a database of serial TEM tomography images from mouse cerebellum neuropil slices. Watertight meshes were created from the traces using new procedures in 3D rendering softwares (CellBlender and GAMer) in order to produce minimal distortion from the original microscopy at a scale of 1.6 nano-meter isotropic voxel size. Differential geometry methods were then used to quantify the mean and Gaussian curvatures, surface areas, volumes, and membrane motifs which can alter the metabolic output of the organelle. Some reconstructed mitochondria were found to have one continuous cristae compartment, a property that can only be identified in reconstructions. Several mitochondria reconstructions along with custom meshing details and smoothing algorithms that preserve accuracy at high curvature features are presented. This lays the foundation for future studies of the internal mitochondrial physiology and metabolism in neurons.

Abstract: Introduction
The metabolic consequences of neuronal activation are relatively unknown. It is thought that glycolysis supports active neurons as a supplement to mitochondrial respiration in times of high metabolic demand which occurs through the astrocyte neuron lactate shuttle. Recent evidence, however, strongly refutes this claim and argues that acute neuronal stimulation directly leads to neuronal glucose utilization through glycolysis, which becomes the primary source of ATP. Furthermore, the metabolic phenotype of frequently stimulated neurons is also unknown. In this study we show that chronically stimulated neurons switch from aerobic respiration to glycolysis through the AMPK/HIF1a hypoxia pathway.
Methods
We activated neurons cultured on a multielectrode array with low Mg2+ media to probe for lactate dehydrogenase A (LDHA), a marker for glycolysis and to determine neuron's metabolic phenotype after chronic stimulation. We analyzed human tissue for LDHA expression based on electrographic characteristics of overlying subdural electrodes, as determined during intracranial monitoring (epileptic vs normal cortex). Finally, we probed the AMKP/HIF1a pathway to determine its involvement in this metabolic switch.
Results
Treatment of cultured neurons with low Mg^{2+} increased neuronal bursting activity which caused LDHA upregulation. In human tissue, LDHA expression was significantly upregulated in epileptic neurons. Neuronal bursting caused depletion of intracellular ATP and subsequent activation of the AMPK/HIF1a pathway through phosphorylation of AMPK. Furthermore, chronic activation of AMPK led to HIF1a and LDHA upregulation and a subsequent switch from an aerobic to a glycolytic cellular phenotype in neurons.

Conclusion
In this study, we show that chronic neuronal activation leads to up-regulation of LDHA and a metabolic switch from aerobic respiration to glycolysis. This metabolic reprogramming occurs through the canonical AMPK/HIF1a hypoxia pathway.

Title: Focused ultrasound treatment of murine non-alcoholic steatohepatitis

Authors: *T. S. HUERTA[1], A. DEVARAJAN[1], T. TSAAVA[1], S. S. CHAVAN[1,2,3], K. J. TRACEY[1,2,3];
[1]Lab. of Biomed. Sci., Feinstein Inst. for Med. Res., Manhasset, NY; [2]Elmezzi Grad. Sch. of Mol. Med., Manhasset, NY; [3]Donald and Barbara Zucker Sch. of Med. @ Hofstra/Northwell, Hempstead, NY

Abstract: Non-alcoholic steatohepatitis (NASH), a progressive form of non-alcoholic fatty liver disease, is closely associated with obesity, hyperlipidemia and insulin resistance. NASH involves hepatic inflammatory changes and apoptosis leading to organ injury and fibrosis, and can ultimately advance to end-stage liver disease including cirrhosis and cancer. Despite the significant burden to the public health system, there are no FDA-approved drugs that are specifically tailored for this condition. Here, we utilize a preclinical model of NASH, which is induced by diet, to study the effectiveness of high-intensity focused ultrasound (HIFU) in modulating specific hepatic neural networks and test HIFU as a therapeutic strategy. Mice were maintained on a high-fat high-carbohydrate (HFHC, 60% kcal from fat) with sugar supplemented water (55%, 45% sucrose) for 16 weeks. The control group was maintained on a low-fat diet (LFD, 10% kcal from fat). After 8 weeks on these diets, animals received daily liver-targeted HIFU or sham stimulation, and were monitored weekly for body weight change (g), blood glucose change (mg/dL) and average food intake (g/week/cage). Exposure to HIFU but not sham stimulation significantly reduced %Δ body weight (HFHC-sham: 154.4 ± 3.9% vs HFHC-stim: 137.1 ± 3.9% $p < 0.0001$) and %Δ blood glucose levels (HFHC-sham: 205.6 ± 18.2% vs HFHC-HIFU: 131.3 ± 6.8 % $p < 0.0001$) at week 16. The HFHC-HIFU group had improved performance in glucose tolerance test and reduced HOMA-IR score. In addition, HIFU attenuated circulating markers linked to metabolic dysregulation. Histological assessment of the liver via H&E staining revealed reduced steatosis and inflammation in the HFHC-HIFU group.

Together, these findings suggest that noninvasive HIFU stimulation targeting liver is a potential therapy for NASH.

Title: Metabolic rewiring in mice with decreased mitochondrial complex I function

Authors: *T. L. EMMERZAAL[1], G. PRESTON[2], B. GRAHAM[3], R. KELLY[4], E. MORAVA[1], R. RODENBURG[5], T. L. KOZICZ[1];

Abstract: Adaptation to adverse life events is metabolically costly competing for energy with the maintenance of normal homeostatic processes. Although the concept of energy production and consumption as a special case of system vulnerability for the brain has been intensively discussed, our understanding of the impact of abnormal energy flows affecting brain metabolism remains an unmet need. Using a genetically engineered mouse model of SMF (the Ndufs4 deficient mouse), we have previously shown that SMF influences the animals' stress response and impacts various biological domains linked to the pathobiology of depression. We report here that chronic stress causes a complete metabolic rewiring as a function of impaired mitochondrial function. To elucidate the metabolic alterations associated with chronic stress in a mouse model of SMF, and to discover novel biosignatures, we performed targeted high-performance liquid chromatography and gas chromatograph mass spectrometry. We focused on amino acids (AA) and their metabolites, acylcarnitines (AC), as well as tricarboxylic acid cycle (TCA) analytes. We found no alterations in acylcarnitines in mice with SMF whereas stress decreased medium-chain acylcarnitines. Furthermore, we found elevated alanine concentration in the brain, which is often used as a biomarker of mitochondrial dysfunction in individuals with mitochondrial disease. Besides alanine, we also found a profound rewiring of amino acid metabolism; specifically, glutamate, hydroxyproline, and serine were increased in mice with SMF, whereas arginine, cystathionine, histidine, phenylalanine, proline, and tryptophan were decreased. Altered amino acid metabolism is also often observed in other models of mitochondrial dysfunction as well as in individuals with mitochondrial disease. Chronic stress mostly further exacerbated the changes found in Ndufs4def mice, i.e., a more pronounced increase in alanine, serine, and hydroxyproline. In addition to this lysine and threonine were elevated in chronically stressed

mice. In addition to the altered AA metabolites, we found evidence for a reversed flux in the TCA cycle. This reverse was indicated by a decreased citrate, cis-aconitase, and isocitrate concentrations and supported by a decreased citrate/malate ratio, probably as a compensatory mechanism to decrease the NADH/NAD+ ratio caused by the lower mitochondrial electron transport chain activity. From these results, we can conclude that mice with SMF show a substantial metabolic rewiring that could be a mechanism to maintain normal energy flows in the stressed brain to promote successful stress adaptation.

Title: Non-guassian diffusion procedure shows microstructural changes in patients with type 2 diabetes mellitus

Authors: *R. KUMAR[1], C. CABRERA-MINO[2], B. ROY[1], L. EHLERT[1], M. WOO[2], S. CHOI[2]; [1]Anesthesiol., [2]Sch. of Nursing, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Type 2 diabetes mellitus (T2DM) patients show brain microstructural changes in mood and cognitive regulatory areas, examined with Gaussian diffusion based diffusion tensor imaging (DTI). However, majority of the brain regions follow non-Gaussian diffusion, and tissue injury assessment is needed with non-Gaussian diffusion procedures. In this study, our aim was to examine regional brain tissue changes using non-Gaussian based diffusion kurtosis imaging (DKI) in T2DM over controls. We performed DKI in 32 T2DM (age, 56.6±7.0 years; 18 female; BMI, 29.7±5.8 kg/mm^2), and 19 controls (52.6±7.1 years; 10 male; BMI, 26.1±4.1 kg/mm^2) using a 3.0-Tesla MRI scanner. Using DKI data, mean kurtosis (MK) maps were calculated, normalized, smoothed; the smoothed MK maps were compared between groups using ANCOVA (SPM12; covariates; age, sex; uncorrected-threshold $p<0.005$). Both increased and decreased MK values emerged in various brain areas in T2DM over control subjects. Multiple areas, including the medulla, pons, cerebellar peduncle and vermis, cerebellum, posterior cingulate, frontal and prefrontal cortices, corpus callosum, lingual gyrus, and temporal cortices showed reduced MK values, indicating chronic changes, in T2DM over controls. Brain regions that showed increased MK values included the ventral medial prefrontal cortices, hippocampus, amygdala, putamen, insula, thalamus, anterior and mid cingulate, temporal, and occipital

cortices. T2DM subjects show increased, as well as decreased MK values, indicating acute and chronic tissue changes in those critical brain areas involved in mood and cognition. These data suggest that non-Gaussian diffusion based MK measure can be used to examine brain microstructural changes in T2DM.

Title: Steady-state intracellular ph and the recovery from NH_4^+-induced acidosis in rat hippocampal neurons and astrocytes: A new look on the analysis

Authors: *V. A. RUFFIN[1], W. F. BORON[2];
[1]Natural Sci., Virginia Union Univ., Richmond, VA; [2]Physiol. & Biophysics, Case Western Reserve Univ., Cleveland, OH

Abstract: Hippocampal neurons (HC) neurons involved in memory formation, and their neighboring and astrocytes, presumably require a tightly controlled resting intracellular pH (pH_i). The Na-H exchangers (NHEs) are the major family of acid-base transporter in the absence of CO_2/HCO_3^-. In the present study, we used the pH-sensitive dye BCECF to examine the regulation of steady-state pH_i and the recovery of pH_i from NH_4^+-induced intracellular acid loads in HC neurons and astrocytes, co-cultured from embryonic (E18-20) Sprague Dawley rats, and studied in CO_2/HCO_3^--free HEPES-buffered ("HEPES") solutions. Traditionally, investigators have transferred cells from a CO_2/HCO_3^- incubator to a chamber with flowing HEPES, begun measuring pH_i (checkpoint 1) allowed pH_i to stabilize (checkpoint 2), and reported "initial pH_i" as the value at checkpoint 2 = $(pH_i)_2$. Here we use a twin-NH_4^+-pulse protocol (both pulses in HEPES/21% O_2) to induce two rapid decreases in pH_i, each followed by an exponential pH_i recovery (increase). We find that—after the pH_i recovery from the first acid load—neuronal steady-state pH_i (now at checkpoint 3) is ~0.3 (astrocytes: ~0.15) lower than $(pH_i)_2$. We then impose the second NH_4^+ pulse and observe that—after the pH_i recovery from the second acid load—steady-state pH_i (now at checkpoint 4) is virtually the same as $(pH_i)_3$. We hypothesize that $(pH_i)_2$ is higher than $(pH_i)_3$ because the absence of HCO_3^--dependent acid loaders prevents cells from fully acidifying. For each recovery from an acid load, we use a novel analysis in which plot

pH_i recovery rate (dpH_i/dt) vs pH_i; the data fall on a line, the slope of which is the pH_i recovery rate constant (k, s^{-1}). We bin k values according to $(pH_i)_3$, using pH_i intervals of 0.2. k is not appreciably different from pulse 1 vs pulse 2, but tends to be greater (faster) for astrocytes than neurons. Surprisingly, we find that k tends to be low for cells in the lowest pH_i bins, highest in moderate-pH_i bins (more dramatically for astrocytes), and low again at the highest-pH_i bins. These new analytical approaches may ultimately provide mechanistic insight into cell-to-cell heterogeneity of pH_i regulation in the nervous system

Abstract: Type 2 diabetes mellitus (T2DM) patients show gray matter changes in mood and cognitive control sites, functions that are deficient in the condition. However, the nature and extent of brain injury in various sites in T2DM subjects are unclear, which can be examined with diffusion tensor imaging (DTI) based mean diffusivity (MD) measures. Mean diffusivity measures water molecular motion within tissue and shows microstructural changes, with reduced values in acute and increased values in chronic pathological conditions. Our aim was to assess nature and extent of regional brain damage in T2DM over control subjects using DTI procedures. We collected DTI data from 28 T2DM (age, 55.96±7.09 years; BMI, 29.89±5.48 kg/m^2; HbA1C, 7.32±1.37%; 11 males) and 30 healthy controls (age, 54.57±6.72 years; BMI, 27.53±3.83 kg/m^2; 13 males) using a 3.0-Tesla MRI scanner. Whole-brain MD maps were calculated, normalized to a common space, smoothed, and compared between T2DM and control subjects using ANCOVA (SPM12; covariates, age and sex; uncorrected threshold, $p<0.005$). Various brain sites showed increased MD values in T2DM subjects, indicative of chronic tissue changes, in areas including the prefrontal cortices, medulla, cerebellar vermis and cortices, ventral medial prefrontal cortex, cingulate, insula, hypothalamus, mammillary body, frontal, parietal, occipital, and temporal cortices over healthy controls. Decreased MD values, suggestive of acute tissue injury, in T2DM

patients in the thalamus, hippocampus, midbrain, putamen and globus pallidus, cerebellar, and temporal cortices. T2DM subjects show chronic and acute wide-spread microstructural changes in cognition and mood regulatory sites. These data suggest that brain tissue changes can contribute to functional deficits accompanying the condition.

Title: Regional brain gray matter tissue changes and associations with cognition and mood functions in patients with type 2 diabetes mellitus

Authors: *B. ROY[1], S. CHOI[2], C. CABRERA-MINO[2], L. EHLERT[1], R. MULLER[3], M. J. FREEBY[4], M. WOO[2], R. KUMAR[1];
[1]Anesthesiol., [2]Sch. of Nursing, [3]Med., [4]Diabetes Ctr. of Santa Monica, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Type 2 diabetes mellitus (T2DM) patients show cognitive and mood symptoms, indicating brain injury in regions that regulate these functions. However, brain tissue integrity in cognition and mood regulatory sites, and associations between brain changes and these functional deficits in T2DM remain unclear. Our aim was to examine gray matter (GM) volume changes in T2DM over healthy controls, and assess any associations between cognition and mood variables and regional brain GM volumes in T2DM subjects. We collected high-resolution T1-weighted images from 28 T2DM (age, 55.6±7.2 years; BMI, 29.9±5.5 kg/m^2; 17 female) and 96 healthy controls (age, 53.3±5.7 years; BMI, 26.4 ±3.7 kg/m^2; 52 male) using a 3.0-Tesla MRI, and examined cognition, depression, and anxiety symptoms with the Montreal cognitive assessment (MoCA), Beck Depression Inventory (BDI-II), and Beck Anxiety Inventory (BAI), respectively. High-resolution T1-weighted images were partitioned into GM and other tissue types; GM maps were normalized, smoothed, and compared between T2DM and controls (ANCOVA, SPM12; covariates, age and sex). Whole-brain GM maps were also correlated with BAI, BDI-II, and MoCA scores in T2DM subjects (Partial correlations; SPM12; covariates, age and sex). Cognition and mood scores between groups were assessed with ANCOVA (covariates, age and sex). No significant differences in age ($p=0.07$) or sex ($p=0.17$) appeared between groups. However, BMI ($p=0.003$) showed significantly higher value in T2DM over controls.

T2DM subjects had significantly increased BDI-II ($p<0.001$), BAI ($p<0.001$), and decreased global MoCA scores ($p = 0.002$) over controls. Multiple brain areas showed reduced GM volumes in T2DM over controls, including the para-hippocampal, cerebellum, insula, cingulate, hippocampus, amygdala, caudate, basal-forebrain, thalamus, prefrontal and frontal, and temporal cortices. Negative associations appeared between anxiety scores and the frontal, cingulate, putamen, thalamus, basal-forebrain, hippocampus, insula, and amygdala, and between depression scores and the frontal, temporal, and occipital sites in T2DM. Global MoCA values showed positive correlations in T2DM with the frontal, prefrontal, temporal, and parietal, insula, hypothalamus, cingulate, hippocampus, and amygdala. T2DM patients show significant brain structural changes in wide-spread areas that are involved in mood and cognition regulation, and associations emerged between functional deficits and these brain regulatory sites. The pathophysiology underlying gray matter changes in T2DM subjects may involve an interplay between endocrinologic, metabolic, and vascular issues.

Title: Low-grade benzene exposure induces sex-specific metabolic imbalance and hypothalamic ER-stress markers

Authors: *L. K. DEBARBA[1], A. MULKA[2], P. FAKHOURY[1], O. DIDYUK[1], A. AWADA[1], M. HOLLAND[1], I. AYYAR[1], M. SACLA[1], J. B. M. LIMA[1], U. KLUEH[2], M. SADAGURSKI[1]; [1]Biol., [2]Bioengineering, Wayne State Univ., Detroit, MI

Abstract: The current global prevalence of type 2-diabetes mellitus is estimated at 8.4% by the World Health Organization, which represents a fourfold increase over the last four decades. The lifestyle, lack of physical activity, diet and the growing aging population is often used to explain the rise of the diabetes pandemic. However, it is now increasingly accepted that insulin resistance, T2D prevalence and mortality have been associated with long- term exposure to air

and traffic pollution. Benzene is a highly volatile liquid, and a constituent of crude petroleum. Given its ubiquitous utilization in industry as well as consumer products, it is classified as a common airborne pollutant. As such, any exposure to petroleum or its products can result in significant occupational benzene exposure. Notably, benzene exposure from motor vehicle exhaust is higher in inner city populations, which suggests a causative role in the pathogenesis of T2D. We hypothesized that benzene, at levels below carcinogenic, contributes to insulin resistance and inflammatory responses linking persistent organic pollutants (POP) exposure to type 2 diabetes mellitus. For this purpose, C57BL/6 mice in inhalation chambers were exposed to benzene concentration of 50 ppm for 6h/day for 4 weeks. We found that under these conditions, exposure to benzene did not significantly influence mice body weight, neither had it trigger any toxic responses in these animals. Benzene-exposed male mice displayed significantly impaired glucose tolerance, higher fasting glucose and insulin levels. Consequently, we detected a significant elevation of hepatic genes associated with gluconeogenesis, *G6Pase* and *Pck1*, and lipid synthesis, *SREB-1c* and *SREB-2* in male mice as compared to controls. Female mice were completely resistant to the negative metabolic consequences of chronic benzene exposure. Further sex differences were apparent in neuroinflammatory responses, with greater male vulnerability observed in the hypothalamus of benzene- exposed animals. Benzene exposure promoted hypothalamic gliosis and robust neuronal activation in the arcuate, paraventricular, ventromedial, and dorsomedial hypothalamic nucleus; and, significantly upregulated proteins associated with ER stress, IRE-1α, XBP1, CHOP in the arcuate nucleus and IRE-1α, XBP1 in the paraventricular hypothalamus. Our results provide evidence that exposure to benzene induces metabolic imbalance, higher hypothalamic ER-stress markers and severe neuroinflammatory in a sex-specific manner. Persistent ambient benzene exposure may be a heretofore unrecognized contributor to metabolic diseases with male bias.

Title: Implications of fatty acid metabolism for bioenergetic and behavioural deficits of NMDAR deficient mice

Authors: *T. V. LIPINA, Y. YAN, L. PEPERA, A. J. RAMSEY;
Univ. of Toronto, Toronto, ON, Canada

Abstract: *Grin1* knockdown (*Grin1*^{KD}) mice have a reduction in NMDA receptors, which causes severe cognitive and social phenotypes. Previous studies indicate deficient glucose uptake and expression of the glucose transporter *Slc2a1* in the brains of *Grin1*^{KD} mice. These findings suggest reduced neuronal glucose transport/utilization, which could contribute to their behavioral deficits. We hypothesize that *Grin1*^{KD} mice rely more on fatty acid utilization to compensate for their impaired glucose-dependent metabolism. Indeed, our previous study found that an omega-3-deficient diet exacerbated cognitive deficits and even increased mortality of *Grin1*^{KD} mice (Islam et al 2017). Hence, the current study further probed the role of fatty acid metabolism in *Grin1*^{KD} mice. First, we asked whether maintenance on a ketogenic diet would prevent *Grin1*^{KD} abnormalities in cell metabolism as well as social and cognitive behaviours. Next, we also assessed effects of beta-hydroxybutyrate (BHB) as a pure metabolite of fatty acids and ketogenic amino acids on behavior, metabolism and mitochondrial function. Behavioural analysis revealed that a ketogenic diet has beneficial effects on *Grin1*^{KD} mice in age-dependent manner, which was given to *Grin1*^{KD} mice and their wild-type (WT) littermates from 3 to 12 weeks of age. In particular, significant improvements in working memory and hyperactivity were detected after five weeks of maintenance on a ketogenic diet without effects on social behavior. However, nine weeks of ketogenic diet corrected deficient social behavior, sensorimotor gating and acoustic startle response in *Grin1*^{KD} mice. To determine whether the beneficial effects of ketogenic diet were due solely to the presence of ketone esters, we also tested behavioral and cellular effects of BHB (60 mg/kg; added in water bottles) given chronically to experimental animals maintained on a normal chow for 9 weeks. In parallel, we probed blood glucose tolerance and glucose levels after exhaustion conditions and found that *Grin1*^{KD} mice fail to elevate blood glucose with exercise, whereas WT animals showed significant raise of glucose after exercise to exhaustion on the treadmill. To directly estimate brain bioenergetics, mitochondrial function was assessed by MitoSox Red in cortical slices from experimental mice. Furthermore, mitochondrial respiration and glycolysis level of primary cortical cells were measured by Seahorse XFe96 analyzer. A comparative analysis of a ketogenic diet and BHB effects on *Grin1*^{KD} mice indicates that fatty acid metabolism plays a critical role to maintain healthy bioenergetics and regulate cognition when NMDARs are hypofunctional.

Title: Vascular changes in the brains of NMDA receptor knockdown mice

Authors: *K. INTSON[1], Y. YAN[1], T. LIPINA[1], L. YU[4], D. EMTYAZI[2], J. G. SLED[4], A. SALAHPOUR[1], A. J. RAMSEY[1,3];

Abstract: NMDA receptor subunit *GRIN1* hypofunctionality has been linked to a spectrum of conditions from schizophrenia, to autism, to intellectual disability with epileptic features. Here, we report features consistent with these disease states in a mouse modeling NMDA receptor hypofunction, the *Grin1*^{KD} mouse. We replicated behavioural findings that *Grin1*^{KD} mice model cognitive features of these disorders, including significant stereotypy, decreased habituation, deficits in social interaction, and disrupted prepulse inhibition (compared to wild-type mice). *Grin1*^{KD} mice also demonstrate spontaneous seizures throughout testing periods. Another disabling aspect of *de novo GRIN1* genetic mutation-induced disorders is muscular hypotonia (Lemcke et al, 2016). Therefore, we also performed the Wire Hang test and find that *Grin1*^{KD} mice have significantly shorter hanging times compared to wild-type mice, indicative that *Grin1*^{KD} mice also model this hypotonia. Given reports of neurovascular changes in the brains of schizophrenia (Lopes et al., 2015) and autism patients (Azmitia et al., 2016), we turned our attention to aspects of blood supply and vascularization in *Grin1*^{KD} mice to investigate why muscular weakness occurs. We analysed vasculature of the brains of *Grin1*^{KD} mice and their wild-type littermates using x-ray microCT and report increased cerebrovascularization. Further, blood-brain barrier (BBB) integrity experiments reveal an increase of *Grin1*^{KD} BBB permeability to Evans Blue dye compared to wild-type. Neovasculogenesis and BBB permeability are regulated by the brain's endothelial cell network (Tang and Conti, 2004; Stamatovic, Keep, and Andjelkovic, 2008). Specifically, NMDA receptors of neuroendothelial cells are proposed to play roles in BBB integrity, glucose uptake, vasodilation, and mitochondrial dysfunction (Hogan-Cann and Anderson, 2016). Our vascular findings, taken together with Agilent Seahorse XF results of increased glycolysis of *Grin1*^{KD} cells (compared to wild-type), suggest that insufficient energy supply leads to muscle weakness in *Grin1*^{KD} mice. Our observations highlight potential therapeutic targets in these disorders. Ongoing experiments examine the system-wide effects of endothelial-specific rescue of NMDA receptors within the global *Grin1*^{KD} mouse.

Title: Photoperiod affects leptin sensitivity and ventilatory drive in the C57Bl/6J mouse

Authors: *A. A. JONES, N. A. CHAPPELLE, D. M. ARBLE;
Biol. Sci., Marquette Univ., Milwaukee, WI

Abstract: Obstructive Sleep Apnea (OSA) is commonly characterized by a reduction or cessation of breathing during sleep and significantly increases one's risk for heart disease and mortality. Symptoms of OSA are exacerbated in the winter months, suggesting a role of seasonal photoperiod in disordered breathing. However, photoperiodic modulation of breathing is an unexplored topic open to novel therapeutic findings. Photoperiod plays a role in many physiological processes including alterations in leptin sensitivity. Given that our lab has previously shown leptin-mediated modulation of breathing in mice, we investigated the effect of photoperiod on leptin sensitivity and ventilatory drive in a mouse model. Male and female C57Bl/6J mice were housed in one of three photoperiods, long-day (20L:4D), short-day (4L:20D), or a standard 12L:12D day for 3 weeks prior to testing. Leptin sensitivity was assessed by reductions in body mass and food intake during 5 days of daily leptin treatment (i.p. 1 μg/g/day). Breathing and ventilatory drive were quantified using a whole-body plethysmograph. We found that mice housed in long-day photoperiods exhibited a greater reduction in body mass and food intake than those in 12L:12D or short-day photoperiods, indicative of increased leptin sensitivity. Ventilatory drive was also significantly reduced in mice housed on long-day photoperiods. Additionally, mice lacking the melanocortin-4 receptor, an important mediator of leptin signaling and body weight homeostasis, do not exhibit photoperiod-dependent changes in breathing. Taken together, these results suggest that a photoperiod-dependent increase in leptin sensitivity decreases ventilatory drive through a leptin-melanocortin pathway. Overall, these findings represent the first step in understanding the broader implications of light-mediated changes in breathing. Future studies will elucidate the underlying neuronal mechanisms and may prove useful for understanding and treating sleep-disordered breathing in humans.

Title: Amygdala GABAergic neuron's abnormal activity pattern during cataplexy

Authors: *M. LIU, Y. SUN, E. BENDELL;
Psychiatry and Behavioral Sci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Cataplexy is one of the main symptoms of the sleep disorder narcolepsy. The involvement of strong emotions in the etiology of cataplexy has been confirmed by recent studies showing selective activation of the GABAergic neurons located in the central nucleus of the amygdala (CeA) triggered cataplexy. Nonetheless there is still no direct evidence on CeA GABAergic neurons' real-time dynamic during cataplexy, which would be crucial to understand how cataplexy is triggered. To obtain this direct evidence, we used the deep-brain calcium imaging tool (nVoke, Inscopix) to image the fluctuation of intrinsic calcium transient as the marker of neuronal activity changes in 186 cells from 5 narcoleptic mice (both sexes) by expressing the calcium indicator GCaMP6 into genetically defined CeA GABAergic neurons. GCaMP6 signal were collected and analyzed by Inscopix data acquisition and processing software to obtain the intensity index (ΔF/F), which were further normalized to Z-score (ΔF/F) for statistical analysis with generalized linear mixed model (SPSS). Upon exposure to predator odor, narcoleptic mice displayed intense fear responses and cataplexy bouts. Z-scores (ΔF/F) of 112 recorded cells were significantly increased upon exposure. 74 out of these 112 "activated" cells continued their maximal Z-score (ΔF/F) level into succeeding cataplexy bouts. Furthermore, 2D activity cross correlation analysis demonstrated significantly higher coefficients among these GABAergic neurons during cataplexy bouts when compared to any other brain states including waking, NREMS (non-rapid eye movement sleep) and REMS (rapid eye movement sleep). We conclude that we have unveiled amygdala cataplexy-ON GABAergic neurons in rodent narcolepsy model. We propose that both the abnormal activation and high synchronization of CeA GABAergic neurons trigger emotion-induced cataplexy.

Title: Adolescent sleep disruption induces long-lasting impairment in social novelty preference

Authors: *W.-J. BIAN, L. DE LECEA;
Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: Sleep takes one-third of our lives, yet its function is largely unknown. A large proportion of young patients with psychiatric disorders such as autism spectrum disorders (ASDs) and schizophrenia were reported to have sleep problems, including delayed sleep onset, shortened sleep duration and fragmentation of sleep continuity, and a correlation has been found between sleep impairment and defects in social interaction, a shared symptom of these disorders. However, the causal relationship between sleep disruption and social deficits as well as the underlying mechanisms have not yet been established despite their importance in understanding the etiology of these disorders and developing potential therapeutic means. Here we found that developmental sleep disruption (SD) in adolescent mice caused significantly reduced preference towards the novel social stimulus in adulthood in the three-chamber social interaction test without affecting the overall sociality. This social deficit was persistent to at least 1 month after the initial test. Interestingly, SD in adulthood did not induce any social defect, indicating a critical period in adolescence during which sleep shapes social novelty preference. Dopaminergic (DA) neurons in the ventral tegmental area (VTA) are important players in social reward processing and motivation, and they are active during waking but mostly silent during sleep. We found adolescent SD abolished the Ca2+ activity of VTA DA neurons in response to novel social stimuli. Furthermore, adolescent over-excitation of the VTA DA neurons, specifically during the light phase when sleep mostly occurs, led to the loss of social novelty preference similar to that caused by SD, while VTA inhibition concurrent with adolescent SD rescued this social novelty phenotype. Collectively, these results suggest a critical role of adolescent sleep and normal activity level of VTA DA neurons in the developmental shaping of social novelty preference.

Title: Social clock influence on Uruguayan adolescent's sleep and performance

Authors: *I. ESTEVAN DEBAT[1], B. TASSINO[2], A. SILVA[3];
[1]Facultad De Psicología, Udelar, Montevideo, Uruguay; [2]Sección Etología, [3]Lab. de Neurociencias, Facultad de Ciencias, UdelaR, Montevideo, Uruguay

Abstract: After puberty, sleep time is delayed as adolescents become more evening-oriented. Besides, sleep duration is reduced as eveningness collides with early morning school. This mismatch of internal and external time is a risk factor for cognitive and health outcomes. Many schools in Latin America arrange their activities in multiple shifts. This naturally occurring experiment represents an opportunity to study the influence of scholar and lifestyle schedules on sleep and cognitive performance. Three hundred students aged between 15 and 18 years participated in this study, attending either morning (7:30 to 11:30 AM) or afternoon shift (11:30 AM to 3:30 PM) in a Public High School in Montevideo, Uruguay. After obtaining informed consent, participants answered three questionnaires: an adaptation of the School Sleep Habits Survey (Wolfson & Carskadon, 1998), the Morningness/Eveningness Scale for Children (Carskadon et al., 1993), and a sociodemographic one. A group of students were also evaluated using an adaptation of the Revised Attention Network Test (Fan et al., 2009), at the beginning and at the end of their respective school shift. Sleep timing and duration were studied in relation to time restrictions imposed by school schedule on weekdays vs free days. Sleep restriction and Morningness-Eveningness influence in performance in the three attentional networks was also studied. As expected, in week vs free days sleep was advanced and reduced in duration as wake time is constrained by school schedules, particularly in students attending the morning shift. Synchrony effect between time-of-day and Morningness-Eveningness was explored. Changes in attention performance across time were more pronounced in the morning than in the afternoon shift. This is the first study addressing the time differences in sleep and attention performance using school shifts as social clock variants. Advances in knowledge about predictors of adolescent sleep are relevant for public policies on adolescent health and education, and constitutes important information to schedule family activities.

Title: Is dim light at night a risk factor for exacerbating autistic behavior?

Authors: *H.-B. WANG[1], D. H.-W. LOH[2], Y. TAHARA[2], C. A. GHIANI[3], C. S. COLWELL[2]; [1]Molecular, Cellular, and Integrative Physiol., [2]Psychiatry and Biobehavioral Sci., [3]Pathology, Univ. of California - Los Angeles, Los Angeles, CA

Abstract: Many studies report that 50 to 80% of patients with autism spectrum disorders (ASD) suffer from delayed sleep onset, difficulty in sleep maintenance, and difficulty waking in the morning. These sleep disturbances are indicative of a possible problem with the circadian timing system. In this study, we first examined sleep/wake cycles in the *Cntnap2* KO (contactin-associated protein-like 2 knockout) mouse model of ASD. Mutations and polymorphisms in this gene have been linked to cortical dysplasia as well as autism symptoms in patients and in mouse models. We found that *Cntnap2* KO mice phenocopy the circadian disturbances in patients as they displayed a reduced rhythm strength and increased sleep fragmentation. There is a growing concern that nighttime light pollution may be negatively affecting our health and the nighttime pollution has been broadly linked to dysfunctions of circadian clock, metabolism, and cognition. Noteworthy, ASD patients have been reported to have more exposure to light via electronic screens during the night. As consequence, it is possible that this inappropriate photic environment caused by nighttime exposure to electric lights and light-emitting devices would further disrupt their unstable circadian clocks and exacerbate the autistic behavior. After applying dim light at night (DLaN, 5 lux) for 2 weeks, we confirmed that DLaN not only dampened circadian rhythms in locomotor activity and sleep, but also significantly affected the sociability and repetitive behavior of the mutants. To unravel possible underlying mechanisms, Per2::Luciferase monitoring from cultured tissues and neuroinflammation biomarkers in prefrontal cortex using qPCR were performed. Moreover, we identified strong cFOS expression in amygdala, a region implicated for social behavior and repetitive behavior, evoked by DLaN. Together, this preclinical work evaluates whether even mild circadian rhythm disruption (i.e.

nighttime light pollution) is an environmental risk factor for ASD populations, and suggests new therapeutic interventions aiming to stabilize the circadian timing system may be useful for ASD. Melatonin has been used successfully in the management of patients with autism spectrum disorders. We found that daily treatment with melatonin improved the strength of the daily rhythm and reduced the excessive grooming of the mutant mice to WT levels. Importantly, the beneficial effects were only found when the treatment was given at a phase aligned with the circadian timing.

Title: Validation of PiezoSleep scoring against EEG/EMG sleep scoring in rats

Authors: I. TOPCHIY[1,2], A. M. FINK[1,2], K. MAKI[1], ***M. W. CALIK**[1,2];
[1]Biobehavioral Hlth. Sci., [2]Ctr. for Sleep and Hlth. Res., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Current methods of scoring sleep in rodents involve invasive surgical procedures to implant EEG and EMG electrodes. Though this an established method of sleep scoring in rodents, there are limitations: postoperative recovery time; infections or mortality from surgery; and issues with misplacement of electrodes or noisy signals. Recently, a new method of measuring sleep, PiezoSleep, has been validated against implanted electrodes in mice. PiezoSleep uses a piezoelectric film to detect the rodent's movements and breathing with high sensitivity and uses an algorithm to automatically score sleep. However, no validation has been completed for rats. Here, we validate PiezoSleep scoring against EEG/EMG implanted electrodes sleep scoring in rats. Adult male Brown Norway, Wistar Kyoto and Long Evans rats were anesthetized and implanted with bilateral stainless steel screws into the skull for EEG and bilateral wire electrodes into the nuchal muscles for EMG. For the Brown Norway rats, the EEG/EMG leads were soldered to a miniature connector and fixed to the skull. For the Wistar Kyoto and Long Evans rats, the EEG/EMG leads were tunneled subcutaneously to a telemetry transmitter implanted in the flank. Rats were allowed to recover from surgery for one week. Brown Norway rats were placed in PiezoSleep cages, and had their headsets connected to a steel

cable for recording EEG/EMG signals, which were then manually scored for sleep in 10-sec epochs. Wistar Kyoto and Long Evans rats were placed in PiezoSleep cages and EEG/EMG signals were recorded using a telemetry system. Sleep was scored automatically in 4-sec epochs using Neuroscore software. PiezoSleep software simultaneously recorded and scored sleep in the rats. Rats implanted with EEG/EMG headsets had 83.6% concurrence with PiezoSleep scoring. Out of 22827 epochs, 6919 (30.3%) wake and 12173 (53.3%) sleep epochs were scored concurrently by the two recording systems. PiezoSleep scored 1060 (4.6%) wake and 2675 (11.7%) sleep epochs when the EEG/EMG headsets scored those epochs as sleep and wake, respectively. Rats implanted with EEG/EMG telemetry had 84.0% concurrence with PiezoSleep scoring. Out of 353391 epochs, 106363 (30.1%) wake and 190481 (53.9%) sleep epochs were scored concurrently by the two recording systems. PiezoSleep scored 40135 (11.4%) wake and 16413 (4.6%) sleep epochs when the EEG/EMG telemetry scored those epochs as sleep and wake, respectively. The accuracy in rats is similar to reports in mice. We show that PiezoSleep is a reliable alternative to EEG/EMG sleep scoring in rat sleep research.

Title: Effect of extremely low frequency electromagnetic fields on locomotor activity rhythm of Wistar rats

Authors: *K. F. ROLDAN-RIZO[1], D. ELIAS-VIÑAS[2], L. VERDUGO-DIAZ[3];
[1]Fisiologia, Univ. Nacional Autónoma De México, Ciudad de Mexico, Mexico; [2]Ingeniería eléctrica, CINVESTAV, Inst. Politécnico Nacional, Ciudad de Mexico, Mexico; [3]Univ. Natl. Autonoma Mexico, Mexico DF, Mexico

Abstract: Technological development has involved an increase in environmental electromagnetic fields and its exposure to living organisms. Animals synchronize their activity to external signals, in such a way that locomotor activity recordings become essential for measuring the effects of certain stimuli, such as electromagnetic fields. For this study Wistar rats (n=8) were exposed to a 60 Hz electromagnetic field for 5 days (1 hour daily) using a pair of Helmholtz coils (2.4 mT, 1uA). Animals were housed in constant dark conditions and locomotor

activity was recorded continuously. Results showed that exposure altered animal locomotor activity for a few hours after exposure ended. Data showed significant differences on period (T) comparing animal locomotor activity before, during and after the exposure. The stimulation induced an increase of locomotor activity in adult rats as well as a change in duration of the period. This change was immediate and transitory. Electromagnetic stimulation is perceived by animals as a mild stressor, as has been proposed by other research groups. Further investigation is required to see if similar effects are induced at other times of the circadian rhythm.

Title: Increasing the arousal level may inhibit cisplatin-induced anorexia in mice

Authors: *K. YAMAMOTO;
Grad. Sch. of Allied Hlth. Sciences, Fac. of Medicine,, Osaka Univ., Suita, Osaka, Japan

Abstract: Sleep problems are major complaints of cancer patients. These patients often develop anorexia during the course of cancer chemotherapy, and sleep problems can aggravate this. They are not life-threatening symptoms, but their insufficient control reduces the patient's quality of life and become a risk factor for refusal to undergo further therapy. Previous studies proposed orexin OX_2 receptors and histamine H_3 receptors as targets for treating sleep disorders, and reported that OX_2 receptor agonists and H_3 receptor inverse agonists are effective for reducing daytime sleepiness. In this study, we investigated the effects of cisplatin on the change of the arousal level in mice, and the involvement of orexinergic and histaminergic systems in their development of chemotherapy-induced anorexia. Mice were housed in individual cages which were equipped with a sensor that detects pressure changes on the cage floor in response to motion. On the day of the experiment, mice received cisplatin (7.5 mg/kg, i.p.), and their sleep and wake states were discriminate by the changes of signals generated from the sensors. Additionally, mice received cisplatin with or without treatment with YNT-185 (an OX_2 receptor agonist, 20 mg/kg, s.c.), ciproxifan (an H_3 receptor inverse agonist, 1 mg/kg, s.c.), or VUF5681 (an H_3 receptor neutral antagonist, 5 mg/kg, s.c.), then their daily food intake was measured. Finally, we investigated the effect of cisplatin on the hypothalamic expression of prepro-orexin (PPO) mRNA, which encodes precursors of orexin. Cisplatin increased sleep state during the active phase and induced anorexia. The administration of ciproxifan or YNT-185, which was

reported to induce wakefulness in mice, significantly inhibited the cisplatin-induced anorexia. The inhibitory effect of YNT-185 was antagonized by the administration of VUF5681. Furthermore, cisplatin decreased the hypothalamic expression of PPO mRNA and the period of expression decreased in parallel with the onset of anorexia. These results suggest that changes in the arousal level may lead to the development of cisplatin-induced anorexia in mice, and the increase of the arousal level via the activation of the orexinergic and histaminergic pathway is involved in the therapeutic effect against cisplatin-induced anorexia.

Title: The caudal paralaminar thalamus plays a critical role in cortical activation and arousal

Authors: *W. YIWEI[1], M. LIU[2], D. CAI[3], F. XIE[4], L. YOU[1], Y. YUE[1], R. CHEN[1], J. ZOU[1], T. LI[1];

Abstract: The midline and intralaminar thalamocortical projection system, which is located anteriorly and innervated by brainstem reticular formation nuclei, was considered as the last link of the dorsal pathway of the ascending reticular activating system (ARAS). In human patients, lesions of the midline and intralaminar thalamus cause decreased cortical and behavioral arousal. Surprisingly, earlier animal studies suggested that the dorsal pathway may not be necessary. A more recent study in mice showed that, although the midline thalamus is important for arousal, it might play its role via thalamostriatal rather than thalamocortical projection system. These opposing findings made in animals raised a fundamental question, namely, whether the dorsal pathway is indeed involved in arousal and, if it is, how. We lately characterized the whole-brain connectivity pattern of a caudal paralaminar thalamic region (CPT), mainly composed of the medial part of medial geniculate body (MGBm), the posterior intralaminar thalamus (PIN) and the peripeduncular nucleus (PP), which was traditionally considered as part of the higher order auditory processing thalamus. We found that the CPT receives direct inputs from both monoaminergic and cholinergic centers of brainstem reticular formation and projects to the

superficial layer of a wide range of temporal cortices, suggesting its involvement in sensation-related arousal. Using fiber photometry and EEG/EMG recordings, we found that the activities of CPT VGluT2-positive (VGluT2+) neurons were high during wakefulness and REM sleep and low in NREM sleep, and increased before cortical activation at the sleep-to-wake transition. Optogenetic activation of CPT VGluT2+ neurons with low light power rapidly and reliably awoke mice from sleep and elicited cortical activation during general anesthesia, and chemogenetic activation led to prolonged wakefulness, indicating that the activation of CPT VGluT2+ neurons strongly promotes cortical and behavioral arousal. On the other hand, optogenetic inactivation of CPT VGluT2+ neurons greatly reduced the probability of awakening by acoustic stimulation of various intensities. The ablation of CPT VGluT2+ neurons led to decreased wakefulness and increased REM sleep in 24 hours, but had little effect on NREM sleep. Furthermore, the activation of the CPT-to-cortex pathway was sufficient to evoke both cortical and behavioral arousal, and this pathway was critical for sound-elicited sleep-to-wake transition. Our study identified a new thalamic region important for arousal control and provided strong support for the dorsal pathway hypothesis.

Title: Hypothalamic MCH neurons contribute to forgetting of hippocampus dependent memory during REM sleep

Authors: *S. IZAWA[1,2], S. CHOWDHURY[1], D. ONO[1], T. MIYAZAKI[1,2], Y. MUKAI[1,2], R. INOUE[1], T. S. KILDUFF[3], A. YAMANAKA[1,4];
[1]Dept. of Neurosci. II, Res. Inst. of Envrn. Med., Nagoya, Japan; [2]JSPS Res. Fellowship for Young Scientist, Tokyo, Japan; [3]Cntr for Neurosci., SRI Intl., Menlo Park, CA; [4]CREST, JST, Saitama, Japan

Abstract: Sleep is thought to both consolidate and impair memory, however, the underlying neural mechanisms are unknown. Here, we found that melanin-concentrating hormone (MCH)-producing neurons in the hypothalamus contribute to forgetting of hippocampal memory. Retrograde-transported beads injection into the hippocampus revealed that MCH neurons densely innervated the dorsal hippocampus. MCH neurons are known to synthesize and release a

variety of neuropeptides/transmitters that are involved in REM sleep regulation. To reveal the role of MCH neurons in hippocampus-dependent memory, the novel object recognition, Morris water maze and contextual fear memory tests were performed in mice. Pharmacogenetic activation of MCH neurons impaired memory in all these tests, whereas inhibition or ablation of these neurons improved memory. These results suggested that MCH neuron activity was involved in hippocampus-dependent memory impairment. Optogenetic activation of MCH neurons during the retention period, but not during the encoding or retrieval periods, impaired memory. To reveal the mechanism of memory impairment, slice patch clamp recordings from hippocampal pyramidal neurons were performed. Optogenetic stimulation of MCH nerve terminals in the hippocampus hyperpolarized and decreased the firing frequency of hippocampal pyramidal neurons. Finally, we tested whether the activity of MCH neurons during REM sleep is involved in memory impairment. MCH neurons were silenced in a vigilance state-dependent manner (wakefulness, REM sleep, and Non-REM sleep) for 14 hr of the memory retention period. Optogenetic silencing during REM sleep but not during wakefulness or Non-REM sleep significantly improved memory, suggesting that MCH neurons impair memory particularly during REM sleep. Taken together, our results demonstrate that MCH neurons impair memory by inhibiting hippocampal pyramidal neurons during REM sleep, a mechanism that could effectively save memory resources by erasing memories that are not important for survival.

Title: Right putamen functional connectivity is associated with chronic pain and sleep quality in older adults

Authors: *S. MONTESINO GOICOLEA, P. A. VALDES-HERNANDEZ, Y. CRUZ-ALMEIDA;
Univ. of Florida, Gainesville, FL

Abstract: Sleep disturbances and chronic pain are common co-morbidities in older adults tied to significant reductions in quality of life. The potential mechanisms underlying sleep disturbances in the presence of chronic pain are not understood. An understudied factor is the detrimental effect of chronic pain on cerebral circuits needed for sleep generation and maintenance. In the present study, we explored associations between sleep quality with resting state functional MRI connectivity (FC) of brain regions involved in sleep and pain in cognitively healthy older adults (60-83, M=72.3±6.3, n=47) enrolled in the NEPAL study. Participants reported presence of pain during the past 3 months (55%, n=26), completed the Pittsburgh Sleep Quality Index (PSQI) and underwent MRI. The fMRIs were preprocessed and denoised using CONN and normalized to MNI using DARTEL. ROI-to-ROI FC was calculated with Fisher-transformed Pearson correlations. Based on the sleep and pain literature, we placed seeds in medial prefrontal cortex, anterior cingulate cortex, middle/inferior frontal gyri, pre/postcentral gyri, supplementary motor areas, paracingulate gyri, precuneus, frontal orbital cortex, basal ganglia, insula, thalami, hippocampi, amygdalae, opercula, right Heslch's gyrus and brain stem. General Linear Model was used to investigate the effect of pain presence, PSQI and their interaction, controlling for age, sex and handedness. FC was FDR corrected (q&lt0.05) for multiple comparisons across whole brain targets, and size/intensity of the resulting networks were FDR corrected (q&lt0.05) using Network-Based Statistics across seeds. As expected, those with chronic pain reported significantly lower sleep quality (p&lt0.05). We found a significant negative interaction on the FC of the right putamen with supplementary motor areas, pre/post central gyri, lateral occipital cortex, bilateral parietal opercula, language areas (right Heslch's gyrus and bilateral planum temporale), right inferior frontal gyrus pars opercularis and left central operculum. To our knowledge, this is the first examination of resting state FC at the intersection of sleep and chronic pain in older adults. Such associations may explain the reported bidirectional relationships between sleep disturbances and chronic pain.

Title: Differential change of light and deep NREM sleep by thalamic PLCβ4

Authors: *J. HONG[1], G. HA[1], H. KWAK[1], Y. LEE[1], H. JEONG[1], P.-G. SUH[2,3], E. CHEONG[1]; [1]Yonsei Univ., Seoul, Korea, Republic of; [2]Sch. of Life Science, Unist of Sci. and Technol., Ulsan, Korea, Republic of; [3]Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: Sleep consists of non-rapid eye movement (NREM) and rapid eye movement (REM) sleep. NREM sleep is further divided into light (slow wave sleep 1, SWS1) and deep (slow wave sleep 2, SWS2) NREM sleep, which are characterized by frequent occurrence of sleep spindle and delta waves, respectively. Both brain rhythms are thought to be mediated in the thalamocortical circuit, consisting of the cortex and thalamus. The thalamus is further dissected into thalamic reticular nuclei (TRN) and thalamocortical (TC) nuclei which reciprocally project each other. Among many inputs to TC neurons, the corticothalamic pathway from cortical neurons in layer VI send massive glutamatergic inputs. The activation of corticothalamic input have been considered to regulate the firing properties of TC neurons, which affect thalamocortical oscillations. However, the function of which on regulating light and deep NREM sleep is unclear. Here, we investigated that the changes of dynamics in light and deep NREM sleep using TC-specific PLCβ4 knock-out (KO) mice.

Title: Sleep quality meaning and its association with the Pittsburgh sleep quality index (PSQI): A population base study across the adult lifespan

Authors: *L. AMORIM[1,2,3], A. SOUSA[4], T. C. CASTANHO[1,2,3], N. SOUSA[1,2,3], N. C. SANTOS[1,2,3];
[1]Life and Hlth. Sci. Res. Inst. (ICVS), Sch. of Medicine, Univ. of Minho, Braga, Portugal; [2]ICVS/3B's - PT Government Associate Lab., Braga/Guimarães, Portugal; [3]Clin. Academic Ctr. (2CA), Braga, Portugal; [4]Sch. of Medicine, Univ. of Minho, Braga, Portugal

Abstract: Sleep is a complex, dynamic and multidimensional phenomenon, with proven effects on health and well-being. However, while dimensions such as 'sleep quantity' are clearly defined, that does not apply to the 'sleep quality' construct. In fact, different conceptualizations

of it have led to a high variability in the methodologies used. Herein, we searched for the meaning of a good sleep quality and its stability across the adult lifespan, as well as the association between sleep quality self-ratings and the Pittsburgh Sleep Quality Index (PSQI). For this purpose, adult community-dwellers were randomly and consecutively invited to participate in the study (n=340; age range: 18-87 years), and asked to provide their interpretation of a good sleep quality and a good night of sleep. Self-ratings of sleep quality, sleep patterns and habits and information on psychological variables were also collected. Content analysis was performed with the qualitative data and the obtained parameters were considered as to their frequency; an exploratory network analysis was also used. Associations between self-rated sleep quality and PSQI were determined and the predictors of good/poor sleep quality explored. Results showed that while the most frequently reported parameters for a 'good sleep quality' are 'sleep continuity', 'sleep characteristics' and a dyad involving these two, for a 'good night of sleep' the most reported information focused on the dyad 'sleep duration'-'sleep continuity' and on 'sleep duration' and 'sleep continuity' individually. From the exploratory network analysis, the strongest association occurred between 'sleep continuity' and 'waking up feelings' but strong associations were also found between 'sleep continuity' and 'sleep characteristics' and 'sleep continuity' and 'sleep duration'. Results also indicated that self-rated sleep quality measures and PSQI are correlated and no differences were found across the lifespan in the distribution of these parameters. In the one-year follow-up, 52% of the invited individuals maintained the definition that they provided in first assessment. Overall, our results point to the need to consider not only sleep information when addressing sleep quality, but also aspects related to the feelings when waking up. Additionally, our results also point to the need of developing a new tool to address sleep quality that goes beyond PSQI that is framed by a clinical context. Overall, our results contribute to the clarification of the meaning of 'a good sleep quality', and provide a relevant framework for future studies addressing the complaints and sleep changes across lifespan.

Title: Inspiratory muscle training may increase gray matter volume in obstructive sleep apnea

Authors: *P. M. MACEY[1], A. PAL[2], A. AGUILA[2], M. SARMA[3], A. SAUCEDO[3], A. M. THOMAS[3], R. S. AYSOLA[4];
[1]Nursing; Brain Res. Inst., [2]Nursing, [3]Radiology, [4]Med-Pulm & Critical Care, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Introduction: Obstructive Sleep Apnea (OSA) is a sleep disorder present in more than 10% of the adult population. One approach to reduce the sleep-disordered breathing is to improve muscle tone through Inspiratory Muscle Training (IMT). We and a group in Tucson found in pilot studies of OSA patients that IMT leads to more than improved respiratory function, with lower reduced blood pressure and improvement in psychological symptoms observed. These changes suggest improvement in brain function, so our objective was to assess regional gray matter volume before and after IMT to assess evidence of improvement in brain structure.
Methods: Five OSA patients perform an IMT intervention over 10 weeks (2 females; age 47-74, mean 62±5 years). Each day, patients performed a set of 30 inspiratory breaths against a resistance of 65% of maximum inspiratory capacity. At pre and post time points, we assessed brain structure with voxel-based morphmetry, a measure of regional gray matter volume (GMV), based on high resolution T1-weighted anatomical scans (0.8mm voxel size). We compared GMV before and after IMT in SPM12 software.
Results: Twelve regions of increased GMV appeared post-IMT ($p<0.001$). Regions of increases included multiple subregions of the bilateral precuneus, bilateral middle occipital gyrus, and left superior parietal-occipital cortex, the right posterior insula, right hippocampus, and left medial prefrontal cortex. No areas showed volume decreases.
Discussion: The findings illustrate an increase in GMV in multiple regions, several of which are associated with common symptoms in OSA. The increase in GMV could reflect a reduction in vascular content or learning-related dendritic growth.

Title: Inspiratory muscle training reduces inflammation markers in brain of obstructive sleep apnea patients

Authors: *A. PAL[1], A. P. AGUILA[1], M. SARMA[2], A. SAUCEDO[2], R. S. AYSOLA[3], A. M. THOMAS[2], P. M. MACEY[4];
[1]Nursing, [2]Radiology, [3]Med-Pulm & Critical Care, [4]Nursing; Brain Res. Inst., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Introduction: Obstructive Sleep Apnea (OSA) affects over 10% of the adult population and is characterized by airway muscle collapse. One approach to prevent this collapse is to improve muscle tone through Inspiratory Muscle Training (IMT). We and another group in Tucson have shown in pilot OSA studies that IMT leads to not only improved respiratory function but also reduced blood pressure and lower psychological stress. Since brain function is associated with these symptoms, we aimed to determine if in OSA IMT leads to brain changes, specifically changes in structure related to reduced inflammation.Methods: We conducted a 10 week IMT intervention study in 5 untreated OSA participants (2 females; age 47-74, mean 62±5 years). The intervention consisted of daily set of 30 inspiratory breaths against a resistance of 65% of maximum inspiratory capacity. At pre and post time points, we assessed brain structure with Diffusion Tensor Imaging (DTI) indices of Mean Diffusivity (MD) and Fractional Anisotropy (FA). These indices are sensitive to changes in inflammation amongst other phenomena. We assessed IMT related changes using a repeated measures linear model in SPM12 software. Results: Post IMT we found significantly ($p<0.001$) increased MD in several brain regions. There were no areas where MD decreased, and we did not find any change in FA. Areas with MD increases included the prefrontal lobe (left cerebral white matter and posterior ventral orbital gyrus); occipital lobe (right lingual gyrus white matter); bilateral temporal poles; and bilateral ventral diencephalon.Discussion: The findings are consistent with IMT causing a reduction in inflammation in brain areas associated with autonomic and stress regulation. The increased MD could reflect decreased cell size, and the lack of FA changes suggests the effects were not due to white matter alterations.

Title: Acoustic pink noise stimulation after sleep spindle may enhance the procedural memory consolidation

Authors: *J. CHOI, S. C. JUN;
Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: Slow wave and sleep spindle activity are well-known components associated with memory consolidation during sleep. Positive effects of acoustic or electrical stimulations on memory consolidation to modulate slow wave sleep or sleep spindles have been reported. On the other hand, there is a suggestion that temporal matching of slow waves and sleep spindles is an important feature of memory integration mechanisms. In this study, we hypothesized that adjusting the slow wave after sleep spindle activity may improve the memory consolidation effect. To verify this hypothesis, we built a closed-loop feedback system that delivers pink noise stimuli (50 ms, 62dB SPL) whenever sleep spindle activity is detected. We set up SHAM condition (no acoustic stimulation) and STIM condition (nap with acoustic stimulation after spindle detection) to investigate the effects of acoustic stimulation on memory consolidation and neurophysiological characteristics. We recruited thirteen healthy male subjects (mean ± SD age: 26.3 ± 2.4 years, right-handed). Subjects proceeded to SHAM and STIM conditions in pseudo-random order after adaptation nap; two conditions were separated at least 2 weeks. All subjects requested to perform word-pair memorization task and finger tapping tasks before and after the nap. We found phase-locked slow wave activities after spindle detection (acoustic stimulation) during the STIM condition. STIM condition yielded a greater improvement in finger tapping task than SHAM condition ($p = 0.014$). Additionally, it was observed that there was a marginal correlation between declarative memory performance change and theta activity change from SHAM to STIM ($r=0.53$, $p=0.059$). In addition, we found that there was no procedural memory consolidation enhancement among subjects who showed larger auditory evoked potential (AEP) than spontaneous slow wave activity. From these findings, it is believed that individual sound amplitude optimization considering individual sensitivity of sound is of great importance to introduce procedural memory consolidation enhancement.

Title: Sleep consolidation of visuomotor adaptation: Differential effects on memory retention and persistence

Authors: *A. SOLANO[1], L. A. RIQUELME[1], D. PÉREZ-CHADA[2], V. DELLA-MAGGIORE[1];
[1]Ifibio-Houssay, Univ. of Buenos Aires, Buenos Aires, Argentina; [2]Dept. of Med., Pulmonary and Sleep Service, Austral Univ. Hosp., Pilar, Argentina

Abstract: Adaptation is a type of learning that allows maintaining precise motor control in face of environmental and/or internal perturbations. Like other types of learning, adaptation may lead to interference or facilitation depending on the level of congruency of sequentially learned materials. We have previously shown that adaptation to opposing visual rotations, A and B, impairs the ability to learn in B and long-term memory measured 24 hours later. Here, we examined the impact of sleep on the retention and persistence of visuomotor adaptation memories, in the presence or absence of a conflicting perturbation. To this aim, we carried out two experiments in which we manipulated the proximity between training and sleep. We hypothesized that if sleep participates in the consolidation of visuomotor adaptation, then there should be a benefit of the promixity of sleep on memory retention and/or persistence. To examine this possibility we carried out two experiments: in Experiment 1 (n=26), subjects performed a visuomotor adaptation task (30 deg CW perturbation); in Experiment 2 (n=31), a different set of participants performed the same task but under a protocol of anterograde interference in which they adapted to two opposing visual rotations (30 deg CCW followed by 30 deg CW) separated by a 5 min interval. In each experiment one group of subjects performed the task in the morning and the other group at night, just before going to sleep. All subjects participated in a whole-night polysomnographic study in the sleep lab, and returned to the lab 24h and 2 weeks post training to measure memory retention and persistence, respectively. In agreement with our previous work, we found that anterograde interference reduced the overall level of memory retention by about 70% ($p<0.001$). Yet, the magnitude of this effect differed depending on the proximity between learning and sleep ($p=0.045$). Specifically, the group that learned ~12 hours before sleep showed a reduction in the level of retention at 24 hs, whereas the group that trained immediatly before sleep was impaired only at 2 weeks. Our findings provide

evidence in favor of a role of sleep in the stabilization of visuomotor adaptation, which may be reflected in the persistence of long-term memories.

Title: Potential role of gut microbiota in neurobehavioral deficits induced by simulated shift work condition in mice

Authors: *S. SHIYANA[1], K. KONDEPUDI[2], M. BISHNOI[2], K. CHOPRA[1];
[1]Panjab Univ., Chandigarh, India; [2]Natl. Agri-food Biotech. Inst., Mohali, India

Abstract: Shorter sleep hours along with altered circadian rhythm may meet the societal needs but impairs the normal physiological responses thus resulting into many gastrointestinal and neuronal pathologies. That's why the population engaged in night shifts e.g. security personnel, nurses, flight crew have gastrointestinal and neuronal abnormalities as the most common phenotypes. Moreover, the interplay between sleep and gut microbiota is evidenced in the recent literature. However, the impact of gut microbiota on chronic sleep deprivation induced neurobehavioral deficits in a simulated shift work condition is not explored. Therefore, the current study was designed to mimic the night shift work condition. Female Laca mice were divided into four groups: control, sleep deprived (SD), antibiotic treated (Ab+NPD) and fecal microbiota transplanted (Ab+NPD+FMT). In SD group, the sleep deprivation was produced using modified multiple platforms model for eight hours daily from 9:00 am to 5:00 pm from Monday to Friday with weekend as sleep recovery period. In Ab+NPD, the cocktail of three non - absorbable antibiotics neomycin, bacitracin and pimaricin was administered orally for seven days along with normal pellet diet (NPD) for the depletion of microbiota. The fecal matter from sleep deprived group was transplanted to the Ab+NPD+FMT following the antibiotic treatment. All the animals were assessed for locomotor activity using actophotometer, stereotype and aggressive behavior, pain parameters using tail immersion test and Von frey test. Fecal samples were collected and analyzed for the selected gut microbiota by polymerase chain reaction**.** The results elucidated the occurrence of mania like behavior and decreased pain threshold in SD animals. The gut microbiota transplantation also induced the similar mania like behavior and decreased pain threshold in antibiotic treated animals. Furthermore, the fecal microbiota analysis showed altered Bacteriodetes to Firmicutes ratio. Hence, the current study substantiates the

adverse modulation of gut microbiota in chronic sleep deprivation and its potential role in resultant neurobehavioral deficits.

Title: Activation of orexigenic neurons induced by binge eating of sugar or fat and sleep delay in a model of night eating syndrome

Authors: *E. ESPITIA-BAUTISTA, L. UBALDO-REYES, C. ESCOBAR;
UNAM, Mexico City, Mexico

Abstract: Night eating syndrome (NES) is an eating disorder, characterized by a delayed circadian pattern of food intake to late at night; it includes night binge episodes (BE) and sleep disorder like insomnia. Sleep and food intake are both controlled by orexigenic neurons (ORX) in the lateral hypothalamus (LH). This neuronal system is also associated with appetite for palatable food. Loss of circadian or homeostatic control in this system may lead to compulsive eating behaviors (CEB), overweight and metabolic syndrome (MSyn). Palatable food contains high levels of sugar and fat. A high sugar diet (HSD) or a high fat diet (HFD) undergo differences in digestion and absorption and stimulate brain systems in a differential manner. This study aimed to investigate two experimental models of NES, food intake into the sleep phase and food combined with sleep deprivation In both conditions we explored the contribution of a HFD or HSD.. We evaluated BE, effort behaviors, MSyn and the activation of ORX neurons. Rats were housed with chow and water *ad-libitum* and were randomly assigned to*:* 1) Control, 2) HSD, 3) HFD, 4) Sleep delay (SD), 5) SD+HSD and 6) SD+HFD. Four hours after starting the rest phase rats exposed to NES had 1 hour restricted access to the diet. Animals with SD were exposed to a slow rotating wheel the first 4h of their rest phase. Experimental protocols lasted 4 weeks. General activity, body weight and food intake were recorded. At the end of the study effort behaviors and metabolic variables were assessed and brains were collected to evaluate c-Fos activation in ORX in the perifornical area (PFA) and the LH. Results indicate that HSD and HFD animals present a delayed peak time (acrophase) of daily activation of ~1.5h and 0.5h, respectively. SD induced a delay of ~3h, SD+HSD of ~2.5h and SD+HFD of ~3.5h, suggesting circadian misalignment. All groups exposed to palatable diet developed effort behaviors to

obtain the diet. HFD and SD+HFD groups developed more BE than HSD, SD+HSD, SD or Control groups; and developed glucose intolerance, high insulin, triglycerides and leptin. Animals exposed to SD were less heavy and accumulated less fat. All groups exposed to SD showed a decrease in the activation of ORX in the LH, as compared with their non-sleep deprived groups. However, in the PFA SD only reduced the ORX of HFD rats. We conclude that a HFD as compared with HSD is a stronger stimulus for producing BE and metabolic syndrome in experimental conditions of NES. The protocol for SD disrupted the circadian phase in general activity, as observed with the acrophases, while the diet alone produced a minimal change. We demonstrate that NES is a risk factor to develop CEB and MSyn, reducing the ORX activation.

Title: Asprosin administration promotes wakefulness and blunts torpor bouts in mice

Authors: *E. M. COHN, K. ODENIGBO, F. GULAMALI, S. J. SWOAP, M. CARTER; Dept. of Biology, Program in Neurosci., Williams Col., Williamstown, MA

Abstract: Hormones that cause an increase in food intake can prioritize feeding behavior over competing behavioral states such as sleep. Furthermore, in small mammals including mice, hormones that affect feeding can also affect torpor, brief (6-8 hours) states of metabolic dormancy characterized by low body temperature and heart rate. Asprosin is a recently discovered peptide hormone released from white adipose tissue that causes an increase in glucose release from the liver and a corresponding increase in food-seeking behavior. We tested the hypothesis that asprosin administration is sufficient to promote wakefulness over other sleep states and to blunt the depth and length of torpor bouts in mice. We found that administration of asprosin caused a reversible increase in wakefulness and increased latency from states of wakefulness to states of sleep. Additionally, we found that asprosin reduced the duration and depth of torpor bouts. Taken together, these data suggest that asprosin negatively regulates states of sleep and torpor, prioritizing food intake over competitive homeostatic and metabolic states that limit food-seeking behavior.

Title: Tetrodotoxin-mediated inactivation of the prefrontal cortex decreases wakefulness and increases the time to emergence from sevoflurane anesthesia in rat

Authors: *E. R. TRAMMEL, A. PARKAR, T. GROENHOUT, L. SHARBA, A. BOOTWALA, T. LIU, G. A. MASHOUR, D. PAL;
Dept. of Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: There is an ongoing debate on the role of prefrontal cortex (PFC) in consciousness. We recently showed that cholinergic stimulation of PFC in sevoflurane-anesthetized rats induced a wake-like state (Pal et al., 2018 Current Biol. 28:2145-2152.e5). In this study, using a within-group design, we tested the hypothesis that inactivation of PFC will reduce wakefulness and increase anesthetic potency. Four adult male Sprague Dawley rats were instrumented for sleep-wake recordings and PFC inactivation through bilateral infusion of tetrodotoxin [TTX: low (15.6μM, TTX-L) and high (156μM, TTX-H) dose]; sterile saline (CTRL) infusion into PFC served as the control group. All injections (500nL) were done 1h before the onset of dark phase. Thereafter, sleep-wake states were recorded through 12h of dark (7pm-7am) and light (7am-7pm) phases. In another set of experiments, 6 rats (4 male) were exposed to sevoflurane anesthesia (2.5%) two hours after bilateral TTX-H or CTRL infusion (500nL) into PFC. Thereafter, the time to loss of righting reflex (LORR), a surrogate for unconsciousness in rodents, was measured. Sevoflurane anesthesia was stopped after 45 minutes and the time to return of righting reflex (RORR), a surrogate for return of consciousness in rodents, was quantified. The injections were counterbalanced, and 5-7 days were allowed between injections. Sleep-wake states were analyzed in 10 second bins into wakefulness, slow wave sleep (SWS), and rapid eye movement sleep (REMS). The data are reported as mean ± standard deviation. Time to LORR/RORR was compared using a paired t-test. The immediate 12h period after TTX infusion into PFC (dark phase) was characterized by decrease in wake state (63.7±11.3% TTX-L and 53.8±22.9% TTX-H vs. 64.7±3% CTRL) and REMS (3.5±2.1% TTX-L and 2.9±0.74% TTX-H vs. 7.3±1.6% CTRL) while the time spent in SWS increased (32.8±10.8% TTX-L and 43.3±23.2% TTX-H vs. 28.0±3.6% CTRL). The overall trend continued as such in the next 12h period (light phase): decrease in wakefulness (44.1±6.3% TTX-L and 43.4±19.4% TTX-H vs.

55.9±8.5% CTRL) and increase in SWS (48.8±4.3% TTX-L and 54.8±20.1% TTX-H vs. 39.5±7.8% CTRL). REMS after TTX-H also showed a similar trend (1.8±1.1% vs. 4.6±2.2% CTRL) but there was an increase in REMS after TTX-L (7.03±2.4% vs. 4.6 ±2.2% CTRL). TTX infusion into PFC produced a significant increase in the time to emergence from sevoflurane anesthesia (13.5±2.6 min after TTX vs. 9.1± 2.6 min after saline infusion, p =0.001). These data further support a causal contribution of PFC in regulating level of consciousness.

Title: Neonatal exposure to isoflurane alters sleep architecture and cognition in adolescent rats in a sex-specific manner

Authors: *F. M. MANZELLA[1], B. F. GULVEZAN[1], Y. H. RAOL[2], V. JEVTOVIC-TODOROVIC[1], S. M. TODOROVIC[1];
[1]Anesthesiol., [2]Pediatrics-Neurology, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Objective & Rationale
Exposure to general anesthetics (GAs) is neurotoxic to the developing rodent and primate brains and is associated with neurocognitive impairment later in life. Yet, little is known about its effect on other behavioral outcomes, such as sleep and exploratory behavior. Sleep plays a major role in cognition, especially during adolescence. Thus, the goal of this research was to understand how neonatal exposure to GAs affects sleep quality and to see if changes in sleep quality are similarly reflected in a cognitive exploratory task.
Methods
At postnatal day (P) 7, male and female Sprague Dawley rat pups were exposed to either six hours of continuous 1.5% isoflurane (ISO) or to compressed air alone (SHAM). At weaning age (P21-P23), rats were implanted with a cortical EEG electrode, and sleep recordings were obtained at P35. Sleep architecture and power spectra were analyzed from six hours of the light cycle and six hours of the dark cycle, for a total of 12 hours of analysis. Sleep stages were categorized as Wake, NREM, REM, or Total Sleep. Following sleep recording, rats were given an object exploration task in which they were allowed to explore one of three objects in

sequential order for 10 minutes.

Results

We found no changes in sleep architecture during the light cycle. However, during the dark cycle, ISO males had more NREM episodes (p=0.027), shorter Wake episodes (p=0.023), and more transitions between sleep stages compared to SHAM males (p=0.024). Moreover, there were no differences in total time spent in each stage. Changes persisted when light and dark cycles were combined. Again, ISO males had more NREM episodes compared to SHAM males (p=0.039). Unlike the dark cycle alone, there were no differences in duration of wake episodes; instead, ISO males had shorter NREM episodes (p=0.029). There were no changes in the total amount of time spent in each stage. For power spectra analysis, there were no changes between ISO and SHAM groups. Finally, for the exploration task, we found that ISO males spent less time exploring all objects compared to SHAM males (p=0.011).

Conclusions

Our results suggest that adolescent males are vulnerable to disturbances in sleep architecture after neonatal exposure to GAs. Specifically, GAs affect sleep quality as manifested as destabilized NREM sleep, and not quantity, as there were no changes in overall time spent in each sleep stage. Moreover, these results are reflected in deficiency seen in a cognitive exploration task, in which ISO males were more greatly affected. Because sleep quality can affect cognition, we propose that sleep deficits associated with neonatal GA exposure may perpetuate cognitive impairments later in life.

Title: Sleep fragmentation increases alcohol sensitivity and alcohol-induced mortality in *drosophila*

Authors: *L. C. LYONS, A. K. DE NOBREGA, C. L. CAMARILLO, E. J. NOAKES; Biol. Science, Program in Neurosci., Florida State Univ., Tallahassee, FL

Abstract: Alcohol abuse is a major global health problem causing individual health consequences and adverse economic impacts on society. Individuals with sleep disorders are more likely to have an alcohol use disorder with increased incidence of alcohol-related pathologies observed in populations prone to sleep disruption including shift workers and older individuals. Sleep disorders affect approximately 70 million Americans resulting in mood

disorders, cognitive impairments, and metabolic disorders. While the effects of alcohol abuse on sleep quality have been well-studied, little is known about the converse effect of sleep loss on alcohol pathologies. *Drosophila* is an excellent model for studies of sleep and alcohol neurobiology providing a model for disentangling the underlying molecular and neural mechanisms of sleep and alcohol interactions. Recently, our lab characterized the effect of 24 hours of total sleep deprivation on alcohol sensitivity and toxicity in *Drosophila* finding that sleep deprivation increased alcohol toxicity and suppressed long-term alcohol tolerance. As sleep fragmentation with decreased sleep quality represents a common sleep problem for millions of individuals, in our current study we investigated the effect of sleep fragmentation on alcohol toxicity. *Drosophila* sleep occurs mostly during the night with sleep bouts averaging approximately 40 minutes. Daytime sleep bouts are less numerous and shorter averaging 27 minutes. Previously, researchers found that deeper sleep states occurred in *Drosophila* approximately 15 and 30 minutes after inactivity (van Alphen et al., 2013). Consequently, as a first step we used a mechanical sleep fragmentation protocol in which young flies (7 days old) were subjected to mechanical rotation and startle for 3 minutes out of every 10 minutes. We found that four days (96 hours) of sleep fragmentation increased behavioral sensitivity to alcohol-induced sedation as well as alcohol-induced mortality in young flies. Ongoing experiments are investigating additional sleep fragmentation paradigms and the amount of recovery sleep necessary to restore baseline alcohol responses.

Title: Investigation novel-sleep related genes in *Drosophila melanogaster*: A follow up on KOMP2 identified genes in *Mus musculus*

Authors: *R. GUERRIERO[1], D. A. HARRISON[1], P. SHAW[2], B. F. O'HARA[1,3];
[1]Univ. of Kentucky, Lexington, KY; [2]Neurosci., Washington Univ. Sch. of Med. In St. Louis, Saint Louis, MO; [3]Signal Solutions LLC, Lexington, KY

Abstract: Sleep is well-conserved across phylogeny, yet the function of sleep and its underlying mechanisms are currently poorly understood. Novel-sleep related genes were previously identified by our lab as part of the Knockout Mouse Phenotyping Program (KOMP2). This international effort generated *Mus musculus* single-gene knockouts on a C57BL6/NJ background and proceeded to gather data on over 200 phenotypes, including five days of sleep and wake

parameters. This sleep data was gathered using the non-invasive, high-throughput PiezoSleep System (Signal Solutions, LLC.), which uses piezoelectric films to gather movement data which can be assigned as wake or sleep. These data identified 122 novel genes that influence sleep phenotypes such as sleep duration and bout length. Homologous proteins were identified in flies and a subset of these genes are under investigation in *Drosophila melanogaster,* including myosin heavy chain (Mhc) and spinophillin (Spn). Using both genetic mutants and RNAi knockdowns, the effect of gene reduction on activity profiles and sleep were analyzed. Conditional mutants/ knockdowns were also made for the central nervous system and subsets of the CNS that are known to impact sleep and circadian rhythms. Sleep and activity data were recorded using DAM2 monitors (TriKinetics Inc.) while being maintained on a 12:12 light dark cycle. Preliminary data analysis show that whole body aberrations in Mhc and Spn impact sleep percentage. Both Mhc and Spn are known to be involved in structure and development of synapses. Spn is involved in the neurexin scaffolding of presynaptic neurons and also help with maintaining these synapses once formed. Synaptic reorganization and regulation is known to take place during sleep, showing a potential connection of these proteins and sleep. Since removal of both of these genes impact sleep in *D. melanogaster* and in *M. musculus,* this may show evidence of the conservation of underlying sleep machinery across many phyla.

Title: Deprivation of ‘sleep-like’ inactivity in an annelid worm disrupts neural mechanisms, but not metabolism

Authors: *M. J. ZORAN, L. H. JORDAN;
Biol., Texas A&M Univ., College Station, TX

Abstract: Many invertebrate animals undergo periods of rest or ‘sleep-like’ inactivity, but the function of these behavioral states is not clear. The aquatic annelid worm, *Lumbriculus variegatus,* exhibits a circadian-regulated inactivity, which involves a ventilatory posture that

facilitates gas exchange. *Lumbriculus* is nocturnal, active at night, and its inactive phase is expressed during the day and subjective day when in constant conditions (n=31). Using physiological (neural and metabolic) recordings, together with behavioral monitoring, the hypothesis that the inactive 'sleep-like' state of this worm functions to enhance both neural and metabolic deficits accrued over a day's activity was tested. Both physical disruption (agitation) and pharmacological treatment (caffeine) were used to deprive animals of inactivity. Deprivation of daily inactivity, and consequently ventilatory behavior, disrupted plasticity associated with regenerative morphallaxis (n=18 per group) and increased the onset of asexual fragmentation (n=13 per group), two mechanisms dependent on neural signaling. In contrast, whole-animal metabolic rate was not detectably impacted by disruption of daily inactivity. Still, chronic deprivation of inactivity with agitation (n=7 per group) or caffeine (n=5 per group) caused a prolonged rebound period of inactivity and an increase in ventilatory behavior. Using specific wavelengths of LED light to entrain the worm's activity rhythms (n=12 per group), we find that inactivity deprivation reduces the threshold for light-evoked escape responses. Our results suggest that *L. variegatus* possesses a 'sleep-like' resting state that when disrupted leads to broad deficits in neural-regulated development and behavior, including escape reflexes.

[1]Martineau and Associates, Menlo Park, CA; [2]Psychiatry and Behavioral Sci., [3]Stanford Univ., Stanford, CA

Abstract: We present Zebratrack: a darkfield-illuminated, Remanent Imaging platform for high accuracy behavioral analysis. Our analytics simultaneously reveal individual and population measures from short timescales, to daily cycles, and potentially to entire organismal lifetimes. Recording objects of various sizes from larval to adult animals as well as sub-pixel microorganisms aid in studying feeding and social interactions. Our platform, verified with the popular zebrafish model, can be extended to other aquatic models.

Title: Cardiorespiratory activity and sleep deprivation in crayfish

Authors: *M. OSORIO-PALACIOS, L. MONTIEL-TREJO, Z. PEÑA-LEAL, I. OLIVER-DOMÍNGUEZ, J. HERNÁNDEZ-FALCÓN, K. MENDOZA-ÁNGELES;
Univ. Nacional Autónoma de México, Ciudad de México, Mexico

Abstract: In vertebrate and invertebrate animals, sleep is necessary for survival. For example in rats, after two to three weeks of sleep deprivation animals loss weight despite a strong increase in food intake, if deprivation continues they finally die. In crayfish, 24 hours of deprivation are enough to cause death. Sleep deprivation in mammals elicit changes in the structure of EEG and disregulation of cardiorespiratory activity. However, we do not know if this occurs also in invertebrates, particularly in crayfish. The main aim of this work was to analyze brain electrical activity and cardiorespiratory rate of adult crayfish *Procambarus clarkii* in order to compare the dynamic of these variables in control conditions and after sleep deprivation. We used male animals in intermolt, synchronized to light-dark cycles 12:12. In cold anesthetized animals we implanted electrodes on deutocerebrum, both gills chambers and cardiac sinus. After two days of recovery, we recorded, simultaneously, behavioral and electrical activity during 8 continuous hours in two different conditions: 1. control and 2. after one hour of sleep deprivation. For behavioral records, we defined two body positions of the animal: walking and lying on one side, and associated each one with the time of recording. To analyze brain electrical activity and cardiorespiratory rate we used no-linear techniques. We found that brain electrical activity from control sleeping animals showed a decrease in power at 30 Hz, as compared to walking animals that had high power in the entire frequency band analyzed, 0-60 Hz. Sleep-deprived animals presented even lower power in all EEG frequencies even when they were allowed to sleep. Both conditions are accompanied by oscillations in cardiorespiratory frequency. To summarize, sleep deprivation modify the dynamic of brain electrical activity and cardiorespiratory regulation in crayfish.

Title: Standardized rice bran supplement enhances non-rapid eye movement sleep in mice through histamine H1 receptors

Authors: *M. UM[1,2], M. YOON[1], J. JUNG[1], J. LEE[1], S. CHO[3];
[1]Korea Food Res. Inst., Wanju, Korea, Republic of; [2]Univ. of Sci. & Technol., Daejeon, Korea, Republic of; [3]Pukyong Natl. Univ., Busan, Korea, Republic of

Abstract: We investigated the effect of rice bran on sleep and the mechanism underlying this effect. Electroencephalography was used to evaluate the effects of standardized rice bran supplement (RBS) and doxepin hydrochloride (DH), a histamine H1 receptor (H1R) antagonist used as a positive control, on sleep in mice. The mechanism of RBS action was investigated using knockout (KO) mice and ex vivo electrophysiological recordings. Oral administration of RBS and DH significantly decreased sleep latency and increased the amount of non-rapid eye movement sleep (NREMS) in mice. Similar to DH, RBS fully inhibited H1R agonist-induced increase in action potential frequency in tuberomammillary nucleus neurons. In H1R KO mice, neither RBS nor DH administration led to the increase in NREMS and decrease in sleep latency observed in WT mice. These results indicate that the sleep-promoting effect of RBS is completely dependent on H1R antagonism. RBS decreases sleep latency and promotes NREMS through the inhibition of H1R, suggesting that it could be a promising therapeutic agent for insomnia.

Title: Leptin increases postsynaptic NMDA receptor-mediated currents and synaptic throughput in LepR neurons of the NTS

Authors: *D. M. NEYENS, N. J. HUSTON, R. C. RITTER, S. M. APPLEYARD;
Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Leptin signaling within the nucleus of the solitary tract (NTS) is necessary for appropriate control of food intake and body-weight regulation. Injections of leptin into the NTS reduce meal size and increase the efficacy of vagus-mediated satiety signals to reduce food intake. Leptin receptors (LepRs) are expressed in both vagal afferents and in some NTS neurons, and loss of LepRs in either increases food intake and weight-gain. However, while selective knockdown of LepRs in NTS neurons induces hyperphagia and stimulates weight-gain in rats, LepR-expressing neurons of the NTS are not well-characterized and the mechanism by which leptin acts within the NTS to control food intake is unclear. Previous work from our lab has shown that NMDA-type glutamate receptors (NMDARs) help maintain the fidelity of vagal-NTS synaptic transmission, and our recent data suggests that NTS LepR neurons express larger NMDAR currents compared to other NTS populations. This is noteworthy since NMDARs are requisite mediators for excitatory actions of leptin in other brain regions, such as the hippocampus. To study electrophysiological outcomes of leptin in the NTS, we used patch-clamp techniques guided by LepR-Cre X Rosa-tdTomato fluorescence in a horizontal brain slice preparation that allows for stimulation of the vagus-containing solitary tract. We found that LepR neurons are located throughout most of the NTS, including regions known to be involved in control of food intake, and they receive both direct and indirect glutamatergic input following stimulation of the vagus-containing solitary tract. When compared to unlabeled NTS neurons, LepR neurons had comparable synaptic AMPAR currents but nearly two-fold larger NMDAR currents during a high frequency (50Hz) stimulus train ($p < 0.001$, two-way ANOVA). Interestingly, bath application of 100 nM leptin increased the size of evoked NMDAR currents in LepR neurons but not AMPAR currents (1.3 fold-change, $p < 0.001$, two-way ANOVA). Furthermore, leptin increased synaptic throughput from ~0.25 to above 1.0 ($p < 0.001$, two-way ANOVA) and total charge transfer (1.55 ± 0.21 fold increase; $p < 0.01$, Mann-Whitney) within fifteen minutes. These effects were blocked by NMDAR antagonists; either bath application of 10 uM DCPP-ene or including MK801 (1 mM) in the recording pipette to selectively block post-synaptic NMDARs. Finally, injection of a DCPP-ene (20 ng in 100 nl) into the NTS also blocked the effects of intra-NTS leptin on overnight food intake. Taken together, these findings suggest leptin decreases food intake by enhancing postsynaptic NMDAR function thus increasing the sensitivity of NTS neurons to vagal input.

Title: Role of selenium utilization in hypothalamic control of energy metabolism

Authors: *D. TORRES, M. W. PITTS, A. C. HASHIMOTO, M. J. BERRY;
Univ. of Hawai'i at Manoa Dept. of Cell and Mol. Biol., Honolulu, HI

Abstract: Selenium (Se), an essential trace element known mainly for its antioxidant properties, is critical for proper brain function and may also play an important role in whole-body energy metabolism. Dietary Se is incorporated into selenoproteins in the form of the unique amino acid selenocysteine (Sec), which requires its cognate selenocysteine-tRNA (Trsp) to be synthesized. Whole-body knockout (KO) of Sec lyase (Scly), a critical participant in selenium recycling, increases susceptibility to developing metabolic syndrome (MetS) in mice, a phenotype more strongly displayed by male mice. Scly KO mice also have decreased expression of several selenoproteins in the hypothalamus, a key regulator of energy homeostasis. The purpose of this project is to elucidate the mechanisms underlying the link between disrupted hypothalamic selenium utilization and the associated metabolic disturbances. Agouti-related peptide (Agrp)-positive neurons, which reside in the arcuate nucleus (Arc), are a nutrient-sensing hypothalamic sub-population that promotes positive energy balance. Resistance to the anorexigenic hormone leptin in Agrp neurons has been linked to energy dyshomeostasis and may result from oxidative stress. We generated a mouse line with Cre-driven Agrp neuron-specific Scly KO (Scly-Agrp KO mice) to determine the contribution of these neurons to the sexually dimorphic MetS phenotype observed in whole-body Scly KO mice. Unexpectedly, Scly-Agrp KO mice had decreased body weight and adiposity as well as heightened sensitivity to glucose compared to controls when fed a high-fat diet. While control mice displayed leptin resistance in the Arc, a known consequence of a high-fat diet regimen, Scly-Agrp KO mice maintained sensitivity to leptin. While no changes in food intake were observed, Scly-Agrp KO mice showed signs of increased brown adipose tissue thermogenesis. We also generated Trsp-Agrp KO mice to evaluate ablation of selenoprotein synthesis within these neurons. Female Trsp-Agrp KO mice had reduced body weight and higher levels of energy expenditure, while male mice exhibited no phenotype. This study sheds light on the important roles of Se utilization and selenoproteins in metabolic disease pathology, provides new information on the interplay between the central

nervous system and whole-body energy metabolism, and may help identify key targets of interest for preventative strategies or therapeutic treatments for metabolic disorders.

Title: A chemogenetic analysis of the nucleus solitary tract role in satiation

Authors: *K. GILLAND, E. A. FOX;
Dept Psychol Sci., Purdue Univ., West Lafayette, IN

Abstract: Excitation of cells during consumption of a meal in the caudal 2/3 of the nucleus solitary tract (cNTS) of the brainstem are thought to produce satiation. It is unknown how excitation of these cells inhibits feeding. A major obstacle has been the inability to selectively manipulate these cells without affecting intermixed cells that mediate other autonomic functions. Our method uses inducible, activity-dependent chemogenetics to test if artificial excitation of cNTS cells activated during satiation can reduce food intake, an effect that could help prevent or reverse obesity. Food intake was measured in 3-month old male and female c-Fos-tTA mice while maintained on standard chow for five days and were then switched to chow containing doxycycline (Dox). Mice increased their food intake over five days on Dox from regular chow ($p<0.05$), demonstrating mice will consume enough Dox throughout experiments and is likely not causing malaise in mice. c-Fos-tTA mice were injected with an AAV-hM_3D_qvirus into the cNTS. Mice were maintained on 40mg/kg Dox chow from the time of injection to prevent hM_3D_qreceptor expression until the start of the meal training. Mice were trained to eat a large meal (Fox, AJP Regu2013;305:11). Mice increased body weight and the daily large meal increased over the course of the meal training (both $p<0.01$). During the large meal training, 1/2 of the mice were taken off Dox which allowed for activation of the c-Fos promoter to produce tTA, and thus activated hM_3D_qexpression. Data demonstrated mice kept on Dox throughout meal training do not express the hM_3D_qreceptor. Mice taken off Dox through meal training expressed the hM_3D_q receptor in the cNTS. Clozapine-N-oxide (CNO) was administered at .8mg/kg to activate the hM_3D_q receptor and c-Fos expression was seen in a proportion of cells expressing the

hM_3D_q receptor. This suggests CNO activated cells expressing the hM_3D_qreceptor. Further behavioral experiments will be conducted to determine if the excitation of the cNTS cells by CNO will result in decreasedfood intake, thus confirming the role of these neurons in satiation, the first step in identifying, characterizing and determining how these neurons produce satiation.

Title: Leptin receptor activity in the nucleus of the solitary tract increases forebrain leptin sensitivity

Authors: *R. B. HARRIS;
Physiol., Med. Col. of Georgia, Augusta, GA

Abstract: We previously reported that fourth ventricle infusions of leptin that cause weight loss are associated with an increase in hypothalamic phosphorylation of signal transducer and activator of transcription 3 (pSTAT3), a marker of leptin receptor (ObRb) activation, implying an integrated response to central leptin. This study tested the impact of ObRb activity in the nucleus of the solitary tract (NTS) on sensitivity to leptin in the forebrain. Leptin-Saporin (Lep-Sap) injections were used to delete ObR-expressing neurons in the NTS of 300g male Sprague Dawley rats. Controls were injected with Blank-Saporin (Blk-Sap). Loss of NTS ObR was confirmed with RNAScope *in situ* hybridization and pSTAT3 response to peripheral leptin in representative Lep-Sap rats. Experimental rats were fitted with 3rd ventricle (3V) guide cannula 12 days after Lep-Sap or Blk-Sap injections. Nine days later cannula placement was tested with Angiotensin II and rats were adapted to calorimeter cages for 4 days. Lep-Sap had no effect on body weight. To test leptin responsiveness rats were food deprived for 5 hours and at 5 p.m. they received 3V injections of 0, 0.05, 0.1, 0.25 or 0.5 μg leptin. Food was returned at 6 p.m., the start of the dark period. Each rat received the injections in random order at 4 day intervals. At the end of the experiment NTS pSTAT3 was used to confirm efficacy of Lep-Sap injections. Seven Lep-Sap and 6 control Blk-Sap rats completed the experiment. There was a dose-dependent inhibition of food intake in Blk-Sap rats, but only 0.5 μg leptin inhibited intake of Lep-Sap rats. Intake was inhibited during the 24 hours following injection and was not compensated for so that cumulative intake was inhibited for 60 hours post-injection. Energy expenditure was not different between groups and respiratory exchange ratio tended to follow food intake. These data suggest that

leptin-induced inhibition of food intake is mediated by an integrated network involving both the forebrain and hindbrain and that activation of NTS ObRb lowers the threshold for leptin responsiveness in the forebrain.

Title: Consumption of dietary emulsifiers alters gene expression in the amygdala, paraventricular nucleus, and arcuate nucleus of mice

Authors: *A. R. ARNOLD, K. L. HUHMAN, B. CHASSAING;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: As obesity, inflammatory disease, and stress disorders continue to rise in western society, the assessment of factors contributing to the increase in these debilitating diseases becomes critically important. The western diet is one such factor contributing to the etiology of these disorders. Food additives, such as emulsifiers, are commonly added to highly processed western foods and have recently been shown to promote gut dysbiosis, low grade inflammation, metabolic disease and alterations in feeding and anxiety-like behavior in mice. However, very little is known about the impact of dietary emulsifiers on brain regions that modulate stress responses and feeding behavior. We investigated here the effect of two broadly used dietary emulsifiers, polysorbate 80 (P80) and carboxylmethycellulose (CMC), on gene expression in the amygdala, paraventricular nucleus, and arcuate nucleus of the hypothalamus using next generation RNA sequencing (RNA-Seq). RNA extracted from brain micro-punches of C57BL/6 male mice treated with 1% P80 or CMC in drinking water for 12 weeks were compared to regular water treated controls. As a quality control measure, quantitative polymerase chain reaction (qPCR) was performed on selected genes of interest to validate the RNA-Seq dataset on a new cohort of animals. Differential gene expression analysis revealed altered expression of immune regulatory genes in each brain area investigated, altered expression of HPA-axis regulatory genes in the amygdala and PVN, and altered expression of obesity-associated genes in the PVN and arcuate nucleus in emulsifier treated animals. Interestingly, P80 and CMC treatment affected different genes within each of these gene categories, suggesting that each

emulsifier acts through different molecular mechanisms to produce similar behavioral phenotypes. Altogether, these data reveal that these commonly used food additives may potentially negatively impact feeding and anxiety-like behaviors by modulation of gene expression in key brain areas. Abstract: Arcuate nucleus (ARC) has been involved in the regulation of feeding behavior and energy expenditure. It has been thought to be comprised of two main populations of neurons. NPY neurons are supposed to be orexigenic and their activation promotes food intake conversely to POMC neurons. In this work we sought to investigate the response of rat ARC neurons to leptin and glucose concentration changes. We used patch clamping methods and biochemical reagents in freshly dissociated neurons and brain slices. Leptin (30 nM) response in NPY/orexigenic neurons induces calcium current inhibition on specific L-type calcium channel population (~50%). Only the amplitude of the current is decreased indicating a lower number of calcium-conducting channels in the absence of kinetic changes. Interestingly, rapamycin diminishes leptin responses suggesting a mTOR-mediated pathway. Rapamycin has been shown to inhibit NPY and AgRP release in ARC neurons. On the other hand, low-glucose exciting neurons (LGE) exhibit higher firing frequencies, little adaptation and higher input resistance compared to low-glucose inhibiting (LGI) neurons. LGE neurons were labeled with an anti-NPY antibody indicating that they are NPY/orexigenic neurons. LGI neurons may represent anorectic POMC cells which are inhibited and excited with low and high concentrations of glucose, respectively. These results advance our understanding on the role of ARC in the modulation of food intake and energy homeostasis.

Title: AgRP neuronal disinhibition is driven by KCC2 dysregulation in obese mice

Authors: *A. C. KORGAN, W. WEI, K. C. GRAHAM, S. L. A. MARTIN, K. M. S. O'CONNELL;
The Jackson Lab., Bar Harbor, ME

Abstract: In the arcuate nucleus of the hypothalamus (ARH), neurons co-expressing the neuropeptides agouti-related peptide (AgRP) and neuropeptide Y (NPY) are essential for maintaining life by driving appetitive behavior and food intake. Consistent with their role in energy balance, their activity is tightly correlated with nutritional status: increased activity is associated with hunger while decreased activity is associated with satiety. AgRP neuronal activity responds quickly to food cues; this response does not require ingestion, suggesting there is strong “top-down” synaptic modulation of AgRP neurons. Our lab has demonstrated that AgRP neuronal activity is sensitive to diet, implicating high-fat diet (HFD)-induced plasticity and alterations to synaptic inputs to AgRP neurons as a potential causal factor in the development of obesity. We have shown that chronic HFD feeding was associated with a significant increase in inhibitory GABAergic input, suggesting an uncoupling of AgRP neurons from these inputs. Because the transporter KCC2 is required for the inhibitory action of GABAergic inputs, we hypothesized that aberrant KCC2 function may contribute to decreased GABA-mediated inhibition of AgRP neurons. Consistent with this, we found that the equilibrium potential of the $GABA_AR$-mediated Cl^- current was significantly depolarized in AgRP neurons from chronic HFD-fed mice. Further, the impact of optogenetic activation of inhibitory presynaptic inputs on inhibitory post-synaptic currents as well as pharmacological activation of KCC2 (CLP 257) or antagonism of NKCC1 (bumetanide) will elucidate the impact of diet on KCC2 efficacy in hyperpolarizing $GABA_AR$-mediated Cl^- currents. Ongoing work using RNAScope and scRNAseq will quantify transcriptional alterations of Cl^- transporters in arcuate neurons, including AgRP neurons. Further, we will validate AgRP disinhibition in intact, unperturbed neurons using *in vitro* imaging of genetically encoded voltage-sensors. Overall, we have shown that chronic HFD feeding is sufficient to reduce GABA-mediated inhibition in

AgRP neurons and that this disinhibition is linked to altered KCC2 functionality. Thus, obesity may result from failure of postsynaptic AgRP neurons to efficiently integrate incoming synaptic information following long-term HFD feeding.

Title: Relation of oxidative stress and phosphorylation of AMPK hypothalamic with the feeding behavior in diabetic rats

Authors: *J. M. MENDOZA-BELLO[1], M. I. BARRAGAN-BONILLA[1], Y. A. FLORES-CORTEZ[1], A. MILLAN-VEGA[2], B. ILLADES-AGUIAR[3], M. RAMIREZ[4], M. ESPINOZA-ROJO[1];

Abstract: Introduction. The AMP-dependent kinase (AMPK) is an important protein to regulate the energy balance in the body. In the hypothalamus, AMPK regulates signals that induce appetite and satiety. The increase in glucose level causes a high production of reactive oxygen species (ROS), which results in a state of oxidative stress (OS), an important factor for diabetic complications. At the level of hypothalamus little has been studied about the relationship between oxidative stress and its effect on phosphorylation of AMPK and food intake in animal models of DM. **Methodology.**To investigate this, Wistar rats were used, diabetes was induced with streptozotocin (60 mg/kg of BW). The animals were divided into 3 independent groups, 7, 14 and 28 days DM (7D, 14D and 28D) each with their respective control group (C). In each of the groups the increase in food intake was calculated (% of change) and at the end of each of the times, the hypothalamic tissue was extracted to evaluate the oxidative stress (malonaldehyde and the activity of glutathione peroxidase) by spectrophotometry , and the phosphorylation of AMPK by Western blot. **Results.**There was a significant increase ($p < 0.05$) in the consumption of food in the groups with DM in comparison with control group(C: 85%, 7D: 120%, 14D: 130%, 28D: 145%). We find that the MDA level decreased to 66%, in group 7D, but in the group 28D this level increased to 190%, these results are significant ($p < 0.05$) compared to group C. On the other hand, the activity of glutathione peroxidase was found to be increased in group 7D (170%) and decreased in group 28D (65%), both significant in comparison with group C.

Phosphorylation of AMPK increased significantly (p. <0.05) in group 28D (168%), compared to group C.**Conclusion.** At 7, 14 and 28 days of diabetic condition, the animals shown an increased in food intake, which is related with increases ofOS and phosphorylation of AMPK, in hypothalamus.

Abstract: Neuropeptide Y (NPY) and proopiomelanocortin (POMC) are neuropeptides expressed in the arcuate nucleus (Arc) of hypothalamus and play a key role in the control of food intake behavior by stimulating appetite or satiety, respectively. Arc is an area that integrates metabolic signals and thus regulates the glucose homeostasis. In diabetic models the hyperphagia is associated with increased NPY and decreased POMC expression level in Arc. It is known that hyperphagic behavior contributes to poor glycemic control. On the other hand, in diabetes the treatments with antioxidants can attenuate or improve several alterations including diabetic hyperphagia, however, it is not known if that effect is associated to changes in NPY and POMC expression levels in Arc. Therefore, the aim of this study was to evaluate the effect of curcumin on NPY and POMC expression in Arc of diabetic rats related to diabetic hyperphagia, blood glucose and oxidative stress markers. For this purpose, male Wistar rats two days old were injected with streptozotocin (70mg/kg bw), after weaning, they were supplemented with 10 % sucrose-sweetened-beverage for 4 weeks. At 10 weeks-of-age, diabetes was confirmed, and we administered the treatments: metformin [MET (100mg/kg)] and curcumin [CUR (50mg/kg)] for 28 days orally; we also included a pair feed group (PF). Food intake and body weight was measured daily, blood glucose and oxidative stress markers such as malondialdehyde (MDA),

carbonyl groups, glutathione peroxidase (GPx) and glutathione S tranferase (GST) enzymatic activity were evaluated at the end of the treatment. Finally, the rats were transcardiacally perfunded to obtain brain and detect NPY and POMC in Arc by immunofluorescence. In our study model, diabetic rats showed hyperglycemia, a low body weight gain, hyperphagia, and a tendency to increase GPx activity and MDA level in blood. In addition, they showed a high NPY and a low POMC level expression in Arc. After 28 days of treatment, MET was incapable to reduce blood glucose, while CUR and PF caused a decreased in blood glucose of diabetic rats. On the other hand, treatment with CUR diminished MDA level in blood. In relation to food intake, none treatment was able to avoid the diabetic hyperphagia, however, our preliminary results showed that treatment with MET and CUR in diabetic groups induced changes in NPY and POMC expression level in Arc, we observed a low and increase of these neuropeptides, respectively. These results suggest that a chronic treatment with CUR could attenuate diabetic hyperphagia in rats and probably it will be related to changes in NPY and POMC expression in Arc.

Title: Sexual dimorphism in the onset of diet-induced obesity is dependent on AgRP-neuronal excitability

Authors: *K. C. GRAHAM, A. C. KORGAN, W. WEI, S. L. A. MARTIN, K. M. S. O'CONNELL;
The Jackson Lab., Bar Harbor, ME

Abstract: The hypothalamus contains several sexually dimorphic nuclei that have clear structural and functional differences between males and females. One such sexually dimorphic area is the arcuate nucleus, which is essential for the control of energy homeostasis and feeding behavior. When activated under normal feeding conditions, neurons expressing agouti-related peptide (AgRP) in the arcuate nucleus respond to peripheral cues of negative energy balance to elicit food-seeking behavior and are then rapidly suppressed once food is presented. In contrast, our laboratory has shown that when male mice are fed an obesogenic diet, regardless of the

length of time on the diet, AgRP neurons in the arcuate rapidly and persistently increase in intrinsic excitability, suggesting that the diet itself may reinforce hyperphagia and promote the development of obesity. Here, we show that, in females, AgRP neurons also increase in excitability in response to high-fat diet (HFD) but not as rapidly or persistently as in males with female mice being more resistant to development of obesity and leptin insensitivity. Additionally, when we measured synaptic inputs to AgRP neurons following long-term HFD we observed an increase in inhibitory post-synaptic current frequency that is consistent with what we find in neurons from male mice; however, unlike in males, there is no shift in the reversal potential of GABA-evoked Cl^- current in AgRP neurons from female mice, suggesting that Cl homeostasis and synaptic signaling mechanisms remain intact in response to HFD exposure. Taken together, these data suggest a potential compensatory mechanism in female AgRP neurons for control of feeding behavior and energy homeostasis that contributes to resistance to diet-induced obesity. Ongoing research will utilize RNA-sequencing techniques to examine the potential for gene or pathway expression that may elucidate this compensatory mechanism.

Title: Elevated dietary sucrose consumption induces AgRP neuronal circuit dysregulation and leptin resistance without altering body weight

Authors: A. C. KORGAN[1], K. ABREU[3], K. GRAHAM[1], W. WEI[1], S. L. A. MARTIN[2], *K. M. S. O'CONNELL[2];
[1]Res., [2]The Jackson Lab., Bar Harbor, ME; [3]Superior Inst. of Biomed. Sci., State Univ. of Ceara, Fortaleza, Brazil

Abstract: The role of agouti-related peptide (AgRP) expressing neurons has been well documented in the context of hunger, satiety, and response to metabolic stress (e.g. fast, high-fat diet). However, the response of AgRP neurons to long-term increases in dietary sucrose, independent of increased dietary fat have not been detailed. While this neuronal population has a canonical role in appetitive behavior, it also serves as a regulator of fat deposition, substrate utilization, and nutrient partitioning. We previously reported that consumption of a high-fat diet

was associated with hyper-excitability of AgRP neurons and subsequent alterations to feeding behavior. In the current study, we aimed to examine the effects of long-term sucrose consumption on AgRP neuronal excitability and synaptic dynamics in addition to changes in peripheral metabolic phenotypes and behavior. Sucrose was provided via the drinking water while feeding the identical diet as controls. We found that similar to mice fed a high-fat diet, AgRP neuronal excitability was increased despite an increase in the frequency of inhibitory synaptic inputs. Further, we found that AgRP neurons from sucrose-fed mice were leptin-resistant. However, unlike HFD, acute sucrose consumption had no effect on AgRP neuronal excitability. Thus, the deleterious effects of sucrose consumption may be related to a non-canonical role of AgRP neurons and/or feedback from peripheral consequence of chronic sucrose consumption, as body weight was not increased after 14 weeks of sucrose consumption despite impairments in both glucose and insulin tolerance. Ongoing work will examine the pattern and penetrance of AgRP dendritic outputs and the effects that these have on feeding behaviors. Altogether, these results suggest that AgRP neurons are involved in mediating specific, diet-dependent, alterations and future studies will focus on circuit specific effects of diet manipulation on metabolic and behavioral outcome.

Abstract: Negative sensory feedback from the digestive tract to the brain is critical for limiting food and water intake. Mechanosensory detection of ingesta is a major source of the signaling, but the underlying gut-brain communication pathways and mechanisms for reducing appetite remain unclear. Here we identify an excitatory subpopulation in the parabrachial nucleus as a key circuit node for mechanosensory monitoring and feedback control of ingestion. By recording calcium dynamics in vivo, we show that the neurons respond to the intake of either fluids or solids regardless of the composition, and the response strength scales with the ingestion rate. Furthermore, this population is activated by mechanical stimuli applied to any parts of the upper digestive tract, but not modulated by taste, osmolality or temperature of ingesta. Activating these neurons suppresses both feeding and drinking, by transmitting sustained negative-valence signals that discourage the initiation of intake bouts. In contrast, inhibiting the same population induces pathological overconsumption, only if a drive for ingestion exists, signifying that these neurons transmit negative feedback signals. Together, our findings provide a neural mechanism underlying mechanosensory monitoring of ingestion and inhibition of intake behaviors upon aversive digestive tract distension.

Title: Modulation of hypothalamic hunger circuits by an ascending catecholamine pathway

Authors: *D. ATASOY[1], I. AKLAN[1], N. SAYAR[1], Y. YAVUZ[2];
[1]Univ. of Iowa, Iowa City, IA; [2]Yeditepe Univ., Istanbul, Turkey

Abstract: Hunger is a hard-wired behavioral state essential for survival. Hunger sensitive agouti-related protein (AgRP)-expressing neurons of arcuate hypothalamic nucleus (ARC) play central role in feeding, yet the signals that modulate AgRP neuron activity are poorly understood. We discovered that tyrosine hydroxylase (TH)-expressing neurons from nucleus of solitary tract (NTS) project densely to the hypothalamus, and their local activation elicit voracious feeding through bidirectional regulation of AgRP and proopiomelanocortin (POMC)-expressing neurons. Neuroanatomical tracing results suggested that ARC projecting orexigenic NTS^{TH} neurons comprise a largely distinct subpopulation than those parabrachial nucleus (PBN)-projecting anorexigenic NTS^{TH} neurons. Finally, optogenetic and chemogenetic analyses showed that

norepinephrine (NE)-signaling from NTS^{TH} terminals in the ARC is critical for appetite stimulation. Collectively, we describe a circuit organization in which an ascending neuromodulatory pathway from brainstem coordinates key appetite neurons in hypothalamus for rapid regulation of hunger.

Title: Effects of vagotomy and lesions of the area postrema on nausea induced by tranexamic acid

Authors: *M. FUJITA, Y. HIRAI, K. HISADOME, M. FUNAHASHI;
Hokkaido Univ., Hokkaido, Japan

Abstract: The aim of the present study is to clarify the mechanism of emetogenic effects of tranexamic acid (TXA) that is offen used as an drug for accidental ingestion of animals in the field of veterinary medicine. TXA is an artificial amino acid that can block the binding of plasmin and plasminogen to fibrin. Therefore TXA is well known as antibleeding, antiallergic and anti-inflammatory drugs. However, we can not explain the mechanism of emetogenic effects of TXA based on the antiplasmin activity. To investigate the details of TXA-induced nausea, we performed the following experiments. Male Sprague Dawley rats (body weight 200~350 g) were used as experimental animals. Since rats are animals that do not vomit, conditioned taste aversion (CTA) was used as an index for evaluating the presence or absence of nausea. 0.1% saccharin was used as a conditioned stimulus, nausea induced by TXA injection (1.5g/kg, 15 ml/kg, i.p.) was used as an unconditioned stimulus. CTA to saccharin was evaluated using the 1-bottle method. Experimental period was for 15 days with same daily cycle of scheduled drinking and voluntary feeding. The training period was the first 7 days (day 0~6). The conditioning was performed at day 7. After recovery period at day 8, saccharin intake was measured at day 9~14. The scheduled drinking protocol consists of water deprivation for 20 h, voluntary drinking for 20 min (measurement period), water deprivation for 40 min, and voluntary drinking for 3 h. On the conditioning day, rats had a first chance of saccharin intake for 20 min instead of distilled water and the saccharin intake obtained this day was used as a control value. We performed measurement of CTA in 3 groups: rats received no operation (control), bilateral subdiaphragmatic vagotomy (VX), and lesions of the area postrema (APX). Saccharin intake was significantly reduced in the control and the VX on the day 9~10 as compared to the conditioning day, indicating that both groups acquired CTA for saccharin as a result of induction of nausea by

TXA. CTA acquisition was suppressed in 2 cases in the APX. These results suggest possible role of the area postrema neurons in the mechanism for inducing nausea by TXA.

Title: Impact of early life gut microbial environment on energy homeostasis, vagal development, and CCK-induced satiety

Authors: *A. K. KAMITAKAHARA[1], V. MAGALONG[1], P. R. LEVITT[1,2];
[1]Children's Hosp. Los Angeles, Los Angeles, CA; [2]Keck Sch. of Medicine, Univ. of Southern California, Los Angeles, CA

Abstract: The vagus nerve directly connects the brain and gastrointestinal tract and is able to sense and fire action potentials in response to microbial signals. However, a critical knowledge gap exists in understanding whether early life microbiome disruption affects vagal development and metabolic function. To this end, we used a mouse model of perinatal antibiotic exposure: [1)] control mice receiving no antibiotics, [2)] mice receiving penicillin 1 week prior to birth through the end of the study (ABX^{Life}), and [3)] mice receiving penicillin 1 week before birth through 4 weeks of age, after which they were maintained on water with no antibiotics (ABX^{Early}). At 12 weeks of age, ABX^{Life} mice (male mean 24.363g, SEM 0.639g; female mean 19.080g, SEM 0.675) tended to weigh less than control mice (male mean 26.837g, SEM 0.907g; female mean 20.528g, SEM 0.270), while ABX^{Early} mice (male mean 28.896g, SEM 0.478g; female mean 21.855, SEM 0.303) tended to weigh more. In addition, body composition analysis revealed that both ABX^{Life} and ABX^{Early} mice exhibited a trend toward increased fat mass compared to controls. To exacerbate these differences in body weight and body composition, a separate cohort of mice underwent the same antibiotic treatment paradigm, followed by weaning onto a high-fat diet. Interestingly, both the differences in body weight and body composition were mitigated by high-fat diet exposure. To assess vagal signaling in early life, control and antibiotic treated pups were injected with choleocystokinin (CCK) on postnatal day 7. CCK is secreted by enteroendocrine cells in the gut and acts largely through the vagus to signal satiety to the central nervous system. Control pups exhibited a robust CCK-induced cfos neuronal activation response in the nucleus of the solitary tract, where vagal afferents connect. In contrast, pups receiving antibiotics exhibited blunted CCK-induced cfos responses, suggesting that satiety signaling via

the vagus nerve may be impaired developmentally. Increased sample number is required to demonstrate statistical significance, but these preliminary data suggest that early life antibiotic exposure may impair vagal afferent signaling of satiety.

Title: Atlas-based spatial analysis of rat hindbrain regions that display rapid activation in association with glycemic challenge

Authors: *G. P. TAPIA[1], L. J. AGOSTINELLI[2,3], S. D. CHENAUSKY[1], J. BARNES[1], D. D. MOLINA[1], A. M. KHAN[1,2];

Abstract: It has been hypothesized that hypoglycemia unawareness may result, in part, from a failure of hindbrain glucosensing neurons to respond effectively to changes in circulating glucose. Subpopulations of hindbrain-originating epinephrine and norepinephrine neurons are necessary to prompt the glucose counterregulatory response (CRR) that protects against hypoglycemic conditions, but the precise atlas-based distribution of glucosensing neuronal populations remains unclear. To assess this distribution, hindbrain regions were re-examined carefully in glucoprivic (2-deoxyglucose, 250 mg/kg, i.v.) and control rats that had been previously processed to identify single- and double-labeled neurons using antibodies against phospho-ERK1/2 (phosphorylated forms of MAP kinase), dopamine β-hydroxylase, and choline acetyltransferase. Wide field epifluorescence images of these immunlabeled tissue sections were aligned with those of an adjacent series of Nissl-stained tissue that served as a cytoarchitectural reference, enabling the data to be mapped to a rat brain atlas (Swanson, *Brain Maps 4.0*, 2018). In glucoprivic animals, we had previously found increased cellular activation in hindbrain noradrenergic and cholinergic regions, suggesting that activation of these areas may be associated with rapid responses to glycemic challenge. Our new mapping analysis shows that, in the anterior hindbrain (e.g., Swanson Atlas Levels (L) 46-53), phospho-ERK1/2+ neurons were distributed in the locus ceruleus, subceruleus, and parts of the parabrachial nucleus. More

caudally (e.g., L54-62), activation was observed in cholinergic cell groups and in the vicinity of the facial nucleus and ambiguus nucleus. At the most caudal hindbrain atlas representations (e.g., L69-72) activation was observed in the nucleus of solitary tract and near the central canal. These initial atlas assignments are a critical step for our ongoing atlas-based mapping of hindbrain glucosensing regions and will facilitate more precise targeting of neural circuitry related to glucosensing in the future.

Title: Examining the effect of antibiotic treatment on emotional health: Comparable findings in rats and humans

Authors: *M. E. GLOVER[1], I. A. KERMAN[2], S. M. CLINTON[1];
[1]Neurosci., Virginia Tech. Univ., Blacksburg, VA; [2]Carilion Clin., Roanoke, VA

Abstract: Gastrointestinal disorders are highly comorbid with emotional disorders such as Major Depression, and changes within the gut microbiome have been linked to a variety of brain disorders. Gut microbiota are essential for healthy gastrointestinal function, but also broadly influence organismal health through effects on the immune and central nervous systems. Several environmental factors can influence microbiome composition, including stress exposure and treatment with drugs such as antibiotics. Stress has well-known negative impacts on emotional behavior and recent evidence suggests that antibiotics, although widely prescribed, may also negatively affect mental health. To further investigate the potential relationship between antibiotic use and altered emotional behavior, we first conducted a study where experimental rats that were bred for emotional behavior differences were treated with antibiotics. High Novelty Responder (HR) / Low Novelty Responder (LR) rats were selectively bred based on their locomotor response in a novel environment. Breeding for this trait behavior leads to consistent behavioral differences in rodent emotionality. HRs exhibit increased aggression, impulsivity, and proclivity to take drugs of abuse while LRs exhibit high levels of anxiety-like behavior, passive stress coping, and susceptibility to chronic stress. Because it was unknown whether HR/LR rats exhibit differences in microbe communities, we used 16S rRNA sequencing to compare the microbiome of HR and LR rats. At baseline, adult HR and LR rats did not exhibit microbiome

differences; however, treating them with broad-spectrum antibiotic cocktails reduced microbe community diversity and exacerbated some of their behaviors, including increasing anxiety-like behaviors in LRs and active coping in both rat strains. These findings prompted us to investigate whether antibiotic use in a human population also increases the risk of mental illness as few population-based studies have interrogated this relationship. To do so, we conducted retrospective studies of patient electronic medical records in the TriNetX database to determine if antibiotics were associated with an increased risk of new mental illness diagnoses. We hypothesized that antibiotic treatment may lead to an increased risk of new mental illness diagnoses. In this analysis, we first investigate the risk associated with 1) any antibiotic class or 2) specific classes with various mental health diagnoses including MDD, anxiety disorders, Bipolar Disorder, and Schizophrenia. The results of this study will help elucidate the relationship between antibiotic-induced dysbiosis and mental health.

Title: Relationship between vagus nerve spikes and physiological signals of central and peripheral organs in a freely moving rat

Authors: *T. OKONOGI[1], Y. SHIKANO[2], Y. NISHIMURA[1], A. YAMANAKA[3], Y. IKEGAYA[1], T. SASAKI[1,4];

Abstract: The vagus nerve serves as a major pathway for communication between the central and peripheral organs. Despite traditional knowledge of vagus nerve functions, detailed neurophysiological dynamics of the vagus nerve in naïve behavior remain to be understood. In this study, we developed a method to record spiking patterns from the cervical vagus nerve while simultaneously monitoring central and peripheral organ bioelectrical signals in a freely moving rat. When the rat transiently elevated its locomotor activity, the frequency of vagus nerve spikes correspondingly increased, which was retained for several seconds after an increase in running speed. During high frequency sniffing behavior, vagus nerve spikes were nearly absent. During

stopping behavior, the vagus nerve spike patterns varied depending on external contexts and peripheral activity states associated with cortical arousal levels. Electrical stimulation of the vagus nerve altered rat's running speed and cortical arousal states depending on running speed. These observations represent a new step to uncover the physiological dynamics of the vagus nerve modulating the visceral organs such as cardiovascular, respiratory, and gastrointestinal systems. In addition, we recently developed a method to activate vagal afferent or efferent fibers by using a transgenic mouse line in which channelrhodopsin2 is selectively expressed in a fiber specific manner. We present preliminary data showing how photoactivation of these fibers could alter emotion and memory function.

Title: Altered spinophilin interactions in the hypothalamus and pancreas of a leptin receptor mutant (db/db) model of obesity

Authors: *K. C. STICKEL[1], D. S. WATKINS[2], A. J. BAUCUM II[3];
[1]IUPUI, Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Biol., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Spinophilin is a multi-domain scaffolding protein that targets protein phosphatase 1 (PP1) to myriad downstream signaling proteins in order to modulate synaptic activity. Little is known about how spinophilin acts in both neuronal and non-neuronal cell types, such as the arcuate nucleus and beta cells of the pancreatic islets, to modulate feeding and glucose homeostasis. Previous studies established that spinophilin KO mice have decreased fat mass and increased lean mass and improved glucose tolerance. Yet, how spinophilin acts in specific cell types to modulate the above metabolic parameters is unclear. In addition to its high expression in the brain (and expression in feeding centers of the brain such as the hypothalamus), we observed spinophilin expression in mouse pancreas. Using proteomics-based approaches we identified multiple putative spinophilin interacting proteins isolated from intact pancreas, including: PP1, the spinophilin homolog neurabin, and myosin-9. We have found that the associations of PP1, neurabin, and myosin-9 with spinophilin were regulated in obese, *db/db* mice as early as 6 weeks. We have also found associations of spinophilin, neurabin, myosin 9, and PP1 in isolated

pancreatic islets and are currently delineating if the alterations in interactions are occurring specifically in islets. Ongoing studies are utilizing a recently developed *floxed* spinophilin mouse line to delineate if loss of spinophilin in pancreatic beta cells specifically improves whole body glucose tolerance and if loss of spinophilin expression in AgRP neurons of the hypothalamus inhibit feeding behaviors.

Title: Excitation and inhibition of limbic corticotropin releasing factor neurons modulates motivation

Authors: *H. M. BAUMGARTNER[1], L. L. HUERTA SANCHEZ[1], J. SCHULKIN[2], K. C. BERRIDGE[1];
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Neurosci., Georgetown Univ., Washington, D.C., DC

Abstract: Corticotropin releasing factor (CRF) is known as the brain's master stress molecule, but also plays a role in reward seeking. Previous pilot work from our lab suggested that optogenetic excitation of CRF neurons in either nucleus accumbens (NAc) or central nucleus of amygdala (CeA) of CRH-Cre rats can amplify and bias incentive motivation to earn and consume natural sucrose rewards, an appetitive motivation effect similar to optogenetic stimulation of general neuronal populations in CeA. By contrast, we find that stimulation of CRF neurons in bed nucleus of stria terminalis (BNST) causes rats to avoid the laser-paired sucrose option and instead choose the alternative sucrose-alone option, and in a progressive ratio task suppresses motivation to work for sucrose rewards. Here, we assess whether optogenetic inhibition of CRF neurons in these areas through halorhodopsin oppositely has negative-valence effects on motivation, causing rats to avoid the NAc or CeA CRF neuron laser-paired sucrose option, while rats receiving BNST CRF neuron inhibition may prefer this laser-paired option. Additionally, we will assess whether CRF neuron laser-inhibition alone will have negative- or positive-valence effects through self-stimulation tasks, and whether CRF neuron excitation can

similarly influence motivation for other salient stimuli (i.e., intravenous cocaine rewards or aversive shocks). Together, these data suggest that CRF neurons in NAc or CeA can focus and influence incentive motivation for natural rewards, whereas BNST CRF neurons may suppress incentive motivation or have aversive effects.

Title: Comparing reward roles of D1 neurons vs D2 neurons in accumbens and amygdala

Authors: *S. ABTAHI[1], E. M. RODBERG[2], K. C. BERRIDGE[1];
[1]Dept. of Psychology, [2]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: Dopamine projections reach mostly separate populations of medium spiny neurons (MSNs) expressing either D1 receptors or D2 receptors within striatal-like structures. Here we sought to examine the role in reward motivation of D1 MSNs and D2 MSNS in the medial shell of nucleus accumbens (NAc) and in the central nucleus of the amygdala (CeA), which shares some striatal features. Past work on D1-Cre or D2-Cre mice found both mice will work for optogenetic channelrhodopsin (ChR2) laser self-stimulation in NAc shell (Cole et al., 2018). However, D2-Cre results are complicated by the fact that D2 receptors are also expressed by acetylcholine neurons in NAc. Here we compared a D1-Cre line to an A2-Cre line of rats, both developed by C. Ferrario and J. Berke labs. Adenosine-2 (A2) receptors are co-expressed by NAc or CeA MSNs that have D2 receptors, but acetylcholine neurons lack A2 receptors. Thus, an A2-Cre approach may more more selectively target D2 MSNs in NAc or CeA than a D2-Cre approach, for better comparison to D1 MSNs. Our preliminary self-stimulation results using D1-Cre rats indicates robust levers laser self-stimulation of D1 MSNs can be obtained in both medial shell of NAc and in CeA. Our results so far on A2-Cre rats indicate at least moderate levels of positive laser self-stimulation of D2 MSNs in NAc shell, and possibly also in CeA, can similarly be obtained. This supports the hypothesis that selective excitation of D2 MSNs, as well as of D1 MSNs in NAc or CeA, can support positive reward motivation at least under some conditions.
Note: We thank Carrie Ferrario and Joshua Berke for allowing us to use their lines of D1-Cre and A2-Cre rats.

Title: Cortical optogenetic stimulation of 'liking' and ventral pallidum inhibition for 'disgust'

Authors: *I. MORALES, K. C. BERRIDGE;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Research in our lab has identified a number of hedonic hotspots that can magnify the hedonic impact, or 'liking' reactions to a taste sensory stimulus. These generators of intense pleasure are small subregions in nucleus accumbens (NAc), ventral pallidum (VP), parabrachial nucleus (PBN), orbitofrontal cortex (OFC), and insula where microinjections of mu-opioid or orexin receptor agonists causally amplify orofacial reactions to sucrose by 200-300%. Of the known hedonic hotspots, the ventral pallidum appears to be especially important for normal hedonic function. It's the only known structure where lesions or temporary inactivations generate intense disgust so that even normally 'liked' sucrose becomes 'disgusting'. Here we study brain causation of 'liking' and 'disgust' reactions using optogenetics by directly controlling the activity of neurons within the hedonic hotspots in anterior medial orbitofrontal cortex, posterior insula, and caudal ventral pallidum. We excited neurons in cortical hotspots, and conversely inhibited neurons in the ventral pallidum. Optogenetic excitation of neurons in anterior-medial OFC hotspot and posterior insula hotspot amplified 'liking' reactions to sweet taste and increased consumption of palatable M&M candies. However, posterior insula, but not OFC stimulation appears to be rewarding on its own and supported laser self-administration as a reward on its own for some animals. We also inhibited neurons ventral pallidum using the inhibitory chloride conducting opsins SwiChR++ and iC++ and tested animals on taste reactivity, food intake, and conditioned place preference tasks. We found optogenetic inhibition of the posterior ventral pallidum may simultaneously reduce hedonic 'liking' reactions to a neutral water taste stimulus and increase negative 'disgust' reactions to both water and bitter quinine. The same optogenetic manipulations also decreased palatable M&M intake, and promoted avoidance of a laser-paired compartment in a conditioned place-avoidance test. Overall, our results suggest that both cortical and subcortical structures are important for generating intense

positive and negative affective responses to taste stimuli. Our experiments may extend our understanding of hedonic dysfunction in psychiatric affective disorders.

Title: Optogenetic excitation of the ventral pallidum and lateral hypothalamus promotes 'wanting' but only the posterior ventral pallidum enhances 'liking'

Authors: *J. J. OLNEY[1], D. C. CASTRO[2], K. URSTADT[3], A. A. KOTIAN[1], K. C. BERRIDGE[1];
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Anesthesiol., Univ. Of Washington, Seattle, WA; [3]Dept. of Cognitive Sci., Occidental Col., Los Angeles, CA

Abstract: The ventral pallidum (VP) and lateral hypothalamus (LH) are subcortical structures whose connectivity with other limbic circuitry makes them ideally positioned to influence reward-related behaviors. Accordingly, previous studies have demonstrated that pharmacological excitation of these areas can enhance food 'wanting' (motivation). Although early investigations implicated the LH in modulating 'liking' (pleasure), subsequent examinations have revealed that only the neighboring posterior VP (pVP), not the LH, contains an opioid/orexin hedonic 'hotspot' that mediates 'liking' enhancements. The aim of the present study was to extend upon earlier neurochemical findings by investigating if direct optogenetic depolarization of the LH, VP, or LH neurons projecting to the pVP (LH-VP) via channelrhodopsin under a nonspecific neuronal promoter (hSyn-ChR2) enhances 'wanting' and 'liking' toward a natural reward. Additionally, we sought to identify the neurochemical mechanisms of VP 'wanting' enhancements using GAD-Cre rats with a Cre-inducible ChR2 virus to selectively target GABAergic neurons of the VP. Findings thus far indicate that hSyn-ChR2 photoexcitation at all sites across the VP is able to amplify and focus incentive motivation for a sucrose reward. Similar excitation of LH or LH-VP projections failed to impact sucrose 'wanting'. However, VP, LH, and LH-VP hSyn-ChR2 stimulation increased food intake. Additionally, laser self-stimulation in the absence of an external reward was reinforcing in only some VP and LH rats.

What is more, activation of the pVP via hSyn-ChR2 enhanced 'liking' reactions to oral sucrose whereas similar excitation of the aVP may suppress 'liking' reactions. Interestingly, although laser stimulation of the LH did not alter 'liking' reactions, stimulation of LH-VP neurons amplified 'liking'. Finally, selective stimulation of GABAergic neurons of the VP in GAD-Cre rats similarly amplified and focused incentive motivation for a sucrose reward, but did not enhance food intake. Photoactivation of VP GABA neurons in these rats promoted robust laser self-administration. Together, these data confirm previous findings that 'wanting' is widely distributed throughout the brain while substrates that mediate 'liking' are restricted to a few subregions.

Title: Dangerous desire: Paired central amygdala photostimulation can turn fear into desire

Authors: *E. E. NAFFZIGER[1], S. M. WARLOW[3], K. C. BERRIDGE[2];
[2]Psychology, [1]Univ. of Michigan, Ann Arbor, MI; [3]Neurosciences, Univ. of California San Diego, La Jolla, CA

Abstract: Here we show that pairing optogenetic stimulation of central amygdala (CeA) in rats with an electrified "shock" rod that delivers shocks to paws or snout when touched turns fearful defensive burying into attracted approach. In this experiment, rats received bilateral stimulation each time they were within 2 cm of the electrified shock rod protruding into the Plexiglas chamber. While control rats contacted the electrified rod at least once and then avoided or buried the rod, rats with the excitatory opsin, channelrhodopsin (ChR2), repeatedly approached, sniffed, touched or even chewed on the rod, receiving repeated shocks. Furthermore, in a test of conditioned reinforcement in which rats could work for an auditory cue previously paired with shock rod encounters (CS+), CeA ChR2 rats worked on a nosepoke task to earn their shock rod associated CS+. In additional follow-up experiments, it was found that systemic dopamine injections of flupentixol suppressed CeA ChR2 shock rod attraction and CeA ChR2 rats were also willing to overcome an experimenter-imposed obstacle to access the rod when occluded. Histological analyses of distant c-fos indicated that mesocorticolimbic circuitry was activated

during CeA ChR2 shock rod attraction. These data emphasize a role of CeA in transforming even a fear-evoking stimulus into an incentive via recruitment of mesolimbic circuitry.

Title: Cortico-striatal circuits mediate compulsive behavior in schedule-induced polydipsia

Authors: *T. ARBAB[1,2], D. DENYS[2], I. WILLUHN[1,2];
[1]Netherlands Inst. For Neuroscience, Royal Netherlands Acad. of Arts and Sci., Amsterdam, Netherlands; [2]Dept. of Psychiatry, Amsterdam UMC, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Compulsive behavior is implicated in psychiatric aberrations such as addiction and obsessive-compulsive disorder, and is characterized by excessive, repetitive actions that persist despite adverse consequence. Dysregulation of cortico-striatal neural circuits correlates with symptom severity. However, the specific contributions of the underlying neural mechanisms remain elusive, and the efficacy of current treatment is limited. Thus, it is imperative to study the specific contribution of cortico-striatal circuits to compulsive behavior.
We employ schedule-induced polydipsia (SIP), a rat model of escalated drinking, to study how cortico-striatal circuits mediate the development and expression of compulsive behavior. In SIP, food-restricted rats are placed daily in an operant box, where they are presented food pellets at a time interval, with free access to water. In between pellet deliveries, some rats develop excessive water consumption (high drinkers), whereas others do not (low drinkers). Water intake is quantified as a measure of compulsivity.
We find that lesions of the prefrontal cortex escalate acquisition and elevate expression of excessive drinking in SIP, which suggests that under normal circumstances, these regions exert control over compulsivity. Preliminary data shows that excessive drinking in lesioned animals is reflected in their affective self-reports (ultrasonic vocalizations). Additionally, we find excessive drinking in SIP is modulated by glutamate signaling and affected by behavioral manipulations that alter the motivational state of the rat. Finally, high-drinking animals maintain their excessive drinking throughout experimental manipulations that link adverse consequences water intake. All

these effects are specific to compulsive drinking in SIP, without affecting general activity or homeostatic drinking of the animals.
We pursue these initial observations of cortico-striatal mediation of compulsive behavior in SIP with multi-tetrode recordings in freely moving rats during this paradigm, characterizing the underlying single unit and local field activity in cortex and striatum. Altered function of these circuits in high-drinking animals identifies neural substrates of compulsivity as potential targets for treatment.

Title: Neurostructural substrates underlying dispositional optimism in late adolescence

Authors: *H. L. LAI, S. WANG, Q. GONG;
Huaxi MR Res. Ctr. (HMRRC), Chengdu, China

Abstract: As a hot subject for positive psychology researches, dispositional optimism reflects one's generalized positive expectancies for future outcomes, and has been considered to be closely related to personal life outcomes and health. However, the neurostructural substrates underlying dispositional optimism in adolescents remains large unknown. Here, to examine this issue, we conducted a whole-brain voxel-based morphometry (VBM) study to identify neuroanatomical basis of dispositional optimism in 231 healthy adolescents and explored whether extraversion could be an essential personality factor for dispositional optimism development via mediation analysis. Specifically, behavioral measures, including Revised life orientation test (LOT-R), NEO Five-Factor Inventory (NEO-FFI) and Raven's advanced progressive matrix (RAPM), were first employed to obtain each participant's dispositional optimism, extraversion and general intelligence score. Then, MRI data of each participant was collected and processed. To identify brain gray matter correlates of dispositional optimism, whole-brain multiple regression analyses were performed and revealed that dispositional

optimism was positively associated with rGMD in the bilateral putamen (left putamen: $r = 0.28$, $p < 0.001$; right putamen: $r = 0.25$, $p < 0.001$). No other significant cluster was identified. Moreover, to investigate whether the identified optimism-related brain regions were stable and robust, prediction analyses using machine-learning approach were performed and showed that dispositional optimism was reliably predicted by the rGMD in the left putamen [$r_{(predicted, observed)} = 0.25$, $p < 0.001$] and the right putamen [$r_{(predicted, observed)} = 0.21$, $p < 0.001$]. More importantly, to explore whether extraversion could explain the effect of brain anatomy on dispositional optimism, a mediation analysis was conducted and showed that extraversion independently played an important mediating role in the association of rGMD of the putamen with dispositional optimism. Additionally, all findings remained significant even when removing the effect of nuisance covariates including gender, age, general intelligence and total gray matter volume. Taken together, the current findings provide a fresh evidence for neurostructural basis of dispositional optimism, demonstrating that the putamen may be a pivotal neuroanatomical site linking extraversion to dispositonal optimism, and give fresh light on the selection of targeted brain regions for dispositional optimism interventions.

Title: Deep-brain stimulation of the internal capsule has distinct effects on neuronal activity in different nodes of cortico-striatal circuits

Authors: *B. J. G. VAN DEN BOOM[1,2], A. ALONSO-ANDRES[1], D. DENYS[2], I. WILLUHN[1,2];
[1]Netherlands Inst. For Neuroscience, Royal Netherlands Acad. of Arts and Sci., Amsterdam, Netherlands; [2]Dept. of Psychiatry, Amsterdam UMC, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Obsessive-compulsive disorder (OCD) is characterized by obsessions (unwanted thoughts) and compulsions (repetitive, stereotyped behaviors), and is often accompanied by anxiety. Aberrant activity in cortico-striatal circuits is considered a neural correlate of OCD. Some evidence indicates that normal cortico-striatal function can be restored in otherwise treatment-resistant patients using deep-brain stimulation (DBS) of the internal capsule (IC).

Here, we examined the effects of DBS on compulsive-like behavior and brain-network activity in SAPAP3 knock-out mice (SAPAP3$^{-/-}$), a model for OCD that exhibits compulsive grooming, increased anxiety, and deficits in cortico-striatal circuit function. Using miniaturized fluorescent one-photon microscopy (miniscope) in freely behaving mice, we measured DBS-induced changes in single-cell calcium dynamics in cortico-striatal regions. The calcium indicator GCaMP6f was delivered via virus injection into the secondary motor cortex (M2), the dorsal striatum (DS), or the nucleus accumbens (NAc). GCaMP6f fluorescence, indicative of neuronal activity, was captured with the miniscope via a GRIN relay lens implanted above the target region.

We found that DBS of the IC rapidly reduced excessive grooming and vice versa, similar to OCD patients, 'symptoms' quickly returned after discontinuation of DBS. This therapeutic effect of DBS was accompanied by instantly increased neuronal activity in all cortico-striatal circuits monitored: M2, DS, and NAc. However, this effect was not uniform throughout these regions. The DBS-induced activity in the NAc returned to baseline almost momentarily, whereas it only tapered off slowly in the DS. Importantly, in the M2, this increase was sustained throughout the DBS period, thus, potentially providing neuromodulation involved in suppression of compulsive-like grooming.

Our results support the idea that IC-DBS effectively reduces excessive grooming in SAPAP3$^{-/-}$ via recruitment of cortico-striatal circuits. We found that DBS modulates cortical and striatal regions differently, with changes in M2 activity reflecting sustained effects of IC-DBS. Thus, M2 may be involved in the generation of compulsive behavior or at least may represent a brain locus that supports anti-compulsory effects of DBS in OCD.

Title: Activation of the metabotropic glutamate receptor 1 attenuates behavioral deficits in NMDA hypofunction models

Authors: *J. GALBRAITH[1], S. YOHN[1], E. RIETH[1], A. J. RAMSEY[2], C. K. JONES[1], C. W. LINDSLEY[1], P. J. CONN[1];
[1]Vanderbilt Univ., Nashville, TN; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Schizophrenia is a devastating disorder that consists of a complex set of positive, negative and cognitive symptoms. Evidence suggests that disruptions in the normal signaling N-methyl D-aspartate (NMDAR) may underlie many of the symptoms associated with schizophrenia. NMDA subunit GluN1 knockdown (NR1-KD) mice have a global reduction in NMDA receptors, which results in a spectrum of altered behaviors that are similar to those induced by NMDA receptor antagonists. Development of ligands that selectively target the metabotropic glutamate 1 (mGlu1) subtype represents an important approach for modulating NMDAR function and could lead to potential therapeutic interventions for schizophrenia. NR1-KD mice were evaluated in behavioral assays associated with positive, cognitive, and negative behavioral assays. Interestingly, administration of the mGlu1 positive allosteric modulator (PAM) VU6004909 attenuated hyperlocomotor activity in NR1-KD mice. The hyperlocomotor response observed in NR1-KD mice was associated with elevated dorsal striatal dopamine (DA) levels, an effect which can be restored to levels similar to littermate controls following administration of the mGlu1 PAM. Additionally, administration of the mGlu1 PAM improved cognitive performance in novel object recognition (NOR), spontaneous alterations in the Y-maze, social interaction discrimination index, and object locomotion memory in littermate controls and NR1-KD mice. Taken together, these findings provide important novel insights into the role of mGlu1 under conditions of chronic NMDAR hypofunction. These findings also confirm and extend accumulating evidence for the broader therapeutic utility for mGlu1 PAMs in the treatment of schizophrenia.

Abstract: Motivational symptoms are debilitating features of several neuropsychiatric disorders and are highly correlated with problems in social function, employment and long-term treatment outcomes. Current neuropsychiatric medications do not have efficacy on motivational phenotypes, and, in many cases, can induce or exacerbate these symptoms. While the neural basis of motivational dysfunctions is still being characterized, it has been suggested that there may be common mechanisms across different disorders, and considerable evidence implicates central dopamine (DA) and microcircuitry of the basal ganglia. A powerful modulator of DA signaling is the cholinergic system, which consists of nicotinic (nAChRs) and muscarinic (mAChRs) acetylcholine receptors. mAChRs belong to the superfamily of G-protein coupled receptors (GPCRs) that either activate or inhibit signaling pathway systems through intracellular second messengers. M1 receptors are densely expressed in the nucleus accumbens (NAc), where they have long been suggested to influence DA release. Previous data suggests that M1 activation could regulate NAc DA release and dependent behaviors. However, the data are contradictory due to poor ligand selectivity. To circumvent this problem, our laboratory has developed highly selective compounds that act at allosteric sites. Through use of highly selective M1 preferring compounds and M1 knockout mice, we now report that activation or potentiation of M1 increases effort-related progressive ratio (PR) choice behavior as well as attenuates deficits induced by the DA D2 antagonist haloperidol. Additionally, through use of *ex* and *in vivo* fast scan cyclic voltammetry (FSCV) we report that activation of M1 increases NAc DA release in a drug naïve state or following haloperidol challenge. Taken together, these findings suggest that activation of M1 may be therapeutic for the treatment of motivational dysfunctions.

Title: The role of the indirect pathway in sex differences in the formation of preference for cocaine over food in rats

Authors: *M. KALYANI, H. EPSTEIN, N. GUREVICH, J. B. BECKER;
Univ. of Michigan, Ann Arbor, MI

Abstract: Women progress through the landmark stages of addiction, from initial use to dependence, at a faster rate than males. Rodents exhibit similar sex differences in their addiction-like behaviors. Female rats acquire drug-taking behaviors more rapidly, progress to addiction-like behavior more rapidly, and are more likely to prefer cocaine over a palatable food pellet compared to male rats. The aim of this study was to investigate the role of the DLS indirect pathway in sex differences in the formation of preference for cocaine over food in rats. We did this using designer receptors exclusively activated by designer drugs (DREADDs) to selectively attenuate activity in the indirect pathway of the DLS. We hypothesized that inhibition of the indirect pathway in the DLS, using DREADDs, would enhance the escalation of cocaine taking and more rapid preference formation in both males and females. Male and female rats received DIO hM4Di DREADDs into the DLS. Second, an AAV-Cre viral vector was infused into the globus pallidus external (GPe) of the same rats. At least 2 weeks after the viral vector infusions, the rats were fitted with indwelling catheters for self-administration (SA) of cocaine. Animals were tested in a 7-week choice SA paradigm, to examine their drug-taking behavior in the presence of an alternative, palatable food reward. Their motivation for food and cocaine rewards was also tested under a concurrent progressive ratio (PR) schedule during weeks 3 and 7. Before testing, rats were injected intraperitoneally with Clozapine-N-oxide (CNO; 2 mg/kg) to activate the DREADDs. Immunohistochemistry was used to confirm selective expression of the DREADDs. In addition, c-Fos expression was examined to confirm the activation of the DREADDS by CNO throughout the 2.5-hour SA paradigm. Control females showed an increasing trend in cocaine infusions during the cocaine-only and choice sessions as compared to DREADDs treated group with no significant difference. None of the male rats showed an increase in cocaine infusions. There was no change in pellet intake during the pellet-only session regardless of sex and treatment. The data obtained from the PR schedule showed that the motivation for pellets was not significantly different during early and late SA sessions in either males or females. This suggests that motivation for food was not affected by the DREADDs. By the end of SA, motivation for cocaine was greater in control males and females. These trends suggest that treatment with DREADDs enhanced the motivation for pellets rather than inducing a shift to cocaine preference, regardless of sex.

Title: Sex differences in motivation for cocaine: Role of progesterone and oxytocin

Authors: *A. S. KOHTZ[1,2], B. LIN[1], H. E. DAVIES[1], A. SHUMYATSKY[1], G. S. ASTON-JONES[1];

Abstract: There are substantial sex and gender differences in drug abuse that influence susceptibility to, subjective experience of, and relapse propensity for, drugs of abuse. A key feature of drug abuse is pathologically high motivation for cocaine. We investigated the role of ovarian hormones on demand for cocaine in female rats using a within-session threshold behavioral economics (BE) procedure. We quantified demand elasticity (α, inverse motivation) and free consumption (Q_0, hedonic setpoint) in female rats across the estrous cycle and in ovariectomized (OVX) and hormone-replaced female rats. Female rats showed lower demand elasticity (greater motivation) for cocaine compared to males. When female rats were in proestrous, they showed greater demand elasticity (lower motivation) for cocaine compared to all other cycle phases. Hormonal cycle phase accounted for 70% of the variance between data points, obscuring individual differences in demand. High serum progesterone (P4; e.g. in proestrous) predicted decreased cocaine motivation, whereas serum estradiol (E2) correlated to greater intake (Q_0). In OVX females the distribution of α was similar to that previously shown in males, revealing high and low demand female rats. Hormone replacement in OVX females with either E2 (0.09 mg/kg; 44-48 hr prior to testing) and/or P4 (4.0 mg/kg; 4-6 hr prior to testing) showed that E2 increased motivation in females, while P4 decreased motivation. Thus, hormonal milieu, in particular P4, impacts initial motivation for cocaine (e.g. estrus cycling or OVX). We then investigated whether long-term cocaine self-administration altered estrous cyclicity. By 13 weeks, proestrous epochs are no longer observed, and cocaine demand was potentiated by permanent estrous. Finally, we investigated the effects of oxytocin (0.1 mg/kg; 0.3 mg/kg) to reduce cocaine demand. Oxytocin was effective in reducing demand for cocaine in female rats, and also restored proestrous epochs in previously acyclic females. Thus, P4 signaling is a key modulator of cocaine demand in females that may underlie previously observed sex differences

in addiction phenotypes, and oxytocin may be a relevant therapeutic. Supported by grants 1K99DA045758 and 4T32ES007148-30 to ASK and R01-DA006214 and DA016511 to GAJ.

Title: Differential control of behavior by cocaine and morphine cues: Role of locus coeruleus and auditory brainstem plasticity

Authors: *M. A. PRESKER, Jr.[1], D. SULLIVAN[1], S. TOMBOKAN[1], K. M. BIESZCZAD[2], G. S. ASTON-JONES[1];

Abstract: A major obstacle in treating addiction is the high propensity for relapse. Stimulus-driven drug seeking occurs despite efforts to remain abstinent, and competes with ongoing alternative preferred behaviors such as occupational or social activities. Noradrenergic locus coeruleus (LC) neurons project throughout the neuraxis, and modulate sensory processing and attention to orient organisms to sensory stimuli. Previous work shows that LC activity is altered acutely and chronically by both morphine and cocaine, and by reward-associated stimuli. This supports a role for LC in mediating stimulus control of behavior by drug cues. However, few studies have examined whether morphine- or cocaine-associated stimuli activate LC or exert control over non-drug-seeking behaviors or how this may differ between drug types. Here we implement a behavioral paradigm specifically designed to examine the effects of morphine-paired, cocaine-paired, and saline-paired auditory stimuli (tones) on operant responding for a natural reinforcer (water) in rats. We found that morphine- and cocaine-paired tones exert control over multiple behaviors and these effects differ between drugs. We also collected tissue to assess Fos expression in LC of rats exposed to each tone type. LC Fos expression will be compared with behavioral measures to determine whether they correlate. Furthermore, we will analyze changes in auditory brainstem responses (ABRs) to each tone over the course of conditioning to identify potential changes in auditory processing of a cocaine- or morphine-associated tone

compared to control tones. We previously found a relationship between LC activity and behavioral response to cocaine tones as well as cocaine-induced changes in ABR. This study will establish whether control of behavior by an opioid-associated cue is also encoded in LC activity, and also whether morphine alters auditory processing. Given the role of cues in relapse to opioids and cocaine, identifying a common neural substrate of attentional control by such stimuli may provide a target for therapeutic intervention. Title: Orexin1 receptor signaling in ventral tegmental area attenuates motivation for cocaine with drug-paired cues

Authors: *C. PANTAZIS[1], M. H. JAMES[1,2], N. SHIN[1], J. E. FRAGALE[1], G. S. ASTON-JONES[1];
[1]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ; [2]Florey Inst. for Neurosci. and Mental Hlth., Parkville, Australia

Abstract: Orexin neuropeptides have been linked to motivation for drugs of abuse. Ventral tegmental area (VTA) is an important target for orexin's effects on addiction-like behaviors, as orexin-1 receptor signaling in VTA drives high effort and cue-dependent drug seeking. To investigate the role of orexin-1 receptor signaling in VTA during motivated drug taking, we infused the orexin-1 receptor antagonist SB-334867 (SB) into VTA prior to a within-session behavioral economics (BE) test. In this paradigm, the duration of cocaine infusions decreases in successive 10-minute bins. Demand curves are fitted to individual lever-pressing data to determine two measures of cocaine demand: demand elasticity (alpha; motivation) and low-effort consumption (Q0). We found that SB reduced motivation for cocaine (increased demand elasticity; alpha) without impacting low-effort consumption of cocaine, general locomotor

activity, fixed ratio-1 (FR-1) responding for sucrose, or high-effort sucrose consumption. We also investigated whether orexin's role in motivation was dependent on the presence of drug-associated cues. SB was only effective at reducing motivation in the BE paradigm when animals were trained to associate cues with drug delivery during FR-1 training and were tested with cues during BE. When cues were removed from the BE paradigm, such that lever-pressing resulted in drug delivery without cues, SB did not attenuate motivation. Finally, we microinjected the retrograde tracer CTb into VTA to determine the source of orexin inputs and found that VTA receives orexin input from all subregions of the orexin cell field. However, a greater proportion of lateral hypothalamus (LH) orexin cells project to VTA than those in perifornical/dorsomedial hypothalamus (Pef/DMH). Collectively, these studies indicate that orexin-1 receptor signaling in VTA is necessary for cue-dependent motivation for cocaine, and that the LH orexin to VTA circuit in particular may be important for orexin's effect on motivation.

Title: Enhanced food motivation following binge-like eating in female rats is dependent on orexin (hypocretin) input to ventral tegmental area

Authors: *M. H. JAMES[1,2], S. LIU[1], K. FERNANDOPULLE[1], C. B. PANTAZIS[1], H. E. BOWREY[1], N. T. BELLO[1], G. ASTON-JONES[1];

Abstract: *Introduction:* Binge eating disorder (BED) is characterized by a progressive escalation of intake of highly palatable food and increased responsivity to food-associated cues. Studies of drugs of abuse indicate that the orexin (hypocretin) system is critically important for motivated behavior. Chronic drug exposure increases the number of orexin neurons and enhances reliance on orexin-1 receptor (Ox1R) signaling. Moreover, orexin inputs to ventral tegmental area (VTA)

augment glutamate-mediated dopaminergic release, and blockade of orexin-1 receptor (Ox1R) signaling in VTA reduces motivated responding for cocaine. Here, we sought to characterize the role of the orexin system and its inputs to VTA in a rat model of BED. *Methods*: Lean and obese (8wk ad libitum high fat diet [HFD]) female Long-Evans rats (n=47) were assessed for baseline sucrose motivation using a behavioral economics paradigm. Binge-like eating was induced by exposing rats to sweetened fat (vegetable shortening/10% sucrose) for 30 min, twice/wk for 4wk; economic demand for sucrose was then reassessed. One group was treated with the Ox1R antagonist SB-334867 (SB; 0,10,30mg/kg, ip) prior to binge-eating or economic demand sessions. In a second group of rats, we chronically silenced orexin neurons that provide input onto VTA by injecting a retroAAV-shOrexin (or scrambled control) virus into VTA prior to the binge-like eating paradigm. In a final group, the effect of binge-like eating on the number of orexin-expressing neurons was investigated using immunohistochemistry. *Results:* Binge eating increased sucrose demand only after HFD-exposure. SB reduced sucrose demand in both lean and obese rats but was effective at lower doses in obese rats following binge. Silencing of VTA-projecting orexin neurons prevented the escalation of intake during binge and the increase in sucrose demand observed following binge. A history of high-fat diet was associated with increased orexin-expressing neurons and this was further augmented by binge experience. *Conclusions:* Our findings reveal an interaction between binge-like eating and excessive weight gain with respect to motivation for food. This is associated with an increase in orexin cell numbers, enhanced reliance on Ox1R signaling and orexin input to VTA. Together, these findings highlight the orexin system as a potential novel target for pharmacotherapies for controlling overeating episodes in individuals with obesity.

Title: Sex differences in effects of GPER1 activation on preference for cocaine in male and female rats

Authors: *J. A. QUIGLEY, J. B. BECKER;
Univ. of Michigan, Ann Arbor, MI

Abstract: There are sex differences in susceptibility to addiction and drug-taking behaviors. A higher percentage of female rodents prefer cocaine to natural rewards than males do and females are more motivated than males to attain drugs of abuse. Research from the Becker Laboratory has shown that these heightened addiction-like behaviors in females are modulated by estradiol, where estradiol potentiates cocaine-induced dopamine levels in the dorsal striatum (dSTR). The role of estradiol receptor (ER) activation on addiction-like behaviors in males, however, has not been investigated extensively. The current experiment used the ERα & ERß antagonist, but GPER1 agonist, ICI 182,780 (ICI), and the GPER1 antagonist, G1, to manipulate ERs in the dSTR. The first experiment used a conditioned place preference paradigm (CPP) to determine whether ER manipulation alters preference for 10 mg/kg cocaine in male or female rats. We found that treatment with ICI or G1 into the dSTR of male rats blocked the formation of CPP for cocaine. Neither treatment altered female's formation of CPP. These data suggest that GPER1 regulates preference for cocaine in males only. The second experiment utilized qPCR to investigate potential sex differences in ER expression within the dSTR. There were no differences discovered in ERα, ERß or GPER1. Together, these data suggest that GPER1 activation decreases the rewarding effects of cocaine in males, but not females. Furthermore, there are sex differences in the effect of ER activation on motivation for drugs of abuse, enhancing motivation in females while attenuating motivation in males, that are regulated by mechanisms down-stream from the receptors.

Title: Graded control of pupil dilation and cortical neuromodulation using selective and parametric stimulation of the mouse vagus nerve

Authors: *Z. H. MRIDHA[1], J. DE GEE[1], Y. SHI[1], R. ALKASHGARI[2], J. WILLIAMS[2], A. SUMINSKI[2], M. WARD[3], W. ZHAMG[1], M. MCGINLEY[1];
[1]Baylor Col. of Med., Houston, TX; [2]Univ. of Winconsin, Madison, WI; [3]Purdue Univ., West Lafayette, IN

Abstract: The vagus nerve relays information about brain state to the body. Vagus nerve stimulation (VNS) is thought to 'back fire' neuromodulatory centers (such as locus coeruleus), releasing neuromodulators (such as norepinephrine) throughout the brain. The neuromodulatory

effects of VNS are thought to mediate its clinical benefits, in for example the treatment for refractory epilepsy, tinnitus, or depression. Furthermore, VNS enhances auditory learning in healthy individuals, hypothetically by boosting cortical plasticity via the same neuromodulators (Engineer et al., 2015). A major challenge in using VNS, for therapeutic purposes or cognitive enhancement, is that there is no known readout of nerve engagement or subsequent neuromodulatory impact. As a result, stimulation parameters are chosen and optimized, largely through trial-and-error and feedback from patients about symptoms and side effects. We have previously shown that the size of the pupil tracks neuromodulatory brain state and its influence on auditory physiology and behavior (McGinley et al., 2015; Reimer et al., 2016). Here, we developed a VNS preparation for awake, head-fixed mice and test if pupil dilation can serve as a biosensor of VNS and associated cortical neuromodulation. We adapted an implanted cuff design from prior work in rats (Ward et al., 2015). Stimulation via our cuff is well-tolerated by mice for up to several months. We performed an extensive search across a VNS parameter space of 4 pulse widths (0.1-0.8 ms), 5 amplitudes (0.1-0.9 mA), and 3 rates (5-20 Hz; 10 s trains), while monitoring pupil size and other eye and facial movements. We found consistent pupil dilation that parametrically increased with increasing pulse width, amplitudes or rate. Experiments with proximal (or proximal and distal) cut of the nerve confirm that the pupil dilation results from selective activation of the vagus nerve. Using two-photon imaging of axons in auditory cortex, we observed that cortical neuromodulation was phasically boosted during VNS, and then decayed back to a stable baseline. We also found that care with grounding and current spread is necessary to avoid major off target effects such as small phase-locked eye movements and further pupil dilation. Taken together, our results provide a foundation for carefully controlled VNS, and pupil dilation as its readout, for the enhancement of auditory learning and other applications requiring closed-loop, graded control of brain state. Title: The modulation of excitation and inhibition by neuropeptides in the ventral pallidum is cell type specific

Authors: *D. NEUHOFER[1], J. A. HEINSBROEK[3], E. DERESCHEWITZ[2], P. W. KALIVAS[4]; [2]Neurosci., [1]MUSC, Charleston, SC; [3]Med. Univ. of South Carolina, Charleston, SC; [4]Neurosci. Res., Med. Univ. S Carolina, Charleston, SC

Abstract: The ventral pallidum (VP) is an integral component of the reward circuitry and is a major target of GABAergic innervation of both D1 Medium spiny Neurons (MSNs) and D2 MSN from the nucleus accumbens. Although the majority of VP neurons are GABAergic (VPGABA), the VP also contains a significant population of glutamatergic (VPGlu) neurons. It was recently demonstrated that VPGABA drive positive reinforcement, whereas VPGlu drive behavioral avoidance. Also MSN afferents in the VP exert opponent control over behavioral reinforcement with activation of D1 MSN afferents promoting and D2 afferents inhibiting reward seeking. However, the innervation pattern onto VP neurons cannot conclusively explain behavioral output, because D1 and D2 MSN afferents innervate overlapping neuronal populations in the VP. How this afferent specific and cell type specific control of reward seeking is established mechanistically remains elusive.In addition to being segregated according to the expression of D1 versus D2 receptors, the two subpopulations of MSNs segregate according to co-expressed neuropeptides, with D1 MSNs expressing substance P and dynorphin (activating NK1 receptors and kappa opioid receptors respectively), and D2 MSNs co-expressing enkephalin and neurotensin (activating mu opioid receptors and neurotensin receptors respectively). Earlier studies show that administration of these neuropeptides or analogues into the VP alters appetitive behavior and cocaine seeking. To test whether neuropeptides differentially modulate VPGlu and VPGAT Neurons, we bred Ai6lsl-zsGreen with Vglut2-IRES-Cre or VGat-IRES-Cre mice to generate Ai6::VPGlu or Ai6::VPGAT reporter respectively. Using whole cell patch clamp recordings, we quantified the relative strength of excitatory and inhibitory inputs (E/I Ratio) onto VPGlu and VPGAT Neurons and how this E/I Ratio changed after pharmacological activation of neuropeptidergic target receptors in the VP. We found that activation of NK1R does not affect E/I ratio in VPGAT Neurons but decreases E/I ratios in VPGlu neurons via inhibition of glutamate transmission. Activation of MOR increase E/I ratios in VPGlu via inhibition of GABA transmission but no clear effect on VPGAT neurons. These results could provide a circuit-based model to explain the antagonistic effect of D1 and D2 MSN afferents in the VP on reward behavior. Future experiments will complete the characterization of this cell type specific neuropeptidergic modulation and will examine whether it is changed after exposure to drugs of abuse such as cocaine and heroin.

Title: Monkey anterior cingulate cortex: Topography and laminar pattern of corticocortical connections indicate hierarchical organization

Authors: H. SAKATA, Y. KIM, M. NEJIME, N. KONOIKE, *S. MIYACHI, K. NAKAMURA;
Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: The anterior cingulate cortex (ACC) has long been implicated in emotion. The region is functionally divided into three subregions, namely, the dorsal, perigenual, and subgenual regions (dACC, pgACC, and sgACC, respectively). The dACC is more related to cognitive functions and expression of emotional behavior, whereas the pgACC and sgACC are more related to regulation of emotion. Recent studies have suggested that the pgACC and sgACC are involved in mood disorders in contrasting manners: activity of the sgACC is correlated with the severity of depression, whereas the pgACC activity is correlated with the effectiveness of antidepressant and/or positive affect. Anatomically, the ACC has rich connections with other emotion-related areas including the amygdala, the medial temporal cortex, and the temporal pole (TP). To understand the neuroanatomical basis of the functional differences between the ACC subregions, we injected neuronal tracers into the pgACC, sgACC, and dACC and compared the afferent connections. Previously, we analyzed the afferent projections from the amygdala, and found a distinct pattern for the sgACC. In the present study, the distribution of the retrogradely labeled neurons were analyzed in the temporal pole and medial temporal areas. After injections in the sgACC, many neurons were labeled in the TP and the subiculum, an output station of the hippocampal formation. In the TP, a majority of the labeled neurons was found in the superficial layers (“feedforward” type projections). Injections in the pgACC labeled neurons mainly in the deep layers of the TP (“feedback” type projection). In the medial temporal areas, labeled neurons were found in the entorhinal cortex and the parahippocampal cortex, which are known to relay cortical inputs to the hippocampus. In each area, a majority of the labeled cells were in the deep layers (“feedback” type projection). Within the ACC, the projections from the sgACC to the pgACC originated predominantly in the deep layers (“feedback” type projection). These data suggest that the sgACC ranks higher than the pgACC in the hierarchy of the emotional system.

Title: Oxytocin signaling in the central amygdala modulates emotion discrimination in mice

Authors: *F. MALTESE[1], V. FERRETTI[1], G. CONTARINI[1], M. NIGRO[1], A. BONAVIA[1], H. HUANG[1], V. GIGLIUCCI[2], G. MORELLI[1], D. SCHEGGIA[1], F. MANAGO[1], G. CASTELLANI[1], A. LEFEVRE[3], L. CANCEDDA[1], B. CHINI[2], V. GRINEVICH[3], F. PAPALEO[1];
[1]Inst. Italiano di Tecnologia, Genova, Italy; [2]CNR, Inst. of Neurosci., Milan, Italy; [3]Schaller Res. Group on Neuropeptides, German Cancer Res. Ctr., Heidelberg, Germany

Abstract: Recognition of other's emotions influences the way social animals interact and adapt to the environment. The neuropeptide oxytocin (OXT) has been implicated in different aspects of emotion processing. However, the role of endogenous OXT brain pathways in the social response to different emotional states in conspecifics remains elusive. Here, using a combination of anatomical, genetic and chemogenetic approaches, we investigated the contribution of endogenous OXT signaling in the ability of mice to discriminate unfamiliar conspecifics based on their emotional states. We found that OXT-ergic projections from the paraventricular nucleus of the hypothalamus (PVN) to the central amygdala (CeA) are crucial for the discrimination of both positively and negatively-valenced emotional states. In contrast, blocking PVN OXT release into the nucleus accumbens, prefrontal cortex, and hippocampal CA2 did not alter this emotion discrimination. Furthermore, silencing each of these PVN OXT pathways did not influence basic social interaction. These findings were further supported by the demonstration that virally-mediated enhancement of OXT signaling within the CeA was sufficient to rescue emotion discrimination deficits in a genetic mouse model of cognitive liability. Our results indicate that CeA OXT signaling plays a key role in emotion discrimination both in physiological and pathological conditions.

Title: Learning-related changes in infralimbic cortical activity during conditioned inhibition of fear

Authors: *K. H. NG[1,2], S. SANGHA[1,2];
[1]Dept. of Psychological Sci., Purdue Univ., West Lafayette, IN; [2]Purdue Inst. for Integrative Neurosci., West Lafayette, IN

Abstract: Expressing fear behavior in the absence of a threat is maladaptive because it decreases an organism's opportunity to seek life-sustaining substances. Learned safety signals can rescue the organism from this immobilizing state to resume exploratory behaviors. The infralimbic (IL) region of the prefrontal cortex is known to be critical for consolidating fear extinction and for suppressing fear in the presence of a safety cue. IL neurons have also been shown to increase activity to an extinguished fear cue during the recall of fear extinction. We thus hypothesized that IL neurons also encode for safety signals that are actively suppressing fear behavior in a situation that may be perceived as potentially dangerous.
We recorded from IL neurons using multi-array electrodes during a safety-fear-reward cue discrimination paradigm that is well established in our laboratory. We monitored multiunit activity to assess global changes in IL activity, and single-unit activity to assess changes in recruitment of individual neurons encoding for safety. During the discrimination task, rats learn that the reward cue results in sucrose delivery and the fear cue results in footshock, but when the fear cue is simultaneously presented with the safety cue as a compound cue (fear+safety cue), there is no footshock. To control for sensory modality effects, we also trained a separate group of animals with the modalities (auditory vs visual) counterbalanced for the fear and safety cues. Male rats showed high freezing to the fear cue and significantly lower freezing to the fear+safety cue, regardless if the fear cue was an auditory or visual cue. Our multi-unit data demonstrated increasing IL neuronal firing to the combined fear+safety cue across learning sessions, matching the magnitude of fear suppression to the fear+safety cue. This learning-related increase was not seen to the fear, safety or reward cues across learning sessions and did not depend on cue modality. These data suggest the IL is engaged when a behavioral fear response is actively regulated during conditioned inhibition.

Title: Capture and modulation of emotion regulation inferred from connectivity analysis

Authors: *R. SHEPARD, L. STEWART, M. XING, A. LEOW, O. AJILORE;
Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Introduction: Individuals with anxiety and mood disorders have been shown to have impaired emotion regulation (ER). For those individuals who are remitted, effective ER may reduce the risk of relapse. Theta frequency activity has been associated with ER difficulties, and as such, the ability to decrease theta connectivity could improve patients' ability to regulate their emotions and avoid relapse.
Objectives: To use brain network connectivity patterns to confirm the effectiveness of and determine an ideal method for enhancing ER with noninvasive stimulation.
Methods: Participants were 11 adults ages 18-64 (average age 32, 2 male 9 female) with a score of 23 or more on the Depression Anxiety Stress Scale (DASS-21) and no major active medical or neurologic problems. 5 participants received transcranial direct current stimulation (tDCS) while 6 received transcranial alternating current stimulation (tACS) during 2 runs of both an Emotion Regulation Task (ERT) and a resting task. We compared subject reported affect collected during the ERT and before/after stimulation using the Spielberger State-Trait Anxiety Inventory (STAI) and Beck Depression Inventory (BDI).
Results: BDI scores for both tACS and tDCS participants significantly decreased from the start of the stimulation visit to the end, while STAI scores showed no significant change. Preliminary analyses of the EEG data comparing connectome measures between sham and active tACS sessions only show a reduction connectivity between stimulation electrodes at all frequencies and in the theta frequency band during the resting task. Conversely, tDCS participants only see a reduction in edge electrode connectivity in all and theta frequencies when performing the ERT. To test overall group differences, we used a mixed model analysis with within-subject variables (sham vs active) and between-subject variables (tDCS vs tACS) and did not find a significant difference across all conditions.
Conclusions: We observed the anticipated effects of tACS reducing theta connectivity more than tDCS during resting tasks, but tDCS reduced theta connectivity more during the ERT than tACS did. These results would suggest that ER can be improved via transcranial stimulation.

Despite the need for further analyses, tCS still appears to be a promising tactic for assisting patients with mood disorders in regulating their emotions.

Title: The role of ventral hippocampal inputs to the anterior hypothalamus in escape behaviours and stress response

Authors: *J. BANG[1], J. K. SUNSTRUM[7], J. ZHAO[1], S. ST-CYR[2], D. GARAND[3], M. RAHMAN[9], G. M. PARFITT[4], M. A. WOODIN[1], P. O. MCGOWAN[5], W. INOUE[8], J. Abstract: Animals rely on innate and conditioned fear responses to maximize their chance of survival. Previous studies found that an intact ventral hippocampus (vHPC) is essential for processing contextual information associated with conditioned fear as well as the expression of innate defensive behaviours such as escape from predators. Furthermore, being a major target of glucocorticoids, vHPC has also been implicated in the negative feedback control of stress-induced HPA activity. We hypothesized that the vHPC conveys contextual information to the anterior hypothalamic nucleus (AHN) to encode and retrieve memory of a predator threat. We found that a direct AHN activation is sufficient to evoke robust escape responses (running, jumping, freezing) in the absence of threat and can act as an unconditioned stimulus in the conditioned place aversion test. Rabies virus tracing and electrophysiological recordings revealed that GABAergic neurons in the AHN receive direct monosynaptic inputs from the

vHPC. Next, we optogenetically manipulated vHPC inputs to the AHN while mice are subjected to natural predator cues or physical restraint stress and then assessed its impact on escape behaviours, autonomic responses, and the formation of contextual memory. In physical restraint stress, the activation of vHPC inputs to the AHN decreased heart rates and respiration while increasing struggle movements. Our data thus far suggest that the hippocampal-hypothalamic circuit plays an important role in modulating escape and stress responses, and establish the AHN as a key hippocampal target that integrates threat signals and environmental contexts.

Title: A focus on primate area 25 and its regulation of reward and threat driven responses

Authors: *C. M. WOOD[1], L. ALEXANDER[1], A. M. SANTANGELO[1], L. OIKONOMIDIS[1], J. ALSIÖ[2], P. L. R. GASKIN[1], S. J. SAWIAK[3], Y. T. HONG[4], T. D. FRYER[4], A. C. ROBERTS[1]; [1]Dept. of Physiology, Develop. and Neurosci., [2]Dept. of Psychology, [3]Behavioural and Clin. Neurosci. Inst., [4]Wolfson Brain Imaging Ctr., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Heightened activity within subcallosal cingulate cortex (including area 25) has been observed in patients with depression, with successful treatment often resulting in normalisation of activity within this region. Recently, we revealed the causal involvement of area 25 activation in blunting reward-driven responses and heightening anxiety-like behaviors, by infusions of a glutamate uptake blocker into area 25 in marmoset monkeys (Alexander et al. 2019, Neuron 101(2) p307-320). Here we extend our findings to address three additional questions: 1) whether the same pattern of effects can be induced via viral-mediated overactivation of area 25 with a hM3Gq DREADD receptor? 2) Whether area 25 overactivation increases the stress hormone, cortisol since FDG activity in area 25 is associated with increased cortisol levels in the rhesus monkey (Jahn et al. 2010 Biol. Psychiatry 67(2) p175-181)? 3) Whether area 25 overactivation induces the same pattern of altered network activity under threat as it does during reward anticipation.
In addressing 1) we infused a DREADD hM3Gq viral construct into area 25 and used the

DREADD activator Clozapine-N-Oxide to show that area 25 overactivation blunts cardiovascular and behavioural arousal in anticipation of reward during appetitive Pavlovian conditioning and heightens negative reactivity to uncertain threat, similar to that seen after the blockade of glutamate uptake. Control studies with DREADD activators indicate no effects, suggesting that the cardiovascular and behavioural response are DREADD-specific. In addressing 2) we show that area 25 overactivation by blocking glutamate uptake increases salivary cortisol during recall of Pavlovian conditioned threat but not under neutral conditions. Finally, to address 3) we are using ^{18}F-FDG imaging in animals exposed to Pavlovian conditioned threat cues following overactivation of area 25.

Title: Ultrasonic vocalizations as a means of inducing anxiety via potential threat exposure: Evidence from behavioral, neural, and fMRI analyses in the rat

Authors: *J. A. HONEYCUTT, L. E. GRANATA, C. DEMAESTRI, P. P. KULKARNI, C. F. FERRIS, H. C. BRENHOUSE;
Psychology, Northeastern Univ., Boston, MA

Abstract: The utilization of ultrasonic vocalizations (USVs) as a means of social communication is well established in rats, with distinct USV frequency ranges indicative of different affective states. Aversive USVs within the 22 kHz range are typically emitted by adult rats as alarm calls during situations involving anxiety or fear (e.g. predator, social defeat), whereas 55 kHz range USVs are indicative of appetitive situations (e.g. play, reward). Previous work from our group and others indicate that playback of USVs to a listening rat can induces acute changes in affective state, as evidenced by increased anxiety-like or approach behaviors following either 22 or 55 kHz USV playback (respectively). Furthermore, we present evidence suggesting that these changes in behavior following USV presentation may be associated with differential activation of key brain regions associated with anxiety. Indeed, cFos quantification following playback within the basolateral amygdala (BLA), bed nucleus of the stria terminalis (BNST), and the

nucleus accumbens suggests distinct differences in activation based on whether the rat heard an aversive or appetitive train of USVs. Additional differentiation was evident within the BNST after 22 kHz playback, with increased cFos density observed within the anterodorsal nuclei, whereas 55 kHz playback showed increased activity exclusively within the oval nucleus. In addition to these findings, we are currently employing a novel USV playback methodology within the fMRI in order to leverage the anxiety-provoking characteristics of 22 kHz playback to probe circuit-specific alterations across the rat brain. Here, we present preliminary evidence suggesting that playback of aversive USVs activates anxiety-related circuitry similar to that seen in analogous human task-based fMRI. Taken together, this work provides critical groundwork for leveraging ethologically-relevant stimuli in the rat to improve our overall understanding of anxiety-related etiology in both typical and pathological populations/models.

Title: Lateral hypothalamic neural outputs drive active coping response

Authors: *E. MARTIANOVA[1,2], A. PAGEAU[3], D. LEBLANC[3], C. PROULX[1,2];
[1]Cervo Brain Res. Ctr., Quebec, QC, Canada; [2]Dept. of Psychiatry and Neurosci., [3]Laval Univ., Quebec, QC, Canada

Abstract: The lateral hypothalamus (LHA) sends neural outputs to brain regions known to control reward and motivated behaviors. However, how these distinct LHA outputs process information to control behavior is poorly known. Here, we use *in vivo* fiber photometry calcium (Ca^{2+}) imaging to characterize LHA outputs in freely moving mice. An AAV encoding the calcium indicator GCaMP6s was injected in the LHA, and optic fiber cannulas were implanted to target three majors downstream LHA targets: the lateral habenula (LHb), the ventral tegmental area (VTA), and the dorsal raphe nucleus (DRN). This allowed to record neural activity simultaneously and specifically at LHA-LHb, LHA-VTA, and LHA-DRN pathways, in mice subjected to different stimuli or placed in different contexts. Ca^{2+} signals in three LHA outputs increased when mice were presented with aversive airpuffs and decreased during rewarding sucrose consumption (SCT). From these three LHA outputs, we found a significant correlation between Ca^{2+} signals and mobility scores in mice free to explore an open field (OFT) or during

tail-suspension test (TST). The correlation was significantly higher during TST suggesting that LHA may guide motivated coping responses in stressful contexts. This assertion was supported by an increased correlation between Ca^{2+} signals and mobility scores after administration of cued foot-shocks. Cross-correlation analysis between LHA outputs showed synchronous increase of Ca^{2+} signal in all three outputs at nearly each event of mobility onset in TST and at delivery of airpuffs. To examine further the contribution LHA outputs for behavioral responses, we injected an AAV-ChR2-eYFP in the LHA and implanted cannulas with the tips above the LHb, VTA, and DRN. Optogenetic activation of individual LHA outputs caused passive avoidance in real-time preference test and increased mobility in OFT and TST. During SCT, optogenetic stimulation of the LHA-LHb at the onset of drinking events significantly reduced total sucrose consumption, stimulation of LHA-DRN only decreased drinking duration, and LHA-VTA stimulation had no impact on sucrose consumption. Combined, these results suggest that LHA outputs may encode different and complementary teaching signals to motivate active coping response in aversive contexts.

Title: Preferential activation for emotional music versus sounds in motor, interoceptive, and language brain areas

Authors: *R. J. LEPPING[1], J. M. BRUCE[5,6], K. M. GUSTAFSON[1,2], J. HU[3], L. E. MARTIN[1,4], C. R. SAVAGE[7,8], R. ATCHLEY[9];

Abstract: Recent meta analyses suggest that there is a common brain network involved in processing emotion in music and in sounds (Koelsch, 2014; Frühholtz, et al, 2016). However, as no studies have directly compared the neural substrates of equivalent emotional music and

emotional sound, we don't fully understand how emotional music is represented in the brain compared to other auditory emotional stimuli, or whether other brain systems, such as the motor or language networks would be more or less involved in processing music versus sounds. Using functional magnetic resonance imaging (fMRI) and a region of interest approach, we investigated whether brain activation in motor cortex, interoceptive cortex, and Broca's language area during an auditory emotional appraisal task differed as a function of whether the emotional information was communicated through music or non-linguistic sounds. Musical and non-musical stimuli were matched for both valence (positive and negative) and arousal level (Lepping, et al. 2016). Thirty-nine adults (Mean age=31.44, SD=12.52 years, 17 men, 22 women; 19 with current major depressive disorder) underwent fMRI scanning while listening to the stimuli and determining emotional valence (positive or negative). An analysis of variance revealed an interaction between stimulus type and region [F(1.18, 44.8)=9.30, p=.002]. Activation was relatively greater to music in motor and interoceptive cortex - areas associated with movement and internal physical feelings - and relatively greater to sounds in Broca's language area. No differences in activation were found based on depression status (all F's&lt2.6). We conclude that emotional sounds are appraised through verbal identification of the source, and that emotional music is appraised through evaluation of bodily feelings. The current results also indicate that at least some neural systems involved in emotional appraisal are functionally intact during a depressive episode, which may help clarify the mechanism of music therapy for depression.

Title: Synaptic organization of amygdala to prefrontal cortex circuits

Authors: *K. MANOOCHERI, A. G. CARTER;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Connections from basolateral amygdala (BLA) to medial prefrontal cortex (mPFC) are important for threat detection and response. Disorders involving aberrant threat processing are linked to disruptions in the normal connectivity of the BLA-mPFC circuit. Distinct classes of projection neurons in the prelimbic (PL) or infralimbic (IL) subdivision of mPFC are believed to

integrate BLA input and thereby regulate either the activation or suppression of threat-evoked behavior. Recent work suggests BLA input targets both corticoamygdalar (CA) neurons and pyramidal tract (PT) neurons in mPFC, but how this targeting differs between PL and IL, and whether this reflects distinct pathways, is unclear. Using whole-cell electrophysiology and optogenetics in acute slices, we show how distinct BLA nuclei target cells in IL and PL. Using soma-tagged optogenetics, we also examine the local circuits that link layers within and between IL and PL. Together, our results indicate that sub-divisions of the BLA target remarkably different networks of cells, which themselves make distinct connections to influence mPFC output.

Title: Spatio-temporal dynamics and individual differences linked to vlPFC's role in emotion-cognition interactions: Evidence from a simultaneous fMRI-ERP investigation

Authors: *M. MOORE[1], A. T. SHAFER[2], R. BAKHTIARI[3], A. SINGHAL[3], F. DOLCOS[1]; [1]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Natl. Inst. on Aging, Baltimore, MD; [3]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Despite extensive evidence identifying brain regions and networks involved in emotion-cognition interactions, the link between spatial and temporal dynamics of mechanisms underlying these phenomena remains unclear. Of particular importance are brain regions that appear to be engaged during multiple processes, suggesting complex and dynamic functional heterogeneity. One such region is the ventrolateral prefrontal cortex (vlPFC), which has been implicated in processing of emotional and salient information, response inhibition, affect regulation, and coping with emotional distraction. Notably, previous evidence suggests dissociable sub-regional specificity between anterior and posterior parts of the vlPFC, with the former showing more general involvement in emotion processing, and the latter being more specifically linked to coping with emotional distraction. Capitalizing on a multimodal imaging

approach in a sample of 22 healthy young adults, we investigated the link between spatial and temporal aspects of processing in an emotional oddball task, and in relation to personality measures assessing basic affective responses and emotion control. First, fMRI captured expected overall greater vlPFC response, and ERPs showed larger late positive potentials (LPPs) to emotional distraction. Second, ERP-informed fMRI analyses showed an association between the fMRI signal in the anterior vlPFC and the LPP amplitude to emotional distraction. Third, analyses linking fMRI and personality data identified opposing relations between responses to emotional distraction and individual scores for cognitive reappraisal and self-control impulsiveness in posterior vlPFC. Namely, participants with reduced tendencies to engage reappraisal and reduced ability to control impulsive responses had increased engagement of the posterior vlPFC during emotional distraction. Together, these results provide novel evidence supporting anterior-posterior functional dissociations within the vlPFC linked to the initial impact of vs. coping with emotional distraction. Overall, these findings highlight the advantage of capitalizing on multidimensional approaches to comprehensively investigate the complex spatial-temporal dynamics of the neural mechanisms associated with emotion-cognition interactions.

Abstract: A psychotherapeutic regimen that uses alternating bilateral sensory stimulation (ABS) has been used to treat post-traumatic stress disorder in humans. However, the neural basis that underlies the long-lasting effect of this treatment—described as eye movement desensitization and reprocessing—has not been identified. Here we describe a neuronal pathway driven by non-invasive visual stimulation of the superior colliculus (SC) that mediates persistent attenuation of

fear. We successfully induced a lasting reduction in fear in mice by pairing visual ABS with conditioned stimuli during fear extinction. Among the types of visual stimulation tested, ABS provided the strongest fear-reducing effect and yielded sustained increases in the activities of the SC and mediodorsal thalamus (MD) throughout the extinction session. Optogenetic manipulation revealed that the SC-MD circuit was necessary and sufficient to prevent the return of fear. ABS suppressed the activity of fear-encoding cells and stabilized inhibitory neurotransmission in the basolateral complex of the amygdala (BLA). The direct MD-BLA projection formed a novel feedforward inhibitory circuit that was required for the observed long-lasting suppression of fear. Together, these results reveal the neural circuit that underlies an effective strategy for sustainably attenuating traumatic memories.

Title: Regulation of prefrontal cortex by two opposing hippocampal pathways

Authors: *C. SANCHEZ BELLOT, A. F. MACASKILL;
Univ. Col. London, London, United Kingdom

Abstract: The subiculum is the main output region of the hippocampus. Despite targeting multiple downstream regions, its efferents are thought to be organised as parallel projections, with any one neuron targeting only one downstream region. Here, we focus on the projection from the ventral subiculum to the prefrontal cortex (PFC). The ventral hippocampal-prefrontal pathway is involved in the production of a range of behaviours including working memory, aversive learning and anxiety, and its dysfunction is linked to key aspects of several psychiatric disorders. Through anatomical, electrophysiological and morphological investigation of the ventral hippocampal-prefrontal pathway, we show that PFC projecting neurons are formed of two distinct populations. These populations are differentially controlled by upstream structures and have unique connectivity within downstream PFC. Finally, these two populations show distinct contributions during different aspects of behaviour.

Title: Input-output mapping of ventral hippocampal circuits

Authors: *R. W. S. WEE, A. MACASKILL;
Univ. Col. London, London, United Kingdom

Abstract: The ventral hippocampal output region in CA1 and subiculum (vH) is comprised of multiple non-overlapping populations of projection neurons that send output to different regions, including prefrontal cortex, nucleus accumbens and ventromedial hypothalamus. These projection-defined populations are involved in many related but distinct aspects of behaviour, suggesting that they integrate different inputs. To investigate the input connectivity of projection-defined vH neurons, we combined anatomical and rabies-based trans-synaptic tracing. We observed that diverse cortical, subcortical and thalamic sources of input provide selective innervation to vH projection-defined neurons. Using regression models, we also probed the relative influence of spatial topology and output region on input source. Finally, we employed channelrhodopsin-2 (ChR2)-assisted circuit mapping to functionally validate newly identified inputs. Together, our findings indicate anatomical segregation of inputs to projection-specific vH neurons, providing a basis for selective control of individual projections during behaviour.

Abstract: The ventral tegmental area (VTA) has three major subclasses of neurons: dopaminergic (expressing the rate-limiting enzyme for dopamine production, tyrosine hydroxylase; TH), GABAergic (expressing vesicular GABA transporter; VGaT) and glutamatergic (expressing vesicular glutamate transporter 2; VGluT2). However, recent evidence has shown that in addition to DA, GABA and glutamate neurons, the VTA contains combinatorial neurons that co-release glutamate and GABA or glutamate and dopamine. While VTA dopaminergic and GABAergic neurons have been further characterized based on their expression of calcium-binding proteins (calbindin, CB; calretinin, CR or parvalbumin, PV), it is unclear whether these calcium binding proteins are expressed in VTA glutamatergic neurons. Here, by a combination of *in situ* hybridization (for detection of VGluT2 mRNA) and immunohistochemistry (for detection of CB, CR or PV), we found expression of CB, CR or PV in some VGluT2 neurons, which were concentrated in the medial nuclei of the VTA. We determined that among the total population of VTA VGluT2 neurons and depending on the VTA rostro-caudal level, 30% co-expressed CB, 3% co-expressed PV and less than 1% co-expressed CR. Given that some VGluT2 neurons co-express VGaT or TH, we examined whether these neurons co-expressed CB. By a combination of RNAscope (for co-detection of VGluT2 and VGaT mRNAs) and immunohistochemistry (for detection of CB and TH), we found that within the total population of VGluT2-CB neurons, 13% co-expressed VGaT mRNA, 19% co-expressed TH and 6% co-expressed VGaT mRNA and TH. These findings show that (a) while CR and PV are infrequently present in VTA VGluT2 neurons, CB is present in almost one-third of the entire population of VTA VGluT2 neurons; (b) within the total population of VTA VGluT2-CB neurons, one-third have the capability to co-release dopamine or GABA; and (c) a small subpopulation of VTA VGluT2-CB neurons has the capability to co-release both GABA and dopamine. These findings further provide evidence for molecular diversity among VTA VGluT2 neurons, neurons that may play a role in specific circuitry and behaviors.

Title: Cytoarchitectural characterization of zona incerta doapmine neurons

Authors: *Z. D. BRODNIK[1], M. F. MORALES[2];
[2]Cell Neurobiol Res. Br., [1]IRP, NIDA, NIH, Baltimore, MD

Abstract: A population of tyrosine hydroxylase expressing (TH^+) neurons in the zona incerta has been identified for several decades, and it has generally been assumed that these neurons are functional dopamine neurons. Nevertheless, recent work has shown that the expression of TH does not necessarily identify a neuron as capable of producing and releasing dopamine. Specifically, some TH^+ neurons do not co-express other proteins that are required for the synthesis (AADC) or packaging (VMAT) of dopamine and are thus unlikely to release dopamine as a neurotransmitter. Additionally, it has been found that some TH^+ neurons are capable of releasing glutamate or GABA. The TH^+ neurons of the zona incerta have not been characterized with such rigor, and thus the neurochemical identity of zona incerta TH^+ neurons remains unclear. We used a combination of immunohistochemistry and in-situ hybridization with radiolabeled probes to identify the proportion of zona incerta neurons that co-express TH and AADC or VMAT as well as the proteins required for the packaging of glutamate (VGluT2) or GABA (VGaT). We found that the majority of TH^+ neurons in the zona incerta express AADC (95%) or VMAT (63%). Additionally, we found that a negligible proportion of TH^+ neurons express VGluT2 (2%), but that a substantial proportion express VGaT (75%). Together, our studies identify that the majority of zona incerta TH^+ neurons express the genes necessary for DA neurotransmission and suggest that many DA neurons in the zona incerta may co-release GABA but not glutamate.

Title: VTA glutamate neurons establish excitatory synapses on mPFC parvalbumin neurons

Authors: *S. ZHANG[1], H. WANG[2], M. F. MORALES[2];
[1]Confocal and ELectron Microscopy Core, Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP,

BALTIMORE, MD; [2]Integrative Neurosci. Res. Br., Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD

Abstract: Dopamine inputs from the ventral tegmental area (VTA) to the medial prefrontal cortex (mPFC) have been implicated in neuropsychiatric pathologies for decades. Recent findings indicate that the mPFC is also innervated by VTA neurons expressing the vesicular glutamate type 2 (VGluT2). We found that the mesocortical pathway was originated from three major subpopulations of VTA neurons: VGluT2-only, TH-only and dual VGluT2-TH neurons. These subpopulations of VTA neurons innervated with higher frequency the infralimbic (IL) than the prelimbic (PrL) cortex (Dr. Wang's SfN 2019 abstract). Here, we analyzed mPFC sections from those brains in which VTA VGluT2 neurons were tagged with ChR2-eYFP or ChR2-mCherry. By confocal microscopy, we found that fibers expressing eYFP were predominantly localized in the deep layers of the IL and dorsal peduncular (DP) cortex. By immunoelectron microscopy, we detected within the IL and DP cortex mCherry (from infected VTA-VGluT2 neurons) restricted to axons and axon terminals, and determined that mCherry terminals co-expressed VGluT2 and established asymmetric (excitatory-type) synapses on IL and DP cortical dendrites. By ex vivo electrophysiological and optogenetic approaches, we found that mPFC photoactivation of fibers from VTA VGluT2 neurons evoked monosynaptic firing of local parvalbumin (PV)-GABAergic neurons, and polysynaptic inhibition of pyramidal neurons. By three-dimensional reconstruction of confocal data analysis and immunoelectron microscopy, we confirmed that dual mCherry-VGluT2 terminals formed asymmetric synapses with cortical PV-dendrites, and with dendritic spines. These findings indicate that VTA VGluT2-mesocortical-fibers establish monosynaptic excitatory synapses with PV-GABAergic neurons and pyramidal neurons. By in vivo mPFC photostimulation of fibers from VTA VGluT2 neurons, we found that this stimulation induced conditioned place aversion, which depended on activation of both glutamate and GABA receptors (Dr. Wang's SfN 2019 abstract). These findings indicate that the VTA provides a glutamatergic excitatory input to a subpopulation of IL cortical PV-GABAergic neurons, and that activation of these PV neurons inhibits neighboring pyramidal neurons, promoting aversive behavior.

Title: VTA glutamate neurons promote aversion by activation of mPFC parvalbumin neurons

Authors: *H.-L. WANG[1], H. WANG[2], M. F. BARBANO[3], A. N. FIGUEROA GONZÁLEZ[2], M. AKBARI[2], M. F. MORALES[4];
[1]IRP/NIDA/NIH, Baltimore, MD; [2]IRP/ NIDA/ NIH, Baltimore, MD; [3]Natl. Inst. On Drug Abuse, Baltimore, MD; [4]Cell Neurobiol Res. Br., IRP, NIDA, NIH, Baltimore, MD

Abstract: Dopamine inputs from the ventral tegmental area (VTA) to the medial prefrontal cortex (mPFC) have been implicated in neuropsychiatric pathologies for decades. Recent findings indicate that the mPFC is also innervated by VTA neurons expressing the vesicular glutamate type 2 (VGluT2). However, it is unclear the extent to which the subdivisions of the mPFC are targeted by the different subclasses of VTA VGluT2 neurons. In this study, we injected the retrograde track tracer fluorogold (FG) in either the prelimbic (PrL) or infralimbic (IL) cortex of wild type rats, and phenotyped the VTA FG-positive (mesocortical) neurons by a combination of *in situ* hybridization (to detect VGluT2 mRNA or glutamate acid decarboxylase, GAD mRNA) and immunohistochemistry (to detect both FG and tyrosine hydroxylase [TH]). For the mouse analysis of mesocortical VGluT2 neurons, we injected the AAV-DIO-eYFP viral vector into the VTA of VGluT2::Cre transgenic mice. In these mice, we also injected FG into the PrL or IL cortex, and evaluated VTA co-expression of FG and eYFP neurons. In rats and mice, we found that (1) both IL and PrL cortex received inputs from VTA neurons, but these VTA neurons provided 4.4 times more inputs to the IL than PrL cortex. (2) Four classes of VTA neurons innervated the mPFC: TH-only, VGluT2-only, dual VGluT2-TH, and GABA-only. (3) The VTA inputs to mPFC were mostly from VGluT2-only, TH-only and dual VGlu2-TH neurons, and less frequently from dual VGluT2-GABA or GABA-only neurons. By photoactivation of mPFC VGluT2 inputs from VTA neurons, we found that this mesocortical VGluT2 pathway induced conditioned place aversion, which depended on activation of both glutamate and GABA receptors. Next, we determined the type of IL neurons activated by the mesocortical VGluT2 pathway and found that this pathway induced c-Fos expression in parvalbumin (PV) GABA interneurons. By electrophysiological and ultrastructural analysis, we found that PV neurons of the IL cortex were the major target of VTA VGluT2 terminals (Dr. Zhang's abstract). Our findings indicate that the VTA provides a glutamatergic excitatory input to a subpopulation of IL cortical PV-GABAergic neurons, and that activation of these PV neurons inhibits neighboring pyramidal neurons, promoting aversive behavior.

Title: Electrophysiological properties of ventral tegmental area combinatorial glutamate-GABA neurons

Authors: *J. A. MIRANDA-BARRIENTOS[1], I. CHAMBERS[1], D. H. ROOT[2], H.-L. WANG[3], G. MATEO-SEMIDEY[1], B. LIU[1], M. F. MORALES[4];

Abstract: The ventral tegmental area (VTA) is a midbrain structure that contains dopamine neurons involved in diverse aspects of motivated behavior. In addition to dopamine neurons, the VTA contains glutamate neurons expressing the vesicular glutamate transporter 2 (VGluT2) and GABA neurons expressing vesicular GABA transporter (VGAT). We have recently shown that the VTA contains combinatorial neurons that co-express VGluT2 and VGAT and co-release glutamate and GABA. In this study, we determined the electrophysiological properties of VTA combinatorial VGluT2-VGAT neurons and compared these properties with those found in VGluT2-only or VGAT-only neurons. To selectively tag each class of VTA neurons, we crossed VGluT2::Cre mice with VGaT::FlpO mice and in the VTA of these dual transgenic mice injected intersectional and subtractive viral vectors that express enhanced yellow fluorescent reporter protein. By combination of immunohistochemistry (for detection of eYFP), *in situ* hybridization (for detection of endogenous VGluT2 or VGAT transcripts), we confirmed the specific expression of the reporter protein in the targeted combinatorial VGluT2-VGAT, VGluT2-only or VGAT-only neurons, and prepared VTA slices to determine their electrophysiological properties by *in vitro* patch clamp electrophysiology. Based on electrophysiological passive properties, we found that combinatorial VGluT2-VGAT neurons had hyperpolarized resting membrane potentials, indicating that these neurons require strong excitatory inputs to fire. By comparing combinatorial VGluT2-VGAT neurons with VGAT-only neurons, we found that VGluT2-VGAT neurons had lower excitability and lower basal firing frequency than VGAT-only neurons, indicating that the firing of VGluT2-VGAT neurons requires stronger excitatory inputs than those required by VGAT-only neurons. By comparing combinatorial VGluT2-VGAT neurons with VGluT2-only neurons, we found that some combinatorial VGluT2-VGAT and some VGluT2-only neurons had Ih currents, though the Ih current amplitude was lower in VGluT2-VGAT neurons. Based on the firing properties, we found two major categories of combinatorial VGluT2-VGAT neurons: those with rapid onset firing (located through the medial VTA), and those with delayed onset firing (located in the dorsomedial part of the VTA), indicating different ion channel configurations in spatially distributed VGluT2-VGAT neurons. In summary, we determined that combinatorial VTA VGluT2-VGAT neurons are diverse in their electrophysiological properties, and depending on their distribution within the VTA they may have rapid or delayed onset firing.

Title: VTA glutamatergic, but not GABAergic, neurons play a role in innate defensive behavior

Authors: *M. F. BARBANO, H.-L. WANG, B. LIU, A. FIGUEROA-GONZÁLEZ, M. MORALES;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Defensive behavior is characterized by different responses, such as freezing, fighting or escape. The brain circuits underlying freezing and fighting behaviors have been extensively studied but those underlying escape are not well understood. Recent studies suggested that dopamine neurons from the ventral tegmental area (VTA) play a role in escape behavior. However, the VTA comprises other type of neurons besides dopamine, such as glutamatergic and GABAergic neurons. We have started to characterize an escape response resulting from the activation of glutamatergic neurons of the VTA by optical stimulation of lateral hypothalamic glutamatergic inputs. However, it is unclear if GABAergic VTA neurons also play a role in this escape behavior. To further characterize the behavioral role of LH glutamate neurotransmission to VTA, we injected Cre-dependent viral vectors encoding ChR2 tethered to eYFP in the LH of VGluT2-Cre mice to tag LH axons expressing the vesicular glutamate transporter 2 (VGluT2). Stimulation of VTA inputs from LH glutamatergic neurons resulted in a specific increase of cFos in VGluT2-positive neurons. Then, we conducted looming tests with or without VTA optical stimulation of LH VGluT2 inputs. The looming stimulus induced escape in both eYFP and ChR2-eYFP mice without stimulation, but only ChR2-eYFP mice showed a significant increase in escape during VTA optical stimulation. By chemogenetics, we found that blockade of VTA VGluT2 neurons resulted in a decreased escape latency when mice were presented with threatening stimuli such as cat or fox urine odor. Next, to evaluate the behavioral consequences of ablating VTA VGluT2- or VGaT-expressing neurons (VGaT, vesicular GABA transporter), we injected Cre-dependent viral vectors encoding caspase and we repeated our odor and looming tasks in VGluT2-Cre or VGaT-Cre mice. We found that the ablation of VTA glutamatergic neurons decreased the latency to escape from predator odor, as well as the escape responses to a looming stimulus, while the ablation of VTA GABAergic neurons was without consequences. From these behavioral findings and cFos data, we conclude that VTA glutamatergic, but not

GABAergic, neurons play a role in innate defensive behaviors; and that one pathway conveying relevant information to this neuronal subpopulation arises from LH glutamatergic neurons.

Title: The prefrontal cortex-ventral tegmental area projection signals movement but not reward in positive and negative environments

Authors: *R. J. POST[1], B. J. SLEEZER[1], V. LEE[1], K. PELLEGRINO[4], N. W. RINGELBERG[5], B. A. MONCRIEFFE[2], M. R. WARDEN[1,3];
[1]Neurobio. & Behavior, [2]Sci. & Technol. Studies, [3]Cornell Neurotech, Cornell Univ., Ithaca, NY; [4]Rockefeller Univ., New York, NY; [5]Univ. of North Carolina Med. Sch., Chapel Hill, NC

Abstract: Major depressive disorder manifests as combinations of symptoms, and may include fatigue or decreased energy, decreased interest in things that were once considered pleasurable (anhedonia), psychomotor agitation or retardation, weight loss or weight gain, and many others. Recent research has begun to unravel distinct neural correlates for these behaviors. The medial prefrontal cortex (mPFC) and its projections to downstream brain regions such as the dorsal raphe nucleus has been shown to influence mobility in high-threat environments like the forced swim test, and ventral tegmental area (VTA) dopamine (DA) neuron stimulation has been shown to reverse both stress-induced immobility in high-threat environments and anhedonia; however, the role of the mPFC-VTA projection in these behaviors remains unclear. To interrogate the contribution of the mPFC-VTA projection to depression-related behaviors, male mice were injected in the mPFC with either AAV-CaMKIIα-ChR2-eYFP or a fluorophore-only control, and a fiber optic was implanted over the VTA. In comparison to fluorophore-only controls, optogenetic stimulation of mPFC axons in the VTA significantly increased struggling behavior

in the tail suspension test (n=21, $p<0.01$), mobility in the forced swim test (n=20, $p<0.05$), locomotion in a brightly lit, novel open field (n=22, $p<0.01$), and locomotion in a dark, familiar open field with home cage bedding (n=13, $p<0.01$), but did not affect the consumption or preference of freely available sucrose or water (n=22). Unlike the stimulation of VTA DA neurons (n=12, $p<0.01$), stimulation of the mPFC-VTA projection did not support place preference (n=13). To measure endogenous mPFC-VTA activity in behaving mice, an AAVretro vector expressing the calcium indicator GCaMP6s was injected in the VTA, and a fiber optic was implanted over the mPFC. mPFC-VTA calcium activity was positively correlated with locomotion in the open field and in an operant task in which mice worked for water, but did not reflect reward delivery or reward prediction error (n=10). These results highlight a selective role for the mPFC-VTA projection in movement.

Title: Infralimbic projections to the basal forebrain regulate fear extinction recall

Authors: *C. FERNANDES-HENRIQUES[1,2], R. ZHANG-SHEN[2], I. GRUNFELD[1,3], M. CORNIQUEL[6], N. BURNEY[2], S. LEI[4], M. LABKOVICH[2], D. SEMIDEY[5], E. LIKHTIK[1,2]; [1]The Grad. Ctr., [2]Hunter College, Biol. Dept., [3]Hunter College, Psychology Dept., [4]Hunter College, Computer Sci. Dept., [5]Hunter College, Chem. Dept., City Univ. of New York, New York, NY; [6]New York Univ., New York, NY

Abstract: Cross-species research shows that projections between the medial prefrontal cortex (mPFC) and the basolateral amygdala (BLA) contribute to extinction learning, although the circuit-level mechanisms of mPFC-mediated regulation of the BLA in extinction remain elusive. One region that may be regulating the mPFC-BLA dialogue during fear extinction is the basal forebrain (BF), a downstream target of the mPFC that also sends cholinergic and GABAergic

projections to the BLA. To probe this circuit, we first studied the anatomical connectivity between the Infralimbic (IL)/Prelimbic (PL) regions of the mPFC with BLA projecting neurons in the BF. We injected the retrograde tracer cholera toxin B (CTB) in the BLA, and the anterograde tracer synaptophysin-mCherry in the IL or PL. We then examined the overlap between tracers in the BF while counterstaining for cholinergic cells (choline acetyl transferase, ChAT+), and GABAergic neurons that express parvalbumin (PV+), and somatostatin (SOM+). We found that ChAT+ and PV+ (but not SOM+) cells project from the BF to the BLA. Further, the PL projects more to ChAT+ BLA projectors, whereas the IL preferentially targets PV+ BLA projectors. We then tested whether ChAT+ and PV+ BF cells are differentially recruited during fear or extinction recall. We injected CTB in the BLA and exposed mice to fear conditioning (4kHz tones) followed by either extinction training or white noise presentations. We then tested extinction or fear recall 24h later, and used cFos as a marker to look at neural activity in the BF. We found that PV+ and ChAT+ BLA projectors are more active during extinction and fear recall, respectively. We then used optogenetic manipulation of IL terminals in the BF to identify whether this circuit contributes to IL driven changes in extinction. Mice received injections of either the inhibitory opsin archaerhodopsin (eArch3.0/eYFP) or the excitatory opsin rhodopsin (ChR2/mCherry) in the IL, and optrodes were implanted in the BF. After fear conditioning, groups of mice underwent extinction training where tones coincided with inhibition (eArch/eYFP, 35s, 9mW) or excitation (ChR2, 35s, 7 or 20Hz, 9mW) of IL terminals in the BF. Extinction recall was tested 24h later. Animals that received inhibition of IL input to the BF during extinction training showed significantly impaired extinction recall, with a concomitant decrease in BF low gamma power. Conversely, animals that received excitation of IL terminals in the BF during extinction training showed enhanced fear extinction recall. Overall, our findings suggest that IL inputs to the BF modulate consolidation of fear extinction learning, likely by strengthening BF PV+ activity.

Title: Auditory safety training improves novel auditory discrimination learning and sensory discrimination curves

Authors: *I. NAHMOUD[1], J. G. VASQUEZ[2], H. CHO[3,4], T. DENNIS-TIWARY[3,4], E. LIKHTIK[1,4];
[1]Biol., [2]Chem., [3]Psychology, Hunter Col., New York, NY; [4]The Grad. Ctr., City Univ. of New York, New York, NY

Abstract: Overgeneralized fear (OF), or indiscriminate fear responses to threat and non-threat, is a core feature of anxiety. While research has focused on maladaptive fear learning in the emergence of OF, recent evidence suggests that maladaptive Safety Learning may play a unique role in OF. Yet, the independent influence of Safety conditioning on OF is not understood. To address this question, we tested how three different Safety Conditioning protocols with varied levels of uncertainty compared to classic Fear Conditioning as to how they impact behavior on subsequent tests of innate anxiety and differential fear learning of new aversive and neutral cues. Using a high anxiety strain of mice (129SvEv, Taconic), we show that animals undergoing Fear Conditioning (n=12) using 5 pairings of a tone (4kHz, 30sec,80dB) with a shock (0.5mA, 1 sec) show little exploration of the anxiogenic center of an Open Field 24 hours later, and poor discrimination during new differential conditioning 7 days later. Three groups of mice underwent Safety Conditioning, where (A) the safety tone was unpaired with a shock (n=12), (B) the safety tone was unpaired with the shock and co-terminated with a 1 sec house light signaling the end of the cue (n=12), and (C) the safety tone was unpaired with the shock and co-started with a 1 sec house light that signaled the beginning of the cue (n=12). All tones were 4kHz, 30sec,80dB, and shocks 0.5mA, 1 sec long. Mice from all Safety training groups (A-C) showed better discrimination on the new differential fear conditioning task than those from the Fear Conditioning group, with the group that underwent Safety Training C showing the strongest discrimination on new learning. We then tested whether Fear and Safety Conditioning differentially affect auditory discrimination curves. To this end, we first Fear or Safety Conditioned mice using paradigm C (beginning of tone co-occurs with a 1s light). Next, we exposed mice to a series of tones in the training context and compared freezing behavior to the target training cue (4 kHz) with a series of tones that were -2 to +2 octaves away from the training cue (1,2,4,8,16kHz). Mice that were Fear conditioned showed freezing to all the presented tones, whereas mice that were Safety Conditioned showed a selective decrease in freezing to the trained target tone (4kHz). These data suggest that Safety Conditioning sharpens auditory discrimination. We are currently investigating how Fear or Safety conditioning affects auditory discrimination during novel learning, and the physiology of auditory cortex, prefrontal cortex, and the amygdala communication that accompany Safety Conditioning.

Title: Nucleus accumbens neurons exhibit cell-type specific coupling to hippocampal inputs

Authors: *E. F. OLIVEIRA[1], L. L. SJULSON[2];
[1]Dominck P. Purpura Dept. of Neurosci., [2]Albert Einstein Col. of Med., Bronx, NY

Abstract: The Nucleus Accumbens (NAc) is a key brain area involved in reward-guided behavior and drug addiction. Besides its many inputs from critical areas responsible for cognitive functions (including prefrontal cortex, amygdala, and thalamus), one of prime interest is hippocampus (HPC). The HPC plays a key role in memory formation and generation of sequences representing environmental variables. The HPC-NAc pathway has the potential to be involved in reinforcing representations developed in the HPC, as presented in previous work. However, little is known about how HPC representations are transformed in the NAc and how the NAc performs computations on HPC inputs. Here, we investigated how NAc units respond to network activity form HPC, such as theta oscillations and sharp-wave ripples. We split the NAc units into putative cell types (medium spiny neurons (MSN) expressing D1 and D2, tonically active neurons (TAN) and fast spiking interneurons (FSI)) and looked at their firing behavior with respect to HPC activity. Our preliminary results show that these cell types respond differentially to theta oscillations and SWRs. Surprisingly, the same cells are not generally modulated by both. Our results also point that cells theta or SWR responsive are usually spatially segregated in the dorsal-ventral and medial-lateral axis of NAc. These results suggest that cells in different regions of NAc are performing different computations with HPC inputs, and that these computations performed by sub-regions of NAc are brain state dependent.

Title: Parsing the neural circuits for visually-evoked emotional contagion

Authors: *H. JUNG[1], A. D. HUBERMAN[2,3,4,5];
[1]Dept. of Neurobio., Stanford Univ. of Sch. of Med., Stanford, CA; [2]Dept. of Neurobio., [3]Dept. of Ophthalmology, [4]Stanford Neurosci. Inst., [5]BioX, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The ability to assess and perceive the behavior and internal state of others is an essential trait of social animals. This process, termed emotional contagion, enables organisms to adapt to their environment with reduced risk as well as promoting social bonds. Failures of emotional contagion are also implicated in developmental cognitive disorders, such as autism spectrum disorder. Despite the considerable study of the neural correlates of emotional contagion in humans and non-human primates, we know very little about the underlying cell types, circuit architectures, and computations that drive this crucial phenomenon.
We have developed a behavioral paradigm that allows precise measurement of the robust behavioral responses triggered in mice ("observer") while viewing innate defensive behaviors of conspecifics ("demonstrator") exposed to visual threat 'looming stimuli'. Using this "visually-evoked emotional contagion (VEEC)" assay, we asked:
1) Do mice visually determine and adopt the internal state of their conspecifics?
2) What behavioral repertoires do the observer mice perform?
3) Which regions in the brain are necessary for visually-evoked emotional contagion?
We found that freezing is the major responsive behavior of the observer mice to an observational threat. Autonomic responses of the observer mice revealed that this is defensive freezing indicating the observer's response is caused by changes in internal state, not by the pure mimicry of the demonstrators' behavior. Circuit mapping revealed increased neuronal activity in the claustrum of the observer mice that experienced observational threat. Chemogenetic inhibition of claustrum neurons impairs defensive freezing in observer mice during VEEC assay while activation of those induces defensive freezing. Interestingly, when mice are directly under looming stimuli, a threat with a higher risk than an observational threat, activation of claustrum neurons promotes arousal-enhanced responses to threat such as confrontational behavior (tail rattling), whereas inhibition of claustrum neurons promotes arousal-reduced responses such as freezing. Moreover, activation of claustrum neuronal activity increases autonomic arousal. These findings reveal that emotional contagion generated by vicarious visual threat exists in rodents and suggest that claustrum plays an important role by gating the saliency level during visual threat perception.

Title: Pair bonding attenuates fear memory acquisition through oxytocin receptor signaling in monogamous prairie voles

Authors: *Y. HIROTA[1], L. J. YOUNG[2,3], S. MITSUI[1];
[1]Gunma Univ. Grad. Sch. of Hlth. Sci., Maebashi, Gunma, Japan; [2]Ctr. for Social Neural Networks, Univ. of Tsukuba, Tsukuba, Japan; [3]Silvio O. Conte Ctr. for Oxytocin & Social Cognition, Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA

Abstract: Social bonds can ease the distress of experiencing of life-threatening events, such as disasters. We have used monogamous prairie voles to explore the relationship between pair bonds and response to stressful events. Previously we found that the single prolonged stress (SPS) paradigm enhances fear memory in a contextual fear conditioning paradigm in non-bonded, but not in pair bonded males. Here, we confirmed the pair bond-dependent attenuation of fear memory using another fear memory paradigm, a passive avoidance test. Adult male voles were cohabited with an unrelated female prairie vole (pair bond group; N = 17) or with a male (cagemate group; N = 16) for 4 days. Pair bonding was confirmed by a partner preference test. The next day subjects were allowed to freely investigate a passive avoidance apparatus. The next day subjects were placed in the light chamber and the latency to enter the dark chamber was recorded. When subjects entered the dark chamber a 2 sec electric shock was delivered twice with 1min interval (conditioning). Subjects were again placed in the light chamber 24 h after conditioning, and latency to enter the dark chamber was recorded (memory test). The pair bond group showed shorter latency compared to the cagemate group in the memory test ($p < 0.001$). Further, the cagemate group delayed the latency in the memory test compared to at conditioning ($p < 0.0001$), while the pair bond group did not ($p > 0.05$). There were no group differences in fear extinction in the absence of shock. We hypothesized that oxytocin (OT) may mediate this phenomenon. OT receptor antagonist (OTA) or vehicle was administrated i.c.v. in pair bonded male subjects 30 min prior to testing. The OTA group showed longer latency to enter the dark chamber than the vehicle group ($p < 0.008$) and OTA delayed the latency to enter the dark chamber in the memory test compared to that at the conditioning ($p < 0.0001$). In contrast, the latency between the memory test and conditioning was not different in the vehicle group ($p >$

0.05). These results suggest that pair bonding attenuates fear memory acquisition probably through central oxytocin receptor signaling.

Title: Central oxytocin is anxiolytic and anti-depressive in B6 mice

Authors: *K. E. NISBETT[1,2], M. E. RAGOZZINO[1];
[1]Dept. of Psychology, [2]Grad. Program in Neurosci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: There is accumulating evidence that the induction of endogenous oxytocin release or exogenous administration facilitates social preference and social bonding. This may result from oxytocin supporting reward in social contexts. Alternatively, oxytocin may be anxiolytic in social contexts or oxytocin may have both rewarding and anxiolytic effects. Other findings suggest that oxytocin also affects reward outside a social context, as oxytocin can modify the rewarding effects of drugs of abuse. The present experiment investigated whether a central infusion of oxytocin, alone, can affect reward and/or anxiety. Because oxytocin has been suggested to be a possible anti-depressive treatment, this study further explored whether an oxytocin infusion affects performance in the tail suspension task (TST). To carry out these experiments, a guide cannula was first unilaterally implanted into the lateral ventricle of C57Bl/6J (B6J) mice. Subsequently, mice received an intracerebroventricular (ICV) infusion of vehicle or one of three doses of oxytocin (100, 200 or 500 ng) and tested on the conditioned place preference (CPP), elevated zero maze (EZM) or TST. In the CPP test, B6J mice received ICV injections of oxytocin during the conditioning phase. Initial findings indicate that oxytocin at 200ng, but not 100ng or 500ng increases time spent in the open zones of the EZM. Correspondingly, ICV infusion of oxytocin dose dependently reduces immobility duration in the TST. In contrast, preliminary results indicate that ICV injection of oxytocin, across all doses, during the conditioning phase of the CPP did not lead to a CPP. Taken together, these preliminary results suggest that central infusions of oxytocin may have an anxiolytic and anti-depressive effect, but does not lead to reward. In an ongoing study, the effects of oxytocin infused directly into the nucleus accumbens core on these various behavioral measures are being explored.

Title: Social buffering in a novel social fear conditioning procedure in male and female rats

Authors: *L. M. DAWUD[1], E. C. LOETZ[2], A. L. HAAS[1], S. TRAN[1], J. WISEMAN[2], I. MAMAYAN[1], B. N. GREENWOOD[2], S. T. BLAND[2];
[1]Integrative Biol., [2]Psychology, Univ. of Colorado Denver, Denver, CO

Abstract: Social fear is a learned behavior that may contribute to stress-related disorders such as Post-Traumatic Stress Disorder (PTSD) and Social Anxiety Disorder (SAD). We have developed an innovative animal model of conditioned social fear in which footshock unconditioned stimuli are paired with social cue conditioned stimuli (CS rats). Here we assess social buffering in our paradigm. Social buffering is a phenomenon observed in social animals, in which an animal better recovers from a stressor if another animal of the same species (conspecific) is present. We have previously observed social buffering in female rats that were exposed to a paired footshock and CS rats in which they had reduced freezing behavior when compared to the footshock only controls following re-exposure to the conditioning apparatus. To further investigate social buffering, we exposed male and female Sprague-Dawley rats to a same-sex conspecific social stimulus during fear conditioning using a two-by-two design. All experimental rats received 4 footshocks (0.8 mA, 1.0 sec) with 1 min interstimulus intervals on Day 1, either with or without a social stimulus and were re-exposed to the conditioning chambers on Day 2, either with or without a CS rat. CS rats did not receive footshocks as they were contained in a special insert. This special insert was built with a Plexiglas platform protecting the CS rat from footshocks and a wire mesh that separates experimental rats from the CS rats. This wire mesh allows for the experimental rats to see and smell the CS rats. Experimental rats were thus assigned to one of four groups: the conditioned social fear (CSF) group that received a social stimulus on Day 1 but not Day 2, the CSF group that received a social stimulus on Day 2 but not Day 1, a social stimulus only group, and a footshock only group. Freezing behavior was the dependent variable analyzed during Day 1 (during each interstimulus interval) and Day 2 for the 8-minute re-exposure. Experimental rats that received foot shocks with a CS rat had decreases in freezing behavior compared to rats that got footshocks with no CS rat. These results suggest that both male and female rats display social buffering of fear conditioning using our procedure.

Title: Visual recognition of mirror, video-recorded, and still images in rats

Authors: *T. YAKURA, H. YOKOTA, Y. OHMICHI, M. OHMICHI, T. NAKANO, M. NAITO;
Dept. of Anat., Aichi Med. Univ., Aichi, Japan

Abstract: Several recent studies have claimed that rodents have high visual recognition abilities. However, extent to which rats can recognize the other rats and distinguish between males and females using visual information alone remains unclear. In the present study, we investigated the ability of rats to visually recognize mirror, video-recorded, and still images and to discriminate between images of males and females. Rat was examined in a place preference apparatus with a mirror, a video recording of a rat, or a still image of a rat at one end. Male and female rats spent significantly more time in the mirror chamber and the video recording chamber than in their respective blank chambers ($P < 0.05$), and male rats also spent more time in the chamber containing a still image. Furthermore, it was found that both male and female rats exhibited significantly more sniffing behavior around the mirror than in the blank chamber ($P < 0.05$), whereas there were no significant differences in the sniffing behaviors in the moving or still image experiments ($P > 0.05$). Identical results were obtained regardless of whether the rat in the image was the same or opposite sex. These results indicate that rats can process the differences in mirror, video-recorded, and still images as visual information, but are unable to use this information to distinguish between the sexes.

Title: An ecologically-relevant paradigm to study fear and foraging strategies in mice

Authors: *P. R. ZAMBETTI[1], B. P. SCHUESSLER[1], J. J. KIM[2];
[1]Psychology, [2]Psychology and Program in Neurosci., Univ. of Washington, Seattle, WA

Abstract: Laboratory models used to investigate fear have consistently relied upon Pavlovian fear conditioning (pairing a neutral cue with an aversive stimulus, and later measuring the fear response to the cue) to understand the neural mechanisms underlying adaptive and maladaptive fear behavior. However, in nature, it is disputed that Pavlovian fear conditioning is the primary mechanism by which animals come to fear stimuli; animals' are typically not afforded multiple conditioning trials to learn that a particular stimulus (e.g., a predator) is dangerous and therefore should be avoided. In contrast, ecological studies from multiple labs investigating innate, unlearned fear responses to artificial predator stimuli have shown that rodents display reliable fear and avoidance behaviors to such stimuli with no prior experiences necessary. Our lab has previously developed a naturalistic, "approach-food avoid-predator" paradigm in rats used to study innate fear and risky-decision making behaviors and their underlying neurocircuitry (Choi and Kim, 2010). Briefly, hungry animals foraging for food pellets encounter a robotic "terrestrial predator", which is programmed to surge at the animal as it approaches a food pellet. Fear responses are measured over multiple predator testing days. In light of the rapidly increasing use of mice in neuroscience research—largely due to the availability and feasibility of transgenic animals—we have adapted our approach-food-avoid-predator paradigm for use in mice. Additionally, we made the predator stimulus more realistic than our rat version by replacing the robotic threat with a taxidermy weasel. We demonstrate that mice naturally forage for food pellets in an open arena as well as flee from a surging predator. Likewise, mice required multiple days of predator testing for fear responses to habituate to the consistent looming threat, as seen in rats. Finally, we show that the presence of stationary but realistic predator does not deter mice from attempting to procure food, suggesting that the looming motion is evolutionarily reliable signal of danger. This paradigm would be useful for researchers seeking to harness the powerful capabilities of transgenic animals to study naturalistic fear behavior and neurocircuitry.

Title: The effects of lateral habenula lesions on foraging and avoidance behavior in rats living in a naturalistic, risky foraging environment

Authors: *B. P. SCHUESSLER[1], J. J. KIM[2];
[1]Psychology, [2]Psychology and Program in Neurosci., Univ. of Washington, Seattle, WA

Abstract: The lateral habenula has long been implicated in associative fear learning, particularly instrumental avoidance and to a lesser extent Pavlovian (classical) fear conditioning. These findings have been predicated on rodent studies using paradigms that implement discrete cues predicting aversive outcome, such as active avoidance or standard tone-shock fear conditioning tasks. These tasks are brief in duration and measure a limited set of behaviors. Additionally, not much is known on how the lateral habenula participates in risky decision-making. To further probe the lateral habenula's contributions to fear-and-anxiety related behavior and decision-making processes, the current study employed a longitudinal, "closed economy" risky foraging paradigm. In this paradigm, animals live continuously and largely undisturbed in modified operant chambers partitioned into a safe nest area and risky foraging area. Animals must acquire all their food and water in the foraging area, which contains a steel rod floor, operant levers and a water port. After a baseline foraging assessment, animals received bilateral electrolytic lesions (or sham lesions; electrodes lowered but no current passed) of the lateral habenula, which was followed by a post-surgery baseline foraging assessment. After the post-surgery baseline assessment, pseudo-random, unsignaled foot shock was introduced in the foraging area. Finally, shocks were terminated to examine extinction behavior. Lateral habenula lesions greatly altered baseline feeding patterns, which persisted throughout the remaining phases of the experiment. However, the introduction of unpredictable foot shocks in the foraging area led to similar compensatory changes in feeding behavior to that of sham lesion animals. Lesioned animals spent more time in the risky foraging zone during the shock period, and consequently received more shocks than sham lesion animals. Lesions also blunted shock-induced drinking suppression, and lesioned animals were quicker to return to baseline water consumption levels during extinction. These results highlight the role of the lateral habenula in regulating both appetitive and defensive behavior.

Title: Potent and quick responses to conspecific faces and snakes in the anterior cingulate cortex of monkeys

Authors: *N. KONOIKE, H. IWAOKI, K. NAKAMURA;
Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: Appropriate processing of others' facial emotion is a fundamental ability of primates in social situations. Several mood and anxiety disorders such as depression cause a negative bias in the perception of facial emotions. Depressive patients show a decrease of activation in the perigenual portion of the anterior cingulate cortex (ACC) and an increase of activation in the amygdala. However, it is not known whether neurons in the ACC have a function in the processing of facial emotions. Furthermore, the existence of predators in their vicinity is life-and-death information for monkeys. In the present study, two adult rhesus monkeys (*Macaca mulatta*) were used (monkey C: 8 kg, male; monkey P: 7 kg, female). We recorded the activity of single neurons from the monkey ACC and examined the responsiveness of the ACC neurons to various visual stimuli including monkey faces, snakes, foods, and artificial objects. About one fourth of the recorded neurons showed a significant change in activity in response to the stimuli. The ACC neurons exhibited very high selectivity to certain stimuli, and more neurons exhibited the maximal response to monkey faces and snakes than to foods and objects. The responses to monkey faces and snakes were faster and stronger compared to those to foods and objects. Many ACC neurons preferred scream, a negative facial emotion. The response characteristics of the ACC neurons were similar to those of the amygdala neurons. Most of the responsive neurons were located just above or anterior to the genu of the corpus callosum, that is, the perigenual portion of the ACC, which has a strong mutual connection with the amygdala. These results suggest that the perigenual portion of the ACC collaborating with the amygdala forms the neural network underlying emotional information processing, especially for negative life-and-death information such as screaming faces and snakes.

Title: Opposing contributions of subregions of the primate orbitofrontal cortex to the regulation of threat in the common marmoset

Authors: *Z. M. STAWICKA, R. MASSOUDI, L. OIKONOMIDIS, N. K. HORST, A. C. ROBERTS;
Dept. of Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Structural and functional abnormalities of the orbitofrontal cortex (OFC) have been implicated in affective disorders such as anxiety and depression. However, the primate OFC is composed of a number of distinct subregions including areas 14, 11, and 13 in the medial, anterior and posterior OFC, respectively. Aside from differences in cytoarchitecture and connectivity, these regions have been shown to contribute to different aspects of the signaling of reward value, but their potentially separable roles in the processing of threat and anxiety remain unclear. To address this issue, the current study compares the effects of inactivation and in some cases overactivation of areas 11, 13 and more caudal area 14 in marmoset monkeys on tests of uncertainty and conditioned threat. Temporary inactivation was induced by infusing GABA A/B agonists (muscimol and baclofen, respectively) into the target regions through implanted cannulae. Overactivation was induced by infusing an inhibitor of the GLT-1 glutamate transporter, dihydrokainic acid, to increase synaptic glutamate. We used the human intruder test, a paradigm used commonly in primates, to examine the natural display of behaviours towards uncertain threat in order to study anxiety. The test revealed differing effects following manipulations of area 11 and 13, compared to caudal area 14. Anxiety was heightened, and avoidance of the human intruder enhanced following temporary inactivation of area 11 or 13, although detailed comparison revealed differences in the specific behavioural repertoire displayed. Conversely, a similar heightening of anxiety was seen following overactivation, rather than inactivation, of medial area 14. Consistent with an increase in threat-driven responses following area 14 activation, inactivation was shown in a subsequent Pavlovian conditioning paradigm to reduce the acquisition and expression of conditioned cardiovascular and behavioural arousal to threat, in which a rubber snake acted as an ethologically relevant unconditioned stimulus. Distinct roles of the medial (area 14) and central (areas 11 and 13) OFC have previously been described in terms of reward value processing and decision-making. However, our findings imply that these theories require further refinement to incorporate the roles of these

subregions in response to threat. Our observations suggest that temporarily altered activity in both the caudal medial and central regions can impact on the expression of fear and anxiety-like behaviours but do so in an opponent fashion. Future studies will be required to tease out the unique functions of these three regions in the regulation of threat driven responses.

Title: Differentiation between physical and emotional response patterns with the application of electrophysiological sensors in a VR environment

Authors: *J. KRITIKOS[1], **M. DOULOUDI**[2];
[1]Electrical and Computer Engin., Natl. Tech. Univ. of Athens, Athens, Greece; [2]Biol., Natl. Kapodistrian Univ. of Athens, Athens, Greece

Abstract: Motion artifact is considered as a serious blockade in electrophysiological measurements, since it leads to ambiguous and less accurate results, making both the recording and data interpretation process more challenging and time-consuming. As a result, instructions concerning the appropriate usage of electrophysiological sensors restricts any possible movement during measurements by urging the patients to remain calm and motionless. However, the expansion of virtual reality systems as an immersive and interactive tool to efficiently provoke specific and actual emotions with the introduction of stronger and more realistic stimuli, necessitates the presence of physical movements during the simulations, making the appearance of motion artifact unavoidable. On the other hand, denoising approaches cannot stand as reliable methods to extract wholly the artifact, considering the risk of fatigue phenomenon that arises in a physical effort - dependent way. In our study, by employing a Virtual Reality (VR) environment, we aim to decipher distinct emotional patterns, adequate enough to distinguish fatigue conditions from non-fatigue ones and also to propose a denoising system, capable to predict and remove motion artifact based on these patterns. For the purpose of our study, we collected ten healthy subjects, six males and five females, all belonging in the same age group (22-30 years old) and with an average physical condition. All volunteers were divided into two different groups of five people and appropriate physiological responses (electrodermal activity and heart rate) where measured by applying the corresponding sensors, while being exposed to the same horror video in the VR. In the first group, we measured the electrophysiological signals of fully rested for a considerable amount of time users, whereas in the second group we measured

electrophysiological signals while users were susceptible to fatigue, which was introduced with a set of specific training exercises prior to the VR session. We deciphered two distinct characteristics in our measurements, each corresponding to our selected sensors. We concluded that these specific motives are consistent with potential fatigue signals and thus we attempted to predict and establish a non-fatigue framework by removing the noise derived from physical exercise.

Title: Resting state functional connectivity of the human periaqueductal grey using 7-Tesla MRI

Authors: ***C. N. WEIS**, A. A. HUGGINS, K. P. BENNETT, E. A. PARISI, C. L. LARSON; Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: The periaqueductal grey (PAG) is a region of the midbrain that has been implicated in a variety of complex behaviors including defensive responses to threat. Functional differences in the longitudinal columns of the PAG in animal models have been well established. The dorsal columns have been implicated in active-coping defensive strategies such as fear, panic, and fleeing behaviors, while the ventral columns appear to facilitate passive-coping strategies such as freezing or quiescence behaviors. Thus, misevaluation or appraisal of threat stemming from aberrant PAG activity may be a potential neural mechanism of human psychopathological disorders such as anxiety and posttraumatic stress disorder. The distinct functional roles of the PAG columns are well-maintained across species including humans; although, most functional connectivity work of the human PAG has examined task-based effects that elicit the distinct behavioral outcomes of PAG columns. Therefore, the current study utilized high resolution 7-Tesla MRI to characterize the functional connectivity of the PAG *at rest*. A sample of 57 neurologically healthy undergraduate participants (M_{age}=22.2, SD_{age}=3.62) underwent structural and resting state functional MRI scans. Whole brain voxel-wise analyses show the PAG is functionally connected to occipital cortices, thalamus, medial prefrontal cortex, pons, superior/inferior colliculi, caudate, and insula. These results support previous work showing the resting connectivity of PAG to emotion regulation and fear networks. Interestingly, comparison of functional connectivity of the dorsal and ventral PAG columns did not reveal any significant

differences. These results may suggest functional distinctions of the columns only emerge when presented with threat directly whereas at rest these regions are functionally indistinguishable.

Title: Brain responses elicited by recollecting a break-up event of oneself

Authors: *L.-Y. CHIEN, W.-J. KUO;
Yangming Univ., Taipei, Taiwan

Abstract: We humans are social animals. Social rejection or exclusion will induce negative emotions and cause psychological feelings of pain. Driven by social attachment, the ancient pain system may have provided neural bases for responding to events of social rejection or exclusion. There is evidence indicating that the neural networks of social pain and physical pain matrix overlapped. However, in studies of social rejection, they mostly included only two conditions, one for social rejection and one neutral control. In this study, in order to have a more comprehensive emotion spectrum to profile the neural bases of social rejection, we included one more condition which could help to induce positive emotions from the same participant for comparison. We recruiting female participants who had just experienced a romantic relationship break-up (being dumped by their ex-partner) within one year. The major task was arranged as follows. By cuing with presenting photos of their ex-partner, their good friend, and an acquaintance, the participants were instructed to recollect their common life event in the past and try to re-experience it. We believed, compared to previous studies, current arrangement of the good-friend condition could serve as a better checking point for brain activities among conditions. For the task, several mental processes were expected to take place, including recollecting autobiographical memories, eliciting corresponding emotions, self-evaluation processing, and emotional regulation. The subjective rating scores indicated that the participants seemed to feel sadder over the ex-partner trials than over the friend and neutral trials. The fMRI results showed that the brain areas activated by the ex-partner condition overlapped with the pain processing network, for example the thalamus, anterior insula, and dorsal ACC. We also found that the mPFC was significantly activated in both the ex-partner and good-friend conditions. It positively correlated with emotional arousal. On the other hand, higher activities in the ventrolateral PFC were only observed in the ex-partner condition. Therefore, we supposed the processes of valuation and emotion regulation were significantly involved. Taken together, we

replicated the findings that the psychological pains will recruit physical pain network for responses. More important is the finding that the valuation and regulation processes were involved as well. It might justify that why some can get rid of grief from the social rejection event and some cannot.

Title: Multimodal affect recognition: Deep learning analysis of physiological, environmental, facial expression, and mobile sensor data for emotion detection in chronic pain patients

Authors: *L. P. WHEELER[1], P. NEJEDLY[2], V. KREMEN, JR[3], B. BRINKMANN[2], G. A. WORRELL[2];
[1]Mayo Clin. Grad. Sch. of Biomed. Sci., Rochester, MN; [3]Neurol., [2]Mayo Clin., Rochester, MN

Abstract: Background: Of the 1 in 6 people worldwide with primary neurological disorders, approximately 40-60% present with chronic pain and affective disorders as frequent comorbidities. The relationship between chronic pain and mood disorders is bidirectional, and neither can be effectively treated until all sensory, affective, psychological, and emotional aspects of both conditions are addressed. The unclear association in which increases in symptom recurrence, severity, and morbidity as well as accurate pain and emotional assessments have limited effective integration of the affective dimension of pain into guiding treatment modalities. The growing popularity of sensors and low power integrated circuits, along with the increasing use of wireless networks have led to the development of affordable, robust, and efficient wearable devices which can capture and transmit data in real time. These data sources provide a unique opportunity for innovative ways in recognizing affect and pain levels through human physiological sensing while also taking into account environmental factors, activity levels, motion patterns, and cognitive function from mobile sensing. Here, we present a novel, multimodal hierarchical fusion strategy which uses a deep learning approach on raw mobile and sensor data to achieve real time, state-of-the art results on emotion recognition.
Methods: We collected raw sensor data including blood volume pulse, electrocardiogram, skin conductance level, respiration rate, mobile key-strokes, electroencephalogram, video, and patient ratings of pain intensity, emotion, and mood from a subset of chronic pain patients. We also

integrated data from databases including DEAP, CK DFAT, and UNBC-McMaster Shoulder Pain Database. Our model learns the spatio-temporal hierarchical features from sensors through a multiple-fusion-layer based ensemble classifier using Deep Neuroevolution optimization of a combination of Convolution Neural Network and Long Short-term Memory Recurrent Neural Network. For the dynamic facial action unit coding system, we extracted textural and geometric features through Gabor wavelet and Procrustes analysis, and then trained Gentle Adaboost classifiers.
Results: Here, we present a state-of-the-art method for physiological affect detection and automated facial action coding for neuropsychiatric research. Using a hybrid deep learning model and multiple sensor modalities, we were able to achieve an objective and quantitative evaluation of affect, valence, arousal, and pain intensity with an %5.2 improved affect recognition accuracy rate over the best emotion recognition algorithms in existing literature.

Title: When and why two emotional experiences are similar to each other

Authors: *M. RIBERTO[1,2], M. C. IORDAN[3], R. PAZ[4], G. POBRIC[2], D. TALMI[5];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]The Univ. of Manchester, Manchester, United Kingdom; [3]Princeton Univ., Princeton, NJ; [4]Neurobiology, Weizmann Institue of Sci., Rehovot, Israel; [5]Sch. of Psychological Sciences, Univ. of Manchester, Manchester, United Kingdom

Abstract: Rationale. Emotional similarity refers to the tendency to group stimuli together because they evoke the same feelings. The study of emotional similarity may impact research about the over-generalization bias in anxiety disorders. No previous studies have investigated the relationship between similarity judgments and anxiety, nor the differences in similarity judgments between neutral and emotional stimuli. Mixed results have been reported about the neural correlates of emotionally similar stimuli. We hypothesized a positive correlation between similarity judgments and anxiety, and higher similarity within emotional than neutral stimuli. We also predicted higher activation in high-order visual areas, as well as in brain regions involved in emotional processing. **Methods.** We selected 72 complex pictures from freely-available sources, and divided them into 4 categories, 2 neutral (i.e., people doing laundry, people on the phone)

and 2 negative emotional (i.e., poverty scenes, car accidents). All categories differed in valence and arousal, and were balanced for visual properties. Before functional magnetic resonance imaging (fMRI), 8 participants filled the State-Trait Anxiety Inventory (STAI). During the scan, participants rated the visual complexity of the pictures. After the scan, the participants judged the similarity of these pictures by using the multi-arrangement method. We analysed the similarity judgments by using Representation Similarity Analysis (RSA). **Results.** We found that participants with the higher STAI scores perceived the pictures within each emotional category to be more similar to each other ($r= 0.72$, $p=0.02$). Second, the emotional pictures within the 'car accidents' category were judged as more similar to each other than neutral stimuli ($p<0.001$). Finally, we observed higher activation for the emotional pictures than neutral pictures in the bilateral Middle Occipital Gyrus (left: $T= 10.26$, $pFDR<0.001$; right: $T= 9.48$, $pFDR<0.001$) and in the right Insula ($T=7.76$, $pFDR=0.02$). We also found that the emotional pictures were associated with lower activation in the right Ventromedial Prefrontal Cortex (VMPFC) than the neutral stimuli ($T= 8.81$, $pFDR=0.02$). **Conclusion.** These preliminary results suggest that anxiety might increase the similarity among emotional stimuli. In line with previous findings, negative and arousing stimuli are perceived as highly similar. This might be related to the higher activation in the Insula, which in turn amplifies the activation in high-order Occipital areas, and leads to a lower recruitment of the VMPFC compared to neutral stimuli.

Title: Prospectively assessed childhood trauma is associated with dysregulation of emotion processing in adulthood

Authors: *L. M. MAYO, Y. CHO, D. MIRO, P. GUSTAFSSON, M. HEILIG;
Linköping Univ., Linköping, Sweden

Abstract: Exposure to trauma in childhood or adolescence is associated with an increased susceptibility to the development of psychiatric disorders in adulthood. One potential contributing factor is disruption of the endocannabinoid (eCB) system, a neuromodulatory system involved in stress and emotion processing. The eCB system undergoes extensive

reorganization during adolescence, and perturbations of this process, such as exposure to trauma, can last into adulthood. Thus, childhood trauma may produce dysregulation of the eCB system, producing deficits in stress and emotion processing that contribute to the development of psychiatric disease in adulthood.
Recently, we have shown (Mayo et al., 2018; Mayo et al., in prep) that potentiated eCB signaling produces beneficial emotion regulation capabilities in healthy adults, including enhanced fear extinction and attenuated stress-induced negative affect. Here, we aimed to determine if childhood trauma is associated with deficits that mirror the beneficial effects produced by enhancing eCB signaling.
We recruited patients (ages 22-36) with prospectively assessed childhood trauma (expected N = 40; current N = 31) and matched non-trauma exposed controls (expected N = 40; current N = 34). Trauma-exposed patients were recruited from a specialized trauma unit of Child & Adolescent Psychiatry at the Linköping University Hospital that has been operating since the mid-1990's. Participants completed a laboratory session assessing fear learning, emotion processing, and stress reactivity using facial electromyography (EMG). We assessed baseline EMG responses to emotional images, reactivity to a standardized laboratory stressor, and stress-induced changes in emotional reactivity. In addition, participants underwent a fear conditioning and extinction using fear potentiated startle.
We find that patients exposed to trauma in childhood show attenuated emotional reactivity at baseline, perhaps reflective of "emotional numbing"; a core feature of PTSD. However, after stress, trauma-exposed patients demonstrate greater negative emotionality. Current analyses are underway to examine the acquisition and extinction of conditioned fear. Together, our preliminary analyses suggest that the deficits in emotion processing and regulation evident in trauma-exposed patients closely mirror the beneficial effects we see find following elevation of the eCB anandamide in healthy adults. Thus, the eCB system may represent a novel target to ameliorate stress- and emotion-related deficits following childhood trauma exposure.

Title: Exploration of the long-term anxiogenic effects of vicarious juvenile stressor experience

Authors: *E. F. ALI[1,3], P. KENT[3], J. S. JAMES[3], C. CAYER[4], A. ABIZAID[2], Z. MERALI[3]; [2]Neurosci., [1]Carleton Univ., Ottawa, ON, Canada; [3]The Royal's Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [4]Psychology/Biology, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The experience of stress is diverse as it can be directly experienced or be vicariously transmitted by witnessing a traumatic event. Stress during childhood can lead to negative long-term mental health effects; vicarious stress in the form of witnessing violence can lead to symptomology of mental illnesses. The behavioural effects of vicarious stress are largely unexplored and therefore crucial to investigate further using animal models. The juvenile period is sensitive as the hypothalamic-pituitary-adrenal axis is hyper-responsive to stress. There is a lack of evidence if vicarious stress can be induced during juvenility and whether there are long-term effects. The objective of this study was to explore if vicarious juvenile stress could elicit a potent stressor response leading to anxiogenic behavioural effects in adulthood. Modifying a juvenile stressor procedure to include a witness, male rats were subjected to six days of stress during postnatal days (PD) 27-32. Groups (n=10) included witnesses that observed their cage mate (demonstrator) endure a 10 minute session of the following: 10x1mA 1s footshocks (PD27 and 32), an inescapable swim stress (PD28 and 30), and restraint stress (PD29 and 31). Control rats remained in their home cage throughout the study and the witness-control group only observed their cage mate undergo no stress in the same contextual stress conditions. Corticosterone response was measured on PD27 and PD32 after the footshock and after a mild stressor in adulthood. Fear expression during the juvenile stressor was observed in the witness and witness-controls. In adulthood, fear expression and elevated plus maze (EPM) was conducted. On the first and last day of the juvenile stressor, corticosterone levels were elevated in all groups when compared to the home cage controls, and were particularly higher in the demonstrators and witnesses. Also, witnesses and witness-controls did not differ in fear expression during the stressor procedure. In adulthood, demonstrators exhibited greater fear expression, when placed back into the footshock context, than witnesses and witness-controls. There were no differences in elevations of corticosterone between the groups after a mild stressor. In the EPM, only stressed demonstrators showed anxiogenic behaviour. In sum, this model of juvenile stressor exposure can elicit a stressor response yet the long-term anxiogenic effects were not robust in the witnesses. It is possible that vicarious stress using this paradigm requires prior direct stress. Also, different central mechanisms could be at play that may explain the differences between direct and vicarious stress during the juvenile period.

Title: Abusive caregivers are not a secure base for their infant: Understand the neurobiology using a rodent model

Authors: *A. I. BLOMKVIST[1], M. OPENDAK[2], D. A. WILSON[3], R. M. SULLIVAN[4]; [1]Stockholm Univ., Stockholm, Sweden; [2]Child and Adolescent Psychiatry, New York Univ., New York, NY; [3]Child and Adolescent Psychiatry, New York Univ. Sch. of Med., New York, NY; [4]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY

Abstract: The human attachment literature highlights the quality of the infants attachment relationship to the caregiver as predictive of later life outcomes. Yet, we understand little of the neurobiology of this relationship. While the attachment literature highlights the infant's proximity seeking of the caregiver, it also highlights the attachment figure's role as a safe haven and secure base. The safe haven characteristic of the attachment figure provides comfort and relief under threat but also provides the infant with a safe base to explore the environment, which significantly impacts the infant's exposure to novel objects and social partners. The goal of the present research is to better understand the neural and behavioral features and balance between two infant behaviors: proximity seeking of the attachment figure vs. exploration of a novel social figure of an unrelated mother. Ten to 13-day old infant rats, with either a typical or atypical attachment to their caregiver, had their neurobehavioral response to simultaneous presentation of their own mother and an novel mother (maternal odor distinct from their own mother). All of pups' behaviors to the two anesthetized mother were recorded during measurement of cortical local field potential (LFP) oscillations. Results suggest that typical attached pups show both proximity seeking of the mother and the stranger, while atypically attached pup remained with the mother. LFP recordings show divergent LFP responses to the mother and stranger based on attachment quality. These results suggest that the neural processing of the mother in atypical attachment diverges from infants with typical attachment.

Title: Maternal suppression of learned fear and developmental transitions in prefrontal activity

Authors: *P. A. ROBINSON-DRUMMER[1], M. OPENDAK[1], A. BLOMKVIST[1,2], R. SULLIVAN[1];
[1]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY; [2]Univ. of Stockholm, Stockholm, Sweden

Abstract: Within the infant-caregiver attachment system, the primary caregiver acquires regulatory control over the developing emotion circuits and can modulate infant physiological and behavioral responses. A less well-understood feature of the attachment system is the caregiver's ability to reduce fear, commonly associated with the notion of a 'safe haven' in the developmental literature. In adult animals, the social support system that attenuates fear is associated with the prefrontal cortex (PFC). Evidence suggests that this system may overlap with the developing infant systems to produce the modulatory effects of maternal presence during fear learning. Here, using odor-shock conditioning in young rodents, we questioned when the infant system transitions to the adult-like system and whether the late-developing PFC is involved in the caregivers' reduction of infant fear. Rat pups were odor-shock conditioned (0.6mA) at either postnatal day (PN)18 or 28 with either the mother present or absent, with PFC assessment during acquisition followed 24hr later by cue testing. Since the human literature suggests poor attachment attenuates the mother's ability to socially buffer the infant, half of the pups at each age were reared with an abusive mother from PN8-12. Results showed that for typical control rearing, the mother attenuated fear in both PN18 and PN28 pups, although the PFC was only engaged at PN28 (infralimbic, ventral prelimbic). Abuse-rearing completely disrupted maternal social buffering at PN18. At PN28, pups showed that while the mother modulated learning in both control and abuse-reared pups, the behavioral and PFC effects were attenuated after maltreatment. Our data suggests that pups transition to the adult-like PFC social support circuit after independence from the mother (PN28), and this circuit remains functional after early life

trauma, although its effectiveness appears reduced. This is in sharp contrast to the effects of early life trauma during infancy, where maternal regulation of the infant, such as fear suppression, is more robustly impacted.

Title: Maternal social buffering reduces infant pain: Understanding the supporting neural circuitry

Authors: *G. A. BARR[1], M. OPENDAK[2], R. PERRY[2], R. M. SULLIVAN[3];
[1]Anesthesiol. and CCM, Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Ctr. for Early Childhood Hlth. & Develop., New York Univ. Sch. of Med., New York, PA; [3]Emotional Brain Inst., Nathan Kline Inst. and NYU Sch. of Med., New York, NY

Abstract: Infants and children have the brain circuitry required to perceive pain and also the brain circuitry to have that pain attenuated by a significant social partner such as an attachment figure. This latter mitigating effect is termed “social buffering”. For example, a child’s normal infrequent pains, such as falling while learning to walk, can be comforted by the caregiver as evidenced by reduced crying and reduced stress hormone levels. Similarly, basic science research finds that social buffering reduces the behavioral and neural response to pain, including the alteration of amygdala function. Over the past decade, social buffering has been introduced into medical settings where it has been useful in dampening frequent procedural pain, reducing the need for opioids for pain relief. However we know little about the neural circuitry supporting social buffering, nor about the long-term impacts of this form of pain relief. Recent animal research indicates that social buffering, *if used frequently*, initiates unique developmental trajectory that disrupts the normal development of the amygdala and alters adult pain processes and emotionality. Here we interrogate if and how infant and adult behaviors, and concomitant amygdala activation, are modified by experiencing infant pain vs. infant pain with social buffering. We tested these hypotheses by using rodent models of pain (foot stick or mild tail

shock) with or without social buffering produced by maternal presence during the age range of the sensitive period of pain programming and infant attachment learning to the mother. Our results show that maternal social buffering, when the infant is in pain, reduces activity and ultrasonic vocalizations, induces coherent changes in GPCR gene expression, and reduces Fos expression in several pain and attachment network brain regions to control levels after one day, although this effect was significantly diminished after 5 days of treatment. Adult assessment showed a slight hypoalgesia to heat but no injury induced hyperalgesia in any treatment group. Disruption of adult social behavior was seen when infant pain was socially buffered, although pain with and without social buffering both impacted threat responding. These studies aid in our understanding of the neural basis of social buffering and suggest it protects against some enduring effects of infant pain, though it worsens others.

Title: Developmental transitions in amygdala PKC isoforms and AMPA receptor expression associated with threat memory in infant rats

Authors: *R. ZANCA[1,2], M. OPENDAK[3], P. A. SERRANO[1,2], R. M. SULLIVAN[4]; [1]Hunter College, CUNY, New York, NY; [2]CUNY Grad. Ctr., New York, NY; [3]Child and Adolescent Psychiatry, New York Univ., New York, NY; [4]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY

Abstract: Although infants learn and remember, they rapidly forget, a phenomenon known as infantile amnesia. While myriad mechanisms impact this rapid forgetting, the molecular events supporting memory maintenance have yet to be explored. To explore memory mechanisms across development, we used amygdala-dependent odor-shock conditioning and focused on mechanisms important in adult memory, the AMPA receptor subunits GluA1/2 and upstream protein kinases important for trafficking AMPAR, protein kinase M zeta (PKMζ) and iota/lambda (PKCι/λ). We use odor-shock conditioning in infant rats because it is late-

developing (postnatal day, PN10) and can be modulated by corticosterone during a sensitive period in early life. Our results show that memory-related molecules did not change in pups too young to learn threat (PN8) but were activated in pups old enough to learn (PN12), with increased PKMζ-PKCι/λ and GluA2 similar to that observed in adult memory, but with an uncharacteristic decrease in GluA1. This molecular signature and behavioral avoidance of the conditioned odor was
recapitulated in PN8 pups injected with CORT before conditioning to precociously induce learning. Blocking learning via CORT inhibition in older pups (PN12) blocked the expression of these molecules. PN16 pups showed a more adult-like molecular cascade of increased PKMζ-PKCι/λ and GluA1–2. Finally, at all ages, zeta inhibitory peptide (ZIP) infusions into the amygdala 24hr after conditioning blocked memory. Together, these results identify unique features of memory processes across early development: AMPAR subunits GluA1/2 and PKC isoform expression are differentially used, which may contribute to mechanisms of early life forgetting.

Title: Infant neurobehavioral processing of the caregiver: Translating across species during typical and maltreatment rearing

Authors: *M. OPENDAK[1], E. THEISEN[2], A. I. BLOMKVIST[3], T. LIND[4], E. C. SARRO[5], M. DOZIER[6], R. M. SULLIVAN[7], D. A. WILSON[8];
[1]New York Univ., New York, NY; [2]New York Univ. Langone Med. Ctr., New York, NY; [3]Stockholm Univ., New York, NY; [4]UCSD, San Diego, CA; [5]Dominican Col., Orangeburg, NY; [6]Univ. of Delaware, Newark, DE; [7]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY; [8]Child and Adolescent Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Infants rely on the mother to provide them with the sensory stimulation needed for normal brain development. Altered maternal care, such as maltreatment, initiates a pathway to pathology, much of which remains dormant until later life when mental health is compromised. However, immediate effects can be detected in the maltreated infant by using the Strange Situation Procedure (SSP), which progressively stresses the child to uncover atypical responses to the caregiver (Ainsworth, 1969). Here we adapted this test for use in rat pups to aid in identifying the pups' atypical neurobehavioral features within a maltreatment-associated dyad. Using the Scarcity-Adversity Model of maltreatment induced by low bedding (SAM-LB) for nest building from postnatal days (PN)8-12, we compared SSP performance in maltreated rodents (PN13-14) and children; both exhibited behavioral features of disordered attachment in the SST. In pups, recording of cortical oscillations using local field potentials (LFP) showed that the mother had reduced ability to modulate the infant's rhythmic brain activity during SSP, compared to pups with no maltreatment experience. Next, we considered the progression of pups' atypical behavior and cortical oscillations by recording LFP in both pup and mother during brief periods of SAM (between PN10-17). Neocortical telemetry LFP elctrodes were implanted in PN10 pups and mothers and LFP recorded during 1 hr periods of SAM (maltreatment) or typical rearing in the same animal. Mother-infant interactions were recorded and then scored for behavior and LFP power was decomposed into delta (0-5Hz), theta (5-15Hz), beta (15-35Hz), and gamma (35-80Hz) frequency bands. During the early days of SAM treatment, maltreatment had produced the largest observable effects on both LFP and behavior. The dynamic range of LFP induced by mother-pup interactions decreased, with both pup and mother showing impaired LFP responses to specific interactions, such as milk ejection and grooming. Blocking stress hormone synthesis via metyrapone during maltreatment and the SSP restored pup behavior, maternal regulation of LFP power, and cross-frequency coupling patterns to control levels. These results suggest that when a mother is stressed, she has impaired ability to modulate both her own and pups' neural function. Considering the critical role of brain oscillations in brain functioning and its critical role programming brain development, these maltreatment-related impairments are likely contribution to the pathological developmental pathway induced by maltreatment in early life.

Title: What happens to the infant during maltreatment? Stress targets hippocampus but stress with mother targets amygdala and social behavior

Authors: *C. RAINEKI[1], M. OPENDAK[2], E. C. SARRO[3], B. S. MCEWEN[4], D. A. WILSON[5], R. M. SULLIVAN[6];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Child and Adolescent Psychiatry, New York Univ., New York, NY; [3]Dominican Col., Orangeburg, NY; [4]Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY; [5]Child and Adolescent Psychiatry, New York Univ. Sch. of Med., New York, NY; [6]Emotional Brain Inst., NKI & NYU Sch. of Med., New York, NY

Abstract: Animal models designed to simulate early-life abuse have provided insight into the role of parental care in determining the trajectory of the child's neurobehavioral development. However, the inherent complexity of maternal abuse has prevented understanding of the mechanisms during the abuse that initiate the pathway to pathology and later-life outcome. Here, we deconstruct the abusive experience to identify which components of trauma are most salient and deleterious in initiating pathology in the developing infant. To this end, we began with a naturalistic manipulation in Experiment 1 and then deconstructed this experience by manipulating stress hormones and maternal behavior and presence in Experiment 2. All treatment occurred between postnatal days (PN)8 to 12. Testing occurred at PN13 using social interaction with an anesthetized mother to facilitate identification of pup behaviors. Experiment 1 used a naturalistic early-life abusive rearing (Scarcity-Adversity Model of Low Bedding) vs. control rearing (PN8-12). Maltreatment pups exhibited elevated levels of the stress hormone corticosterone (CORT), impairments in infant social behavior, and alterations in amygdala structure and function, including elevated c-Fos, volumetric changes, modified neurogenesis and changes in local field potentials (LFP). These pups also showed morphological changes in the hippocampus, including neurogenesis and volume. In Experiment 2, we deconstructed the complex maltreatment paradigm in the following conditions to identify specific links between pups' experiences and outcome. In each condition, pups received either a CORT or vehicle injection paired with opportunities to interact with an awake mom, an anesthetized mom or a polyethylene tube. In all conditions, CORT injections recapitulated the hippocampal deficits produced by maltreatment. However, the amygdala and social behavior deficits were only produced in the pups receiving CORT injections in the presence of awake and anesthetized mothers. The results indicate that increased stress hormone impacted hippocampal development regardless of the type of stimulus present during treatment, but amygdala structure and function were only disrupted if stress hormone increases occurred within a social context with the mother, including an anesthetized mother. The critical role of the amygdala in producing abnormal infant social behavior was verified by temporary amygdala suppression, which eliminated pups' disrupted social behavior. Taken together, these results highlight the critical role of trauma context in initiating distinct outcomes for brain development and social behavior.

Title: The fluctuation of anxiety behavior dependent on female estrous cycle

Authors: *G. HA[1], H. J. KWAK[2], D. LEE[1], E. CHEONG[1];
[2]Biotech., [1]Yonsei Univ., Seoul, Korea, Republic of

Abstract: The prevalence of stress- and fear-related disorders, such as major depressive disorder, anxiety disorder and post-traumatic stress disorder, has been known to be higher in women than men. Although it is supposed that these phenomena may be caused by sex differences in biological and pharmacological factors, most researches investigating neural mechanisms of mental disorders has been limited to the use of male rodent models due to variance in female hormone levels. To elucidate the neurobiological mechanisms of anxiety disorders in consideration of sex difference, we focused on female estrous cycle, recurring physiological changes that are induced by reproductive hormones, by using naive female mice. We observed that anxiogenic behavior of female mice was fluctuated dependent on female estrous cycle stages. Therefore, we investigated the molecular mechanism by which female sex hormones, such as estrogen and progesterone, modulate to anxiety behavior.

Title: Sex differences in macrocircuitry and microcircuitry of the Tac2 pathway in fear conditioning

Authors: *A. FLORIDO[1], E. R. VELASCO GARCIA[1], J. A. GONZÁLEZ-PARRA[1], A. GOMEZ-GOMEZ[2], Ó. J. POZO[2], R. ANDERO GALI[1];
[1]Inst. of Neurosci., Autonomous Univ. of Barcelona, Barcelona, Spain; [2]Integrative Pharmacol. and Systems Neurosci. Group (FINS), IMIM, Barcelona, Spain

Abstract: Fear-based disorders are highly disabling conditions and current treatments are not successful in many cases. Women endure almost three times more life prevalence of these disorders than men. Recent research has shown that centromedial amygdala (CeM) tachykinin 2 (Tac2) neurons are crucial for the regulation of fear conditioning (FC) in male mice. Here, we have found that systemic administration of a Tac2 antagonist after cued-fear acquisition altered memory consolidation in a sex-opposite manner. Further, this pharmacological manipulation altered the normal rise in testosterone to FC in male mice. Interestingly, females only exhibited memory consolidation alterations when the drug was given in the proestrus stage of the estrous cycle (high estradiol and progesterone). Concordantly, chemogenetic silencing of CeM-Tac2 neurons after FC mimicked the memory consolidation alterations observed after systemic drug administration. CeM-Tac2 anterograde transynaptic neuronal tracing showed differential density of projections to limbic areas in males when compared to females. The current experiments using *in vivo* calcium imaging in freely moving mice (Miniscopes) in this FC paradigm may reveal different neuronal activation patterns in both males and females. Altogether, these data uncover differences in the neurobiology of fear memory consolidation between males and females by aiming research towards sex-specific treatments for fear-related disorders.

Title: PACAP-PAC1R system in females: Contributions to fear learning and adaptations to stressors

Authors: *E. R. VELASCO GARCIA[1], A. FLORIDO[1], Á. FLORES[1], E. SENABRE[2], A. TORRES[3], A. ROCA[3], L. GARCIA-ESTEVE[3], R. ANDERO GALI[1];

Abstract: Anxiety and fear-based disorders are conditions that are twice as prevalent in women compared to men. In the case of Posttraumatic stress disorder (PTSD), the experiencing or witnessing of a highly stressful event triggers neuronal changes that result maladaptive for a subset of people. The Pituitary adenylate cyclase-activating peptide (PACAP) and its main receptor, the type1 receptor (PAC1R), are implicated in neuroendocrine stress responses and neuronal survival. Previous studies have shown that dysregulations of the PACAP-PAC1R system can result in abnormal stress responses in women with PTSD, but not men. Also pointing at an estrogen-dependent regulation of this system. For this, we aim to study the contribution of the PACAP-PAC1R system to the processing of fear memories in naturally cycling women and female mice, also identifying stress responsive circuits modulated by PACAP. Here we describe convergent evidence from rodents and humans regarding the impact of the estrous/ menstrual cycle phase during trauma. In a cohort of women victims of sexual assault, we observe no influence of the phase of menstrual cycle at the time of trauma for the subsequent development of posttraumatic symptoms. Likewise, female mice undergoing acute immobilization stress show further impairments in cued- fear extinction regardless of the estrous cycle phase. However, immobilized female mice had upregulation of PACAP and PAC1R mRNA in the amygdala and hypothalamus after a fear extinction session. Additionally, immunohistochemistry studies reveal that immobilization stress increases PACAPergic neuronal activation in stress responsive areas and decreases their activity in medial prefrontal structures. Ongoing tracing studies from the BNST and prelimbic cortex are being used to identify the PACAPergic afferent and efferent circuits driving these behavioral adaptations, which will further undergo chemogenetics manipulation. In sum, this study provides circuit mechanisms for the PACAP-PAC1R system adaptation to stressors that may be useful for PTSD or fear-related disorders.

Title: TGFB-inducible early growth response protein 2 (TIEG2) gene: Impact of genetic variation on anxiety-related traits in healthy individuals

Authors: *L. B. KOLLERT[1], C. ZIEGLER[4], M. SCHIELE[4], H. WEBER[1], M. ROMANOS[2], T. B. LONSDORF[5], P. ZWANZGER[6,7], A. REIF[8], P. PAULI[3], J. DECKERT[1], K. DOMSCHKE[4]; [1]Dept. of Psychiatry, [2]Dept. of Child and Adolescent Psychiatry, [3]Dept. of Psychology, Univ. of Wuerzburg, Wuerzburg, Germany; [4]Dept. of Psychiatry, Univ. of Freiburg, Freiburg, Germany; [5]Dept. of Systems Neurosci., Univ. of Hamburg-Eppendorf, Hamburg, Germany; [6]Dept. of Psychiatry and Psychotherapy, Univ. of Muenster, Muenster, Germany; [7]kbo-Inn-Salzbach-Hospital, Wasserburg am Inn, Germany; [8]Dept. of Psychiatry, Univ. of Frankfurt, Frankfurt, Germany

Abstract: The most frequent mental disorders are anxiety disorders (AD) with a life-time prevalence of 21.0% in the US. Twin studies suggested a moderate genetic component with a heritability of up to 48%. A functionally relevant variable number tandem repeat (VNTR) in the monoamine oxidase A (*MAOA*) gene promoter region has repeatedly been found to be associated with AD, particularly in female patients. The TGFB-Inducible Early Growth Response Protein 2 (*TIEG2*) is an activating transcription factor and binds to Sp1 binding sites in the *MAOA* gene promoter. Genetic variation in the *TIEG2* gene could therefore be a new potential risk factor for anxiety disorders such as panic disorder.

In this study, 3,156 healthy probands (w=1,733; age=25.26±5.644) recruited within the CRC-TRR58, subproject Z02, from 2008 through 2016 were genotyped for six tagSNPs [rs4669519 (A/G), rs4669520 (G/A), rs35927125 (G/A), rs4444493 (A/C), rs4669522 (C/T), and rs7632 (T/C)] by competitive allele-specific polymerase chain reaction (KASP). Furthermore, anxiety-related traits were assessed by several psychometric instruments, e.g. the State-Trait-Anxiety-Inventory, Trait version (STAI-T) (not available for all probands). Linear regression analyses controlled for age and gender revealed the following associations: First, the minor A allele of tagSNP rs4669519 was shown to be associated with an increase in STAI-T scores (N=2,927, b=0.5373, p=0.026). Second, the minor C allele of tagSNP rs7632 was shown to be associated with a decrease in STAI-T value (N=2,937, b=-0.4419, p=0.024). With regard to other investigated tagSNPs as well as all remaining psychometric instruments, no significant associations could be detected (all ps>0.05).

The current study partly confirms the hypothesized association between genetic variations in the *TIEG2* gene and anxiety-related traits in healthy probands. Both associated SNPs are predicted to be functionally relevant, with rs4669519 altering a transcription binding site in the *TIEG2* promoter region and rs7632 being located in a microRNA binding site in the 3'-UTR region of the gene. However, this predicted functionality on gene expression remains to be validated experimentally (e.g. by quantitative PCR analysis). Furthermore, given the observed opposite associations of two minor tagSNP alleles, *TIEG2* gene variation might differentially influence anxiety risk and resilience and thus constitute a 'plasticity' rather than a 'risk' gene for anxiety. However, the failure to discern association of the remaining tagSNPs with any anxiety score

points towards a generally rather weak impact of the *TIEG2* gene on anxiety-related traits in healthy individuals.

Title: Exposure treatment in spider phobia: Associations between resting state connectivity, symptom severity and within-session extinction

Authors: *F. R. SEEGER[1], H. SCHWARZMEIER[1], N. SIMINSKI[1], B. GATHMANN[2], T. STRAUBE[2,3], J. REPPLE[4], J. BOEHNLEIN[4], E. J. LEEHR[4], U. DANNLOWSKI[4], K. ROESMANN[5,3], M. JUNGHOEFER[5,3], M. J. HERRMANN[1];

Psychology and Systems Neuroscience, Univ. of Muenster, Muenster, Germany; [3]Otto Creutzfeldt Ctr. for Cognitive and Behavioral Neuroscience, Univ. of Muenster, Muenster, Germany; [4]Dept. of Psychiatry, Univ. of Muenster, Muenster, Germany; [5]Inst. for Biomagnetism and Biosignal Analysis, Univ. of Muenster, Muenster, Germany

Abstract: Objective. Even though specific phobia is a frequent anxiety disorder, it is largely unknown how state and trait symptom severity and within-session extinction (WS-ext) during exposure treatment are associated with pre-treatment resting state connectivity. Gathering information about potential associations between those variables might aid in selecting appropriate neurobiological predictors for machine-learning or the establishment of Research Domain Criteria. Therefore, the aim of the present analysis was to identify resting state signatures linked to state and trait pretreatment symptom severity and WS-ext in spider phobia patients. **Methods.** 72 patients (female n = 63) underwent an 8 min resting-state measurement within a 3T fMRI scanner prior to behavioral exposure. ROI-to-ROI connectivity measures were computed with *CONN*. Trait symptom severity was assessed using the Spider Phobia Questionnaire (SPQ). State symptom severity was assessed via a behavioral avoidance task with a living bird spider. All patients received a one-session exposure-based cognitive behavioral

therapy treatment in virtual reality. Self-reported anxiety ratings during exposure were used to compute WS-ext values. Patients were divided into subgroups of high and low symptom severity and WS-ext via a median split. Regression analyses and group comparisons were performed in *CONN*. **Results.** Trait anxiety was negatively associated with connectivity between anterior cingulate cortex (ACC) and rostral prefrontal cortex (rPFC) in the high SPQ group. WS-ext was negatively associated with connectivity between hippocampus (HC) and medial PFC (mPFC). Group comparisons revealed significantly stronger negative connectivity between amygdala and ACC as well as rPFC within the group of high WS-ext patients. Similarly, negative connectivity between the insula and rPFC was stronger in the high WS-ext group. Furthermore, significantly stronger positive connectivity was found between amygdala and HC among high WS-ext patients. **Discussion.** Findings highlight the relevance of inhibitory functional connectivity between frontal and defensive system structures in phobic patients. In line with our hypothesis, enhanced extinction learning was associated with stronger inhibitory mPFC-HC connectivity and ACC/rPFC-amygdala connectivity as well as positive connectivity between the amygdala and HC. Findings underline the relevance of those neural networks conferring emotion regulation and context conditioning involved in behavioral exposure. As there are no comparable studies addressing connectivity in specific phobia our results are preliminary and need replication.

Title: Mindfulness meditation alters neurophysiological symptoms of anxiety in preadolescents

Authors: *N. A. SHANOK[1], C. REIVE[2], K. D. MIZE[2], K. COBTY[2], I. BAKIR[2], N. A. JONES[1];
[1]Florida Atlantic Univ., Jupiter, FL; [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: Mindfulness meditation interventions (MMI) are formal training programs which utilize mindfulness techniques to improve attentional control and reduce stress and anxiety. During individual sessions of training, mindfulness-elicited electrophysiological changes have been reported including increased alpha and theta waves; a pattern reflecting a mental state of “relaxed alertness”. Prior investigations have shown that mindfulness-based interventions are effective in improving symptoms of anxiety and depression in both adolescents and adults, making this a promising natural approach to treating mood disorders. However, the lasting

resting-state electrophysiological effects of mindfulness training programs are less well-understood. The primary aim of this study was to expand on prior research by examining the effects of a 10-week MMI on resting-state electroencephalogram (EEG) measures relating to anxiety and negative affect. These measures included frontal alpha asymmetry, intrahemispheric alpha coherence, and cortical-wide power values for theta, alpha, and beta bands. The novel contributions of this project were the wide array of resting-state EEG measures and the relatively unexplored age-range (7- to -10-year-olds) in the mindfulness literature. Participants trained with MMI demonstrated significant increases in intrahemispheric alpha coherence from pre- to -post, F (9, 585) = 4.46, p = .008, as well as increased theta, alpha, and beta power particularly in frontal and central areas; reflecting a lower neurological risk for anxiety development during the adolescent years (all p's < .05). The precise changes in EEG power from pre- to -post can be seen in the table below. However, two common measures linked to anxiety, frontal and posterior alpha asymmetry remained largely unchanged following the training period. None of these results were altered with gender and ethnicity entered as covariates. These preliminary results exemplify the utility of MMI for preadolescents as an alternative method for mitigating electrophysiological symptoms of anxiety. Future studies should expand on these findings given that this age-range has traditionally shown poorer responses to medication and cognitive behavioral therapy than adults.

Title: Temporal unpredictability modulates brain activity in threat confrontation

Authors: *N. SIMINSKI[1], S. BOEHME[2], J. ZELLER[1], M. P. I. BECKER[3], A. MUEHLBERGER[2], T. STRAUBE[3], M. J. HERRMANN[1];
[1]Ctr. of Mental Health, Dept. of Psychiatry, Psychosomatics, and Psychotherapy, Univ. Hosp. of Wuerzburg, Wuerzburg, Germany; [2]Dept. of Clin. Psychology and Psychotherapy, Univ. of Regensburg, Regensburg, Germany; [3]Inst. of Med. Psychology and Systems Neurosci., Univ. of Muenster, Muenster, Germany

Abstract: Objective. Brain networks recruited during threat anticipation and threat confrontation differ widely and depend on stimulus predictability. Paralleling findings from animal electrophysiology, human functional magnetic resonance imaging (fMRI) suggests that an initial, phasic response in Amygdala can be distinguished from a sustained response in the Bed Nucleus of the Stria Terminalis (BNST). Moreover, these effects seem to be gated by stimulus predictability. However, given the importance of predictability for learning and conditioning there is a surprising lack of neuroscientific studies in humans investigating the modulatory role of predictability on confrontation with a threatening stimulus in Amygdala and BNST. **Methods**. During fMRI, 109 healthy individuals (37 male, age = 27.1 ± 6.3 years) anticipated either a negative or a neutral stimulus. An additional cue either predicted the exact moment of the impending confrontation with these stimuli or it signaled that the moment was temporally unpredictable. Mean estimated parameter values of these four conditions were extracted from Amygdala, BNST and Insula and analyzed in a repeated-measures analyses of variance using Brain Voyager 20.6.
Results. Brain activation to confrontation with threat revealed significant main effects of predictability and valence in Amygdala and BNST. These regions showed higher activation during confrontation with threat as well as during confrontation with unpredictable threat. Furthermore, Insula showed higher activation during unpredictable compared to predicted confrontation. No interactions were found. **Discussion.** Higher activation of BNST and Insula during confrontation with unpredictable stimuli supports theories suggesting an important role of unpredictability for neural brain activity related to anxiety. However, higher Amygdala activation during confrontation with unpredictable stimuli questions the separation of fear and anxiety. Therefore, future studies should use this study design in clinical anxiety groups to

further evaluate modulation effects of temporal predictability in fear- and anxiety- related brain activity.

Psychology and Systems Neuroscience, Univ. of Muenster, Muenster, Germany

Abstract: Objective. Behavioral exposure, a first-line treatment for spider phobia (SP), is conceptionally based on fear-inhibitory learning during fear extinction. Although showing large effect sizes, a significant proportion of patients does not benefit sufficiently. Identifying potential predictors of treatment response and (neural) mechanisms that are instrumental for fear inhibition may help in personalizing treatments. The present study aimed at identifying brain-structural markers of within-session extinction during behavioral exposure in SP.
Methods. From 75 recruited patients, quality-controlled T1-weighted magnetic resonance imaging (MRI) was obtained before exposure therapy from 69 SP patients (n= 60 female, mean age = 28.3 yrs) at two different time points, separated by one week, to assess test-retest-reliability. Voxel-based morphometry (VBM) analysis was carried out using the CAT12 toolbox and SPM12. Multiple regressions were performed on grey matter density (GMD) across the brain (p=0.001, uncorrected, cluster-level extent threshold k_E = 50) and trait spider anxiety (Spider Phobia Questionnaire; SPQ), state spider anxiety (behavioral-avoidance-test; BAT) and the

magnitude of fear reduction within the exposure-based therapy session. Total intracranial volumes (TIV), age and gender were entered as variables of no interest into the statistic model. **Results**. GMD in the visual cortex, encompassing, among others, bilateral calcarine sulcus and bilateral lingual gyrus prior to exposure correlated reliably in both MRI sessions with a significantly higher within-session fear reduction. No correlations were observed with trait or state spider anxiety.
Discussion. Structural alterations in basic visual processing areas in SP mirror previous functional findings on the involvement of visual cortices in specific phobia in general. Findings may reflect abnormalities in the visual network in SP possibly resulting from excessive vigilance as an early cortical marker underlying increased defensive reactivity as a function of psychopathology. A higher within-session extinction may be mediated by enhanced situational monitoring or by intensified visual processing of the feared stimulus during exposure as conferred by greater visual cortex GMD. Since activity in the visual cortex immediately after therapy predicted long-term therapeutic outcome in a functional MRI study on SP (cf. Hauner et al.,2012), future studies are needed to clarify the relationship between brain morphometry and long-term outcome in SP.

Title: Effects of a smartphone-based virtual reality exposure app to treat fear of heights, a randomized-controlled trial

Authors: *D. BENTZ[1,2], N. SCHICKTANZ[1,3,2], N. WANG[1,2], M. K. IBACH[1,2], A. AERNI[1,2], A. ZIMMER[1,2], D. J.-F. DE QUERVAIN[1,3,2], A. PAPASSOTIROPOULOS[4,3,2];
[1]Div. of Cognitive Neuroscience, Univ. of Basel, Basel, Switzerland; [2]Transfaculty Res. Platform, Univ. of Basel, Basel, Switzerland; [3]Univ. Psychiatric Clinics, Univ. of Basel, Basel, Switzerland; [4]Div. of Mol. Neuroscience, Univ. of Basel, Basel, Switzerland

Abstract: Fear of heights is a common problem with a lifetime prevalence of around 20% and with 2-5% of the general population meeting diagnostic criteria for specific phobia (natural-environmental type: heights). Despite the plethora of research supporting exposure as treatment of choice with high success rates, its translation into clinical practice is still limited. Low

threshold treatment options are therefore needed. The rapid development of virtual reality (VR) technologies and the use of VR via smartphones is facilitating new treatment avenues. We developed a stand-alone VR heights-exposure app for smartphones in which sufferers from fear of heights are exposed to heights situations in a gradual manner. The course of exposure is adapted to subjective fear levels using a gaze selection-based visual analog scale. To test for immediate effects of our VR heights-exposure app (study phase 1), we randomized 70 participants with a fear of heights (42 fulfilling DSM-V criteria for specific phobia) to either one exposure session (3x20min units) with our VR heights-exposure app (experimental condition) or one session (3x20min units) with a Google Street View VR app (control condition). To test for delayed effects of repeated administration of our VR heights-exposure app (study phase 2), participants of the experimental condition of study phase 1 were offered to take part in an additional 2-week home-training (6x30min units) with the VR heights-exposure app, whereas participants of the control condition received no further treatment. Strength of fear of heights was measured with a real-life behavioral avoidance test (BAT) on a lookout tower, and with questionnaires specific to the fear of heights (timepoints at study phase 1: before and after using the VR app and at study phase 2: 3-5 weeks after the end of home-training). During the BAT, participants were instructed to climb the tower as far as their current fear allows; subjective fear on the reached platform (1-14) was prompted on a scale of 0-10 (0=no fear, 10=maximal fear). The results will be presented at the conference. An amelioration of fear of heights after repeated use would recommend the app as a low-threshold treatment option for fear of heights. Short-term effects after a single exposure session with our VR heights-exposure app would most likely promote the acceptability of the app and might lead to less attrition under real-life conditions.

Title: Therapeutic effects of ketamine on treatment refractory generalized anxiety and social anxiety disorders are unrelated to plasma levels: A double blind active controlled study

Authors: *S. M. SHADLI[1], P. GLUE[2], N. MCNAUGHTON[1], N. MEDLICOTT,[3];
[1]Psychology, [2]Psychological Med., [3]Sch. of Pharm., Univ. of Otago, Dunedin, New Zealand

Abstract: Ketamine acts swiftly in a range of neurotic disorders even in patients resistant to conventional antidepressant and anxiolytic drugs. We recently reported effects of ketamine on frontal EEG in patients with treatment-resistant (TR) generalised anxiety (GAD) and social anxiety (SAD) disorders. Ketamine increase high frequency EEG power, and decreased low frequency power. Interestingly, only the decrease in "theta" power at the right frontal site F4 significantly correlated with changes in Fear Questionnaire (FQ) scores. Here we report blood levels of ketamine, norketamine and BDNF in the same patients. Three ascending ketamine dose levels (0.25, 0.5 and 1 mg/kg) and midazolam (0.01 mg/kg), were given double blind at 1-week intervals to each patient, with the midazolam counterbalanced in dosing position across patients. Twelve patients with DSM-IV TR-GAD and/or TR-SAD provided blood samples pre-dose and at 15, 30, 60 and 120min post-dose. Plasma concentrations of R- and S-ketamine and norketamine were measured using a chiral mass spectroscopy assay and plasma BDNF concentrations using an ELISA, validated for human plasma. Other assessments included ratings of anxiety and dissociation, safety and tolerability. A dose-response profile was noted for anxiolytic effects, dissociative side effects, and changes in blood pressure and heart rate after ketamine dosing. Midazolam had minor brief effects on anxiety ratings. Ketamine produced dose-related decreases in FQ and HAM-A scores. ANOVA by ranks showed a significant effect of FQ vs dose (differences of ranks 342.5, $q=20.2$, $p<0.001$), FQ vs time (differences of ranks 187.0, $q=11.0$, $p<0.001$), and time vs dose (differences of ranks 155.5, $q=9.2$, $p<0.001$). Ketamine was safe and well tolerated, with dissociation ratings correlated with pharmacokinetics. Plasma BDNF was not changed and neither ketamine or norketamine concentrations related to anxiety ratings. In sum, we replicated ketamine's therapeutic effect in TR GAD/SAD but this did not related to plasma levels of the compounds we measured. Ketamine may be an important therapeutic alternative for neurotic disorders with high rates of treatment resistance and few alternative treatment options but its mechanism of action remains obscure.

Abstract: Anxiety sensitivity (AS), the tendency to interpret bodily symptoms as dangerous, is a modifiable risk marker of anxiety disorders (AD). Recently, overgeneralization of conditioned fear has been proposed as a learning mechanism involved in AD development and maintenance. Here, we present preliminary data on the role of AS in the modulation of fear generalization in healthy adults.
N=1,082 (f=646, age= 25.43 ± 5.73 yrs) healthy probands underwent a fear conditioning and generalization (GEN) task. Two neutral faces served as conditioned stimuli (CS), one was paired with an aversive scream (CS+), while the other was not (CS-). During GEN, four gradual morphs of CS+ and CS- were presented. Subjective ratings of arousal and valence were recorded after the 1st and 2nd half of acquisition and GEN phases. Probands were assessed for AS (Anxiety Sensitivity Index-3; ASI-3) and grouped according to AS (high, ASI-3 ≥ 17 vs. low, ASI-3 < 17). Differences in subjective ratings were tested via repeated measures ANOVA with AS group as between-subject factor.
No group differences were found prior to conditioning (ps≤.193), despite overall higher arousal ratings in the high AS group (p=.014). After conditioning, the CS+ was rated as most arousing/least pleasant and vice versa for the CS- (p<.001). As indicated by a significant interaction stimulus x phase (p≤.003), CS- was rated less arousing/more pleasant than CS+ in the

2nd phase. The high AS group displayed overall higher arousal (p=.001) to all stimuli, which was further qualified by a significant interaction phase x AS (p=.026): the low AS group showed a higher decrease in arousal in the 2nd phase whereas arousal remained high in the high AS group. During GEN, a decrease in arousal/increase in valence ratings was observed with decreasing similarity to the CS+ (p<.001), again with overall higher arousal in the high AS group (p<.001). As indicated by a significant interaction stimulus x phase (p<.001) and a significant three-way interaction stimulus x phase x AS (p=.038), overgeneralization of conditioned fear as indexed by arousal ratings remained higher in the high AS group in phase 2, whereas no stimulus overgeneralization was observed in the low AS group in the 2nd compared to the 1st phase, indicating better discrimination learning and/or facilitated habituation in the low AS group. The present results indicate that fear GEN may be modulated by AS. Probands with high AS displayed less stimulus discrimination and less habituation of conditioned fear, which may contribute to an elevated risk for the development and maintenance of AD and could serve as a starting point for preventive measures for AD, e.g. in form of a discrimination training.

Title: Dissociation between striatal volume and risky decision-making in OCD

Authors: P. S. MOREIRA[1], P. MARQUES[1], A. COELHO[1], P. COSTA[1], J. MACOVEANU[2], H. R. SIEBNER[3], N. SOUSA[1], ***P. MORGADO**[1];

Abstract: Background: Impaired decision-making has been proposed as one of the core behavioral manifestations of the Obsessive-Compulsive Disorder (OCD). Here, we explored the association between structural brain patterns and risky decision-making in OCD. **Methods:** Eighty individuals (40 OCD patients and 40 matched healthy controls) underwent were assessed with structural Magnetic Resonance Imaging. Risk-taking attitude was assessed during a risky decision-making task. The study was approved by ethical committee and informed consent was obtained from all participants. **Results:** Healthy controls displayed a positive association between the volume of striatal regions and risk taking, whereas this pattern was absent in OCD patients. **Conclusions:** The lack of a normal structure-behavior relationship between striatal

volume and risky choices in OCD patients may be a structural marker of aberrant basal ganglia function in this psychiatric condition.

Title: Effects of phychological and physical stress on intestinal microbiota, generalized anxiety and depressive disorders and serum levels of kynurenine metabolites

Authors: G. S. AZPILCUETA-MORALES[1], B. PALACIOS-GONZALEZ[2], V. PEREZ-DE LA CRUZ[3], L. RAMOS-CHAVEZ[3], ***L. SANCHEZ-CHAPUL**[4], E. ESTRADA-CAMARENA[1]; [1]Neuropsicofarmacologia, Inst. Nacional de Psiquiatria "Manuel de La Fuente", Ciudad de Mexico, Mexico; [2]Vinculacion Cientifica, Inst. Nacional De Ciencias Genomicas, Ciudad de Mexico, Mexico; [3]Neuroquimica, Inst. Nacional de Neurologia Y Neurocirugia "Ramon de La Fuente", Ciudad de Mexico, Mexico; [4]Div. de Neurociencas, Inst. Nacional De Rehabilitacion, Ciudad de Mexico, Mexico

Abstract: High psychological stress increases the risk of developing anxiety, depression, changes in the proportions of the intestinal microbiota, particularly in the bacterial phylum *Firmicutes / Bacteroidetes* and in levels of circulating kynurenine metabolites. Kynurenine metabolites in a state of peripheral inflammation can accumulate in the brain and has been associated with depression; however, this accumulation can be suppressed by activating kynurenine clearance in exercised skeletal muscle. The practice of regular exercise is associated with the decrease of continuous psychological stress and an improvement of microbiota balance. However, the effect of high intensity physical exercise is unknown. Thus, our aim was to describe the effect of continuous psychological stress and high intensity physical exercise on the proportions of Bacteroidetes and Firmicutes of the gut microbiota, and relate them to the stress perception, generalized anxiety, major depressive disorder and serum levels of kinurenine metabolites.
A quasi-experimental, prospective and longitudinal study of two measurements was made. We obtained blood and fecal samples from 49 individuals (18 to 35 years, 38 male) who performed high intensity exercise (5-6 hours / day, 6 times a week) for a month following a standardized diet. Biological samples were taken in two times: at the beginning of the high intensity exercise (basal) and 1 month later. The change in the proportions of the bacterial phylum was evaluated, as well as the anxiety, depression and perceived stress scales. Serum levels of Trp, kynurenine

(Kyn), kynurenic acid (KYNA), QUIN and 3-hydroykynurenine (3-HK) were measured. Results showed that the prevalence of depression, anxiety and stress increased compared to the basal measurement ($p < 0.05$). The Firmicutes / Bacteroidetes ratio ranged from 1: 1 at the beginning of the study to 4:1 ($p < 0.001$) after 1 month. The serum levels of Trp ($p<0.0001$), KYNA ($p < 0.0280$), QUIN ($p < 0.0006$) and 3-HK ($p < 0.0001$) diminished after 1 month, not those of Kyn that increased ($p < 0.0001$) after 1 month. Also serum ratios of Kyn/Trp ($p<0.0362$), KYNA/Trp ($p<0.0037$) increased while 3-HK/Trp ($p<0.0003$) decreased one month after training. Then, the effect of psychological stress in combination with high intensity exercise increases the perception of stress, anxiety and depression, as well as the Firmicutes / Bacteroidetes ratio. Results suggested that implementation of high intense exercise increased psychological stress perception reducing the advantages of making exercise.

Title: The interplay between neural and cognitive risk factors in individuals with high trait anxiety: A network analysis

Authors: *L. FANG[1], J. A. ANDRZEJEWSKI[1], T. SUSA[2], H. GILBERTSON[1], J. M. CARLSON[3];
[2]Psychology/Neuroscience, [3]Psychology, [1]Northern Michigan Univ., Marquette, MI

Abstract: Individuals with high levels of trait anxiety demonstrate hyperactive attention bias to threat and this hyperactivity is associated with the development of anxiety disorders. Previous research has shown elevated attentional bias toward threat and conflict monitoring among high anxious individuals. Moreover, dysfunction within resting state networks has been associated with trait anxiety. However, how hyperactive attention bias and conflict monitoring interact with resting state network dysfunction remains unknown. This study explored the interplay between neural and cognitive risk factors in individuals with high levels of self-reported trait anxiety. Attention bias to threat was measured with the dot-probe task, and conflict-monitoring levels were assessed by the flanker task. The resting state fMRI data was collected via a 1.5T scanner, and functional connectivity in the fronto-parietal and salience networks was examined as

potential neural risk factors in the network analysis. We tested different network models to gain a more comprehensive understanding of how neural and cognitive factors relate to levels of trait anxiety. The results suggest that the reduced functional connectivity in regions of the fronto-parietal network could be a central hub in the concentration network, as it was consistently associated with attentional bias to threat, trait anxiety level, conflict monitoring, and functional connectivity in the salience network. In addition, after considering the effects of all the other variables, the functional connectivity in the salience network still showed a relatively strong association with conflict monitoring. Therefore, our findings suggest that the fronto-parietal network may play an important role in the interactions between impaired cognitive control and dysfunction in resting state networks associated with trait anxiety.

Title: Alterations in resting-state functional connectivity following mindfulness training in adolescents with attentional and emotional disturbances: A pilot investigation

Authors: *S. JUN[1], A. T. SHAFER[2], Y. HU[1], A. D. IORDAN[3], S. DOLCOS[1], A. SINGHAL[4], S. VOHRA[5], F. DOLCOS[1];

Abstract: Research on mindfulness has provided strong support for its benefits in a multitude of aspects related to well-being, in both healthy functioning and psychopathology. However, few studies have examined mindfulness-induced changes in the neural mechanisms associated with spontaneous thoughts, as measured by resting-state functional connectivity (RSFC). This is an important limitation in the literature, given that many psychopathologies emerge during this developmental period marked by important neural and psychological changes. Also, maladaptive alterations in the RSFC of specific brain regions have been associated with clinical conditions. Hence, the present study aimed to clarify adaptive changes in the RSFC associated with behavioral and psychological benefits following meditation-based stress reduction (MBSR) training in adolescents with attentional and affective disorders. The main focus was on two brain regions associated with emotion processing that have been identified by previous research as sensitive to meditation training in young adults: the amygdala (AMY) and the insula (INS).

Twenty-six adolescents were recruited from a residential mental-health treatment facility and randomly assigned to either receive only a typical socio-emotional treatment (Control Group) or to also receive a supplemental MBSR training (MBSR Group). All participants underwent resting-state fMRI recordings before and after an eight-week treatment/training period. RSFC results showed decreased RSFC of both AMY and INS with brain regions associated with top-down emotion control (medial orbitofrontal cortex), possibly reflecting changes in valuation processes of emotional and interoceptive information, as a result of present-centered, non-judgmental mindfulness training. Moreover, functional decoupling between the AMY and the DLPFC, and between the INS and the left IFC, may reflect reduced bottom-up emotion signaling as a result of mindfulness training. Taken together, these results suggest that MBSR training in adolescents with psychopathology alters the spontaneous brain activities at rest, reflected in functional decoupling between regions signaling bottom-up salience (AMY, INS) and regions of higher-level integration and top-down control (OFC, dlPFC).

Title: Suicidal ideation and the salience network: Modeling connectivity with MEG and dynamic causal modeling

Authors: *J. R. GILBERT[1], E. BALLARD[1], C. S. GALIANO[1], A. NUGENT[2], C. A. ZARATE, JR[1];
[1]Exptl. Therapeut. and Pathophysiology Br., [2]MEG Core Facility, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Defining the neurobiological underpinnings of suicidal ideation (SI) is crucial to improving our understanding of risk for suicide. This study used magnetoencephalographic (MEG) changes in gamma power as a surrogate marker for population-level excitation/inhibition balance and synaptic potentiation in order to explore the underlying neurobiology of SI and depression. In addition, effects of pharmacological intervention with the glutamatergic modulator ketamine, which has been shown to rapidly reduce SI and depression, were also assessed. Data were obtained from 29 drug-free patients with major depressive disorder and corresponding SI who participated in a double-blind, crossover, placebo-controlled experiment comparing an

intravenous subanesthetic dose of ketamine to a placebo-saline infusion. MEG recordings were collected prior to the first infusion and six to nine hours after both ketamine and placebo infusions. During scanning, patients rested with their eyes closed. SI and depression were assessed across timepoints using several clinical measures, and a linear mixed-effects model was used to identify brain regions showing associations between gamma power and SI and depression. Two regions of the salience network, the anterior insula and anterior cingulate cortex, were then probed using dynamic causal modeling to test for ketamine effects on modeled parameter estimates.
Clinically, patients showed significantly reduced SI and depression following ketamine administration. In addition, distinct regions in anterior insula were found to be associated with SI compared with depression. When modeling anterior insula to anterior cingulate connectivity, ketamine was found to lower the membrane capacitance for superficial pyramidal cells, which are thought to be the primary generators of the MEG signal. Finally, AMPA-mediated connectivity between anterior insula and anterior cingulate was associated with improvements in depression symptoms, but not SI.
These findings suggest that the anterior insula plays a key role in SI, perhaps via its role in salience detection. In addition, these findings suggest that transient changes in superficial pyramidal cell membrane capacitance and subsequent increases in cortical excitability might be one mechanism via which ketamine improves SI.

Title: Reduced habituation of the amygdala in women with borderline personality disorder when experiencing shame and guilt

Authors: *M. GÖTTLICH[1], A. L. WESTERMAIR[2], F. BEYER[4], M. L. BUßMANN[2], U. SCHWEIGER[2], U. M. KRÄMER[1,3];
[1]Dept. of Neurol., [2]Dept. of Psychiatry and Psychotherapy, [3]Inst. for Psychology II, Univ. of Luebeck, Luebeck, Germany; [4]Queen Mary Univ. of London, London, United Kingdom

Abstract: Borderline Personality Disorder (BPD) is characterized by instability of affect, emotion dysregulation and interpersonal dysfunction. Especially shame and guilt, so-called self-conscious emotions, are of central relevance in BPD. To date, there is however only little experimental work on the experience of shame or guilt in BPD and none on its neurobiological

underpinnings. Furthermore, the involvement of the amygdala in BPD is still unclear as previous neuroimaging studies showed inconsistent results. In the present functional magnetic resonance imaging study, we took a scenario-based approach to experimentally induce feelings of shame, guilt and disgust. Scenarios with neutral content were used as control condition. With this approach, we set out to investigate the higher shame proneness in persons with BPD and its neural basis. We included 19 women with BPD (age 26.4±5.8 years; DSM IV diagnosed; medicated) and 22 healthy female control subjects (age 26.4±4.6 years) in the study. Compared to controls, women with BPD reported more intense feelings when being confronted with affective scenarios, especially higher levels of shame, guilt and fear. In terms of imaging results, we found increased amygdala reactivity in BPD to shame and guilt relative to disgust scenarios (p=0.05 FWE corrected at the cluster level; p<0.0001 cluster defining threshold) caused by a diminished habituation in women with BPD relative to control participants. This effect was specific to guilt and shame scenarios whereas both groups showed habituation of amygdala activity to disgust scenarios. Our work thus shows that dysregulated levels of self-conscious emotions can be experimentally induced in BPD and that this is associated with reduced habituation of amygdala activity. These findings might help to clarify inconsistencies in previous imaging work regarding the involvement of the amygdala in BPD. Our results suggest that persons with BPD might not present generally increased amygdala activation but aberrant habituation to self-conscious emotions.

Abstract: Background—Anorexia nervosa (AN) is a serious eating disorder characterized by self-starvation and extreme weight loss, with the highest mortality ratio among all psychiatric disorders. Recent functional/structural neuroimaging research indicates that impaired cognitive-behavioral flexibility is associated with an intact functioning of cortico-striatal loop systems, including the caudate, pallidum, the nucleus accumbens, and anterior/posterior cingulate. However, the pathophysiology in AN remains unknown, with many interacting developmental, genetic, environmental, and neurobiological factors. **Objective**—To clarify the pathophysiology in AN, by investigating the neuropathology of the patients' brains. **Materials and Methods**—We investigated the neuropathology of 3 AN patients by some antibodies, such as tyrosine hydroxylase (TH), a faithful marker of dopaminergic neurons, and glia cell markers in serially-cut paraffin sections. Ethical issues were carefully considered in this study. **Results**—Macroscopically, they show the slight frontal atrophy with enlargement of lateral ventricles. Histologically, neuronal loss and gliosis were seen in the frontal cortex and cingulate. In the nucleus accumbens, comparison of the adjacent sections stained for TH and GFAP indicates that gliosis preferentially occurs in areas where the fine, mesh-like TH staining is relatively light. **Conclusion**—The results indicate that impaired functional connectivity in a reward-related network may induce neuro-psychiatric conditions in AN. The findings should be helpful in developing more effective treatments in AN.

Title: Stress responses, inhibitory control and food intake in women with eating disorders

Authors: *M. L. WESTWATER[1], H. ZIAUDDEEN[1], A. X. GORKA[3], F. MANCINI[1], C. GRILLON[4], M. ERNST[3], P. C. FLETCHER[2];

Abstract: Stress profoundly affects eating behavior, inducing both increases and decreases in food intake and body weight across individuals. Notably, among patients with eating disorders,

stress has been shown to precede episodic binge eating; however, the neural mechanisms underpinning this relationship remain poorly understood. One model suggests that binge-eating emerges when stress attenuates prefrontally mediated inhibitory mechanisms, leading to impulsive behavior and ensuing loss-of-control eating. The present study explored this model by characterising the effect of stress on inhibitory control and food intake in women suffering with binge-eating disorders. We recruited eighty-five women (three matched groups: anorexia nervosa, binge-purge subtype = 22, bulimia nervosa = 33, healthy controls = 30) for two functional MRI scanning sessions on consecutive days. One scan involved an acute stress induction and the other a neutral condition, and conditions were counterbalanced across individuals. Immediately pre- and post-induction, participants performed the stop-signal anticipation task (SSAT) as a measure of proactive (anticipation of stopping) and reactive (outright stopping) inhibitory control. Our analyses related SSAT performance and neural correlates to subsequent energy intake at a free-choice meal that followed each MRI scan. Preliminary results suggest an effect of inhibitory control, indexed as stop-signal reaction time, on food consumption, and this association was modulated by stress. Results further characterize the effect of eating disorder status on neural responses in the inferior frontal cortex, striatum and posterior parietal cortex during successful and failed inhibitory control, as well as anticipation of stopping a motor response. Moreover, using linear mixed-effects modeling, findings will provide novel insight into how the interaction of stress and eating disorder status modulate neural and behavioral responses to the SSAT, relating these responses to food intake within each participant. Our results are the first to characterize the impact of acute stress on impulsivity and eating behavior in women with severe eating disorders.

Psychiatry, Dept. of Psychiatry, Hadassah - Hebrew Univ. Med. Center; Jerusalem Israel, Jerusalem, Israel

Abstract: Background: The aim of the current study is to prospectively characterize neuroendocrine reactivity among adolescent ED patients and correlate them with treatment response.
Methods: ED patients referred to the ambulatory clinic, day care facility and in patient unit of the Herman Dana Child Psychiatry Center were assessed using a structured clinical interview with repeated psychological and physical assessments. Hormonal assays were sampled at baseline and following treatment, correlated with treatment response measures, and compared with healthy age matched adolescents.
Results: Analysis of ED patients revealed at 6 months of treatment a significant prospective increase in BMI compared with baseline, and improvement in pathological eating attitudes. Findings replicate previously described hypercortisolism among ED, partly adaptive to energy conservation during chronic malnourishment and that be informative regarding long term weight restoration. Additional hormonal reactivity including cortisol, and testosterone has been similarly analyzed and will be described.
Significance: Reprograming of neuroendocrine function may be partly adaptive to energy conservation during chronic malnourishment and may be informative regarding long term weight restoration.

Title: Effects of juvenile stress on social behavior and impulsivity: Relationship to changes in dopamine-related proteins

Authors: *T. A. PAINE, C. TANNOUS-TAYLOR, S. BRAINARD, E. HARDEBECK, I. SCHWOB, S. CHANG;
Oberlin Col., Oberlin, OH

Abstract: Early adverse experiences are associated with a number of adult health consequences, including an increased risk of developing a substance use disorder. A majority of the research investigating early adverse experiences has focussed on the early post-natal period with relatively fewer experiments focussing on stress exposure during the juvenile period. Moreover, many studies examine the effects of early adverse experiences on male, but not female, rats. The goal of the current experiment was to investigate the effects of juvenile (post-natal days (PND) 25-29) stress exposure on behaviors associated with an increased risk of developing a substance use disorder, including social behavior and impulse control. Litters were culled to 8 (4 males and 4 females) pups at PND 10 and rats were weaned at PND 21. At weaning rats were pair housed with a same sex rat from a different litter. At PND 25 rats in the "stress" condition began the stress exposure protocol in which they were singly housed and underwent 10-min forced swim, 30-min restraint *or* 10-min intermittent foot shock once a day for 5 days. At the end of the stress exposure protocol, the rats were re-paired with their previous cage mate. Control rats were weighed daily but were otherwise undisturbed from PND 25-29. At PND 55, rats underwent a social interaction test, a sucrose intake test and then were trained on the 5-choice serial reaction time task (5CSRTT). At the end of the experiment, rats were sacrificed, their brains rapidly extracted and the expression of dopamine transporter (DAT) protein, tyrosine hydroxylase (TH) and dopamine D2 receptors (DRD2) were quantified using Western blots. Male rats exposed to the stress exhibited a reduction in the amount of time they spent interacting with a novel rat during the social interaction test; they did not exhibit any changes in behavior in the 5CSRTT. Female rats exposed to stress did not exhibit changes in social behavior but exhibited increased cocaine-induced impulsivity in the 5CSRTT. Expression of DRD2 in the caudate-putamen was increased in female rats that had been exposed to stress. These data point to a sex difference in the behavioral response to early adverse experiences. Future research will investigate whether DRD2 contribute to the increased cocaine-induced impulsivity in female rats.

Title: OCD symptom dimensions predict the degree of dorsal anterior cingulate cortex network dysfunction in obsessive-compulsive disorder

Authors: *T. D. MERAM[1], T. J. ATTISHA[2], A. Z. CHOWDURY[3], P. EASTER[5], G. HANNA[6], P. ARNOLD[7], D. R. ROSENBERG[4], V. A. DIWADKAR[8];

Genet., Univ. of Calgary, Calgary, AB, Canada; [8]Psychiatry & Behavioral Neurosci., Wayne State Univ. SOM, Detroit, MI

Abstract: Introduction: Obsessive-Compulsive Disorder (OCD) is characterized by intrusive thoughts/urges (obsessions), and repetitive behaviors (compulsions) (Rosenberg et al., 2004). Interest in OCD's pathology has focused on brain network profiles of the dorsal Anterior Cingulate Cortex (dACC) given the dACC's role as a principal control region (Paus 2001). Both motor control (Diwadkar et al., 2015) and memory (Friedman et al., 2017) induce dysfunctional dACC profiles in OCD. Here, we investigated the relationship between OCD symptom dimensions (obsessions, compulsions) measured using the Y-BOCS (Scahil et al., 1997), and the degree of dysfunctional modulation by the dACC.
Methods: fMRI data were collected for 28 OCD subjects (10 males, mean age = 16.35 years, right handed) (Siemens Verio 3T) during motor control and working memory. The motor task required participants to tap their right forefinger in response to a flashing white probe; the memory task was a standard 2-back. fMRI data were processed using the unified segmentation method (Ashburner & Friston, 2005) in SPM12. Psychophysiological Interactions (PPI), a model of directed functional connectivity, were employed with a dACC seed. The 1st level PPI maps for each subject (Motor, Working Memory) were submitted to separate regression analyses using Obsession and Compulsion scores as covariates of interest (COIs). Both positive and negative relationships were assessed ($p<0.05$, cluster level).
Results: For the motor task, an increase in obsessive symptoms strongly predicted increased dACC modulation of areas including the Postcentral, Middle frontal, and Supramarginal gyri. By comparison, for the memory task, an increase in compulsive symptoms strongly predicted increased dACC modulation of areas including the Superior occipital lobule, Precentral and Postcentral gyri. Conversely, during memory, increases in obsession symptoms associated with decreased dACC modulation, observed in the Insula and Superior frontal gyrus. Under the motor task, decreased dACC modulation tracked with increases in obsession symptoms in the Inferior frontal operculum and Angular gyrus, and with increases in compulsion symptoms in the Rolandic operculum and Supramarginal gyrus.
Conclusions: The dACC is ideally positioned to translate intentions to actions, placing heavy emphasis on the link between cognition and motor responses (Paus, 2001). Here, we link the dimensions of OCD—obsessions and compulsions—to the pathology of the dACC in OCD. Our findings demonstrate that OCD symptom dimensions can predict distinctive dysfunction in motor and memory tasks, and that different dimensions are associated with each task.

Title: Adolescent environmental enrichment prior to social stress induces resilience in a novel rodent model of vulnerability

Authors: *A. M. O'CONNOR, E. K. HEBDA-BAUER, S. J. WATSON, Jr., H. AKIL; Univ. of Michigan, Ann Arbor, MI

Abstract: Selectively bred High Responder (bHR) and Low Responder (bLR) rats are a novel rodent model of mood disorders. bHRs emulate externalizing mood disorders and are resilient to stressors, while bLRs emulate internalizing mood disorders and are vulnerable to stressors. Adult environmental enrichment (EE) decreases anxiety-like behavior of bLRs and alters social behavior of bHRs. Adolescence is a critical period for emotional circuitry and a time of increased vulnerability to environmental influences and stressors. bHR and bLR rats show differing phenotypes by adolescence, suggesting that they may respond differently to EE and stressors during this time. This study examines the impact of adolescent EE on anxiety-like behavior of bHR and bLR animals experiencing a social stressor. Male animals from generations F49, F53 and F56 of the bHR/bLR colony were placed in EE for 1 hour/day/5 days a week starting at 35 days postnatal (P35) and ending at P60. Control animals were standard housed with no handling. Half of all animals underwent social defeat (SD) from P61-P64. All animals underwent behavioral testing consisting of open field on P65, social interaction on P66 and elevated plus maze (EPM) on P67. All animals were sacrificed on P68 and brains and plasma collected. Plasma hormone levels were assessed using ELISA kits for testosterone and corticosterone. Social defeat increased bLR freezing, and bHR exploration, within the open field; EE increased exploratory behavior on the EPM in bHRs but not bLRs. Adolescent EE prior to SD decreased social anxiety in bLRs, with EE + SD animals showing decreased social avoidance, increased social interaction and altered ultrasonic vocalizations (USV) compared to standard housed bLR rats experiencing SD. Social interaction behavior was similarly changed in bHRs, without the

concomitant changes in USVs. Thus, bLR EE + SD animals behaved similarly to bHR EE + SD animals during social interaction testing, and were more sociable than baseline bHRs. Adolescent EE decreased bLR plasma testosterone and there was no impact of either EE or SD on plasma corticosterone levels. This data shows that bLR animals that experienced EE prior to SD showed bHR-like patterns of social interaction behavior, with greater changes in USV production and social engagement than bHRs. Adolescent EE flips the bLR social behavior phenotype after social stress, providing evidence that genotype-environment interactions can induce resilience in a usually vulnerable line. This behavioral change does not appear to be mediated by circulating testosterone or corticosterone; work is underway to determine the neural underpinnings of this adolescent reprogramming.

Title: Effect of chlordiazepoxide on cardiovascular and behavioral measures in a rat model of panic

Authors: *S. LOIODICE[1], E. C. O'CONNOR[2], S. NOURRY[1], G. VIARDOT[3], E. P. PRINSSEN[2], C. L. DRIEU LA ROCHELLE[1];
[1]Biotrial Pharmacol., Rennes, France; [2]Roche Pharma Res. & Early Develop., F. Hoffmann-La Roche Ltd, Basel, Switzerland; [3]Neurosci., Biotrial, Rennes, France

Abstract: Panic is characterized by a sudden onset of intense distress, anxiety and a strong desire to escape the situation. These emotions are coupled to heightened autonomic responses, including stimulation of the cardiovascular system. From a drug discovery perspective, physiological responses to panic measured in rodents may offer objective and translational efficacy biomarkers that are not so readily obtained from solely behavioral-based measures. Here we sought to establish a rodent model of panic, namely ultrasound-induced defensive behavior in Lister-Hooded rats, and to evaluate the effects of a reference panicolytic drug on behavioral and cardiovascular endpoints. Rats were operated for electrocardiogram (EGC) and electromyogram (EMG) telemetry recording. To establish the panicogenic effect of ultrasound, ECG and EMG were first recorded for 3 hours during 3 consecutive, once daily sham sessions (no ultrasound) followed by 1 session with ultrasound stimulation (1 min, 93 dB, 22 kHz). Thereafter the effect of chlordiazepoxide (10 mg/kg, po) or vehicle was evaluated on 1 sham session and 1 ultrasound session using a crossover study design. Ultrasound presentation led to a strong increase in heart

rate (~20%) and EMG power (~600%) compared to baseline, indicative of defensive escape behavior. Confirming its panicolytic properties, chlordiazepoxide reversed the ultrasound-triggered heart rate response, without affecting heart rate during the sham session. Chlordiazepoxide decreased EMG power following ultrasound presentation, but also during sham sessions. Taken together, these data illustrate the value of the ultrasound-induced cardiovascular and behavior test for drug discovery in panic disorder.

Title: SSRI exerts anxiolytic action via 5-HT1A and 5-HT2A receptors in the amygdala

Authors: *T. IZUMI[1], K. KONNO[2], M. WATANABE[2], K. TANAKA[4], T. YOSHIDA[3], H. SHIKANAI[1], M. YOSHIOKA[3];
[1]Dept. of Pharmacol., Pharmaceut. Sciences, Hlth. Sci. Univ. of Hokkaido, Ishikari-Tobetsu, Japan; [2]Dept. of Anat., [3]Dept. of Neuropharm., Hokkaido Univ. Grad. Sch. of Med., Sapporo, Japan; [4]Dept. of Neuropsychiatry, Keio Univ. Sch. of Med., Sapporo, Japan

Abstract: SSRIs are widely used as anxiolytics. Previously, we demonstrated that local injection of an SSRI into the basolateral nucleus of the amygdala (BLA) had anxiolytic effect in rats. In the present study, we investigated the effect of local co-administration of an SSRI and 5-HT_{1A} or 5-HT_{2A} antagonists into the BLA on conditioned fear in Wistar/ST rats, and indicated the expression of 5-HT_{1A} and 5-HT_{2A} receptor mRNAs in the BLA by *in situ* hybridization in C57BL/6 mice. All protocols complied with the guidelines of the Animal Research Committee of the Hokkaido University. Local injection of citalopram (SSRI) into the BLA attenuated conditioned freezing, and this effect was blocked by local co-administration of WAY100635 (5-HT_{1A} antagonist) or MDL11939 (5-HT_{2A} antagonist). In *in situ* hybridization, 5-HT_{1A} mRNA was mainly expressed in GABAergic interneurons expressing somatostatin (SOM) mRNA, and 5-HT_{2A} mRNA was in those expressing parvalbumin (PV) or SOM mRNA. From these results, it is speculated that SSRIs exert anxiolytic effect via 5-HT_{1A} and 5-HT_{2A} receptors in the BLA. Because PV- and SOM-positive GABAergic interneurons are known to form local neural circuits

with glutamatergic pyramidal neurons, the anxiolytic action of SSRIs is likely to be mediated by serotonergic modulation of pyramidal neurons via these interneuron subclasses.

Title: Prefrontal excitatory and inhibitory balance in stress-induced anxiety: Evidence for over-inhibition

Authors: *C. PAGE[1], L. COUTELLIER[2];
[1]The Ohio State Univ., Columbus, OH; [2]Dept. of Psychology, Ohio State Univ., Columbus, OH

Abstract: Chronic stress-induced emotional disorders like anxiety and depression involve imbalances between the excitatory glutamatergic system and the inhibitory GABAergic system in the prefrontal cortex (PFC). However, the precise nature and trajectory of excitatory/inhibitory (E/I) imbalances in these conditions is not clear, with the literature reporting glutamatergic and GABAergic findings that are at times contradictory and inconclusive. We have previously found that chronic stress increases the activity of prefrontal parvalbumin (PV)-expressing neurons in both sexes, and chemogenetic activation of this cell population increases anxiety-related behaviors in female mice only. These findings support the idea that chronic stress could lead to emotional dysfunction due to increased activity of the inhibitory GABAergic system, thereby inducing hypoactivity of the PFC. Here, we wanted to investigate further this idea by enhancing pharmacologically the activity of the GABAergic system during exposure to chronic stress. To this end, we exposed female mice to 4 weeks of chronic stress and administered the GABA agonist lorazepam (or vehicle) during the first 2 weeks of chronic stress exposure. We find that GABA agonism during the first 2 weeks of a 4-week chronic stress exposure exacerbates anxiety-like behaviors. In addition, the lorazepam-treated stress group showed elevated mRNA expression of prefrontal *GAD1*, the gene for the GABA-synthesizing enzyme GAD67, indicative of increased pre-synaptic inhibition. Increased *GAD1* expression in the PFC significantly correlates with increased anxiety-like behavior. These findings suggest that increased GABAergic system activity in the PFC during chronic stress plays a role in anxiety. Our combined chemogenetics and pharmacological findings lend support for an overly inhibited PFC in chronic stress-induced emotional dysregulations. We are continuing to investigate possible

mechanisms underlying the effects of chronic stress combined with chronic lorazepam administration on anxiety-like behavior, and will discuss implications for the treatment of stress-induced anxiety disorders.

Title: Moderate prenatal alcohol exposure on gestational day 12 alters social behavior and prelimbic cortex glutamate transmission in adult rats

Authors: *K. R. PRZYBYSZ, J. M. JOHNSON, E. I. VARLINSKAYA, M. R. DIAZ; Psychology - Behavioral Neurosci., Binghamton Univ., Binghamton, NY

Abstract: Prenatal alcohol exposure (PAE) is associated with a variety of cognitive and behavioral deficits collectively termed Fetal Alcohol Spectrum Disorders (FASDs). The most common behavioral dysfunction associated with FASD is social impairment. Animal models investigating binge-level PAE have identified gestational day (G) 12 as a critical period for increasing anxiety-like states, including social anxiety in exposed offspring. However, low-moderate PAE is more common than binge-level PAE, and we have shown that moderate PAE is capable of producing increases anxiety-like behaviors. Whether moderate PAE on G12 also produces social impairment is currently unknown. Additionally, the neural disruptions related to social deficits caused by PAE are poorly understood. One brain area that is critical for modulating social behavior is the medial prefrontal cortex, and the prelimbic subdivision (PL) of the medial prefrontal cortex has been shown to regulate negative social interactions. However, whether PAE alters PL function to produce the social deficits characteristic of FASD has not been investigated. Therefore, the current study was designed to determine whether moderate PAE on G12 is capable of producing alterations to 1) social behavior and 2) PL physiology in adult animals. Pregnant Sprague-Dawley rats were exposed to ethanol vapor or air for 6 hours on G12 (blood ethanol concentration ≈ 60-90 mg/dl), and their male and female offspring were group-housed with same-sex littermates until adulthood. Animals were either behaviorally tested (postnatal day (P) 77) using a modified social interaction paradigm, or were sacrificed for whole-cell patch-clamp electrophysiology (P100+). Behaviorally, PAE males and females exhibited

decreased social investigation relative to their air-exposed counterparts. Additionally, a trend toward a reduction in social preference was evident in PAE males, but not females, indicating a potential sex-dependent effect in PAE-induced social anxiety-like alterations. For physiological experiments, PL-containing brain slices from adult males and females were made and spontaneous excitatory postsynaptic currents (EPSCs) and miniature EPSCs were recorded from layer 2/3 pyramidal cells. PAE resulted in reduced spontaneous EPSCs in males, while females were unaffected. These sex-dependent physiological results may contribute to reduced social preference in male PAE offspring. Overall, this work lends support to the importance of investigating moderate PAE in both sexes and provides further evidence that G12 is a key developmental point for moderate PAE-induced behavioral deficits.

Title: Localization of brain regions with enhanced synaptic plasticity associated with avoidance learning in Wistar-Kiyoto rats

Authors: *N. A. MCCARTHY[1], R. C. PETERSON[1], D. R. COOK-SNYDER[1], D. P. MILLER[1,2,3], R. J. SERVATIUS[2,4,3];
[1]Neurosci., Carthage Col., Kenosha, WI; [2]Central New York Res. Corp., Syracuse, NY; [3]Stress and Motivated Behavior Inst., Rutgers Biomed. Hlth. Sci., Rutgers, NJ; [4]Psychiatry, State Univ. of New York Upstate Med. Univ., Syracuse, NY

Abstract: Behavioral inhibition is a personality temperament characterized by a tendency to avoid novel stimuli. Behaviorally inhibited people show increased vulnerability to anxiety and stress disorders. *Wister-Kiyoto* (WKY) rats display behavioral inhibition, attain signaled lever press avoidance at a higher rate, and are more resistant to extinction than control, Sprague Dawley (SD) rats. Thus, we have proposed that WKY rats are a model for anxiety and stress research. In previous research, we trained WKY and SD rats on either 100% tone-shock pairing or 50% tone-shock pairing in a signaled lever-press avoidance task. WKY rats in both the 100% and 50% contingency displayed the highest rate of avoidance learning, while SD rats in the 50% contingency failed to acquire avoidance learning. WKY rats appear to acquire avoidance based on the expectation of shock, whereas SD rats appear to acquire avoidance based on the presence

of shock reinforcement. In the present study, we sought to determine areas of the brain that are associated with enhanced avoidance acquisition in behavioral inhibition by staining for Zif using immunohistochemistry. Zif is an immediate early gene that is correlated with synaptic plasticity of neurons. WKY and SD rats were run in either 50% or 100% tone-shock pairings for 3 days, and then stained for Zif activation. We examined the habenula, periaqueductal gray, cingulate cortex, and the amygdala as our regions of interest. The habenula is correlated with motivational behavior. The periaqueductal gray is associated with the sensation of pain, corresponding with the delivery of shocks. The cingulate cortex receives input from the limbic system which processes emotion, learning, and memory. The amygdala is associated with fear and fear learning. Future studies will examine these areas linked with behavioral inhibition to assess the cellular and molecular changes that occur with avoidance learning. Knowing how these areas are associated with avoidance acquisition in behavioral inhibition may shed light on the acquisition of symptomology in anxiety and stress vulnerable individuals and suggest areas for treatment.

Title: Neuropharmacological profile of the bertholletia excelsa seeds and its influence on the metabolism of lipids in mice

Authors: *O. FRAUSTO-GONZÁLEZ[1,2,3], **M. E. GONZÁLEZ-TRUJANO**[1], C. J. BAUTISTA[3];
[1]Lab. de Neurofarmacología de Productos Naturales, Inst. Nacional de Psiquiatría Ramón de la Fuente Muñiz, Mexico City, Mexico; [2]Facultad de Química, Univ. Nacional Autónoma de México, Mexico City, Mexico; [3]Dept. de Biología de la Reproducción, Inst. Nacional de Ciencias Médicas y Nutrición Salvador Zubirán, Mexico City, Mexico

Abstract: Overweight and obesity are part of the main health problems in the world. Limited efficacy and adverse effects of the current pharmacological treatment makes that population do not follow it adequately and seeks alternatives to decrease their body mass and reduce comorbidity, such as those affecting the central nervous and reproductive systems. *Bertholletia*

excelsa (Brazil seed) is a natural alternative used by population. People say that it is useful to control body weight and it also reduces anxiety or the desire to eat impulsively. However, there is not enough preclinical and/or clinical research to support its efficacy and safety. From the above, it is of interest for this project to obtain pharmacological evidence of the anxiolytic activity of an hexanic extract of *B. excelsa* (SBHX) and its effects on body weight, influence on the male reproductive system (epididymis and testicle), and in the metabolism of lipids in mice. The experimental design consisted of 5 groups (n&gt=5) of SW mice (25-30 g b.w) fed with a standard diet (Purina 5001) and water rich in carbohydrates (34% sucrose) as a high caloric diet. Groups consisted in vehicle, reference drug and different doses of SBHX (30-300 mg/Kg, i.p). The initial administration was acute and 30 min later, the neuropharmacological profile was evaluated using the open field, hole-board and plus-maze tests; as well as the sodium pentobarbital-induced potentiation of the hypnotic-like effects, nociceptive behavior induced with 1% formalin and in the PTZ-induced tonic-clonic seizures. Subsequently, a chronic administration was continued using the same doses to determine the weight, as well as the intake of water and food, every 5 days for 40 days. Finally, the tissues of the testis, epididymis and liver were extracted for the determination of weight and fat content, triglycerides and cholesterol, as well as the histological analysis. The results indicate that SBHX produces anxiolytic, sedative and analgesic effects. It significantly decreases the weight of the mice at doses of 100 and 300 mg/Kg, i.p. without altering the consumption of water and food. The tissues evaluated maintain their morphological integrity. The exploration of acute toxicity allowed the calculation of the mean lethal dose>2000 mg/kg, placing it in the minimum toxicity classification. Therefore, it is concluded that constituents of a non-polar nature of the *B. excelsa* seed produce a decrease in body weight and anxiolytic effects, giving evidence of the properties attributed to this natural product that is currently commercially available as a natural alternative to this global health problem, without any acute or chronic effects in a preclinical study.

Abstract: Women are more vulnerable than men to present psychiatry and metabolic disorders; thus therapies that contribute to treat both pathological conditions are warranted. Pomegranate (*Punica granatum*) has been proposed as hypoglycemic, lipid-lowering and antidepressant treatment; therefore, it is feasible that it could be useful to regulate glucose, lipids profile and anxiety-like behavior in an animal model of menopause subjected to a cafeteria diet The present study aimed to explore whether the Aqueous extract of *Punica granatum* (AE-PG) prevents the anxiety-like behavior, body weight, glucose and lipids increases induced by a cafeteria diet in middle-aged ovariectomized Wistar rats. Also, we evaluated the effect of AE-PG on the expression of RNAm PPARα and PPAR -γ in liver and protein of AT1, MAS and PPAR -γ, p-PPAR -γ and the ratio pPPAR-γ/PPARγ receptors in hippocampus and amygdala. Results showed that cafeteria diet-induced anxiety-like behavior and augmented cholesterol, triglycerids, glucose and insulin serum concentrations. This diet also increased body weight, promotes insulin resistance and decreased mRNA of PPARγ in the liver in comparison to control diet ($p<0.001$). AE-PG prevents anxiety, and reduce insulin resistance in rats under the cafeteria diet ($p<0.001$) which was associated with an increase of PPARγ in the liver ($p<0.001$). In the brain, cafeteria diet increased the expression in AT1 and MAS receptor only in the ventral hippocampus; this increase was prevented by AG-PG ($p<0.001$). In the amygdala, the protein expression of both receptors was reduced by AG-PG independently of diet. The expression of ratio pPPAR-γ/PPARγ suggest that a different regulation is depending on diet and the brain area evaluated, whereas in the dorsal hippocampus the AE-PG induced an increase of phosphorylation state of the receptor in control rats; this effect was canceled by a cafeteria diet. In contrast, in the ventral portion of the hippocampus, the cafeteria diet decrease phosphorylation of PPARγ and this effect is prevented by AE-PG. Finally, in the amygdala, the increase of phosphorylation induced by AE-PG in control rats was prevented by the cafeteria diet. Further, in this area, a decrease of the phosphorylation by the cafeteria diet was evident. Data suggest that AE-PG prevent anxiogenic effect induced by cafeteria diet and reduce the insulin resistance. Both effects could involve the modulation of PPARγ in the brain and hepatic levels.

Title: Differences in the morphology of microglia cells in the hippocampus of selectively bred high- and low-responder rats: Implications for emotional temperament

Authors: *P. M. MARAS, E. HEBDA-BAUER, H. AKIL, S. WATSON;
Univ. of Michigan, Ann Arbor, MI

Abstract: Mood regulation is a complex process, influenced by both genetic and environmental factors, and reflecting underlying differences in emotional vulnerability. Individual differences in affective temperament clearly play an important role in mood disorders, yet their neural mechanisms remain unclear. Our laboratory uses a selective breeding technique, which has generated rats with contrasting emotional temperaments, to study the neurobiology of mood disorders. Specifically, rats bred for high locomotor responses when placed in a novel environment (bHRs) exhibit low anxiety and are resilient to depression, whereas rats bred for low locomotion in a novel environment (bLRs) are highly anxious and vulnerable to depression. Among the possible factors underlying the bHR/bLR phenotype, recent mRNA expression studies suggest that bLRs have elevated expression of key microglia-specific genes within their hippocampus compared to bHRs. Although intriguing, and consistent with a role for microglia in mood regulation, these expression data do not reveal the anatomical details of the microglia population, or distinguish between variations in the total number of microglia vs. their state of activation. The goal of the current set of experiments was therefore to fully characterize the number and morphology of microglia cells within the hippocampus of bHRs and bLRs under basal (non-stimulated) conditions. To this end, coronal brain sections from adult male bHRs and bLRs were labeled for the microglia marker Iba-1 using immunohistochemistry. Unbiased stereological procedures were used to estimate the total number of Iba-1-positive cells within the dorsal hippocampus. Further morphological analysis was accomplished using Neurolucida software to create detailed 3-D reconstructions of a subset of microglia cells. Although bHRs and bLRs did not differ in their total numbers of microglia cells, reconstruction analysis revealed interesting differences in the morphology of microglia, particularly within the resting state.

These results provide a comprehensive comparison of the microglia population between rats bred for vulnerable or resilient phenotypes, and suggest that variability in microglia morphology may have functional consequences for emotional regulation and the development of mood disorders.

Title: Importance of optimization and pharmacological validation of behavioral assays in a rodent behavioral core

Authors: *M. C. TSUDA[1], T.-Y. J. WU[2], I. LUCKI[3];
[1]HJF/Uniformed Services Univ., Bethesda, MD; [2]Uniformed Services Univ., Bethesda, MD; [3]Dept. of Pharmacol. and Mol. Therapeut., Uniformed Services Univ. of the Hlth. Scienc, Bethesda, MD

Abstract: Behavioral core facilities are important research resources that become a hub for innovation at an institution by connecting investigators with tools and expertise that help to advance research projects to the next level. At the Uniformed Services University (USU) Rat Behavior Core (RBC), we provide the necessary tools and expertise to assess the functional consequences of military relevant psychiatric and neurodegenerative disorders. In our RBC, we believe it essential to optimize procedures and establish baselines for each behavior test to ensure ability, reliability, and sensitivity of the assays. Upon establishing optimal test conditions, pharmacological validation of the assays is critical to demonstrate that under the conditions being tested, a positive control can produce the expected results. In the absence of this, understanding whether the experimental variable failed to produce an effect in the assay or whether there was a fault with the testing environment becomes challenging to interpret. The present study optimized and pharmacologically validated in-demand anxiety and cognitive behavior tests that are highly sensitive to environmental factors: open field (OFT), light-dark transition (LDT), elevated zero maze (EZM), novel object recognition (NOR), and object location (OL) tests. Adult female and male Sprague Dawley rats were used to optimize testing conditions in these tests. In the OFT, LDT, and EZM anxiety tests, we determined optimal lighting intensity, light vs. dark phase testing, and start position within the maze. In NOR and OL test, we evaluated the best object types (size, shape, material), object placement, and apparatus size. Using optimal testing conditions, we then pharmacologically validated each assay. In the

OFT, LDT, and EZM tests, administration of chlordiazepoxide, an anxiolytic benzodiazepine, 30 min prior to testing increased the time spent in the anxiogenic region of the test compared to saline administered control rats, demonstrating reduced anxiety levels. In the NOR and OL tests, administration of scopolamine, a nonselective muscarinic acetylcholine antagonist, 20 min before the acquisition trial impaired discrimination between a novel and familiar object (NOR) or impaired recognition when an object has been relocated (OL) during the retention trial, demonstrating recognition or spatial memory deficits. Both the optimization of testing conditions and successful pharmacological validation of these assays will guide the establishment of standard operating procedures for the RBC, which in turn enables USU investigators to conduct reliable and reproducible research.

Title: Identification of neuronal circuits underlying leptin actions on anxiety

Authors: *M. GUO[1], H. YANG[1], D. ZHAO[1], J. WANG[1], X.-Y. LU[2];
[1]Inst. for Metabolic and Neuropsychiatric Disorders, Binzhou Med. Univ. Hosp., Shandong, China; [2]Med. Col. of Georgia At Augusta Univ., Augusta, GA

Abstract: Our previous studies have shown that leptin receptor LepRb signaling in ventral tegmental area (VTA) dopamine neurons regulates anxiety-related behaviors (Liu et al., 2011, 2015). While intra-VTA infusion of leptin elicits anxiolytic effects, deletion of LepRb in the VTA or specifically in dopamine neurons causes anxiogenic behavior. The objective of this study was to identify neuronal circuits underlying the actions of leptin/LepRb signaling in VTA dopamine neurons on anxiety. LepRb-expressing neurons in the VTA were labeled in Lepr-Cre mice with intra-VTA AAV-DIO-mCherry, and their projections of VTA LepRb neurons to the amygdala and the bed nucleus of the stria terminalis (BNST), two brain regions implicated in anxiety, were examined. We found that dense axonal terminals of VTA LepRb neurons were concentrated in the central nucleus of the amygdala (CeA) and the oval nucleus of BNST (ovBNST). DREADD inhibition of LepRb neurons in VTA induced anxiolytic effects as indicated by increased open-arm time in the elevated plus-maze test, whereas DREADD stimulation of these neurons showed no effects on anxiety. The role of LepRb/VTA-CeA and

LepRb/VTA-ovBNST projections in mediating the effects of VTA LepRb neurons on anxiety is currently under investigation.

Title: Evaluation of the Rhizoma anemarrhena herb for potential to reduce reactive oxidative species

Authors: S. SOWA, *N. SWALVE;
Alma Col., Alma, MI

Abstract: Neurological disorders such as anxiety affect hundreds of millions of people around the world each year. Research has identified cellular damage by oxidative stress to be a contributing factor in the physiological manifestation of cognitive dysfunction. Current pharmaceutical treatments are uncertain and sometimes ineffective. Metabolic defense systems, such as the blood brain barrier, prevent a majority of synthetic drugs from reaching the brain. Natural antioxidants are favorable neurotherapeutics for their biocompatibility with the body and capacity to bypass most molecular deterrents. The traditional Chinese herb, Rhizoma Anemarrhena (ZM), is a potential neuroprotective agent that has expressed the ability to penetrate the the blood brain barrier but few studies have been done to quantify the antioxidant efficiency of this species. To further investigate the medicinal characteristics of ZM, a series of scavenging assays was done for the following reactive oxidative species (ROS): DPPH, OH-, NO-, O_2-, and H_2O_2. Spectroscopy was used to measure solution color changes induced by chemical transformation upon reduction. Results indicate the tendency of the herb to seek out and reduce the different types of reactive oxidative species. The antioxidant capacity results from these experiments will be used to support a subsequent in-vivo procedure to evaluate the capability of ZM as a behavioral treatment. A reduction of ROS presence in the brain could be implicated as a preventative or healing remedy. Positive findings highlight Rhizoma Anemarrhena herbs to be assessed for use in neurological treatments.

Title: Neuropharmacological actions of the diterpene tilifodiolide

Authors: *C. ALBA-BETANCOURT[1], **A. RUIZ-ARREDONDO**[2], M. GONZÁLEZ-CHÁVEZ[3], D. GASCA-MARTÍNEZ[4], M. DEVEZE-ÁLVAREZ[1], Á. ALONSO-CASTRO[1]; [1]Univ. De Guanajuato, Guanajuato, Mexico; [2]Univ. de Guanajuato, Guanajuato, Mexico; [3]Autonomus Univ. of San Luis Potosi, San Luis Potosí, Mexico; [4]Inst. of Neurobio., Querétaro, Mexico

Abstract: Tilifodiolide (TFD) is a clerodane diterpenoid obtained from *S. tiliifolia*. Several studies have reported an *in vivo* antidiabetic activity, and *in vitro* antioxidant effects from *Salvia tiliifolia* Vahl (Lamiaceae), a plant native to the American continent. *S. tiliifolia* is used as a folk medicine for the treatment of neurodegenerative diseases, among others. In this work, the sedative, anxiolytic, and antidepressant effects of 1-100 mg/kg TFD were evaluated with the pentobarbital-induced sleeping time assay, the elevated plus maze test (EPM), the light-dark test, the cylinder exploratory test, and the forced swimming test. TFD did not disturb the start of sleep or extended the length of sleep, 1.5 mg/kg clonazepam (CNZ) diminished the start of sleep by 74% and extended the length of sleep by 2.4-fold. In the EPM, 50 and 100 mg/kg TFD augmented ($p<0.05$) the time consumed in open arms but showed no effects on the number of entries in open arms. In the light-dark test, TFD augmented ($p<0.05$) the time in the light chamber with similar action in comparison to CNZ (1.5 mg/kg). Nonetheless, this effect was no dose-dependent. TFD showed no actions on the amount of entries in the light compartment. TFD reduced the quantity of rearings in a dose-dependent manner: 10 mg/kg (37%), 50 mg/kg (67%), and 100 mg/kg (65%). CNZ (1.5 mg/kg) reduced the quantity of rearings by 95%. In the forced swimming test, only 100 mg/kg TFD diminished ($p<0.05$) the immobility time, and 20 mg/kg fluoxetine reduced the immobility time by 60%. In summary, TFD did not have sedative properties but exhibited moderate anxiolytic and antidepressant actions in mice.

Title: Distinct anxiety outcomes following traumatic brain injury

Authors: *J. POPOVITZ[1], S. P. MYSORE[2], H. ADWANIKAR[1];
[2]Psychological and Brain Sci., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Traumatic brain injury (TBI) is a prominent health problem and can lead to significant affective deficits. Among those, anxiety-related disorders, such as generalized anxiety disorder and post-traumatic stress disorder, are highly prevalent among TBI patients. Here, we hypothesized that individual variability significantly impacts the development of anxiety phenotype following TBI, particularly over the long term. To test this, we tracked anxiety-like behavior following a moderate injury in adult male mice for a period of 7 weeks using classic behavioral tests: the elevated zero maze, the elevated plus maze, and the open field test. Using clustering-based approaches on the high dimensional dataset, we identified two different behavioral profiles of TBI animals. Animals in one cluster presented an injury-susceptible anxiety phenotype, with significant increases in the proportion of time spent in the open arms/center of field, while those in the other did not present an anxiety phenotype following injury (no change in proportion of time spent in anxiogenic zones). There were no differences between the groups in their anxiety-like behavior prior to injury. Immunohistochemical analysis of GABA (GAD65/67) and glutamate (vGlut1) in key brain regions implicated in the control of anxiety, namely, basolateral amygdala, medial prefrontal cortex, and ventral hippocampus, showed distinct changes in GAD and vGlut signaling in the animals with the injury-susceptible anxiety phenotype, as compared to mice in the unaffected cluster, indicating possibly different mechanisms of injury underlying the different anxiety phenotypes.
Key-words: TBI, anxiety phenotype, variability, elevated plus maze.

Title: Molecular and cellular mechanisms underlying the contributions of the G protein-gated inwardly rectifying K+ channels to anxiety-related behavior

Authors: *B. N. V. VO, E. MARRON, H. OBERLE, K. WICKMAN;
Univ. of Minnesota, Minneapolis, MN

Abstract: G protein-gated inwardly rectifying K+ (GIRK/Kir3) channels mediate the postsynaptic inhibitory effects of many neurotransmitters in the central nervous system. Dysregulation of GIRK channel activity has been associated with several neurological disorders such as autism, schizophrenia, epilepsy, Down syndrome, Alzheimer's disease, addiction, mood-related disorders, and pain. ML297 is the prototypical small-molecule GIRK channel modulators, and ML297 selectively activates GIRK1/GIRK2 channels, which are the most dominant GIRK channel subtypes in the brain. Systemic administration of ML297 in mice decreased anxiety-related behavior without evoking sedation, and without impacting depression- or reward-related behavior. The anatomic and cellular mechanisms underlying the anxiolytic efficacy of ML297 are not well understood. The present exploratory study seeks to identify the brain region(s) where the selective activation of this GIRK channel subtype contributes to the reduction in anxiety-related behavior. We performed intracranial manipulations to deliver ML297 to two key brain regions implicated in anxiety: the ventral hippocampus (vHPC) and the basolateral amygdala (BLA). We assessed the impact of these manipulations on anxiety-related behavior using the elevated plus maze (EPM). Male mice, ~ 50 d at the time of surgery and ~ 70-80 d at the end of behavior (sample sizes: 8-10 mice/group), are used in this study. ML297 infusion into the ventral hippocampus (vHPC) reduced anxiety-related behavior in mice in the elevated plus maze test in a dose-dependent manner. In contrast, intra-BLA administration of ML297 increased anxiety-related behavior. We next used a viral chemogenetic approach to acutely-inhibit defined neuron sub-populations in the vHPC to identify cell types mediating the anxiolytic influence of ML297 on anxiety-related behavior (male and female mice, same age, group sizes as above). Chemogenetic inhibition of ventral dentate gyrus, but not ventral CA1 pyramidal, neurons reduced anxiety-related behavior, whereas selective inhibition of inhibitory interneurons in the vHPC evoked seizures. Collectively, our data provide insights into the anatomic region and cellular details underlying the contribution of GIRK channels to anxiety-related behavior. This insight into the neural circuits and substrates underlying anxiety highlights GIRK channels as a novel therapeutic target for anxiety disorders and other relevant diseases.

Title: The role of ventral tegmental area subcircuit in mediating anxiety following repeated social stress

Authors: *C. S. MOREL[1], S. MONTGOMERY[2], S. M. KU[2], B. JUAREZ[2,3], M. FLANIGAN[2], J. J. WALSH[4,2], E. S. CALIPARI[5], L. LI[2], S. J. RUSSO[2], A. K. FRIEDMAN[6], M.-H. HAN[2]; [1]Pharmacol. Sci., [2]Mount Sinai Icahn Sch. of Med., New York, NY; [3]Dept. of Pharmacology, Univ. of Washington, Seattle, WA; [4]Psychiatry, Stanford Univ., Stanford, CA; [5]Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN; [6]Hunter College, City Univ. of New York, New York, NY

Abstract: Anxiety disorders, including generalized anxiety disorder, panic disorder, post-traumatic stress disorder and phobia, affect more than 18% of the American population, and are a major contributor to the global burden of psychiatric diseases. A substantial number of patients (>60%) suffering from anxiety disorders also present depressive-like symptoms. However, the shared or segregated mechanisms underlying both of these diseases remain largely unknown. An increasing body of evidence from human brain-imaging and animal studies implicate the dopaminergic system in the emergence of anxiety disorders and depression. In particular, dopamine (DA) neurons from the ventral tegmental area (VTA) encode rewarding, salient and aversive stimuli and support adaptive behaviors. VTA DA neurons project heavily to the medial prefrontal cortex (mPFC), the nucleus accumbens (NAc), and the amygdala (AMG). We previously described alterations of VTA DA neuronal firing activity following a repeated social defeat stress (RSDS) paradigm, a rodent model that induces different behavioral alterations. Following RSDS, mice can be segregated into two pathological groups: A/D mice that display anxiety and a depressive phenotype (*i.e.* social avoidance behavior, anhedonia, despair and anxiety; susceptible to depression), and A mice that only display anxiety-related behaviors (anxious; resilient to depression). Utilizing neural circuit-probing techniques, we previously observed maladaptive firing activity in VTA-mPFC projecting DA neurons and VTA-NAc projecting DA neurons selectively in A/D mice (depression-susceptible mice), but not in A mice (depression-resilient group). Our current results show that the firing activity of VTA-AMG projecting neurons is dramatically decreased in both A/D and A mice. Additionally, using *in vivo*

calcium imaging in freely moving mice, we correlated VTA-AMG circuit activity with the expression of the anxiety phenotype but not the depressive-related phenotype. Finally, we further demonstrated the causal link between the firing maladaptations in the VTA-AMG subcircuit and anxiety phenotype. Based on our findings, our hypothesis is that the VTA-AMG circuit may play a crucial role in mediating the anxiety-like behaviors observed in both A/D and A mice following RSDS.

Title: Activity regulated cytoskeleton associated protein differentially regulates mood related behavior in the male and female nucleus accumbens

Authors: *R. D. PENROD, C. W. COWAN;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Anxiety disorders are highly prevalent and increased anxiety is a common symptom in numerous neuropsychiatric diseases. Females experience anxiety at a greater rate than males, and some studies find a nearly 60% greater lifetime risk for anxiety in females compared to males. Given the high prevalence, there is a need for novel therapeutic strategies requiring a better understanding of the underlying neurobiology mediating anxiety disorders. Furthermore, despite the significant sex differences in anxiety (and other stress-related) disorders, we have little understanding of the molecular mediators driving these differences. Recent work from our laboratory has identified Arc in the adult nucleus accumbens (NAc) as a potential mediator of sex differences in anxiety-like behavior. We find that Arc knockdown (shArc) in the NAc reduces anxiety-like behavior in males, but not in females. Interestingly, Arc expression is induced following an anxiety-associated experience in the male, but not female, NAc. Ongoing work is focused on: 1) identifying the mechanism for Arc dependent behavioral regulation in the male NAc, and 2) determining if Arc interacts with estrus to mediate female NAc-associated

behaviors. Using cre-dependent shArc, we are examining the cell type-specific roles for Arc in the NAc for regulating anxiety-like and related behaviors, which will enable future work that focuses on cellular and molecular mechanisms of Arc function in the NAc. To address the relationship between estrus, Arc, and behavior, we are examining whether Arc expression is regulated by sex hormones in the NAc and whether Arc plays an estrus-dependent role in mediating anxiety-like behaviors. Together, these ongoing studies should help advance our knowledge of the novel role for Arc in regulating sex-dependent, anxiety-related behaviors.

Title: Dorsal periaqueductal gray and medial hypothalamus involvement in the panic-modulating effects caused by serotonergic activation of dorsal raphe lateral wings

Authors: *M. MATTHIESEN[1], L. DANIEL MENDES[2], H. ZANGROSSI JR[2];
[1]Univ. Estadual Paulista, Araraquara, Brazil; [2]Univ. de São Paulo, Ribeirão Preto, Brazil

Abstract: BACKGROUND: A wealth of evidence indicates that the lateral wings (lwDR) subnucleus of the dorsal raphe (DR) is a key structure in the modulation of panic-associated behaviors, such as escape and flight. Pharmacological stimulation of serotonergic neurons in this subnucleus promotes a panicolytic- like effect. It has been hypothesized that this effect is due to serotonin release in two other major panic-associated areas, the dorsal periaqueductal gray (dPAG) and dorsomedial hypothalamus (DMH), where facilitation of 5-HT_{1A} neurotransmission inhibits escape performance. However, it is unknown whether blockade of 5-HT_{1A} receptors in the dPAG or in the DMH interferes with the anti-escape effect caused by lwDR serotonergic neurons stimulation. **METHODS:** Male Wistar rats (280-310 g) were stereotaxically implanted with a guide-cannula directed to the lwDR and other to the dPAG or DMH. Local microinjection of a small volume of the 5-HT1A receptor antagonist WAY-100635 (0.74 nmol/50 nl) was used to indirectly stimulate serotonergic neurons in the lwDR. Ten minutes before the administration in the lwDR, rats were infused with the same drug into the dPAG (0.37 nmol/200 nl) or into the DMH (0.74 nmol/200 nl). Escape behavior was investigated in the elevated T-maze. **RESULTS:** Previous treatment with WAY-100635 in the dPAG or DMH fully blocked the anti-escape effect caused by the injection of this drug in the lwDR [interaction between dPAG and lwDR treatment factors: $F(1,28)=6.40$; $p<0.05$], two way ANOVA; interaction between DMH and lwDR treatment factors: $F(1,25)=5.67$; $p<0.05$], two way ANOVA]. **CONCLUSION:** Our results show that 5-HT_{1A} receptors activation in the dPAG and DMH mediated the panicolytic-like effect

caused by lwDR stimulation. Dysfunctions in the serotonergic pathways that connect the lwDR to the dPAG and to the DMH may be critically involved in the pathophysiology of panic disorder.

Title: Neurotrophin modulation of a social circuit to mediate preadolescent stress effects on adult social interaction

Authors: *N. TSE[1], F. S. LEE[2];
[1]Weill Cornell Med. Grad. Sch., New York, NY; [2]Weill Cornell Med. Col., New York, NY

Abstract: Adversity experienced during childhood, such as through emotional abuse and neglect, increases the likelihood that an individual will be diagnosed with a psychiatric disorder later in life. Within these disorders, asocial behavior, characterized by avoidance of or decreased motivation toward social interaction, is a common shared characteristic. Our lab has recently identified a projection from the orbitofrontal cortex (OFC) to the basolateral amygdala (BLA) in which suppression of circuit activity produces a reduction in social interaction. OFC projections to the BLA begin to form during preadolescence, and so adversity suffered within this period may alter the development of this circuit and drive asocial phenotypes in adulthood, though to date, no studies have confirmed this. Additionally, the mechanisms underlying abnormal social circuit development in response to preadolescent stress are unknown. In this current study, we optimized a preadolescent stress paradigm and found that a variable foot shock stress delivered within a specific developmental window produces impairments in social interaction at a remote adult time point. Furthermore, we investigated the molecular mechanisms potentially driving these developed social deficits, namely through post-stress upregulation of the p75 neurotrophin receptor within the OFC. These findings suggest that developing OFC structures and circuits related to sociality are uniquely vulnerable to perturbation during a sensitive preadolescent period, and that imbalance in neurotrophin receptor signaling may underlie the detrimental effect of preadolescent stress.

Title: Prefrontal cortical control of the paraventricular thalamus

Authors: *N. MACK, W.-J. GAO;
Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Altered neurotransmission within the medial prefrontal cortex (mPFC) has long been associated with the pathogenesis of anxiety, yet there is little consensus and even conflicting evidence on the role of the mPFC activation on anxiety-like behaviors. Indeed, lesion studies and pharmacological manipulations in animal models along with functional imaging in the patient population have revealed that both inactivation and activation of the mPFC is related to increased anxiety. One possibility is that these contradictory findings are a consequence of differential effects on distinct subdivisions, neuronal cell types, and projection pathways within the mPFC. Recent evidence suggests that increased excitability in mPFC pyramidal neurons may underly the expression of anxiety-like behaviors. However, a downstream projection pathway from the mPFC where enhanced activity is anxiogenic has yet to be identified. Here we demonstrate that the paraventricular nucleus of thalamus may be a downstream target engaged by the mPFC to modulate anxiety-like behaviors in males. We use chemogenetic manipulations to alter the activity in mPFC-PVT along with multiple well-validated behavioral assays to determine whether modulation of this circuit affects the expression of anxiety-like behaviors. Our preliminary results suggests inhibition the mPFC-PVT has anxiolytic effects on the elevated plus maze (EPM) in male mice without affecting locomotor or exploratory behaviors. Using both chemogenetics and optogenetics, our future directions include probing whether bidirectional modulation of this circuit in male and female mice alters the expression passive-like anxiety behaviors. We also aim to probe the cellular excitability of mPFC neurons that project to the PVT.

Title: Physiological characterization of lateral orbitofrontal cortical projection neurons to nucleus accumbens and basolateral amygdala

Authors: *C.-W. LAI[1], C.-H. CHANG[2,1];
[1]Inst. of Mol. Med., Natl. Tsing Hua Univ., Hsinchu, Taiwan; [2]Inst. of Systems Neurosci., Natl. Tsing Hua Univ., Hsinchu (city), Taiwan

Abstract: The lateral orbitofrontal cortex (lOFC) projects to the nucleus accumbens (NAcc) and the basolateral nucleus of the amygdala (BLA). The two projections regulate different behaviors, for example, compulsive drug seeking and reward outcome encoding. In series of studies, we started to investigate the lOFC collateral modulation of these downstream targets and the physiological characterization. We used in vivo extracellular single unit recordings in anaesthetized rats in the experiments. In Experiment 1, we recorded a total of 19 neurons from 10 rats. Among our sampled units, eight neurons projected from lOFC to NAcc, while five neurons projected from NAcc to lOFC. We found one neuron projected from lOFC to BLA, while four neurons projected from BLA to lOFC. Among all the neurons recorded, we only found one lOFC neuron collaterally projected to both NAcc and BLA. Under our filter settings (bandpass 300-10K Hz), 17 of the sampled neurons had low firing rate with relative long spike duration, suggesting the majority of these units were putative projections neurons. In our on-going Experiment 2, we further characterize the physiological characteristics of NAcc- or BLA-projecting lOFC neurons by testing the thresholds (the stimulation current to evoke spike response probability of 2 - 12%) and stimulus intensity-response probability curves (I-O curves). The stimulation electrode was placed in lOFC in search of orthodromic responsive units in NAcc or BLA. So far, we found 4 neurons in NAcc from 8 rats, with a threshold at 0.54 ± 0.19 mA (range 0.35 to 0.70 mA). We did not find any responsive units in BLA yet in 8 rats. Our preliminary results supported the idea that the lOFC to BLA projections were sparse. We will combine tracer study to examine if there is topographic segregation of NAcc- and BLA-projecting neurons in lOFC.

Title: Physiological function abnormal of anterior dorsal bed nucleus of the stria terminalis and ventromedial hypothalamus contribute to the social-isolation-induced behavioral deficits

Authors: *C. ZHENG, L. WEI, B. BO, Z. LIANG, Z. WANG;
Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China

Abstract: Sociality is an indispensable property among most species. The reciprocal links between individuals and social network contribute to the improvement of the cognition capability and maintenance of the mental health. The sociality is vital for individual to live in the society, however, the underlying neural mechanism of sociality still largely unknown. In this study, by utilizing the model of post-weaning social isolation (PWSI), we established the social interaction deficit rats. The results of elevated plus maze test confirmed that the rats of PWSI show high level of anxiety. The results of social preference test show that social preference ratio reduced in PWSI group. In addition, there is a negative correlation between the anxiety level and social preference ratio. The rest-state functional magnetic resonance imaging data show that the functional connectivity between bed nucleus of the stria terminalis (BNST) and ventromedial hypothalamus (VMH) reduced after PWSI. By using in vitro slice recording, we found that the frequency of miniature excitatory postsynaptic current (mEPSC) increased while the decay time decreased in anterior dorsal BNST after PWSI. Furthermore, we found that rest membrane potential and the threshold of action potential in VMH decreased in PWSI group. These results suggested that function abnormal of adBNST and VMH and synaptic transmission between these two nucleuses contribute to the social isolation-induced behavioral deficits.

Title: Effects of combined psychological and metabolic stress on behavior and physiology

Authors: *B. MELANSON, T. LAPOINTE, F. LERI;
Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Chronic stress is highly implicated in the development of depression, possibly through elevation of inflammatory cytokines such as interleukin (IL)-6, IL-1β, IL-17A and tumour necrosis factor (TNF)-α. The primary objective of the current project in laboratory rats was to explore the relationship between combined psychological and metabolic stressors, inflammatory cytokines, and depressive-like behavior to uncover markers of response to antidepressants. Two experiments have been performed in male Sprague-Dawley rats. In Experiment 1, rats were exposed to repeated sessions of inescapable swimming stress to explore behavioral indices of despair (forced swim test), as well as circulating levels of inflammatory cytokines. In Experiment 2, repeated swimming stress was combined with exposure to a metabolic stressor (0, 200 and 300 mg/kg 2-deoxy-D-glucose; 2DG) to explore impact on behavioral despair, anhedonia (saccharin preference), as well as circulating levels of corticosterone and inflammatory cytokines. Experiment 1 indicated that multiple sessions of swimming stress induced long-lasting behavioral despair ($p < 0.001$), but levels of inflammatory cytokines were not affected ($p > 0.05$). In Experiment 2, the addition of the metabolic stressor dose-dependently increased despair responses ($p = 0.048$), corticosterone ($p = 0.001$) and TNF-α ($p = 0.020$). Moreover, rats treated with 200 and 300mg/kg 2DG displayed a significant reduction in saccharin consumption ($p < 0.001$). In summary, the current results in laboratory rats suggest that inflammatory cytokines may play a role in depressive-like behaviors when exposure to uncontrollable stress is of considerable intensity and duration. Moreover, establishing a functional protocol for inducing a significant inflammatory response to multimodal stress allows further investigation into the effects of conventional and novel antidepressant medications.

Title: Putting on the brakes: An EEG investigation of inhibitory control and action monitoring in HIV+ abstinent substance users

Authors: *K.-M. WAKIM-TAKAKI[1], N. VIEYTO[1], C. J. MOLLOY[2], Z. CAO[1], E. G. FREEDMAN[3], J. J. FOXE[4];
[1]Neurosci., Univ. of Rochester, Rochester, NY; [2]Psychiatry, Trinity Col., Dublin, Ireland; [3]Del Monte Inst. for Neurosci., Univ. of Rochester - Neurosci., Rochester, NY; [4]Neurosci., Univ. of Rochester Sch. of Med., Rochester, NY

Abstract: Individuals with human immunodeficiency virus (HIV) with a history of substance use are at risk of engaging in behaviors that interfere with treatment, such as relapse, medication non-adherence, unprotected sex, and needle sharing. Active users of cocaine, both with and without HIV, show clear perseverative response patterns, as well as deficits in the ability to implement flexible problem-solving strategies. The executive functions of "inhibitory control"—the ability to withhold a thought, action or feeling—and "action monitoring"—the ability to assess a cognitively demanding situation and entertain response alternatives—are critical for relapse prevention. Although recent behavioral and neuroimaging evidence indicates normalization of these processes in former cocaine users as function of drug abstinence, it is unknown whether this recovery trajectory persists in former users with comorbid HIV. To better understand the executive changes underlying risky behavior in the high-risk population of individuals with comorbid HIV and history of substance dependence, we collect high-density EEG recordings as patients perform a 'Go/NoGo' response inhibition task. Outcome measures of interest include task performance, as well as amplitude and onset times of the fronto-central N2/P3 ERP components during correct trials, and ERN/Pe components during error trials. By building a deeper understanding of the neural substrates associated with maladaptive executive function, we hope to pave the way for targeted treatments aimed to reduce risky behavior and facilitate positive health outcomes. Consistent with prior literature, we found that both behavioral performance and electrophysiological markers of inhibitory control at task-relevant scalp sites did not differ substantially between HIV- abstinent cocaine users and healthy controls,

suggesting a partial recovery of inhibitory control capabilities in former cocaine users. Preliminary data suggests that neural and behavioral deficits in inhibitory control are more severe in HIV+ individuals with a history of cocaine dependence compared to HIV+ individuals without former cocaine dependence. These data indicate that inhibitory control capabilities in HIV+ former cocaine users do not normalize to the level of HIV- individuals, suggesting that further or more targeted interventions may be needed to facilitate positive health outcomes in this vulnerable population.

Title: Cocaine cue-induced brain activations in recreational cocaine users

Authors: *S. G. SCALA[1], S. M. L. COX[1], M. LEYTON[2];
[2]Dept Psychiatry, Psycholology, & Neurol., [1]McGill Univ., Montreal, QC, Canada

Abstract: The development of pathological drug use is thought to reflect an accumulation of difficult-to-disengage habits and sensitized goal-directed behaviors. As part of our research program investigating whether these phenomena occur in humans, we recently reported the first evidence that the presentation of behavior dependent cocaine-paired cues elicits dopamine release in the habit fostering dorsal striatum prior to the development of a substance use disorder (Cox et al, *Sci Reports* 2017). Now we report evidence that recreational cocaine users exhibit activations of the ventral striatum in response to non-contingent cocaine cues. In brief, we used 3T functional magnetic resonance imaging (fMRI) to measure responses to cocaine-themed videos in recreational cocaine users (n=18) and stimulant drug-naïve healthy controls (n=13). Whole brain voxel-wise analyses found that, in the cocaine users, exposure to the drug (*vs.* neutral) videos elicited BOLD responses in the substantia nigra/ventral tegmental area (peak-level, $p < 0.05$, FWE-corrected), ventral caudate (cluster-level, $p < 0.001$, FWE-corrected), posterior cingulate (cluster-level, $p < 0.001$, FWE-corrected), premotor cortex/supplementary motor area (cluster-level, $p < 0.05$, FWE-corrected), supramarginal gyrus (peak-level, $p < 0.001$, FWE-corrected), precuneus (cluster-level, $p < 0.001$, FWE-corrected), and angular gyrus (cluster-level, $p < 0.001$, FWE-corrected). Controls showed cocaine cue-induced activations in

the angular gyrus only (cluster-level, $p < 0.05$, FWE-corrected). To our knowledge, these findings characterize for the first time brain regional responses to non-contingent drug cues in recreational cocaine users.

Title: Conditioned place preference with low dose mixtures of 3,4-methylenedioxypyrovalerone (MDPV) and 3,4-methylenedioxymethamphetamine (MDMA) in male and female Sprague-Dawley rats

Authors: *H. I. RISCA, C. N. CONWAY, J. D. SHAYKIN, L. E. BAKER;
Psychology, Western Michigan Univ., Kalamazoo, MI

Abstract: 3,4-Methylenedioxypyrovalerone (MDPV) is a novel synthetic cathinone reported to have a high abuse potential and to produce adverse medical consequences when used recreationally. Preclinical research indicates the psychopharmacology of MDPV is comparable to both cocaine and 3,4-methylenedioxymethamphetamine (MDMA). MDPV is commonly used as a substitute or in combination with other psychostimulants, which may be a contributing factor to MDPV-related toxicity. Despite the prevalence of concomitant use of synthetic cathinones and other psychostimulants, few studies have investigated the combined behavioral effects of these substances. The current study evaluated the combined effects of MDPV and MDMA in a rodent model of conditioned place preference (CPP). Adult male (n=72) and female (n=60) Sprague-Dawley rats underwent an eight-day biased CPP procedure. Treatment groups consisted of saline, MDPV (1 or 3.2 mg/kg), MDMA (3 mg/kg), 1 mg/kg MDPV + 3 mg/kg MDMA, or 3.2 mg/kg MDPV + 3 mg/kg MDMA. Activity was monitored during all conditioning trials. To assess evidence for CPP, difference scores were calculated by subtracting time spent in the drug-paired chamber pre-conditioning from time spent in the same chamber post-conditioning. Activity levels during drug conditioning trials were highest among the 3.2 mg/kg MDPV-treated animals. A two-way ANOVA on the difference scores indicated a statistically significant treatment effect. Sex and the treatment by sex interaction were not statistically significant. Although difference scores were higher in all MDPV and MDPV+MDMA treatment groups compared to the saline control groups, only the females treated with 3.2 mg/kg MDPV + 3 mg/kg MDMA exhibited statistically significant evidence for

CPP. Interestingly, 3 mg/kg MDMA appeared to attenuate the locomotor stimulant effects of 3.2 mg/kg MDPV but increase its effects on conditioned reward. These findings indicate females are more sensitive to the rewarding effects of MDPV and these effects may be enhanced by co-administration of MDPV and MDMA. Moreover, concurrent use of MDPV and MDMA may pose an enhanced risk for abuse, particularly in females.

Title: Blockade of hypocretin/orexin receptors prevents sleep deprivation-induced enhancement of cocaine conditioned place preference

Authors: *T. E. BJORNESS[1,2], R. W. GREENE[3];
[1]VA Med. Ctr. of North Texas, Dallas, TX; [2]Univ. of Texas Southwestern, Dallas, TX; [3]Dept Psychiatry & Dept Neurosci., UTSW, Peter O'Donnell Brain Inst., Dallas, TX

Abstract: Cocaine, a psychostimulant with abuse potential due to blockade of dopamine transporters, alters sleep under active use, withdrawal, and abstinence conditions. Furthermore, recovery of lost SWS time during abstinence is associated with an increase in relapse such that there may be a bidirectional influence of sleep and addiction-related behaviors. We have previously demonstrated that acute sleep deprivation both enhances the rewarding properties of cocaine using the conditioned place preference task and induces preference to a low, subthreshold dose of cocaine. However, the mechanism(s) by which sleep deprivation influences

reward-related behavior are still unknown. Here, we investigated a possible role of orexin, a neuromodulator which facilitates waking and has been implicated in reward related behavior, including both natural rewards and drugs of abuse. Adult male C57BL/6 mice underwent unbiased conditioned place preference (CPP) training using a three chambered CPP box. CPP expression was tested using a protocol consisting of a pre-test (doors open) to ensure a lack of side bias, followed by alternating daily cocaine and saline conditioning trials (doors closed), and a 20 min post-test (doors open). Mice were sleep deprived via a slowly moving treadmill belt for 4 hours immediately prior to the post-test (experimental group), or allowed to sleep undisturbed (control group). All animals were injected with 1 mg/kg SB334867 (selective orexin 1 receptor antagonist), approximately 15 min prior to the post-test. A moderate cocaine dose (8 mg/kg) was used; this dose is typically reinforcing and supports CPP in mice. Several days after the end of the CPP protocol, mice underwent an additional experiment in which weight was used as an indirect measure of SB334867 efficacy based on reports of potential hydrolysis leading to an orexin 1-inactive product. Mice were weighed daily and then injected with vehicle (DMSO in sterile water) or 1 mg/kg SB334867 approximately 15 min before the end of the light phase. All mice experienced both vehicle and SB334867 injections. Both control and sleep deprived mice showed preference for the cocaine-paired chamber; however, there was no significant difference in degree of preference between groups. This differs from previous experiments in which acute sleep deprivation enhanced expression of cocaine conditioned place preference. Weight change was significantly lower following 1 mg/kg SB334867 compared to vehicle suggesting that the SB334867 was effective in influencing orexin activity. Overall, these results suggest involvement of the orexin system as a mediator of sleep disturbance's influence on reward behavior.

Title: Effects of aromatase inhibition on cocaine-seeking behavior in male rats

Authors: *J. K. ALVARADO TORRES[1], F. MONTALVO-LOPEZ[1], J. WILSON[1], J. PLA-TENORIO[1], A. ECHEVARRIA-RIVERA[1], M. T. SEPULVEDA-ORENGO[2], D. MUELLER[3];

Abstract: Females are more susceptible to cocaine abuse but more responsive to treatment than males. In females, low estrogen levels impair extinction learning of drug seeking behavior suggesting that estrogens are critical mediators of extinction memory formation. Males also utilize estrogens within the brain through aromatase conversion of circulating androgens. However, it is unclear whether estrogens mediate extinction in males as in females. Thus, we determined if estrogens regulate extinction of cocaine seeking in males, and whether epigenetic changes are responsible. We hypothesized that males lacking estrogens would show impaired extinction and decreased histone H3 acetylation within reward-related brain structures. To test, we examined the effects of a potent aromatase inhibitor, Fadrozole (FAD), on extinction of cocaine-conditioned place preference (CPP). Following conditioning, male rats were injected with FAD (0.5, 1 or 2.5 mg/kg) or vehicle before each CPP test across days. Tissue from the infralimbic medial prefrontal cortex was subsequently screened for 21 different histone 3 modifications with colorimetric assay. Naïve context-exposed rats were used as a control. We observed a dose-dependent effect of FAD, where 0.5 and 1.0 mg/kg doses facilitated extinction and 2.5 mg/kg impaired extinction as compared to vehicle. These findings suggest that estrogens modulate extinction of cocaine seeking in male rats. Preliminary epigenetic data shows high levels of histone 3 modifications in cocaine-vehicle group compared to naive control group. In addition, H3K36 me1 and me2 differed in 1.0 mg/kg FAD group compared to vehicle. This epigenetic data may reveal how estrogens mediate gene transcription important for extinction of cocaine seeking in males.

Title: The role of serotonin 5-HT_{2C} receptors at the RMTg in cocaine conditioned avoidance

Authors: *Y. S. CHAO, J. PARRILLA-CARRERO, M. EID, P. J. VENTO, T. C. JHOU; Med. Univ. of South Carolina, Charleston, SC

Abstract: The neurobiology of cocaine's rewarding effects has been extensively characterized, but relatively little is known about the pathways and processes that underlie cocaine's aversive effects. Aversive responses to cocaine are significant because they may modulate both the acquisition of drug-seeking, and later behaviors such as relapse in experienced animals, and may underlie individual differences in susceptibility to cocaine addiction. Prior work from our lab showed that activation of the rostromedial tegmental nucleus (RMTg) by cocaine critically drives cocaine conditioned avoidance. While some of this cocaine-induced RMTg activation is due to glutamatergic inputs from the lateral habenula (LHb), a majority arises from unknown mechanisms. Using RNAseq we made the unexpected discovery that the RMTg expresses robust and enriched levels of mRNA for the serotonin 2C receptor (gene name *htr2c*) relative to surrounding regions. Because cocaine binds to both serotonin and dopamine uptake transporters, we postulate that 5-HT_{2C}R activation at the RMTg might be a novel mechanism by which cocaine activates the RMTg and drives avoidance. To test the hypothesis that activation of 5-HT_{2C}R following cocaine administration is critical for RMTg excitation that in turn drives conditioned avoidance responses to cocaine, we use a runway operant task developed by Ettenberg and colleagues, in which rats traverse a 5-foot long corridor to obtain a single cocaine infusion. We find that intra-RMTg injection of SB-242084 (a specific 5-HT_{2C}R antagonist) and RMTg site-specific shRNA knockdown of the *htr2c* gene block the development of cocaine conditioned avoidance, while injection of Ro60-0175 (a specific 5-HT_{2C}R agonist) is sufficient to induce conditioned place aversion. In addition to behavioral studies, we use slice electrophysiology to examine the *in vitro* effects of cocaine and 5-HT_{2C}R antagonist and agonist on RMTg neurons. Preliminary data show both cocaine and 5-HT_{2C}R agonist induce delayed depolarization of RMTg neurons that project to the VTA. Future studies will focus on further testing and establishing the specificities of these *in vitro* responses, since another serotonin receptor gene *htr2a* was also identified at the RMTg, albeit expressed at a significantly lower quantity, and studying the role of the 5-HT_{2C}R in RMTg neuron *in vivo* functions via live single cell wire recording. Preliminary data in our lab and prior findings support the notion that aversive effects of cocaine contribute to subsequent relapse drug seeking behaviors. The current studies may identify a valid target for treating cocaine's aversive effects and relapse drug seeking behaviors.

Title: Behavioral and biochemical studies of novel allosteric modulators of the dopamine transporter with therapeutic potential

Authors: *C. D. RICE[1], S. LEWANDOWSKI[1], X. LIU[1], S. AGGARWAL[1], J. SALVINO[2], *O. V. MORTENSEN[1];
[1]Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Wistar Inst., Philadelphia, PA

Abstract: Repetitive cocaine seeking, and use is attributed to cocaine's ability to inhibit the dopamine transporter (DAT). Many attempts have been made to prevent cocaine's actions on DAT but this resulted in drugs that also had addictive properties. By understanding DAT functionality, and more specifically how DAT interacts with cocaine we will be better positioned to develop therapeutics for treating cocaine use disorders. Dopamine and cocaine bind to the primary orthosteric binding pocket on DAT, S1, and previous studies from our lab and others have elucidated a second allosteric binding pocket on DAT, S2. We speculate that modulation of the S1 binding pocket by an allosteric site, S2, can affect the way cocaine binds to the S1 site. Computational modeling and virtual screening of a chemical library against the S2 site of DAT identified a compound, KM822 that acts as an allosteric modulator of DAT function. To further understand the mechanism of allosteric modulation of DAT, analogs of KM822 were designed and synthesized. In this study we show that one of these analogs, NP-1-152, interacts with the S2 site in our computational model and we have confirmed *in vitro* that NP-1-152 binds to the allosteric site by using the substituted cysteine accessibility method (SCAM). We also find that like KM822, NP-1-152 decreases the apparent affinity of cocaine for DAT in dopamine uptake studies. To test the behavioral effects of NP-1-152, we used two different cocaine-associated paradigms. One being cocaine-induced locomotion, testing the psychostimulatory effects of cocaine. The other being cocaine conditioned placed preference, testing the rewarding effects of cocaine. In both assays, we found that NP-1-152 attenuated the effects of cocaine by decreasing cocaine-induced locomotion and cocaine-induced association with a specific environment. We conclude that allosteric modulation of DAT can affect not only cocaine's primary mechanism of action *in vitro* but the psychotropic effects of cocaine *in vivo.* Our work has implications of a novel therapeutic for cocaine use and abuse.

Title: Effects of indirect cocaine exposure and early postnatal fostering on epigenetic DNA modification and behavioural phenotypes of drug naive mice

Authors: *D. C. AJONIJEBU[1], M. V. MABANDLA[2], W. M. DANIELS[3];
[1]Physiol., Nelson Mandela Univ., Port Elizabeth, South Africa; [2]Lab. Med. and Med. Sci., Univ. of Kwazulu Natal, Westville, South Africa; [3]Univ. of the Witwatersrand, Johannesburg North, South Africa

Abstract: Here, we explored the hypothesis that parental cocaine exposure could alter epigenetic machinery in drug-naïve offspring while early postnatal fostering may further modify the accompanied neurochemical and functional components. Variant drug naïve pups were produced from cocaine exposed or non-drug exposed C57BL/6 female mice that were matched with their male counterpart for mating. Within three days of birth, some of the pups were fostered and nurtured by non-biological lactating dams. The pups were initially examined for locomotor activity and memory performance and subsequently for changes in DNA methylation in promoter regions of cAMP response element modulator (*Crem*) and *Fosb* in the prefrontal cortex (PFC) at 48 days postnatum. The impact of postnatal fostering on these parameters was also investigated to further evaluate the influence of the environment on epigenetic expression. Our results showed that cocaine exposure significantly decreased both *Crem* and *Fosb* methylation in the prefrontal cortex of the progenitor mice compared to their controls. We also found that similar patterns of methylation in the parents were replicated in the same brain region of all groups of drug naïve non-fostered offspring mice. Whereas, fostering the offspring at early life did not only prevent expression of epigenetic marks associated with parent's cocaine experience but also impaired recognition memory, especially in descendants lineally inclined with either paternal (ME) and/or both progenitors' (MFE) cocaine exposure, as opposed to intact memory performance in their non-fostered counterparts. We also found that locomotor activity was unaltered in all groups of mice tested in the open field. Our data provide some evidence that indirect exposure to cocaine may cause marked epigenetic changes within the cortical networks of drug naïve descendants and that mediation by *Crem*/*Fosb* signalling in this brain region may be beneficial, while early postnatal fostering may further engineer molecular switching that may predispose the individual to future risky behaviours as well as accumulative potential to developing cognitive impairment later in life.

Title: Cocaine-induced structural brain changes in rhesus monkeys: Lasting changes and regions of recovery after two years of abstinence

Authors: *H. P. JEDEMA[1,2], X. SONG[1], H. J. AIZENSTEIN[2], E. A. STEIN[1], Y. YANG[1], C. W. BRADBERRY[1,2];
[1]Intramural Res. Program, NIH, Baltimore, MD; [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In order to provide insight into the observed differences in gray matter between cocaine users and control subjects that are observed clinically, we previously examined the longitudinal changes in gray matter density (GMD) in brains of rhesus monkeys following a 12-month period of intravenous cocaine self-administration (n=8 cocaine group vs n=6 controls). Using a novel analysis pipeline optimized for longitudinally collected structural imaging data and voxel-based morphometry, we observed reduced GMD in the cocaine group in multiple brain regions, including orbitofrontal cortex, thalamus, temporal cortex, and insula. In addition, we found increased GMD in the temporal pole, ventral frontal cortex, caudate, cerebellum, and occipital cortex. In a select subset of cortical clusters, the decreases in GMD correlated with impairment in cognitive function in these subjects, highlighting the functional impact of the GMD changes. The clusters of longitudinal GMD changes in monkeys correspond well to the cross-sectional differences in gray matter observed clinically and suggest that chronic cocaine use likely contributes to the reduced gray matter in cocaine users. Following a 2-year period of abstinence from cocaine, a 3rd MRI scan on a subset of the subjects (n=6 cocaine groups vs n=5 controls) revealed that the changes in GMD following cocaine exposure had largely reversed in most regions, including the thalamus, occipital cortex, and cerebellum. This reversal is consistent with recovery of cognitive function we observed after 3-5 months of abstinence. However, we observed a lack of change in GMD in temporal cortical regions, the caudate, and insula after this prolonged abstinence, suggesting that these areas reflect more lasting alterations that might contribute to an enhanced risk of relapse observed in drug addiction.

Title: Sex differences in cocaine reward and estradiol-mediated hypersensitivity to cocaine cues are associated with changes in ERK activity within the mesolimbic reward pathway

Authors: *S. S. KOKANE, A. C. HOCH, R. J. ARMANT, L. I. PERROTTI;
Psychology, The Univ. of Texas at Arlington, Arlington, TX

Abstract: Previous research has shown that the increased vulnerability of women and female animals to the subjective effects of cocaine and hypersensitivity to cocaine-associated cues is mediated by estradiol. Estradiol mediates these effects of cocaine by potentiating dopaminergic synaptic transmission in the mesolimbic reward pathway. At the neuronal level, estradiol-mediated neuroadaptations in dorsal striatum (dStria), nucleus accumbens shell (NAc shell) and core (NAc core) are implicated in regulating these effects. Previous studies from our group have demonstrated the ability of estradiol to enhance cocaine-cue associations in a cocaine-conditioned place preference (cocaine-CPP) paradigm. Studies conducted in males animals have well established that activation of extracellular signal-regulated kinase (ERK) plays an important role in mediating neuroadaptations within the mesolimbic pathway that are important for the development of cocaine-cue associations. However, studies exploring the induction of ERK in females and the influence of gonadal hormones on the induction of ERK in the mesolimbic system in response to cocaine-CPP are severely lacking. Thus, the goal of the present study was to identify sex differences in the induction of ERK activation after cocaine-CPP and to examine the influence of estradiol's enhancement of cocaine-cue associations on ERK induction in the mesolimbic system. Intact adult male and female, and ovariectomized (OVX) female rats were subjected to a cocaine-CPP paradigm using a 3/3 conditioning procedure with 10mg/kg of cocaine hydrochloride (i.p.). To systematically compare the effects of estradiol on cocaine-cue associations, OVX female rats were treated with estradiol benzoate (EB; 5 µg; s.c.) 30 minutes prior to the start of each cocaine-conditioning session. Expression of cocaine-CPP was assessed under a drug- and hormone-free state 24h after the last conditioning session. Immediately after the CPP test, animals were euthanized and brain tissue comprising ventral tegmental area (VTA), NAc and dStria was isolated to assess the expression of phosphorylated ERK (pERK) protein. Overall, females exhibited a higher preference for cocaine and had higher levels of pERK in VTA, NAc, and dStria than males. EB-treatment during cocaine-conditioning potentiated cocaine-CPP and increased pERK in dStria and NAc shell in females. In conclusion, our results

demonstrate, that **sex differences in cocaine preference and estradiol-mediated potentiation of cocaine-cue associations may be due to increased ERK activation in the nucleus accumbens shell and dorsal striatum.** Funding support: NIH/NIDA R15DA040809 (LIP).

Title: The role of Gadd45b in striatal physiology and cocaine reward

Authors: *M. E. ZIPPERLY, F. SULTAN, G.-E. GRAHAM, N. A. SIMPKINS, K. E. SAVELL, J. S. REVANNA, J. J. DAY;
Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Exposure to drugs of abuse leads to alterations in neuronal activity and synaptic organization, which outlive the direct effects of the drug and may contribute to addiction. Furthermore, drug experience contributes to activity-dependent changes in DNA methylation, an epigenetic modification that is critical for synaptic plasticity and plays an important regulatory role in the function and development of the mammalian nervous system. The *Gadd45* (Growth arrest and DNA-damage inducible) family is involved in activity-dependent DNA demethylation, but little is known about how this family regulates the activity of brain reward circuits and subsequent behavioral responses to drugs of abuse, such as cocaine. The present study utilizes unbiased genome-wide transcriptional profiling, pharmacological manipulations, electrophysiological recordings, and CRISPR tools in both *in vitro* and *in vivo* rodent model systems to characterize the importance of *Gadd45b* in dopamine-dependent epigenetic regulation and cocaine reward. In primary rat striatal cultures *in vitro*, acute dopamine treatment increased *Gadd45b* mRNA. This increase was blocked by the dopamine receptor type 1 (Drd1) antagonist SCH-23390 and was mimicked with the Drd1 agonist SKF-38393, suggesting that Drd1 activation is required for dopamine-induced increases in *Gadd45b*. Furthermore, RNAi knockdown of *Gadd45b* in cultured striatal neurons resulted in downregulation of immediate

early genes (IEGs), such as *Fos*, *Fosb*, and *Arc*, as well as reduced action potential bursting activity, compared to scrambled controls. *In vivo, Gadd45b* and IEGs were upregulated in the rat nucleus accumbens following acute cocaine reward. CRISPR/Cas9-driven *Gadd45b* knockdown attenuated cocaine-paired place preference *in vivo*, suggesting that *Gadd45b* action is required for cocaine memory. Ongoing studies aim to further investigate the role of *Gadd45b* by characterizing the effects of overexpression on neuronal activity and IEG expression. Overall, our results suggest that *Gadd45b* is induced by dopamine receptor activation and regulates transcriptional and physiological dynamics in striatal neurons.

Title: The role of fragile X mental retardation protein in striatal plasticity and drug-related behavior

Authors: *J. HUEBSCHMAN[1], L. N. SMITH[2];
[1]Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Cocaine, and other drugs of abuse, are known to alter dendritic spine density and synaptic strength of medium spiny neurons (MSNs) in the nucleus accumbens (NAc) and dorsal striatum (DS), implicating such changes in connectivity in the development and/or maintenance of addiction. However, key regulators of this process remain unclear. The fragile X mental retardation protein (FMRP), an RNA binding protein which controls the translation of hundreds of brain RNAs, has been shown to regulate spine density in multiple brain regions. Our work has highlighted FMRP's function in the promotion of basal spine stability, as well as in limiting cocaine-induced increases in dendritic branching and spine density, in multiple striatal sub-regions. Here, we continue to examine the role of FMRP in striatal cell plasticity and how this process relates to the development of addiction-related behaviors in mice, using both embryonic mouse cortical-striatal cell co-culture and *in vivo* mouse drug self-administration models. In the absence of FMRP, cultured striatal cells show no differences in synaptic puncta density after 10 days *in vitro* (DIV) but develop a significant deficit in puncta by 14 DIV, suggesting that FMRP plays an important role in striatal cell synapse formation and maintenance. Further, our preliminary *in vivo* drug self-administration data suggest that FMRP may be required for shifts in hedonic preferences associated with repeated drug exposure. Ongoing work in our lab is

examining the role of FMRP's specific RNA-binding regions in regulating striatal plasticity, which will provide insight into the FMRP targets involved in this process. We are also investigating the role of FMRP in D1- and D2-receptor expressing MSN's and how its activity in each of these cell types may regulate drug-related behaviors.

Title: Correlation among striatum coexpression networks and drug-related sensation-seeking behaviors in diversity outbred mice

Authors: *M. C. SAUL, P. E. DICKSON, L. H. GAGNON, T. WILCOX, T. ROY, U. DATTA, E. J. CHESLER;
The Jackson Lab., Bar Harbor, ME

Abstract: Novelty-related and sensation-seeking behaviors are strong predictors of drug use phenotypes in both mice and humans. These behaviors are heritable in both species, implying conserved brain gene regulatory networks for drug use predisposition. To enumerate genes whose brain expression covaries with such behaviors in a genetically diverse population, we measured open field, novel place preference, light-dark box, and hole board behaviors in the Diversity Outbred population. We correlated these behavioral traits with striatum gene expression using bulk RNAseq. We found varying distributions of association between global transcript abundance and novelty and sensation-seeking phenotypes. Open field and light-dark box traits showed many statistically significant associations (at FDR < 0.10) with striatum transcript abundance, hole board exploratory traits showed fewer associations, and novel place preference traits showed almost no associations. Effect sizes were lower than previously observed behavioral associations with striatum gene expression in less diverse mouse stocks, suggesting that diversity expands mechanisms of gene regulatory stabilization relative to inbred mice. However, coexpression network analysis revealed strong correspondance among gene networks membership and behavioral correlations with genes. For example, within one module containing a large cluster of synaptic genes, module membership showed a very strong (r = 0.67) correspondance with gene correlation to novel place preference. Among the most highly connected nodes within this module was the synaptotagmin gene *Syt13*, which was strongly

coexpressed with multiple glutamatergic and GABAergic receptor genes. These results reinforce that in genetically diverse populations, behaviorally relevant gene expression phenomena arise at the network level.

Title: Novelty facilitates formation of long-term extinction memory of cocaine-associated context

Authors: *J. LIU, R. WU, J.-X. LI;
SUNY At Buffalo, Buffalo, NY

Abstract: Repeated exposure to drug-associated cues would induce extinction. Extinction of drug-associated cues is a new associative memory that inhibits original drug reward memory. It is believed that facilitating extinction memory is an effective strategy to control drug addiction. Previous studies showed that extinction can be promoted or enhanced by non-pharmacological strategies such as a brief exploitation of a novel context (novelty). However, it is unclear whether novelty would affect extinction memory of drug-associated cues. Here, we investigated the effect of novelty on extinction memory of cocaine-associated contextual cue in cocaine-induced conditioned place preference (CPP) in rats. After the conditioning of cocaine-induced CPP, rats were allowed to freely move (30 min per day) in the CPP chambers for three days to induce extinction. We found that the three-day extinction had no effect on subsequent expression of cocaine-induced CPP. Interestingly, exposure to novelty 1 hour before extinction sessions (novelty-extinction) suppressed subsequent expression of cocaine-induced CPP, suggesting that novelty facilitated formation of long-term extinction memory of the cocaine associated contextual cue. However, exposure to novelty 6 hours before extinction had no effect on extinction memory, indicating that novelty affected extinction in a time-dependent manner. Furthermore, we found that the long-term extinction memory induced by “novelty-extinction” procedure persisted for at least three weeks. “Novelty-extinction” procedure did not disrupt cocaine reward memory, since cocaine reward memory recovered 6 weeks after extinction. Although long-term exposure to drug-associated cues induce extinction, brief exposure to drug-associated cues retrieves drug reward memory and may trigger reconsolidation. Extinction and

reconsolidation are two opposite processes. We then examined whether exposure to novelty before memory retrieval would affect cocaine reward memory. Rats were placed in the cocaine-paired side for 10 min to retrieve cocaine reward memory. We found that exposure to novelty 1 hour before retrieval for three days had no effect on subsequent expression of cocaine-induced CPP. Taken together, these results indicate that novelty facilitates formation of long-term extinction memory of cocaine-associated context, suggesting that "novelty-extinction" may be a novel behavioral strategy to regulate drug addiction.

Title: The effects of escalated cocaine intake on decision-making dynamics

Authors: *M. J. STEPHENS, J. S. BECKMANN;
Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Cocaine Use Disorder (CUD) is characterized partly by the use of cocaine at the expense of other alternatives; in other words, it is a decision-making pathology (Kalivas and Volkow, 2005). Probabilistic reinforcement-learning choice (PRLC) tasks are able to assess decision-making behavior in a dynamic scenario that more closely resembles the conditions of daily human life. In order to compare decision making in rats with regulated and dysregulated cocaine intake, a PRLC task was run in tandem with an escalation procedure. First, animals were trained on a PRLC task until responding was stable, and they were then implanted with an indwelling jugular catheter and trained on a cocaine self-administration procedure (0.3mg/kg to the animal's weight) using a fixed ratio 1 schedule under 1-hr access until responding was stable. For the escalation procedure, some animals remained on 1-hr access and others were given 6-hr access to cocaine for 21 days. Then all rats returned to 1-hr access. The animals were trained such that they performed the PRLC task in the morning (while not under the influence of drugs) then were taken to rest in their home-cage and were later put back into the operant boxes for self-administration sessions.
Escalation of cocaine intake was evident in the 6-hr exposed animals while intake was stable in the 1-hr exposure animals. Preliminary analyses indicate that the choice behavior between groups did not differ over the 21-day period, despite differences in intake between the groups. The results suggest that despite dysregulated drug taking, when not under the influence of drugs

and when making choices for non-drug alternatives, the rats decision making was unaffected. Thus, drug-associated decision-making may be context dependent and any drug-related changes in decision making are not necessarily universal.

Title: Activation of GABA projection neurons from the ventral tegmental area to the nucleus accumbens attenuates incubation of cocaine craving

Authors: *M. SUAREZ[1], E. CANTRELL[2], C. E. BASS[3];
[1]Pharmacol. and Toxicology, [2]Neurosci., Univ. at Buffalo, Buffalo, NY; [3]Univ. at Buffalo SUNY, Buffalo, NY

Abstract: The symptoms of cocaine use disorder are often expressed, or only expressed, during periods of prolonged abstinence, leading to relapse. Several brain areas play a role in sensitivity to both cocaine and cocaine-associated cues; the Ventral Tegmental Area (VTA) is heterogeneous midbrain region with dense afferents to the Nucleus Accumbens (NAc) that has been extensively studied for its role in natural- and cocaine-associated behaviors. Most of the neurons in the VTA are dopaminergic, however, the VTA also contains GABA interneurons, as well as GABA projection neurons (GPNs). Approximately one third of mesoaccumbal afferentss are GABAergic and are critical for cue-motivated responding. Using a combinatorial viral approach to target activating designer receptors exclusively activated by designer drugs (DREADDs) to VTA glutamate decarboxylase 1 (GAD1)-positive neurons in rats, our lab has previously demonstrated that chemogenetic activation of VTA GABA neurons decreases motivation for sucrose-predictive cues. Furthermore, when reward value was unexpectedly reduced by decreasing the volume of sucrose earned, clozapine N-oxide (CNO) in the NAc reduced responding to the sucrose-predictive cue when compared to controls. Currently, the role of these GPNs in cocaine-mediated behaviors is unknown. Rats were trained to self-administer cocaine (0.5 mg/kg/inf), by lever pressing, for 14 days and then were tested in early (< 3 days) or late (> 30 days) forced abstinence, to establish the expression of incubation of craving. At both test times, we chemogenetically activated either all VTA GABA neurons by giving the CNO systemically (0.3 mg/kg i.p.), or just the VTA GABA neuron terminals in the NAc by microinfusion of CNO. Our results show that rats readily express incubation by increased

responding on the previously active lever when tested > 30 days, compared to < 3 days. Additionally, systemic CNO, which simultaneously activates all VTA GABA neurons locally and at their distal projection sites, decreased responding on the active lever on all test days. Interestingly, microinfusion of CNO into the NAc, which activates only accumbal terminals of VTA GABA projection neurons, normalized the incubation response to levels seen at < 3 days. CNO had no effect in virus control rats. These results clearly establish that mesoaccumbal GABA neurotransmission facilitates either a reduction in motivation for a previously active lever, or an enhancement of extinction learning to a previously drug-paired environment.

Title: Posterior parietal cortex inactivation abolishes the acquisition of cocaine reward-context association

Authors: *S.-J. JEONG[1], S. XU[2], U. KANG[2,3], J. KOO[1];
[1]Dept. of Neural Develop. and Dis., Korea Brain Res. Inst., Daegu, Korea, Republic of; [2]Inst. of Human Behavioral Med., Med. Res. Center, Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Dept. of Psychiatry and Behavioral Sci., Seoul Natl. University, Col. of Med., Seoul, Korea, Republic of

Abstract: Reward-induced behavior is closely affected by the learned context in a particular environment. However, the neural substrates for reward-context relations have not yet been fully elucidated. The posterior parietal cortex (PPC), known to act as a multisensory integrating area, receives inputs from various areas that accept contextual elements (e.g., visual cortex, auditory cortex, thalamus). To investigate a novel role of the PPC in cocaine reward-context associations, we performed cocaine conditioned place preference (CPP) after manipulating PPC neurons by irreversible lesion, temporary inhibition, and optogenetic inactivation. We observed that excitotoxin N-methyl-D-aspartic acid (NMDA) lesion to PPC induced the diminished the expression of cocaine CPP (p<0.01). To determine which session of the CPP is associated with the PPC function, muscimol was infused for temporary inhibition before training or preference

test session, respectively. As a result, we found that PPC plays a role in the acquisition, not in the expression, of cocaine CPP ($p<0.05$). In addition, the optogenetic inactivation of PPC during the training session also abolished the expression of cocaine CPP ($p<0.05$). However, inactivation of PPC did not have any effects in cocaine-induced locomotion, suggesting the inhibition of PPC was not due to a motor effect. Together, these results suggest that the PPC plays an important role in reward-context association during the pair formation rather than retrieval procedure.

Title: Histone deacetylase 5 (HDAC5) in the prelimbic cortex regulates cocaine self-administration and seeking behaviors

Authors: *S. M. BARRY[1], N. AGNIHOTRI[2], J. D. WOLFE[3], M. TANIGUCHI[1], C. W. COWAN[1];
[1]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Col. of Charleston, Charleston, SC; [3]Wesleyan Univ., Middletown, UT

Abstract: Relapse to drug-seeking remains a major obstacle in the treatment of cocaine addiction in individuals suffering from substance use disorders. Underlying this clinical obstacle are neuroadaptations and changes in gene expression within limbic structures critical for reward and goal-directed behavior. Drug-induced changes in gene expression in the medial prefrontal cortex (mPFC) promote drug-seeking or develop as a compensatory mechanism to oppose drug reward. These changes occur in part through epigenetic mechanisms such as histone acetylation and deacetylation, which changes chromatin structure through post-translational modifications. Expression of a nuclear-localized Histone Deacetylase 5 (HDAC5) in the nucleus accumbens (NAc) reduces drug seeking after cocaine self-administration (SA). However, the role and regulation of HDAC5 in addiction-relevant NAc efferents has not been investigated. We tested the hypothesis that nuclear HDAC5 in the prelimbic (PrL) cortex, a subregion of the mPFC associated with the promotion of drug-seeking behavior, would decrease cocaine-seeking, but have an opposing role in a related subregion, the infralimbic cortex (IL). We found that

expression of nuclear HDAC5 in the PrL augmented cocaine SA behavior, but it suppressed context-related drug seeking without altering cued or cocaine-primed reinstatement of drug seeking following extinction training. Interestingly, no significant effects on cocaine SA behavior were observed in rats expressing nuclear HDAC5 in the IL. Ongoing studies are investigating the role of the HDAC5 target gene, *Npas4*, in cocaine SA, and the possibility that HDAC5 in the PrL might regulate cocaine-context associations via regulation of NPAS4. Together our findings suggest that HDAC5 plays a region-specific role in the mPFC to regulate cocaine SA in a context-dependent manner, and ongoing studies will elucidate the mechanisms through which this regulation occurs.

Title: The cell type-specific role of nucleus accumbens NPAS4 in cocaine-conditioned behaviors

Authors: *B. W. HUGHES, M. TANIGUCHI, C. W. COWAN;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Substance use disorder is a chronic, relapsing behavioral disorder that is characterized by compulsive drug seeking and use despite negative consequences to the individual. During the course of drug use, persistent neuroadaptations develop in the nucleus accumbens (NAc), a brain region predominately composed of dopamine D1 receptor- and D2 receptor-expressing medium spiny neurons (MSNs) and whose activity is associated with reward and motivation. The progression from casual drug use to abuse is mediated in part by the strong association between the rewarding effects of the drug and the environmental contexts and cues linked to drug use experiences. As such, these external cues can become powerful triggers for relapse in abstinent addicts. However, the molecular and cellular mechanisms underlying these drug-context memories are not well understood. One possible regulator of neuroadaptations in the NAc responsible for drug reward-related learning is the activity-dependent transcription factor, neuronal PAS Domain Protein 4 (NPAS4). In the forebrain, NPAS4 regulates excitatory and

inhibitory synapse balance and synaptic transmission in a cell type-dependent manner. Here, we show that following exposure to a novel drug-paired environment, a small population of NAc neurons induce NPAS4 and, of those, ~50% are D1R- or D2R-expressing MSNs. Cell type-specific reduction of NPAS4 in the adult NAc, using a cre-dependent shRNA virus in D1- or D2-cre mice, revealed a critical role for NPAS4 in D2-MSNs for cocaine reward-context learning and memory without altering sensitivity to cocaine-induced locomotor responses and sensitization. In addition, ongoing studies reveal important roles for NPAS4 in MSN synaptic transmission. Together, our current findings suggest an important cell type-specific role for NPAS4 in the NAc for regulating the development of drug reward-context associations.

Title: Double dissociation of two PPTg neuron populations mediating prepulse inhibition and reward

Authors: *N. FULCHER, E. AZZOPARDI, C. DE OLIVEIRA, R. HUDSON, S. LAVIOLETTE, S. SCHMID;
Univ. of Western Ontario, London, ON, Canada

Abstract: The pedunculopontine tegmental nucleus (PPTg) is a complex structure involved in many innate functions, such as arousal, reward association, and sensorimotor gating. Accordingly, PPTg neurons project to a host of brain regions, including the basal ganglia, the ventral tegmental area (VTA) and the pontine reticular formation. The PPTg is a cholinergic structure, however, it also contains a considerable number of glutamatergic and GABAergic neurons. It has also been assumed for a long time that cholinergic projections to the reticular formation mediates sensorimotor gating, i.e. prepulse inhibition (PPI) of the startle response. PPI deficits accompany many neuropsychiatric illnesses, such as schizophrenia, autism spectrum disorder (ASD), and Tourette's Syndrome, yet underlying mechanisms are unclear. Additionally, literature suggests that cholinergic PPTg projections to the VTA mediate opioid-induced

dopamine activation via VTA M5 muscarinic receptors. While prior studies find chronic lesions of PPTg neurons block conditioned place preference (CPP) and disrupt PPI and, we and others provide recent evidence that transient selective inhibition of PPTg cholinergic neurons does *not* alter PPI. Here, we aim to further decipher the differential role of PPTg glutamatergic and cholinergic neurons in reward association and PPI by intracranially delivering cholinergic- or glutamatergic-neuron specific inhibitory DREADDs bilaterally into the rat PPTg. Subjects were tested for startle, PPI, and morphine-induced CPP after receiving an i.p. injection of DREADD activator, clozapine-N-oxide (CNO), or saline (control). We provide evidence that DREADD inhibition of cholinergic PPTg neurons does not disrupt PPI, but impedes the acquisition of morphine-induced CPP. In contrast, transient inhibition of glutamatergic PPTg neurons significantly disrupts PPI, but has no effect on the acquisition of morphine-induced CPP. Our results highlight, for the first time, a double dissociation between the role of PPTg glutamatergic and cholinergic neuron populations in reward association versus sensorimotor gating. It further corroborates the evidence that cholinergic PPTg neurons do *not* mediate PPI, suggesting that instead glutamatergic PPTg neurons mediate PPI.

Abstract: Introduction: Despite lower rates of cocaine use disorder (CUD), females experience a more severe course of the disorder, have greater difficulty quitting, and are at increased risk for relapse following abstinence compared to males. Notably, sex differences in addiction have not only been reported clinically, but also in the context of neural responses to cue-induced craving and stress reactivity. Neuroanatomical alterations may underlie sex differences given that gray matter volume (GMV) varies in select brain areas between males and females (e.g., limbic regions). This study applied voxel-based morphometry to investigate potential sex differences in GMV using the largest prospective sample of individuals with CUD derived from the ENIGMA Addiction Consortium.
Method: Structural T1-weighted MRI scans and clinical data were pooled from 7 sites. Participants received a clinical interview for DSM Axis I Disorders; CUD participants met for cocaine dependence. The final sample was 420 sex- and age-matched (mean age= 37.7±9.8) participants: CUD males (CUDM, n=140); CUD females (CUDF, n=70); control males (CTLM, n=140); control females (CTLF, n=70). Images were prepared for voxel-based morphometry with modulation using the CAT12/SPM12 toolbox. Differences in GMV were assessed using a 2×2 (sex by diagnosis) ANCOVA that included age, total intracranial volume, and site as covariates. Variables that differed between groups and correlated with GMV regions showing significant interaction effects were also included as covariates (education, race). Whole-brain voxel-wise linear regressions were conducted to explore relationships between GMV and lifetime cocaine use. The voxel-wise threshold was $p<0.001$ uncorrected with clusters >50 contiguous voxels and family-wise error (FWE) rate of $p<0.05$ cluster-level corrected.
Results: Significant GMV diagnosis differences were replicated in frontal regions, inferior temporal gyrus, and supplementary motor cortex (CUD<controls). The sex × diagnosis interaction revealed lower left anterior insula (x=-32, y=23, z=8, $p_{FWE}=0.013$) and left lingual gyrus (x=-2, y=-84, z=-8, $p_{FWE}=0.007$) GMV in CUDF compared to CTLF but not in males. A whole-brain negative relationship emerged between cocaine use and GMV in the right hippocampus (x=36, y=-36, z=-12, $p_{FWE}=0.003$) in CUDM, but not CUDF.
Conclusion: Given the importance of the insula to interoception and the hippocampus to extinction of no-longer rewarded associations and craving, results suggest differential sexually dimorphic mechanisms may be associated with cocaine addiction. The development of gender-tailored interventions for CUD remains to be explored.

Title: Psychophysiological and neural correlates of cognitive reappraisal mediated down-regulation of attention to drug-related cues in addicted individuals and the role of negative emotionality

Authors: *P. MALAKER, R. A. RABIN, N. ALIA-KLEIN, R. Z. GOLDSTEIN, M. A. PARVAZ;
Psychiatry, Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Background: Cognitive reappraisal (CR), an adaptive technique associated with personality traits through which the value and emotional impact of stimuli are modified through self-distancing or reinterpretation, has shown to be effective in down-regulating biased attention to drug-related cues in addicted individuals. Reduction of EEG-derived late positive potential (LPP) amplitude has previously shown to track CR-mediated down-regulation of drug cue-reactivity. While its neural underpinnings using task-related functional MRI have been explored, the underlying structural integrity of these neural correlates in addicted individuals is still not well understood. **Methods:** EEG data was collected on 30 individuals with cocaine use disorder (iCUD) and 28 healthy controls (HC) during a CR task. CR was measured as the difference in LPP between 'Look' (i.e., passive viewing) and 'Decrease' (i.e., down-regulation using CR) conditions. Separately, T1-weighted MRI scans were also acquired on 29 iCUD and 26 HC and regional gray matter volumes (GMV) were assessed using voxel-based morphometry. Whole-brain regression was conducted to investigate the relationship between extent of CR (LPP amplitude difference) and GMV. In addition, given prior associations with both CR and regional GMV, moderation effects of trait negative emotion (NEM; assessed via Multidimensional Personality Questionnaire-Brief Form) on LPP - GMV association were also explored. **Results:** Whole-brain group by LPP amplitude difference interaction revealed that greater down-regulation of drug cue-reactivity via CR (increased LPP difference) was positively associated with higher GMV in the right orbitofrontal gyrus (p_{FDR}=0.004), inferior frontal gyrus (p_{FDR}=0.019), post-central gyrus (p_{FDR}=0.021), cuneus (p_{FDR}=0.005), and left thalamus (p_{FDR}=0.014) in iCUD compared to HC. Additionally, thalamic GMV in iCUD was negatively correlated with NEM ($p<0.001$), and the moderation analysis revealed that iCUD with lower

NEM demonstrated a stronger association between CR and thalamic GMV (p=0.002). **Conclusions:** We show that greater structural integrity of regions typically implicated in cognitive control, value attribution and mindfulness is also associated with improved CR of drug-related cues in iCUD. In addition, iCUD with lower NEM showed stronger thalamic GMV-LPP association. These results highlight the importance of morphological integrity of select brain regions, and emotional functioning in the ability to use CR to down-regulate attention, perhaps via a corticothalamic pathway, to drug-related cues in iCUD.

Title: Lorcaserin inhibits cocaine-induced changes in brain functional connectivity

Authors: *S. J. KOHUT, M. L. ROHAN, F. B. MOURA;
Harvard Med. Sch., Belmont, MA

Abstract: The 5HT2C/2A agonist lorcaserin has been shown to attenuate the abuse-related behavioral effects of drugs of abuse; however, little is known about its underlying neural mechanisms. The present study aimed to determine the neural correlates of lorcaserin's effects in nonhuman primates self-administering cocaine during functional magnetic resonance imaging (fMRI) sessions. Three adult rhesus macaques (2 male, 1 female) were trained to self-administer intravenous cocaine in a mock MRI scanner under a fixed ratio 3 schedule of reinforcement. During test sessions, monkeys were transported to a 3.0 Tesla MRI scanner in which they could earn two injections of 0.1 mg/kg/inj cocaine during a 30-min scan session. The effects of pretreatment with 1.0 mg/kg lorcaserin on cerebral blood volume (CBV) response to self-administered cocaine was analyzed in two ways: (1) using an empirically derived pharmacological regressor (phMRI) to elucidate patterns of neural activation in response to bolus cocaine injections, and (2) using a seed-based approach centered in the bilateral putamen to determine alterations in functional connectivity following cocaine self-administration. Results found that all subjects self-administered both cocaine injections during all scan sessions. The CBV response to cocaine injections indicate functional inhibition of putamen, motor/pre-motor cortex, prefrontal areas, and temporal regions. Cocaine self-administration also altered functional connectivity with increased connectivity observed between the putamen and other striatal regions

(e.g., nucleus accumbens, caudate), and decreased connectivity between putamen and regions involved in motoric and/or cognition-related behavior (e.g., primary motor cortex and anterior cingulate). Pretreatment with lorcaserin did not appreciably alter the pharmacologic response to cocaine but did alter cocaine self-administration-induced changes in putamen functional connectivity. Specifically, lorcaserin attenuated the increased striatal connectivity and also decreased putamen connectivity with insula following cocaine self-administration. These results suggest that lorcaserin may not alter the direct pharmacological effects of cocaine but rather, disrupt processing of information related to pharmacological stimuli.

Title: Tmod2 is a regulator of cocaine responses through control of striatal and cortical excitability, and drug-induced plasticity

Authors: *V. KUMAR[1], A. MITRA[1], S. P. DEATS[1], P. E. DICKSON[2], B. J. NIEMAN[3], J. ZHU[4], N.-P. TSAI[5], E. J. CHESLER[2], Z.-W. ZHANG[2];

Abstract: Drugs of abuse induce neuroadaptations, including synaptic plasticity, that are critical for transition to addiction, and genes and pathways that regulate these neuroadaptations are potential therapeutic targets. *Tropomodulin 2* (*Tmod2*) is an actin-regulating gene that plays an important role in synapse maturation and dendritic arborization and has been implicated in substance-abuse and intellectual disability in humans. Here we mine the KOMP2 data and find that *Tmod2* knockout mice show emotionality phenotypes that are predictive of addiction. Detailed addiction phenotyping showed that *Tmod2* deletion does not affect the acute locomotor response to cocaine administration. However, sensitized locomotor responses are highly attenuated in these knockouts, indicating a potential lack of necessary drug-induced plasticity. In addition, *Tmod2* mutant animals do not self-administer cocaine indicating lack of hedonic responses to cocaine. Whole brain MR imaging shows differences in brain volume across multiple regions although transcriptomic experiments did not reveal perturbations in gene co-expression networks. Detailed electrophysiological characterization of *Tmod2* KO neurons,

showed increased spontaneous firing rate of early postnatal and adult cortical and striatal neurons. Cocaine-induced synaptic plasticity that is critical for sensitization is either missing or reciprocal in *Tmod2* KO nucleus accumbens shell medium spiny neurons, providing a mechanistic explanation of the cocaine response phenotypes. Combined, these data provide compelling evidence that *Tmod2* is a major regulator of plasticity in the mesolimbic system and regulates the reinforcing and addictive properties of cocaine.

Title: Prior cocaine self-administration differentially alters state encoding in distinct dorsomedial striatal neuron populations in rats

Authors: *L. MUELLER[1,2], A. M. WIKENHEISER[3], M. SHARPE[3], D. M. DIETZ[2], T. A. STALNAKER[1], G. SCHOENBAUM[1];
[1]Natl. Inst. on Drug Abuse, Baltimore, MD; [2]State Univ. of New York, Buffalo, NY; [3]The Univ. of California Los Angeles, West Hollywood, CA

Abstract: When the rules that govern our actions change, it is useful to learn about the new situation in a way that preserves old learning, building a library of associations that can be deployed as needed to match the current context. One way to achieve this is to compartmentalize learning about different contexts into distinct “states”, each containing information relevant to a particular scenario. Using inputs from the orbitofrontal cortex, cell populations within the dorsomedial striatum (DMS), including medium spiny neurons (MSNs), fast-spiking interneurons (FSIs), and cholinergic interneurons (CINs), work together to maintain such state-specific rules. Since drugs of abuse are known to disrupt state-dependent behaviors and decision making, neural encoding of state within the DMS may be impaired by drug exposure.
Here, we assessed how a history of cocaine self-administration affected neural representations of state in MSNs and FSIs, the major cell populations of the DMS. Single-unit activity was recorded from rats that had self-administered either sucrose or cocaine for several weeks prior to recording. Units were recorded while rats performed an odor-guided decision making task comprised of two blocks of trials, or “states”. In one state, odor cues were delivered to a central port and signaled the availability of a large reward from one fluid well and a small reward from

another well. In the second state, the odor-reward size contingencies were reversed. We found that cocaine-experienced rats were slower to adjust responding for large rewards following a state change as compared to sucrose-experienced controls. This behavioral change was accompanied by differences in state encoding by DMS MSNs and FSIs. Prior to odor onset, MSNs in the cocaine-experienced group exhibited decreased trial type classification accuracy, suggesting a loss of state representation relative to sucrose controls. However, following odor onset, FSIs in the cocaine group displayed increased trial type classification accuracy, demonstrating enhanced outcome representation. Together, these results indicate that DMS state encoding is disrupted by cocaine experience. These findings are consistent with a role for DMS cell populations in the regulation of behavioral flexibility and suggest that alterations in task encoding may contribute to the poor decision-making observed in individuals following exposure to drugs of abuse.

Title: Role of anterior dorsal lateral hypothalamic area perineuronal nets in VTA neuron excitability

Authors: *J. M. BLACKTOP[1], B. A. SORG[2], J. T. WILLIAMS[3], S. L. INGRAM[4];
[1]Washington State Univ. Vancouver, Vancouver, WA; [2]Integrative Physiol. and Neurosci., Washington State Univ., Vancouver, WA; [3]Vollum Inst., Oregon Hlth. Sci. Univ., Portland, OR; [4]Dept. of Neurolog. Surgery, L-472, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Addiction involves drug-induced neuroplasticity of the circuitry for motivated behavior, which includes the medial forebrain bundle and the lateral hypothalamic area (LHA). Emerging at the forefront of neuroplasticity regulation are specialized extracellular matrix structures that form perineuronal nets (PNNs) around parvalbumin positive (PV^+) fast-spiking interneurons, making them a promising target for the regulation of drug-induced neuroplasticity. We previously reported that the dorsal anterior lateral hypothalamic area (LHAad) exhibits robust PNN expression using the PNN marker *Wisteria floribunda* agglutinin (WFA), and that approximately two-thirds of WFA positive neurons co-expressed PV. Removal of PNNs with the enzyme chondroitinase ABC (Ch-ABC) blocks the acquisition of cocaine- but not sucrose-

induced behavior (conditioned place preference and self-administration) and cue-induced reinstatement of cocaine- but not sucrose-seeking behavior. LHAad PNN-surrounded neurons receive dense glutamatergic input and are predominantly GABAergic. The LHAad receives robust prelimbic prefrontal cortex (PL PFC) input, while providing moderate input into both the PL PFC and ventral tegmental area minimal input into the nucleus accumbnes. The overarching hypothesis is that PNNs in the LHAad are a necessary substrate for drug-induced plasticity. One possible mechanism by which LHAad PNN removal inhibits cocaine-induced behavior is increasing VTA dopamine neuron inhibition. The goal of this first set of experiments is to determine if LHAad neurons project onto DA or non-DA neurons of the VTA, if these projections are GABAergic or glutamatergic, and whether PNN-removal alters the activity of this projection. Here we report 1) the effects of light-activated Chronos-induced LHAad terminal excitation of VTA neurons, and 2) the effect of LHAad PNN-removal on excitation of VTA neurons. The results of these studies will define the circuit at cellular and synaptic levels to provide a better understanding of the mechanisms underlying PNN modulation of drug-seeking behaviors.

Title: Perineuronal net removal in the rat medial prefrontal cortex alters cocaine reinstatement and fast-spiking interneuron excitability

Authors: *E. T. JORGENSEN[1], A. N. TOURTELLOT[1], J. A. AADLAND[1], T. E. BROWN[2]; [1]Neurosci., [2]Sch. of Pharm., Univ. of Wyoming, Laramie, WY

Abstract: Our laboratory is interested in the molecular underpinnings that mediate pervasive drug memories. Perineuronal nets (PNNs) are specialized extracellular matrix structures that primarily surround parvalbumin-containing fast-spiking interneurons (FSI). Our research group previously published that removal of PNNs within the medial prefrontal cortex (PFC) attenuates cocaine-induced reinstatement of cocaine-conditioned place preference (cocaine-CPP) and increases the firing rate of pyramidal neurons within the prelimbic PFC. Our on-going research suggests that PNNs have a time-dependent effect on modulating firing activity of FSIs to

influence pyramidal neuron activity. Rats underwent cocaine-CPP training and extinction. After meeting extinction criteria, rats were microinjected into the prelimbic PFC 3d prior to cocaine-induced reinstatement with either vehicle or chondroitinase ABC (ch-ABC) to degrade PNNs. This procedure has shown to previously reduce cocaine-CPP. 2 hr following reinstatement, brain slices containing the mPFC were prepared for whole-cell electrophysiological recordings. PNN degradation resulted in an attenuation in the number of current-induced action potentials (APs) (vehicle: 99.0±7.31; ch-ABC: 53.33±1.43). In addition, we found significant changes in both the halfwidth and afterhyperpolarization potential (AHP) of APs in FSIs following ch-ABC treatment when compared to controls. Differences in these specific intrinsic properties suggest that there could be alterations in the currents responsible for the AHP and halfwidth. Through this work, we aim to further identify how PNNs are altering intrinsic and synaptic transmission following cocaine-associated learning, which contributes to persistent drug craving.

Title: Acute restraint stress augments the rewarding effect of cocaine through the activation of α1 adrenoceptors in the medial prefrontal cortex of mice

Authors: S. WADA[1], J. YANAGIDA[1], H. SASASE[1], T. ZHANG[1], H. KAMII[1], M. DOMOTO[1], X. LI[1], S. DEYAMA[1], E. HINOI[1], A. YAMANAKA[2], N. NISHITANI[3], K. NAGAYASU[3], S. KANEKO[3], M. MINAMI[4], ***K. KANEDA**[1];
[1]Kanazawa Univ., Kanazawa, Japan; [2]Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan; [3]Kyoto Univ., Kyoto, Japan; [4]Dept Pharmacol, Grad Sch. Pharm Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Stress augments cocaine craving in addicted individuals. To elucidate neural mechanisms underlying this effect of stress, we have developed an experimental paradigm combining cocaine-induced conditioned place preference (CPP) test with restraint stress in mice. After cocaine conditioning, acute (30 min) restraint stress exposure immediately before posttest significantly increased cocaine CPP scores. During stress exposure, the level of extracellular noradrenaline (NA) has been reported to be increased in the medial prefrontal cortex (mPFC). Thus, we hypothesized that NA in this brain region plays a critical role for stress-induced

augmentation of cocaine CPP. Whole-cell recordings from layer V pyramidal cells in mPFC slices demonstrated that bath-application of NA induced depolarization and increased frequency of excitatory postsynaptic currents (EPSCs). Blockade of α1, but not α2 or β, adrenoceptor suppressed these excitatory effects of NA. Additionally, NA did not increase EPSC frequency in the presence of tetrodotoxin, suggesting that the effects of NA are mediated by a postsynaptic mechanism. Intra-mPFC injection of an α1 adrenoceptor antagonist reduced the stress-induced enhancement of cocaine CPP. Moreover, silencing the neuronal activity of mPFC pyramidal cells with DREADD attenuated the stress-induced enhancement of cocaine CPP. Taken together, our findings suggest that stress-induced increase in NA transmission excites pyramidal cells in the mPFC via α1 adrenoceptor stimulation, resulting in the enhancement of cocaine craving.

Title: Cocaine extinction induces dendritic spine alterations in projection-specific sub-populations in the rat infralimbic cortex

Authors: *K. NETT[1], S. A. ROMIG-MARTIN[2], J. J. RADLEY[2], R. T. LALUMIERE[2]; [1]Interdisciplinary Grad. Program in Neurosci., [2]Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Prior studies suggest ventral medial prefrontal cortex (mPFC), known as the infralimbic cortex (IL), mediates the extinction and inhibition of cocaine seeking, particularly through a small population of projections to the nucleus accumbens (NA) shell. Previous work from our laboratory indicates cocaine self-administration, but not passive receipt of cocaine, induces regressive plasticity within the dorsal mPFC, as indicated by dendritic spine density reductions in pyramidal neurons. These results suggest an intersection between cocaine itself and learned instrumental behavior in terms of prefrontal plasticity. However, it is unclear whether similar changes occur in the IL and whether extinction training reverses or further alters dendritic plasticity in the IL. Moreover, it is unknown whether structural alterations induced by behavior

globally affect dendritic plasticity within the IL or specific subpopulations of projection neurons. To address this issue, male Sprague-Dawley rats (250-275 g) received bilateral microinjections of a retrograde virus containing a GFP tag into the NA shell and were implanted with intrajugular catheters. Rats then underwent two weeks of daily 6 h cocaine self-administration, in which active lever presses produced a cocaine infusion (400 μg/infusion) and light/tone cues, or served as yoked-saline controls. Rats then underwent 3 weeks of extinction training (1 h per day), in which active lever presses had no consequence, or 3 weeks of homecage withdrawal, prior to being euthanized. We then used an intracellular dye cell-loading technique to fill NAshell-projecting IL pyramidal neurons with Lucifer yellow. Neurons were imaged with 3D confocal imaging followed by deconvolution and analysis using NeuronStudio software to classify individual spine subtypes, quantify each subtypes' density on basal, proximal and distal dendrites, and analyze spine clustering. Preliminary results suggest that extinction learning rescues reductions in dendritic spine density and clustering that are observed following cocaine self-administration and withdrawal. Specifically, this rescue effect was observed only in IL neurons that project to NA shell. Ongoing work is determining the extent of these changes and whether the behavioral manipulations differentially alter specific subtypes. These findings point to an important interplay between cocaine self-administration and behavioral training that can alter and reverse plasticity within the mPFC in a functionally specific manner. Moreover, as spine morphology alterations often accompany learning events, these changes may be indicative of extinction encoding.

Title: Neuronal activity-based brain-wide profiling of relapse-promoting and relapse-suppressing afferents to the infralimbic cortex in rats trained to self-administer cocaine or ethanol

Authors: *H. NEDELESCU[1], G. E. WAGNER[1], H. C. CHANG[1], G. DE NESS[1], A. CARROLL[1], Y. LIU[1], A. THAN[1], C. RICHIE[2], B. T. HOPE[3], F. WEISS[1], N. SUTO[1];
[1]The Scripps Res. Inst., La Jolla, CA; [3]Behav Neurosci, [2]NIH/NIDA, Baltimore, MD

Abstract: Environmental cues modulate appetitive behavior, an effect that extends to maladaptive behaviors including drug addiction. In the context of addiction, environmental cues predictive of drug availability can promote learned drug seeking responses; conversely, environmental cues predictive of drug non-availability can suppress this behavior. This bidirectional modulation of drug-motivated behavior is mediated by two distinct coactive groups of neurons - neuronal ensembles - within the infralimbic cortex (IL). These two IL neuronal ensembles are reactive selectively to either relapse-promoting or relapse-suppressing cues. However, the neuroanatomical source of afferents that activate these ensembles remains unknown. To address this gap in knowledge, we conducted brain-wide neuroanatomical analysis to identify neuronal ensembles that project to IL and that are differentially reactive to relapse-promoting or relapse-suppressing cues. To this end, we first delivered a retrograde tracer (AAV2retro) into the IL in order to identify somata and their axonal projections with direct input to the IL. We then trained the rats to press a lever for cocaine or alcohol. Next, drug availability and non-availability was conditioned to the presence of distinct environmental cues. While the cue predictive for drug availability promoted lever-pressing, the cue predictive for drug non-availability suppressed drug-seeking behavior. After behavioral testing, we used Fos to identify the IL afferent ensembles that were reactive to either the cue predictive of drug availability or the cue predictive to drug non-availability. We found IL-projecting Fos-expressing ensembles in different brain areas that were selectively activated by either relapse-promoting or relapse-suppressing cues. Together, this study expands our current knowledge of cue-reactive IL neuronal ensemble circuitry contributing to cocaine- and alcohol-seeking behavior.

Title: The effects of cocaine self-administration and ceftriaxone on nucleus accumbens GLT-1 trafficking

Authors: *Y. PADOVAN HERNANDEZ, L. A. KNACKSTEDT;
Psychology, Univ. of Florida, Gainesville, FL

Abstract: Ceftriaxone is a beta-lactam antibiotic which increases the expression and function of the glutamate transporter GLT-1. We have demonstrated that expression of GLT-1 is decreased in the nucleus accumbens core (NAc) following extinction from cocaine self-administration. We have also shown that ceftriaxone attenuates cue- and cocaine-primed reinstatement while restoring GLT-1 in the NAc. While there is evidence that ceftriaxone upregulates GLT-1 mRNA in cell cultures continually treated with ceftriaxone, we recently found that neither cocaine self-administration itself or the later treatment with chronic ceftriaxone altered NAc GLT-1 mRNA. Here we utilized proteomic approaches to decipher the mechanism of action of both cocaine and ceftriaxone in the NAc following cocaine self-administration and extinction. Male Sprague-Dawley rats self-administered intravenous cocaine or received yoked-saline infusions for 12 days. Rats underwent extinction training for 21 days. During the last 6 days of extinction, half of the cocaine rats and half of the saline rats received ceftriaxone (200 mg/kg IP) immediately after the extinction session, while the remaining rats received vehicle. Rats were euthanized 24-hrs following the last ceftriaxone/vehicle injection, in agreement with the timing of our previous assessments of behavioral and molecular effects of ceftriaxone treatment. The NAc was dissected and frozen for global proteomic analysis. In a separate group of rats, following NAc dissection, tissue underwent immunoprecipitation of GLT-1 or tandem ubiquitin binding entities. In agreement with the publications of our labs and others, following cocaine, ceftriaxone downregulated proteins associated with glutamate signaling and long termdepression. Novel pathways for ceftriaxone action included clathrin mediated endocytosis and ubiquination. Follow-up immunoprecipitation and western blotting established that surface, intracellular and total protein expression of GLT-1 is reduced by cocaine and restored by ceftriaxone. Ubiquitin c-terminal hydrolase-1 was reduced by cocaine and restored by ceftriaxone, indicating a potential mechanism underlying the changes in GLT-1 expression. In conclusion, we have identified both novel and established pathways as being affected by ceftriaxone in rats with a history of cocaine self-administration. Future work will determine mechanistic roles for these pathways in the ability of ceftriaxone to attenuate cocaine reinstatement.

Title: Characterization of infralimbic cortical neurophysiological dynamics during the extinction of cocaine-seeking behavior in rats

Authors: *V. A. MULLER EWALD, J. KIM, R. T. LALUMIERE;
Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Prior work has implicated the infralimbic cortex (IL) in the consolidation of extinction learning following cocaine self-administration. However, most studies investigating this role for the IL have *manipulated* this cortical region, and little work has *observed* IL activity during the extinction of cocaine seeking. To determine how activity in the IL relates to the extinction of cocaine-seeking behavior, we used *in vivo* electrophysiology to record from the IL of behaving rats as they underwent extinction training. Male Sprague-Dawley rats (250 - 275 g) underwent surgery for implantation of an intravenous catheter and a fixed 9-channel electrode array aimed at the IL. Animals then underwent cocaine self-administration for a minimum of 15 d. During self-administration, animals lever pressed for cocaine in 30s epochs during which the lever remained extended (availability window). If animals failed to respond within this availability window, the lever was retracted and an intertrial interval ensued. Extinction training directly followed self-administration and lasted a minimum of 5 d. During extinction, lever presses did not produce cocaine infusions. Neural recordings were conducted every day, and data were analyzed for the early, middle and late extinction time points. Single unit findings indicate largely separate subpopulations of IL units that are responsive to lever presses and availability-window onset. Local field potential findings indicate theta-band oscillations in the IL throughout the task during all extinction time points, suggesting the importance of hippocampal inputs into this region throughout extinction training. Spectrogram analyses revealed increases in theta power following availability-onset, which were especially prominent during early extinction training. Together with prior work using brain-based manipulations, these findings suggest that IL activity guides behavioral outcomes during extinction of cocaine-seeking behavior.

Title: Escalation of cocaine self administration requires norepinephrine

Authors: *H. BELDJOUD, G. DE GUGLIELMO, M. KALLUPI, O. GEORGE;
Neurosci., The Scripps Res. Inst., San Diego, CA

Abstract: Understanding how and what are the changes in neuronal plasticity that underlie the switch from a regular drug intake to inadaptive compulsive, drug intake is critical for investigating any potential drug treatment. Although there is no doubt that the reward aspect of drug addiction is mediated by dopamine, we still need to consider how other neuromodulators such as norepinephrine might modulate these primary dopaminergic effects. The aim of this study was to interfere with the escalation of cocaine intake, a model of cocaine dependence, and disturb the development of dependence by the administration of the β−adrenergic receptor antagonist propranolol. Rats acquired cocaine self-administration with 2 h daily access for 5 days after which two groups, equated for acquisition levels, were defined according to treatments prior to sessions, and switched to 6h self-administration for an additional 15 days. In the first phase one group of rats was treated with Propranolol, before the start of each 6h session, whereas the control group received saline. Upon completion of phase 1, the treatment was switched: half of the rats from the saline group then received propranolol instead of saline, and the previous propranolol group was switched to saline treatment. The motivation for cocaine was also tested. In order to control for propranolol effects on a natural reward, another group of rats was trained to press for saccharin solution. Then, underwent the same experimental procedure and propranolol treatment as for cocaine. Results Following acquisition, the control group displayed a robust escalation of cocaine intake whereas, the propranolol prevented the escalation and maintained a lower cocaine intake as well as a lower motivation to cocaine. The Saline group that subsequently was switched to propranolol did not show any significant variation when compared to controls. Switching the propranolol group to saline increased cocaine intake without reaching the intake level of the escalated cocaine group. The motivation for cocaine was maintained lower long after propranolol treatment was stopped. Propranolol had no effect on saccharin rewards and did not alter the motivation for it. Conclusions Propranolol prevented cocaine escalation and the motivation for cocaine. The propranolol effect was restricted to escalation. Propranolol reduced the motivation for cocaine and this effect was maintained long after propranolol treatment was stooped. These results show that propranolol, had affected the neuronal plasticity related to the escalation and the motivation for cocaine intake without affecting the hedonic property of cocaine.

Title: Epigenetic effects of sex and early-life stress on cocaine addiction vulnerability

Authors: D. ROCKS[1], I. JARIC[1], D. SHOSHAN[1], J. M. GREALLY[2], M. SUZUKI[2], ***M. KUNDAKOVIC**[1];
[1]Dept. of Biol. Sciences, Fordham Univ., Bronx, NY; [2]Ctr. for Epigenomics, Dept. of Genetics, Albert Einstein Col. of Med., Bronx, NY

Abstract: Early-life stress, such as neglect and abuse, increases the risk for drug abuse and addiction in later life. In addition, there are sex differences in cocaine addiction with females progressing more rapidly into substance use disorder, which is at least in part related to estrogen effects. The mechanisms underlying stress- and sex hormone-induced addiction vulnerability are poorly understood although epigenetic mechanisms provide a plausible candidate. To address this question, we performed the early-life stress (maternal separation) paradigm in mice from postnatal day (PD) 1-14 and examined the risk for cocaine addiction in later life (PD50-60) using cocaine-induced conditioned place preference (CPP). Our study shows that early-life stress increases cocaine preference in a dose- and sex-dependent manner. Male mice exposed to early-life stress show increased cocaine CPP after a low (2.5 mg/kg) cocaine dose that is not sufficient to induce cocaine preference in control males. On the contrary, both low (2.5 mg/kg) and high (10 mg/kg) cocaine doses have a more profound effect in stress-exposed female mice compared to control females. Interestingly, we found that the cocaine CPP results in females vary with the estrous cycle, with early-life stress shifting this behavior in favor of increased cocaine preference. To address whether epigenetic mechanisms may be involved in sex-specific cocaine effects, we performed chromatin accessibility (ATAC-seq) assay on purified neuronal nuclei isolated from the nucleus accumbens of proestrus (high-estrogenic) females, diestrus (low-estrogenic) females, and male mice following 1-hour and 4-hour cocaine (10 mg/kg) treatments. We found sex-specific chromatin organizational changes in response to cocaine, which included the loci nearby genes implicated in the reward pathway and cocaine addiction. The glutamate transporter 1 gene (Glt1, *Slc1a2*), which is strongly implicated in addiction, showed a sex-specific chromatin accessibility profile both at baseline and following cocaine exposure, and this was associated with a sex difference in Glt1 gene expression. This study has implications for improving our understanding of the role of early-life stress in addiction vulnerability and reveals a candidate epigenetic mechanism underlying sex differences in drug abuse and addiction.

Title: Single cell Ca^{2+} activity of dopamine D1 and D2 receptor expressing medium spiny neurons of the nucleus accumbens core during extinction and relapse of cocaine seeking

Authors: *R. M. CHALHOUB[1], C. GARCIA-KELLER[1], J. A. HEINSBROEK[2], A.-C. BOBADILLA[1], P. W. KALIVAS[1];
[1]Dept. of Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Dept. of Anesthesiol., Univ. of Colorado, Aurora, CO

Abstract: The nucleus accumbens core (NAc) plays a central role in drug addiction. Its constituent D1- and D2- expressing GABAergic medium spiny neurons (D1- and D2-MSNs) integrate cortical and limbic inputs to regulate drug seeking behavior. Recent data challenge the functional dichotomy of these cells in the direct/indirect pathways hypothesis. To investigate the functional role of D1- and D2-MSNs during drug seeking, we recorded single cell Ca^{2+} dynamics in D1- and D2-MSNs of freely behaving D1- and D2-cre transgenic mice using a miniature microscope (nVista) and virally expressed Cre-dependent Ca^{2+} indicator (GCaMP6f). Mice were trained to self-administer cocaine in daily 2 hours-session during which a single nose-poke (FR1) resulted in an intravenous cocaine injection and presentation of drug-contingent cue. Following a brief abstinence period, drug seeking was assessed during a post-abstinence test (PA), wherein cues but not cocaine were present. Drug seeking behavior was then extinguished to the cocaine-associated context over 8-10 days, before undergoing a second cue-induced reinstatement session. Calcium activity was recorded throughout representative sessions of the entire behavioral paradigm; recordings were pre-processed and normalized, and single cell calcium activity were isolated and aligned to behavioral responses (i.e. nose-pokes). We found that during PA test, individual nose-pokes were associated with a significant change in the activity of D1-MSNs. This change in activity gradually decreased in the absence of cocaine-associated cues during extinction training. In contrast to D1-MSNs, changes in Ca^{2+} activity in D2-MSNs preceded nose-pokes during PA session. D2-MSNs retained their response during extinction training, but the response pattern gradually shifted to follow the active nose-pokes. Our data suggest that NAc encodes drug-seeking behavior through an interaction between both D1- and D2-MSNs during behavioral reinstatement following abstinence. On the other hand, extinction training is associated with a sustained D2-MSNs response, and a decrease in D1-MSNs response. These data set the stage for further analyses into the population coding of drug seeking by NAcore subpopulations of neurons.

Title: Dissecting the influence of D_2 dopamine and $GABA_B$ receptor signaling pathways in ventral tegmental area dopamine neurons on drug-induced behavior

Authors: *M. C. DEBAKER, E. MARRON, N. M. MCCALL, A. M. LEE, K. WICKMAN; Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Dopamine (DA) neurons of the ventral tegmental area (VTA) play critical roles in reward and motivation and are key targets of drugs of abuse. In addition to enhancing VTA DA neurotransmission, drugs of abuse such as cocaine engage inhibitory G protein-dependent signaling pathways mediated by D_2 DA receptors (D_2R) and $GABA_B$ receptors ($GABA_BR$) in VTA DA neurons. However, the relative influence of D_2R and $GABA_BR$-dependent signaling pathways on VTA DA neuron excitability and cocaine-related behaviors is unknown. To investigate this issue, we developed CRISPR/Cas9 tools to ablate $GABA_BR$ or D_2R in VTA DA neurons in the adult mouse. Adeno-associated viral vectors harboring guide RNAs (gRNAs) targeting either $GABA_BR$ or D_2R, or a control vector, were injected into the VTA of young adult (50 d) male and female DATCre(+):Cas9GFP^{flox} mice. Following a 5 wk viral incubation period, the impact of viral treatment on $GABA_BR$- or D_2R-dependent signaling in VTA DA neurons was assessed by measuring postsynaptic somatodendritic whole-cell currents (V_{hold} = -60 mV) evoked by the $GABA_BR$ agonist baclofen (200 µM) or the D_2R agonist quinpirole (20 µM). Currents evoked by baclofen (365 ± 50 pA, n=6) and quinpirole (59 ± 16 pA, n=4) were reliably observed in VTA DA neurons from control subjects, but were absent in neurons from mice treated with $GABA_BR$ (5 ± 1 pA, n=10; t_{14}=9.5, P<0.0001) or D_2R (4 ± 1 pA, n=5; t_7=4.0, P<0.01) gRNA, respectively. Importantly, D_2R-dependent responses were preserved in VTA DA neurons treated with the $GABA_BR$-specific gRNAs, and vice versa, confirming the specificity of the CRISPR/Cas9-mediated target ablation. Having established the efficacy and selectivity of this viral CRISPR/Cas9 approach, we are currently testing the behavioral sensitivity of mice lacking either D_2R or $GABA_BR$ in VTA DA neurons to cocaine. In preliminary studies, we have found that mice lacking $GABA_BR$ in VTA DA neurons exhibit significantly increased motor activity responses to acute systemic cocaine (15 mg/kg i.p.) compared to control subjects

($F_{3,12}$=5.8, P<0.05, Bonferroni posttest, n=3/group). We intend to use this approach to probe the impact of D_2R- and $GABA_B$R-dependent signaling in VTA DA neurons on other cocaine-induced behaviors, and to explore how these inhibitory receptors impact sensitivity to other drugs of abuse. Understanding the relative influence of D_2R- and $GABA_B$R-dependent signaling pathways on the actions of drugs of abuse may suggest drug-specific approaches for treating certain behavioral aspects of addiction.

Title: Cocaine conditioning induces alterations in ventral hippocampal synaptic function and plasticity mediated by the presence of calcium-permeable AMPA receptors during abstinence

Authors: *C. J. PRESTON[1], K. A. BROWN[2], J. J. WAGNER[2];
[2]Dept Physiol. & Pharmacol., [1]Univ. of Georgia, Athens, GA

Abstract: We investigated the incubation of drug-seeking by utilizing an escalating i.p. cocaine dosing schedule with the conditioned place preference (CPP) paradigm to assess synaptic function and plasticity in the ventral hippocampus (vH) after various abstinence periods. CPP was achieved using a modified conditioning protocol similar to one described by Itzhak and colleagues (2012), except that cocaine-treated mice received a double escalating-dose protocol (4,8,16,24,16,24,32,32 mg/kg). CPP and vH function were assessed either 2, 9, or 28 days after the final injection of cocaine. When CPP was assessed after a 28 day abstinence period there was a significant increase in time spent in the cocaine-paired compartment on the second test day compared to the first test day which occurred one day after the final injection. This incubation of cocaine craving has been previously observed following self-administration of cocaine and is thought to be caused by progressive changes in synaptic function and plasticity. Slices prepared from the vH and fEPSPs were recorded in the CA1 region up to 28 days after the final injection day to assess changes in vH function during abstinence. We observed significantly decreased vH long-term potentiation (LTP) in animals that received cocaine conditioning compared to those that received the saline vehicle. Interestingly, the cocaine- treated animals also exhibited a significant leftward shift in the input-output curve of the baseline fEPSP measurements. Together, these findings are consistent with the hypothesis that a cocaine-induced enhancement of neurotransmission contributes to a partial occlusion of LTP in the vH of cocaine-exposed mice that persists 28 days after the final drug exposure (Preston et al, 2019). To further investigate this

change in basal synaptic transmission, whole-cell voltage clamp was used to record from CA1 pyramidal neurons from cocaine-treated animals after 28 days of abstinence. These neurons exhibited an increase in the rectification index compared to saline-treated animals suggesting the presence of calcium-permeable AMPA receptors (CP-AMPARs). When NASPM (a CP-AMPAR specific antagonist) was bath applied to the vH slices, there was a significant decrease in EPSC amplitude in cocaine treated animals compared to saline-treated animals. Here, we have shown a decrease in ventral hippocampal LTP and increased basal synaptic transmission associated with the presence of CP-AMPARs following 28 days of abstinence from cocaine conditioning.

Title: The role of RMTg-mediated cocaine aversion in addiction

Authors: *M. EID[1], J. PARRILLA-CARRERO[1], H. LI[2], A. THOMAS[1], T. C. JHOU[1];
[2]Neurosci., [1]Med. Univ. of South Carolina, Charleston, SC

Abstract: Although cocaine's aversive responses are relatively less widely acknowledged than its rewarding effects, they are experimentally robust. Particularly elegant experiments by Ettenberg and his group have shown that single doses of cocaine produce an initial rewarding phase followed by an aversive crash about 15' later that is sufficient to condition a net aversion to cocaine, that in most (but not all) animals, is strong enough to overcome cocaine's rewarding effects. In our lab, we investigated behavioral responses to cocaine in rats performing a runway operant task that is particularly suited for assessing the combined rewarding and aversive properties of cocaine. In this task rats traverse a 5-foot long corridor to obtain a single daily dose of cocaine. After 4-7 trials, we found large variations in animals responses to cocaine, where some animals slowed down dramatically (high avoiders) and others remained fast (low avoiders). In recent years, our lab and others have demonstrated that cocaine avoidance depends critically on the rostromedial tegmental nucleus (RMTg) and its afferents. The RMTg is a major GABAergic midbrain input to midbrain dopamine (DA) neurons that plays major roles in avoidance. We have thus shown that there are individual differences in RMTg neurons firing rate that correlate with cocaine-conditioned avoidance behavior. Indeed, compared to low cocaine avoiders, high avoider animals have similar RMTg inhibition during the rewarding phase of the

drug (5’ post injection), but have significantly higher RMTg firing rates during its aversive phase (15’ post-infusion). To investigate the molecular driver of these differences in the RMTg, we used *in vitro* electrophysiology and demonstrated that low avoiders have less RMTg firing during the aversive phase of cocaine, partly driven by downregulation of the GluR1 subunit of the AMPA receptor. Indeed, when we inhibited this subunit pharmacologically using NASPM, all animals shift to becoming low avoiders on the runway task. These results imply the existence of a phenotypical organization of cocaine evoked plasticity in VTA projecting RMTg neurons that might be critical to signal aversion to cocaine. Thus, RMTg neurons adaptations are in a crucial position for relaying aversive information to the mesocorticolimbic DA neurons, and these changes might contribute to cocaine addiction vulnerability. We are planning on using the DLight sensor to investigate if differences in RMTg firing between high and low avoiders translate in differences in dopamine levels in the accumbens during the aversive phase of cocaine.

Abstract: Drugs of abuse are known to cause long-term neuroadaptations in the brain that possibly contribute to the individual's vulnerability to addiction. These modifications of brain normal function are mediated by epigenetic regulations in gene expression such as chromatin remodeling. One type of chromatin remodeling is histone acetylation, which is under the control of histone acetyltransferases (HATs) and histone deacetylases (HDACs). Cocaine sensitization alters the intrinsic properties of dopamine (DA) neurons of the ventral tegmental area (VTA), which in turn alter dopamine transmission in the mesocorticolimbic network. One intrinsic property of VTA neurons affected by exposure of drugs of abuse is the hyperpolarization-activated cation current (Ih), which is mediated by HCN channels. Previously, our laboratory has demonstrated a reduction in Ih and cell capacitance in VTA DA neurons from cocaine-sensitized rats. Little is known about epigenetic regulation of ion channels by drug exposure. No studies of epigenetic regulation of h-current have been performed. Using the whole-cell patch clamp technique, we investigated the effects of an HDAC inhibitor (SAHA) on cocaine-induced changes in Ih current. Additionally, we explored the effect of SAHA on rebound excitation and cell capacitance in brain slices from cocaine-sensitized rats. *In vitro* incubation of midbrain slices with SAHA (3 μM for two hours) reversed the cocaine-induced reduction in VTA DA Ih to baseline levels (cocaine-control 250 ± 5.0 pA vs cocaine-SAHA 460 ± 8.3 pA, $p<0.001$). Current clamp traces also demonstrated SAHA reversal of cocaine-induced Ih reduction concomitant with a reduced action potential firing (cocaine-control 5 ± 1.4 pA vs cocaine-SAHA 1 ± 0.34 pA, $p<0.01$). Interestingly, the membrane capacitance was significantly increased in the cocaine-SAHA group (cocaine-control 112 ± 30 vs cocaine-SAHA 306 ± 6, $p<0.003$). These results support the idea that the reduction of Ih current and cell size in VTA DA neurons after cocaine sensitization is epigenetically regulated and suggest the possibility that HDAC inhibitors could reverse cocaine-induced neuroadaptations in reward circuits.

Title: Cell type-specific knockdown of hypocretin receptor 1 in ventral tegmental area neurons leads to contrasting effects on dopamine responses to cocaine

Authors: *E. M. BLACK[1], D. L. BERNSTEIN[2], J. R. BARSON[1], C. E. BASS[3], R. A. ESPAÑA[1];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Temple Univ. Lewis Katz Sch. of Med., Philadelphia, PA; [3]Univ. At Buffalo SUNY, Buffalo, NY

Abstract: Extensive evidence indicates that the hypocretin system impacts the reinforcing effects of cocaine via actions on hypocretin receptor 1 in the ventral tegmental area. For example, our lab has shown that hypocretin receptor 1 antagonists or hypocretin receptor 1 knockdown in the ventral tegmental area decreases the motivation for cocaine and that these effects are associated with disrupted dopamine responses to cocaine. In general, these findings have been interpreted as an indication that the effects of hypocretin receptor 1 antagonism occur via actions on dopamine neurons of the ventral tegmental area. However, this assumption is complicated by the observation that hypocretin receptor 1 are located on both dopamine and GABA neurons of the ventral tegmental area where hypocretin acts in an excitatory manner on both of these neuronal populations. Consequently, it remains unknown to what extent hypocretin actions at dopamine versus GABA neurons of the ventral tegmental are necessary to drive alterations in cocaine-associated behavior and dopamine responses to cocaine. To address this gap in knowledge, we employed a combinatorial viral approach to selectively knockdown hypocretin receptor 1 on either dopamine or GABA neurons in the ventral tegmental area. We used *ex vivo* fast scan cyclic voltammetry to examine the effects of cell type selective hypocretin receptor 1 knockdown on downstream dopamine dynamics in the nucleus accumbens. Our preliminary observations suggest that knockdown of hypocretin receptor 1 on dopamine neurons leads to disrupted dopamine dynamics at baseline and reduced dopamine responses to cocaine, while knockdown of hypocretin receptor 1 on GABA neurons enhances the effects of cocaine. These findings provide a more comprehensive understanding of hypocretin modulation of dopamine neurotransmission and may uncover potential targets for future development of treatment strategies for cocaine use disorder.

Title: Dynamic dopaminergic activity during abstinence from extended- and limited-access of cocaine self-administration

Authors: *A. SALIN, V. LARDEUX, M. SOLINAS, P. BELUJON;
Lab. de Neurosciences Experimentales et Cliniques, Univ. de Poitiers, Poitiers Cedex 9, France

Abstract: The chronic relapsing nature of cocaine addiction suggests that chronic cocaine exposure produces persistent neuroadaptations in brain areas such as the dopaminergic system, a main actor in motivated behaviors. Throughout abstinence, neuroadaptations may be temporally and regionally dynamic. For example, early cocaine abstinence is characterized by a negative emotional state whereas with extended abstinence, the sensibility to drug-associated cues increasing leading to incubation of craving. Recent A PET-imaging study by our group (Nicolas et al., 2017) showed that the metabolism of dopaminergic-targeted structures, the nucleus accumbens and the dorsal striatum, is differentially altered after early and late abstinence, respectively. However, because of the resolution of this technique, we were not able to measure the specific changes within the midbrain dopamine system (VTA/SNc). We thus hypothesized that time and region-specific changes in the VTA and SNc dopaminergic neurons could be associated with short and long-time abstinence. Male rats had either an extended access to cocaine (Long-Access group (LgA); 6h/session) or a recreational cocaine use (Short-Access group (ShA); 1h/session) for 25 sessions. We then used *in vivo* electrophysiological recordings isoflurane anesthetized rats and recorded spontaneously active VTA and SNc DA neurons during early (D7) and late (D30) abstinence. No change in DA neuron population activity was found in ShA rats in the VTA and the SNc at any time of abstinence. In contrast, a significant decrease in the number of spontaneously active VTA DA neurons of LgA rats was found after 7 days and 28 days of abstinence. After 7 days of abstinence we also found a significant decrease in the bursting activity of VTA DA neurons of LgA but this effect disappeared after 28 days. In the SNc of LgA rats, we found a significant increase in the firing rate of DA neurons during early abstinence but no significant change was found in all three parameters of DA activity during late abstinence. These findings first suggest that dopaminergic activity state is altered only in rats that experimented extended addiction-like access to cocaine self-administration. These effects were time- and region-specific. The present study also suggests that during early abstinence, the negative state could be mediated by both a decrease in VTA DA activity and a decreased signal-to-noise ratio in SNc DA neurons target structures. Interestingly, we found no change in SNc activity after prolonged abstinence, but a persistent decrease in VTA activity suggesting a persistent role of VTA DA activity in enhanced cocaine seeking.

Abstract: Ventral CA1 hippocampus (vCA1) afferent neurons play a critical role in drug behavior, and activation of ventral CA1 glutamatergic projections to nucleus accumbens (NAc) drive seeking for cocaine. However, the mechanism by which cocaine shapes the function of this vCA1-NAc circuit is poorly understood. Evidence suggests that cocaine drives synaptic plasticity in this circuit and our preliminary evidence suggests that it reduces vCA1 excitability. We propose an innovative role for ΔFosB, a transcription factor, in the activity of vCA1-NAc neurons and cocaine behavior. ΔFosB is induced in hippocampus by chronic cocaine and we show that it regulates hippocampal function and reduces CA1 excitability. Here, we used viral-mediated, circuit-specific fluorescent labeling and whole cell patch-clamp electrophysiology to determine chronic cocaine effects on vCA1-NAc physiology. We found that cocaine, similar to ΔFosB expression, reduces vCA1-NAc excitability, suggesting that cocaine induces ΔFosB leading to decreased neuronal excitability. Studies are ongoing to identify the ion channel mechanism underlying this change. Using circuit-specific CRISPR-mediated gene editing , we have also determined that ΔFosB expression in vCA1-NAc neurons is necessary for cocaine reward and seeking. *FosB* KO in vCA1-NAc neurons specifically decreased cocaine reward and seeking. Ongoing studies are currently identifying the pattern of gene expression regulated by cocaine in the vCA1-NAc circuit. Collectively, these findings demonstrate that cocaine functionally reshapes the vCA1-NAc circuit to drive cocaine-dependent behaviors. Furthermore, they suggest that ΔFosB and its gene targets in hippocampus afferents may serve as promising therapeutic inroads for drug addiction.

Title: Cocaine alters gene expression in ventral ca1 afferents to nucleus accumbens that underlie drug seeking and reward

Abstract: Cocaine use remains a massive public health concern. Cocaine dependence and cocaine-seeking behavior are widely studied, and drug dependency drives drug-seeking behavior. Pyramidal neurons of the ventral hippocampus (vHPC) - a key region for memory -project to the nucleus accumbens (NAc) - a significant reward center - and facilitate drug seeking behavior. Additionally, chronic cocaine use leads to physiological changes within the vHPC-NAc circuit that reinforce seeking behavior, but the role of gene expression in these physiological changes is not well understood. We have identified that the transcription factor ΔFosB, which is induced by cocaine in the hippocampus, drives changes in drug-seeking behavior and the physiology of this circuit. This suggests that ΔFosB induction in vHPC-NAc is a key mechanism by which cocaine drives changes in physiology and drug-seeking behavior. We aimed to determine how gene expression is altered by chronic cocaine in vHPC-NAc neurons and the potential role of ΔFosB in this process. First, we used circuit-specific TRAP-Seq with viral-mediated gene manipulation and transgenic mouse lines to identify altered patterns of gene transcription in vHPC-NAc neurons after chronic cocaine. Furthermore, we used conditional knockout models under cocaine and drug-free conditions to determine whether transcriptional changes were regulated by ΔFosB. We are currently validating gene targets via traditional molecular assays, including immunohistochemistry, to identify novel gene expression regulated by cocaine within the vHPC to NAc circuit. This will ultimately lead to future studies to assess the role of specific gene targets in vHPC-NAc physiology and subsequent effects on drug seeking behavior.

Title: Dopamine receptor dependence of cocaine-mediated plasticity in specific excitatory synapses onto midbrain dopamine neurons

Authors: *A. R. KARLA[1], C. Y. GUO[1], L. D. MUZYKA[1], A. C. TOLER[1], A. J. DAVIS[1], G. M. BEAUDOIN, III[2];
[2]Biol., [1]Trinity Univ., San Antonio, TX

Abstract: Dopamine plays an important role in communication between neurons, notably in the neural pathway that is involved in motivation and reward-seeking behavior. The mesolimbic dopaminergic pathway is activated by excitatory inputs, which are affected by a single exposure to cocaine. Our research is characterizing cocaine's mechanism within these excitatory inputs by studying the synapses between the midbrain regions pedunculopontine tegmental nucleus (PPN) and substantia nigra pars compacta (SNc). Prior research has shown that cocaine induces changes in receptor composition at synapses between glutamatergic neurons in PPN and dopaminergic neurons in SNc. The ratio between two glutamate receptors, NMDA and AMPA, is used to assess this synaptic plasticity in response to in vivo cocaine exposure in mice. A virus encoding a fluorescent protein (YFP) and a light-operated cation channel (ChR2) is injected via stereotaxic surgery, allowing us to selectively excite PPN-innervated synapses on SNc dopamine neurons. Using electrophysiological recordings, in vivo cocaine exposure causes a decrease in the AMPA to NMDA receptor ratio after 24 hours. It is unknown, however, whether excitatory D1-like or inhibitory D2-like receptors are involved in this change. We are investigating the effect of a D1-like receptor antagonist (SCH 23390) and D2-like receptor antagonist (eticlopride) on the cocaine-induced decrease in the AMPA/NMDA ratio. Based on cocaine's established role in inhibiting the dopamine transporter, we suspect that one or both of these receptors are required. Preliminary evidence suggests that D1 receptors are involved in cocaine-mediated plasticity of PPN-SNc synapses.

Title: Cocaine-induced structural and functional changes of input-specific excitatory synapses on nigral dopaminergic neurons

Authors: J. F. MORENO[1], S. R. RODRIGUEZ[1], K. E. WINDSOR[1], A. C. TOLER[1], P. VOIT[1], A. B. LITCH[1], A. R. KARLA[1], C. Y. GUO[1], S. HEMANI[1], *G. M. BEAUDOIN, III[2];

Abstract: *In vivo* cocaine exposure has been shown to induce changes in excitatory synaptic responses to mesostriatal dopamine neurons. These neurons may be a part of the reward pathway and could be important for controlling motivation and addictive behavior. In early work, cocaine was shown to initially change excitatory synapses on dopaminergic neurons without identification of the source of the glutamate. Using optogenetics, we are able to label and activate PPN by injecting in mice a virus encoding a light operated cation channel, channelrhodopsin (ChR2), and yellow fluorescent protein (YFP). Using this system, we have shown that glutamatergic projections from the pedunculopontine tegmental nucleus (PPN) onto dopamine neurons in the substantia nigra pars compacta (SNc) have altered glutamatergic receptor ratios one day after a single injection of cocaine administered *in vivo*. Specifically, the PPN-SNc synapse has an increase in N-methyl-d-aspartate (NMDA) receptor function, as tested using electrophysiology. We are now further characterizing the underlying structural and functional changes at this synapse that underlies this increase in NMDA receptor-mediated currents. We are using a combination of electrophysiology and immunofluorescence with confocal imaging to ascertain if the increased NMDA receptor-mediated current is due to one of several hypotheses including, but not limited to, an increase in the number of synapses, an increase in the number of NMDA receptors at the same synapse, a change in localization of receptors at the synapse and/or a change in subunit composition. Thus, we have begun to characterize the postsynaptic responses of SNc dopamine neurons to excitatory projections from PPN to identify the receptor subunit composition at these glutamatergic subtypes. As expected, NMDA receptors (NMDARs), have a typical, outward rectifying I-V relationship suggesting the presence of standard NMDAR1/2 heteromers. Additionally, distribution of NMDAR1 subunit localization is not globally affected by cocaine in SNc. We are using the YFP-labeled PPN axons to identify changes in localization of glutamatergic subunits at these synapses on dopamine neurons. We have developed an automated image analysis routine to identify putative synapses

between PPN and dopamine neurons from confocal images in order to assay changes in localization, size, and quantity of specific glutamate receptor subunits. By measuring the synaptic response of dopamine neurons and imaging localization of NMDA receptors to putative synapses, we are able to identify what is affected by cocaine at these synapses.

Title: Blood mitochondrial copy number as a biomarker for altered motivational states in mouse models of stress and drug addiction

Authors: ***C. A. CALARCO**[1], R. CHANDRA[1], S. VAN TERHEYDEN[1], M. E. FOX[1], M. ENGELN[1], G. MORAIS-SILVA[2], M. F. PAGLIUSI, JR[3], M. TURNER[1], M. LOBO[1]; [1]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Sch. of Pharmaceut. Sci., Sao Paulo State Univ., Araraquara, Brazil; [3]Biol. Inst., State Univ. of Campínas, Campinas, Brazil

Abstract: Exposure to chronic stress changes many aspects of the reward pathways in the brain and their functions. These changes in neuronal morphology and electrophysiological function are influenced and supported by available cellular energy stores, provided to the cell by mitochondria. Mitochondrial health and function are dynamically regulated in a cell-type and brain region selective manner, and impacted by environmental changes. While understanding the changes that occur in reward processing regions of the brain, such as the nucleus accumbens, are fundamental to understanding the motivational changes associated with chronic stress or exposure to drugs of abuse, this data is not readily available in a clinical population. Therefore, the use of biomarkes as proxies for changes in the brain are necessary. Recently, the proliferation of mitochondria in blood leukocytes has emerged as a potentially useful biomarker for depression, bipolar disorder, and substance abuse, with the added benefit that this metric can be remeasured over multiple stages of disease, recovery or relapse. Increased copy number of mitochondrial DNA relative to nuclear DNA, indicating an increase in the number of mitohcondria per cell, has been linked to depression severity as well as other diseased states. In the current study we examined mitochondrial copy number in blood from animals that have

undergone chronic social defeat stress (CSDS). Mitochondrial copy number is significantly increased in animals that have undergone CSDS, with the largest increases in animals observed to be susceptible to the stress, as determined by their behavior in a social interaction test. Further, blood mitochondrial copy number is significantly correlated with time spent interacting with the social target in this social interaction test. Additionally, we examined the relationship between blood mitochondrial copy number and CSDS-induced changes in mitochondrial copy number and gene expression in the nucleus accumbens. Finally, we examined if this relationship between blood mitochondrial copy number and behavior is specific to CSDS or if there is a comparable relationship after exposure to drugs of abuse, such as after cocaine self-administration or exposure to the opioid, fentanyl.

Title: Transcriptional adaptations in the ventral pallidum following cocaine self-administration

Authors: *M. ENGELN, R. CHANDRA, S. THOMAS, H. QADIR, R. HERMAN, H. NAM, M. E. FOX, M. LOBO;
Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Growing evidence suggests the ventral pallidum (VP) is critical for drug intake and seeking behavior. Receiving dense projections from the nucleus accumbens as well as dopamine inputs from the midbrain, the VP plays a central role in the control of motivated behaviors. Repeated exposure to cocaine is known to alter VP neuronal firing and neurotransmission. Surprisingly, there is limited information on the molecular adaptations occurring in VP neurons following cocaine intake. To provide insight into cocaine-induced transcriptional alterations we performed RNA-sequencing on VP of mice that underwent 10 days of cocaine self-administration (0.5mg/kg/infusion) followed by twenty-four hours of abstinence. We observed differential gene expression in 363 genes between animals that self-administered cocaine and saline controls. Subsequent Gene Ontology analysis pointed toward alterations in dendrite- and spine-related genes. Searching for a common regulator for these sets of genes, we found that the expression of the transcription factor Nr4a1 showed a robust increase following cocaine self-

administration. Further, we observed an increase in the Nr4a1 transcriptional target Plk2, a molecule important for synaptic and structural plasticity. Analysis of Plk2 molecular targets showed alterations in Actin and Rap2 dynamics after cocaine exposure, confirming alterations in dendritic and spine functions. Overexpression of Nr4a1 in the VP reduced cocaine seeking supporting its role in drug-related behavior. Using fluorescent *in situ* hybridization, we are now determining which VP projection neuron population displays increased Nr4a1 and Plk2 levels after cocaine self-administration. This includes VP- ventral tegmental area, VP-lateral habenula, VP-mediodorsal thalamus, or VP-nucleus accumbens projection neuron populations. Additionally, we are using adenoassociated virus (AAV) overexpression and CRISPR knockdown manipulation of Nr4a1 and Plk2 to interrogate the role of these molecules in VP circuits during cocaine self-administration and relapse-like behavior. Altogether, our work can provide crucial information into the molecular adaptations occurring in VP neuron supporting cocaine self-administration and relapse-like behavior.

Title: Optically induced CRISPR tool for epigenome editing in cocaine abuse

Authors: *E. Y. CHOI[1], R. CHANDRA[2], M. MCGLINCY[2], A. CHOW[2], M. LOBO[2];
[1]Grad. Program in Biochem. & Mol. Biology, Dept. of Anat. & Neurobio., [2]Dept. of Anat. & Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Drug abuse is a debilitating chronic disease which is a leading cause of disability around the world. Drug seeking after repeated drug exposure is prevalent despite the devastating personal consequences. Studies have shown that repeated exposure of drugs, such as cocaine, leads to changes in epigenetic processes, including nucleosome modifications. Such changes can alter cocaine-induced behavior as well as other motivational behaviors. However, the lack of tools to induce histone modifications with precise spatiotemporal control, *in vivo,* is a major barrier in studying the complex molecular and behavioral dynamics occurring during the addictive process. In this study, we developed an optically induced CRISPR mediated histone modification tool that can be targeted to precise loci in selective neuron subtypes using the CRY2-CIBN blue light heterodimerizing complex system. These novel constructs are packaged

into AAVs for *in vivo* delivery into the brain. In cell culture, our novel constructs, which code for catalytically dead (d)Cas9-CIBN and CRY2-KDM1A fusion proteins on a Cre dependent backbone (termed Opto-CRISPR-KDM1A), were co-transfected into Neuro2A cells along with sgRNA targeting for early growth response 3 (Egr3) and NGFIA-binding protein 2 (Nab2). We focus on Egr3 and Nab2 because we observe differential induction of these molecules in nucleus accumbens (NAc) dopamine receptor 1 vs 2 medium spiny neurons (D1-MSNs vs D2-MSNs) after repeated cocaine. After 1 hour of blue light exposure, Egr3 mRNA level was significantly down-regulated in cells transfected with the sgRNA targeting Egr3, and Egr3 mRNA was significantly up-regulated in cells that were transfected with sgRNA targeting Nab2. Consistent with this, Nab2 mRNA level was significantly up-regulated in cells with Egr3 targeting sgRNA, and down-regulated in cells with Nab2 targeting sgRNA. To confirm that the system is interchangeable across multiple histone modifying enzymes, we created a new fusion protein, CRY2-p300, which contains the truncated functional core of histone acetylation enzyme p300 fused with CRY2. After 1 hour or 4 hours of blue light exposure with Opto-CRISPR-p300, Egr3 mRNA level was significantly increased in cells transfected with sgRNA targeting Egr3, and significantly reduced in cells transfected with sgRNA targeting Nab2. Nab2 mRNA expression was significantly increased in cells transfected with Nab2 targeting sgRNA. We can now begin to confirm and utilize the Opto-CRISPR systems *in vivo*, including during cocaine self-administration and relapse like behavior.

Title: Cocaine impacts CNS innate immune responses via MAVS and STING regulation during HIV-1

Authors: C. EZEOMAH[1], A. L. PERSONS[2], T. NAPIER[3], ***I. E. CISNEROS**[1];
[1]Dept. of Pathology, Univ. of Texas Med. Br., Galveston, TX; [2]Psychiatry, [3]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Cocaine, a highly addictive psychostimulant, negatively impacts the users' ability to initiate an innate immune response to invading pathogens such as human immunodeficiency

virus (HIV)-1. Cocaine and HIV-1 act through multifaceted processes from increased Ca^{+2} dysregulation, oxidative stress, gliosis, mitochondrial dysfunction and generation of proinflammatory mediators. Astrocytes, the most abundant cell in the central nervous system, potently respond to foreign substances, and induce neuroimmune adaptations that transpire across a scattered set of neural circuits and contribute to assorted outcomes related with cocaine exposure and dependence, including participation in the development in the plasticity of dendritic spines, synapses and neurotransmission. Reactive astrocyte phenotypes that occur during cocaine-dependent states and/or HIV-1, may drive the behavioral transformations that lead to cocaine dependence and addiction. Astrocytes express a plethora of pattern recognition receptors (PRR)s that may dictate these neuroimmune alterations. These include cyclic GMP-AMP synthase (cGAS)-stimulator of interferon genes (STING) that are canonically activated by pathogen or self-genetic material, and mitochondrial antiviral signaling (MAVS) protein, which is regulated by mitochondrial events. Whether these mechanisms contribute to astrocyte-induced neuroimmune adaptations during cocaine use disorder (CUD) remains elusive. As the shared neurotoxic outcomes of cocaine and HIV-1 regulate both MAVS and STING, w**e hypothesized that MAVS and STING activate cocaine-induced inflammation in the context of HIV-1.** Our preliminary data, in primary human astrocytes shows that cocaine +/- HIV-1 differentially regulate IL6, IL8, IL10, results in phosphorylation of NF-κB, increases TNFα and results in activation of type I interferon signaling, including increases in IFNβ1, phosphorylation of TBK1 and phosphorylation and translocation of IRF3. Moreover, we observed that MAVS and STING expression and localization in the frontal cortex of HIV-1 transgenic rats, with or without cocaine, is significantly altered. Taken together, our *in vitro* and *ex vivo* data demonstrate that cocaine and HIV-1 activate neuroimmune signaling pathways that may partly be dictated through MAVS and STING.

Title: Cortical and subcortical local field potencials involved in a go/no-go task in rats

Authors: *C. MUÑOZ REDONDO, A. GRUART, J. DELGADO-GARCIA;
Div. of Neuroscience, Pablo de Olavide Univ., Sevilla, Spain

Abstract: Go/No-Go tasks allow to assess decision making in behaving rats and, in addition, help to determine their ability to suppress a specific action according to the context, or their ability to cancel an action in progress when an unpredictable cue indicates that it should be avoided. In many of these experimental procedures, food is used as a positive reinforcement to study associative learning or decision-making processes. In the present experiments, Lister Hooded male rats were used. Animals had to discriminate in an iPad screen between two visual stimuli (Go or No-Go) disposed in horizontal or vertical ways and in white or green colors. In this situation, the execution (Go) or non-execution (No-Go) of the behavioral selected action (to touch or not to touch the visual display) would be reinforced. Rats were trained in a modified Skinner box equipped with an iPad, where stimuli appeared. The maingoal was to record and to analyze local field potentials (LFPs) collected from different cortical and subcortical brain structures, when the visual stimuli were shown in the iPad screen and during the subsequent behavioral activities. Animal behavior was videotaped and quantified. Following an introductory tone, the rat had to press a white horizontal rectangle (Go) or to avoid touching a green vertical one (No-Go), getting in this way a pellet as reward. Previously, rats had gone through caloric restriction and maintained to 85-90% of their initial weight. The experiment consisted of five phases, two pure phases and then mixed. In the first one, rats learned to approach the iPad and touch the stimulus in the case of Go trials as well as not to approach it in No-Go phase trials. In the next phases, Go and No-Go stimuli were mixed in an increasing way (50%, 25%, and intermingled specified patterns). Rats were implanted with recording electrodes in motor and prelimbic (PLc) cortices, accumbens nucleus core (Acc), dorsolateral and dorsomedial striatum, hippocampus, mediodorsal thalamic nucleus (MD), and basolateral amygdala (BLA). Each animal was implanted with recording electrodes in five of the indicated sites. Preliminary results indicate that rats were able of acquiring this rather complicate task with a significant performance even when stimuli were mixed at a 25%. Spectral analyses of collected LFPs indicate the specific involvement of PLc, Acc, BLA, and striatum, but not hippocampus, during the proper execution of Go and No-Go tasks. Spectral power changes were observed mainly in delta, theta and gamma bands. Thus, these brain areas are involved in cognitive and motivational processing, execution of motor responses, and contribute to reward-directed behaviors.

Title: Neuronal activity in the primate gustatory cortex during economic choices

Authors: *A. JEZZINI, C. PADOA-SCHIOPPA;
Washington Univ. in St Louis, Saint Louis, MO

Abstract: The gustatory cortex (GC), located in the anterior insula, receives anatomical projections from sensory and associative thalamic nuclei (VPMpc, MD, Pulvinar) and is densely interconnected with the amygdala, the orbitofrontal cortex (OFC) and the anterior cingulate cortex. Classic work showed that neurons in GC respond to the chemosensory properties of foods. More recently, it was suggested that GC participates in more complex processes such as the representation of the food's subjective or hedonic value (Jezzini et al., 2013). Importantly, the behavioral paradigms used in previous studies of GC did not provide any operational measure of subjective value. Furthermore, it remains unclear whether and how the GC might contribute to food-related and/or value-driven behaviors. To address these outstanding questions, we recorded the activity of neurons in the GC of monkeys performing an economic choice task. In each session, a monkey chose between two juices, labeled A and B, offered in variable amounts. Offers were represented by sets of squares on a monitor and the animal indicated its choice with a saccade. For each session, the relative value of the juices was inferred from the choice pattern. We recorded and analyzed the activity of 912 cells. Roughly 50% of neurons were significantly modulated by the offer type and/or by the animal's choice. In contrast, only few cells were modulated by the spatial contingencies of the task. As in previous studies of OFC, we defined and examined a large number of variables. Our analyses revealed that neurons in GC encoded two variables: the *chosen value* (i.e., the value of the chosen option independently of the juice type) and the *chosen value A|B* (i.e., the juice-specific chosen value). For both variables, neuronal modulation in GC started during the delay intervening between offer presentation and the go signal, and was most pronounced upon juice delivery. More specifically, neurons encoding the *chosen value* peaked shortly before juice delivery; neurons encoding the *chosen value A|B* peaked after juice delivery. Additional analyses confirmed that *chosen value* responses reflected the subjective nature of value, as distinguished from the physical and chemical properties of the juices. Thus neurons in GC reflect the integration of chemosensory inputs and the motivational state of the animal. Conversely, our results indicate that GC does not contribute to the formation of the current economic decision.

Title: Afferent projections of frontal cortical area 12o in rhesus macaques

Authors: C. CLEVELAND, M. MOYER, E. MURRAY, *R. C. SAUNDERS;
Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: The medial and lateral subdivisions of orbitofrontal cortex (OFC) are thought to support distinct components of reward-based learning and decision making, and the anatomical connections of these subdivisions appear to support their distinct roles. Although much is known about the anatomical connections of lateral OFC areas 11 and 13, much less is known about the adjacent area 12o, the portion of area 12 lying on the orbital surface. Until recently, 12o has not been considered part of the decision making circuit. To gain a better understanding of how area 12o interacts with other brain regions, we mapped the anatomical connections of area 12o in rhesus monkeys. 1 µl injections of standard retrograde neuronal tract tracers were placed in different levels of 12o as well as in nearby frontal cortical areas (e.g. 11, 13, 12l). Retrograde label after 12o injections suggest a robust set of projections from the frontal pole area 10, adjacent OFC areas 11 and 13, with only a light projection from area 14. On the medial surface area 32 had fairly dense label while area 24 had dense label rostrally but only light label caudal to the genu of the corpus callosum. Lateral PFC contained only sparse retrograde label in area 46, along the banks of the principal sulcus, and in areas 9 and 8. As expected, outside of the frontal lobe we found dense retrograde label within the rostral temporal cortical areas, particularly the temporal pole areas 38 and 36p. The rostral auditory cortical area, TS1, had substantially more label as compared with the rostral visual association cortical area TE. Caudal to the pole the multi-sensory area of the upper bank of the STS had heavy label throughout. In the medial part of the temporal lobe there was light label in the parahippocampal cortical areas including rostrally the perirhinal cortex and intermediate entorhinal cortex. There was also light label more caudally in areas TF/TH. Subcortically, the most prominent label was found in the basal nuclei of the amygdala and the medial thalamic region including the midline nuclei, mediodorsal nucleus, and the medial pulvinar. Labeled cells were also found in the source nuclei of many of the neuromodulators such as the substantia nigra, the raphe nuclei, and the basal forebrain. In summary, area 12o in macaques receives inputs from frontal cortex regions similar to those of both the proposed medial frontal and orbital frontal cortical networks (Ongur and Price, Cerebral Cortex, 2000), from the temporal lobe, as well as the medial thalamus, and from regions containing cholinergic, serotonergic and dopaminergic neurons. Future studies should address the role of area 12o in reward-based learning and decision making.

Title: A modified actor-critic learning model suggests anterior cingulate cortex maintains eligibility traces for learning

Authors: *D. R. SCHUWEILER, D. VAZQUEZ, M. R. ROESCH;
Univ. of Maryland, College Park, MD

Abstract: We have established a task to study fundamental neural signals related to learning and decision-making and their disruption in addiction. During this task, rats are presented one of three odor cues that direct them to go to a left fluid well, a right fluid well, or either to receive reward. The task is divided into four blocks of trials, and there are no cues indicating the current block or block switches. In the first block the left side, for example, is paired with a short delay before reward and the right side with a long delay. This pairing is reversed for the second block. In the third block, the left side is paired with a large reward and right side with a small reward. The pairing is reversed for the last block. Thus, rats experience unexpected changes in reward value every time a new block begins.
During this task, we have recorded distinct types of learning-related neural signals. Dopamine (DA) neurons in the ventral tegmental area (VTA) increase or decrease firing when rewards are better or worse than expected, respectively. Thus, VTA DA neurons appear to signal classic reward-prediction errors (RPEs). Neurons in the basolateral amygdala (BLA) increasing firing when rewards are better or worse than expected. Thus, BLA neurons appear to signal unsigned RPEs. Neurons in the anterior cingulate cortex (ACC) increase firing at the start of the trial, and the firing rate decays to baseline after the cue is presented. For many ACC neurons, this cue-related activity increases after unexpected changes in value, and the increase correlates with response latency, a measure of attention. We have hypothesized that DA activity drives learning, while BLA activity encodes how surprising an outcome is; this latter information is sent to the ACC to modulate attention, and ACC activity converges with striatal DA to direct behavior. However, it is still unclear exactly what is being encoded by the ACC in this context.
We fit a modified actor-critic learning model to the behavior observed in our task. In our model DA-like RPEs drive Pavlovian learning by the critic, as usual, but we have added BLA-like unsigned RPEs which set the learning rate for the operant actor and the magnitude of the eligibility traces. The eligibility traces included in actor-critic models control how well a cue becomes associated with a reward, and they enable the model to associate cues with rewards that

are delivered after a delay. Our model produces eligibility traces which appear similar to the activity of the ACC units that is thought to encode attention. Thus, our model generates the novel hypothesis that one function of the ACC is to maintain neural representations of cues that enable the development of cue-outcome associations.

Title: The effect of ventral striatum lesions on choices based on reward availability versus desirability in rhesus macaques

Authors: *M. S. PUJARA[1], B. M. BASILE[2], V. D. COSTA[3], B. B. AVERBECK[4], E. A. MURRAY[5];
[1]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Health, NIH, Bethesda, MD; [3]Dept. of Behavioral Neurosci., OHSU/ONPRC, Portland, OR; [4]NIMH/NIH, Bethesda, MD; [5]Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD

Abstract: Reward value is determined by the likelihood of reward receipt as well as the current worth of the reward. The ability to use existing knowledge about a reward — whether it is likely to become available or whether it is desirable or not — represents two distinct processes that are both critical for driving adaptive choices. Though the ventral striatum (VS) has been implicated in guiding reward-based learning, the extent to which it is necessary for guiding choices based on information about reward availability, desirability, or both, has not been fully explored in rhesus macaques. We therefore compared monkeys with VS lesions (n=3) and intact controls (n=4) on two touchscreen tasks where reward value changed as a function of either availability or desirability. Choice based on reward availability was tested using a three-arm bandit task, wherein monkeys learned to choose between three probabilistically rewarded images. Periodically, one of the options was replaced with a novel image that had not yet been associated with reward. Monkeys therefore had to choose between exploring the novel option or exploiting their existing knowledge about the two familiar options that remained available, where the availability of reward was known. Impairments in optimizing rewards via novelty exploration present as either increased novelty seeking or novelty aversion. Choice based on desirability was tested using a reinforcer devaluation task, wherein monkeys learned to choose between two stimuli, each associated with a unique food reward. Critically, monkeys were sated on one of the two outcomes, and stimulus choice was assessed immediately following satiety. Monkeys that are impaired on this task are unable to shift choices away from stimuli that predict the outcome

they were sated on, relative to their choices at baseline, before satiety. We found that monkeys with VS lesions were impaired on the probabilistic three-arm bandit task, showing increased novelty seeking as indexed by choice and reaction times upon the first presentation of a novel stimulus, especially when the overall probability of reward was greatest prior to the presentation of a novel image. However, VS lesions produced only mild impairments in stimulus choice following selective satiety. The results of these experiments suggest that the VS may be specialized to guide choices based on information about reward likelihood rather than reward palatability in rhesus macaques.

Title: Hippocampal-related memory deficits in Sprague-Dawley rats with spontaneous ventriculomegaly

Authors: D. GASCA-MARTINEZ[1], L. CONCHA[2], L. C. MARQUEZ-BRAVO[2], *H. LUNA-MUNGUIA[2];
[1]Unidad de Analisis Conductual, [2]Neurobiologia Conductual y Cognitiva, Inst. de Neurobiologia UNAM, Queretaro, Mexico

Abstract: Purpose. Spontaneous ventriculomegaly has been observed in rats that were presumably normal. While external phenotype of these animals is unremarkable, they show considerable enlargement of the ventricular system and hippocampal atrophy. Given the role of the hippocampus in memory consolidation, we evaluated long-term memory retention while decision-making in rats with spontaneous ventriculomegaly.
Methods. Animals included (adult male Sprague-Dawley rats) were those identified as having spontaneous ventriculomegaly while performing baseline MRI scanning intended for a different research protocol. Control (n=8) and lesioned (n=8) animals were submitted to a delayed-alternation task (no-delay, 30, 60, and 180s) and to an object-in-context recognition task. During

the first one, we evaluated the number of correct choices as well as the latency to find the reward during each trial. The second task assessed the rodents' ability to remember where they had previously encountered a specific object, calculating the context recognition index (0.5 reflects no preferences for any of the objects while higher values show a preference for familiar objects in novel contexts).
Results. When compared to Control animals, rats with ventriculomegaly showed a significantly reduced delayed-alternation performance in each of the four evaluated times ($p<0.0001$), as well as increased latencies while trying to reach the reward ($p<0.01$). When evaluated the long-term memory formation during the object-in-context recognition task, subjects with ventriculomegaly spent less time ($p<0.05$) investigating the familiar object. Recognition index value was 0.8 and 0.5 for Control and lesioned animals, respectively.
Conclusion. Our results are the first to show how spontaneous ventriculomegaly-induced hippocampal damage impacts upon decision-making behaviors, in particular, when deciding between immediate and delayed rewards. Moreover, this lesion disrupts the animals' ability to recall or express contextual information.Thanks to Juan Ortiz Retana and Carlos Flores Bautista for technical support.

Title: Stimulus specific value coding in motivational circuits is not a bug, it's a feature

Authors: *V. D. COSTA;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Motivational brain regions, such as the amygdala, ventral striatum, and orbitofrontal cortex encode stimulus and action values. A prevalent view is that value coding in these regions is general and not stimulus or action specific. However, prior studies have typically only examined responses to a limited set of stimuli or actions, sometimes confounded value with the identity of an action or stimulus, or relied on statistical rather than experimental controls. To determine the extent to which value coding in motivational regions is general or stimulus specific we recorded activity in the amygdala, ventral striatum, and orbitofrontal cortex in rhesus macaques as they played a multi-arm bandit task where they had to learn visual stimulus-outcome relationships. Every so often an existing choice option was randomly replaced with a novel option, allowing us to assess how individual neurons encoded the value of choices across

35 stimuli assigned different reward probabilities. The proportion of task responsive neurons in each brain region that showed evidence of general value coding did not exceed chance. Rather the majority of neurons in each brain region showed evidence of stimulus specific value coding. Neuronal preferences for specific stimuli were not readily discernable from natural image statistics. Despite weak evidence of general value coding at the level of individual neurons, we were still able to decode the value of choices from pseudo-populations constructed for each region. These results are consistent with increasing evidence that value coding in the brain is heterogenous and multidimensional.

Title: Investigating the role of the gut microbiome in decision-making in mice

Authors: *S. L. THOMPSON, S. M. GROMAN, J. H. MEYERS, G. HUANG, J. R. TAYLOR; Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Goal-directed, or model-based, behavior is a type of decision-making that is vital for flexibly updating choices in a dynamic environment. In contrast, habitual or automatic, also known as model-free, behavior is efficient but inflexible. Rigid, repetitive behaviors that persist in the absence of a goal have been observed in individuals with various psychiatric disorders. These compulsive behaviors may arise from disruptions in the reinforcement learning (RL) systems that enable flexible, adaptive decision-making. The dynamics between model-based and model-free RL systems can be quantified in multi-stage decision-making (MSDM) tasks. MSDM tasks consist of sequential decisions, whereby choices made in one stage transition probabilistically (i.e., common or rare) to the options available in the next stage, and ultimately to the possibility of reward based on reinforcement probabilities assigned to the final stage options. The gut microbiome has recently emerged as a major modulator of neuropsychiatric phenotypes. However, the role of the gut microbiome in decision-making is unknown. Here, we adapted a version of the MSDM task developed in rats for use in mice and assessed the role of the gut microbiome in decision-making. Adult male C57BL/6 mice were water-restricted, trained

using water as the reinforcer, and tested on the MSDM task using a probabilistic, alternating block schedule of reinforcement. Mice were then provided with a cocktail of nonabsorbable antibiotics in the chow or a control diet for one week and then retested on the MSDM task while maintained on the antibiotic regimen. Mice were then placed back on the control diet and retested on the MSDM task eight weeks later. Mice were able to learn the state transitions and reinforcement schedules in the MSDM task and exhibited strikingly similar decision-making strategies compared to those observed in humans and rats, suggesting that mice use both model-free and model-based RL systems when making decisions. Exposure to antibiotics reduced both model-based and model-free strategies in the MSDM task, which persisted eight weeks after washout of antibiotics. These results provide preliminary evidence of a role for the gut microbiome in RL strategies of decision-making that may be relevant to psychiatric disorders in which compulsivity is a core behavioral feature.

Title: Prefrontal cortico-amygdalar interactions are required for social associations to guide operant behavior

Authors: H. W. KIETZMAN, *S. L. GOURLEY;
Emory Univ., Atlanta, GA

Abstract: Navigating a complex world requires the formation of associations between cues, our behaviors, and their outcomes. Over the past 50 years, the circuitry underlying the ability of Pavlovian cues to motivate instrumental behavior has been carefully dissected utilizing procedures such as Pavlovian-to-instrumental transfer (PIT). We have discovered that social associations, such as experience with a novel conspecific, can motivate food-reinforced operant behavior in mice, through PIT-like processes. We hypothesized that the prelimbic (PL) subregion of the medial prefrontal cortex, known to process social information, but not classically associated with PIT, might be necessary for social associations to guide instrumental behavior. Chemogenetically silencing the PL, when social associations would otherwise be expected to motivate operant behavior, ablated such “social PIT.” PL inactivation also reduced social approach in a social interaction test, while leaving social memory intact. Next, we

chemogenetically silenced PL projections to the basolateral amygdala (BLA), rendering mice again unable to utilize social associations to guide instrumental decision making. Meanwhile, social approach remained intact. Together, these results suggest that top-down communication from the PL to BLA is not necessary for attending to social stimuli per se, but enables social associations to guide operant behavior.

Title: Signal dynamics corresponding to transformation from value to choice in midbrain dopamine neurons and orbitofrontal neurons during economic decision-making in monkeys

Authors: *M. YUN[1], T. KAWAI[2], M. NEJIME[2], H. YAMADA[2], M. MATSUMOTO[2];
[1]Grad Sch. of Comprehensive Human Sci., [2]Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan

Abstract: In economic decision-making, individuals evaluate the value of options, and then decide to choose or not to choose the options based on the value. To identify the neural mechanism underlying this behavior, it is critical to understand how the brain transforms value information into choice commands. Yet, although many studies have reported brain regions that participate in the valuation process, the value-to-choice transformation mechanism remains unclear. Here we focused on midbrain dopamine (DA) neurons that are well-known as a part of the valuation system, and examined whether and how these neurons contribute to the value-to-choice transformation process. We recorded single-unit activity from DA neurons in monkeys performing an economic decision-making task in which the monkey was required to decide to choose or not to choose an option based on its value immediately after the option was offered. We found that DA neurons represented diverse signals related not only to the option's value but also to the animal's choice; some neurons represented the value of the offered option, some represented whether the animal would choose or not choose the option, and some represented the value of the option only when the option was chosen by the monkey -we therefore called this activity pattern as *choice-dependent value* signal that was influenced by both value and choice. We next analyzed the time course of these DA signals and found that the order of signal representations corresponded to the value-to-choice transformation. Shortly after the onset of the option, the value signal rapidly appeared, which was followed by the choice-dependent value signal. The choice signal arose at last. For comparison, we also recorded single-unit activity from the orbitofrontal cortex (OFC) that has been implicated in economic decision-making, and found that OFC neurons also represented the three signals and exhibited the same order of signal

representations. Notably, the last-arising choice signal appeared before the monkey executed a motor action to choose the option in both DA and OFC neurons. Thus, both neurons could regulate the monkey's choice behavior. On the other hand, the choice signal of DA neurons preceded that of OFC neurons, suggesting the value-to-choice transformation process has completed earlier in DA neurons. We finally observed that the choice signal of DA neurons did not simply reflect the monkey's motor action using a control motor task in which the monkey just executed the same motor action without economic decision-making. Our findings provide evidence that not only prefrontal regions but also the subcortical DA system plays a crucial role in value-based choice formation.

Title: Value and choice representations in the primate ventral striatum during economic decision-making

Authors: *M. NEJIME[1], M. YUN[2], T. KAWAI[1], H. YAMADA[1], M. MATSUMOTO[1]; [1]Fac. of Med., [2]Biomed. Science, Grad Sch. of Comprehensive Human Sci., Univ. of Tsukuba, Tsukuba, Japan

Abstract: To choose an appropriate option in economic decision-making, animals evaluate the value of offered options and then decide to choose or not to choose the options based on the value. Although the ventral striatum (VS) is known as a key structure in the neural network that evaluates reward value, how its value signal regulates choice behavior remains poorly understood. To address this issue, we recorded the activity of phasically active neuron in the VS and electrically stimulated this structure in monkeys performing an economic decision-making task. In this task, six visual cues were associated with different amounts of a liquid reward, and two of them were randomly and sequentially presented to the monkey as available options. When one of the cues was presented as the 1st option, the monkey was required to decide to choose or not to choose the option. Note that the monkey needed to make the decision before seeing the 2nd option. We observed that the monkey more often chose the 1st option as its value became larger. After the decision, the 2nd option was presented. If the monkey had chosen the 1st option, the animal was unable to choose the 2nd option and obtained the reward associated with the 1st

option at the end of the trial. If the monkey had not chosen the 1st option, the animal obtained the reward associated with the 2nd option. Of 131 recorded VS neurons, 43 and 30 neurons encoded the value of the 1st option in manners that these neurons increased and decreased, respectively, their activity as the value became larger. We found that their population activities were modulated not only by the value of the 1st option but also by whether the monkey would choose the 1st option. That is, on average, the 43 positive-value-coding neurons were more strongly activated by the 1st option with the same value when the monkey would choose the option, whereas the 30 negative-value-coding neurons were more strongly activated when the monkey would not choose the option. Next, to examine the causal relationship between the activity of VS neurons and the monkey's choice behavior, we electrically stimulated the VS during the presentation of the 1st option (n = 35 stimulation sites) and compared the choice rate of the 1st option between the stimulation and the non-stimulation conditions. On average, we found that the monkey significantly more frequently chose the 1st option in the stimulation condition, although four and two stimulation sites exhibited a significant increase and decrease, respectively, in the choice rate in the stimulation condition. Our findings suggest that the value signal of the VS supports the brain to regulate value-based choice behavior.

Title: Representations and causal contributions of multiple brain regions during context-dependent accumulation of evidence

Authors: ***M. PAGAN**[1], V. D. TANG[1], C. D. BRODY[2];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst. and Dept of Mol. Biol., HHMI / Princeton Univ., Princeton, NJ

Abstract: Our ability to flexibly select, based on context, the relevant information to form decisions is a fundamental cognitive process, yet its underlying neural mechanisms are still largely unknown. To address this issue, we have trained rats to perform a task requiring context-dependent selection and integration of sensory information (adapted from Mante et al., Nature, 2013). As we described in Pagan et al., SFN 2016, on each trial of the task rats are presented

with a train of auditory pulses, where each pulse can either be high-frequency or low-frequency, and each pulse is either played by a speaker to the left or a speaker to the right of the rat. In blocks of "location trials" rats are rewarded if they orient toward the side where the largest number of pulses was played (thus ignoring the frequency of the pulses). In blocks of "frequency trials" rats are rewarded for orienting right if the total number of high-frequency pulses was greater than the total number of low-frequency pulses, and for orienting left if the total number of low-frequency pulses was greater than the total number of high-frequency pulses (thus ignoring the location of the pulses). Therefore on each trial the rat is required to select the relevant feature depending on the task context. Here we present data obtained from electrophysiology and optogenetics experiments targeted at multiple brain regions while the rats performed the task.

Title: Connecting the dots: The role of striatal projections from frontal orienting fields during perceptual decision-making

Authors: *D. GUPTA[1], T. Z. LUO[1], C. D. KOPEC[1], C. D. BRODY[1,2,3];
[1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Dept of Mol. Biol., Princeton Univserity, Princeton, NJ; [3]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Making decisions based on sequential observations of noisy observations is a fundamental cognitive process. While research across different species has successfully modeled this process as a feedforward computation - graded accumulation of evidence followed by choice categorization (e.g. Hanks and Summerfield 2017), it might be neurally implemented through recurrent dynamics across brain areas. Indeed, strong projections exist from the Frontal Orienting Fields (FOF), a rodent frontal cortical area shown to be involved in late stages of decision-making such as choice maintenance (Hanks et al., 2015) and the anterior dorsal striatum (adStr), an area involved in the early stages of decision-making such as graded evidence accumulation (Yartsev et al., 2018) - suggesting that these brain areas might act in a distributed, recurrent fashion during perceptual decision-making. Here, we investigate the causal role of the FOF-adStr projection by optogenetically silencing it during decisions based on the accumulation of pulsatile auditory evidence (the Poisson Clicks task, Brunton et al., 2013). We injected rats with AAV5-

CaMKIIa-eNpHR3.0-eYFP (halorhodopsin, a light activated chloride pump) in FOF and delivered light (25mW, 594nm) via a sharp fiber optic implanted in adStr to perturb the activity of the axon terminals of FOF-adStr projection neurons. We found that unilateral stimulation throughout the trial impaired decisions by biasing the rats to favor an ipsilateral response relative to the site of inhibition, without affecting movement-related parameters. This demonstrates a causal role for this projection, inconsistent with a purely feedforward account. To better understand the contribution of this projection to various stages in decision-making, and to compare it with direct inhibition of the FOF itself, we explored temporally specific inactivation windows during different epochs within trials of the Poisson Clicks task.

Title: Large scale dynamics during evidence accumulation in freely moving rats using functional ultrasound imaging

Authors: *A. EL HADY[1], D. TAKAHASHI[2], Y. ZHANG[1], A. URBAN[3], G. MONTALDO[3], C. BRODY[1];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Brain Insitute, Federal Univ. of Rio Grande do Norte, Natal, Brazil; [3]Neuro-Electronics Res. Flanders, Leuven, Belgium

Abstract: Evidence accumulation is a well characterized decision making paradigm, in which the subject continually processes evidence until making a specific choice. Drift-diffusion models provide a moment by moment quantitative estimate of the animal's internal accumulation process. Experimenters have investigated a myriad of neuronal mechanisms underlying the accumulation processes, e.g., the contributions of different brains areas such as frontal orbital field, posterior parietal cortex and dorsal striatum that differentially accumulate evidence over time (Hanks 2015; Yartsev 2018). Although evidence accumulation likely involves the coordinated activity of many brain areas, previous studies primarily focus on one area at a time and fail to take into account the contribution of other brain areas during evidence accumulation. To probe a large number of brain areas simultaneously, we used functional ultrasound imaging (fUSi) technology. fUSi has a large spatial coverage (16x20mm^2), high spatial resolution

(~100x100x400 μm^3) and temporal (500ms) resolution. We obtained stable imaging in freely moving rats performing evidence accumulation over many months. Rats were trained on an auditory evidence accumulation task with trials slow enough (spanning up to 5s) to capture the full hemodynamic response. Using fUSi to image during the behavior, we report a number of brain areas with choice-related activity, and directed and temporally ordered activation of brain regions during evidence accumulation.

Title: Mesoscale cortical dynamics during parametric working memory in freely moving rats using wide-field imaging

Authors: *E. J. DENNIS, A. EL HADY, C. BRODY;
Princeton Univ., Princeton, NJ

Abstract: Working memory, the maintenance and manipulation of information over short periods of time, is fundamental to many cognitive processes like language, decision making, and planning. We use a parametric working memory task, where the rat hears a sound, followed by a variable delay period, and then hears a second sound (Akrami *et al.* 2018). After a "GO" cue, the animal then reports whether the first or second sound was louder by poking their nose into either a left or right port and receives a water reward for a correct answer. To receive a reward at the end of a trial, the animal should extract the relevant parameter (loudness) from the first stimulus, retain it through the delay, extract the same parameter (loudness) from the second stimulus, compare them, and report their decision. While previous work identified that the rat posterior parietal cortex (PPC, also called parietal association cortex) is critical for the influence of stimulus history in this task, other regions required for this behavior, notably the memory or persistence of the first stimulus, are unknown. To look at large areas of the dorsal cortex with the goal of identifying additional regions recruited in this task, we used the cScope, a recently developed head-mounted microscope to image Thy-1 transgenic rats broadly expressing GCaMP6f (Scott *et al.* 2018). We implanted a large (4 x 8 mm) glass window into the posterior dorsal surface of the cortex and recorded both hemodynamic and calcium signals at the

mesoscale level during tethered, freely-moving behavior. We report the activity dynamics within this area and correlate it with task parameters.

Abstract: Complex behaviors, such as the gradual accumulation of evidence, depend on the simultaneous activity of many neurons across multiple brain areas. Electrophysiological measurement of large scale neuronal population activity is facilitated by recently developed high-density microelectrode recording probes (Neuropixels). While these probes have been widely applied to record acutely from animals performing tasks when they are head-fixed, chronic use for freely moving behaviors remains limited. An approach for chronic recording from freely moving mice has been recently described (Juavinett and Churchland, 2018). We describe a compact and scalable system for chronic recording and subsequent probe recovery from freely moving rats. The system consists of three components: an internal mount that attaches directly to the probe, an external chassis that encloses the internal mount and attaches to the skull, and a connector that houses the headstage and mates with the external chassis. The probe can be readily removed from the rest of the implant and recovered for future use. During a task that requires the gradual accumulation of auditory evidence, recording from tethered, freely moving rats took place for multiple hours without experimenter supervision. Rats performed at a similar behavioral performance as when they are untethered. Robust spiking signals from up to hundreds of neurons were recorded stably for multiple months. The small size of the system allows multiple probes to be implanted in the same animal, in addition to optical fibers or infusion cannulae for simultaneous recording or pharmacological perturbation. This system thus provides a simple, modular, and scalable approach for deploying Neuropixels probes in freely moving rats. We show data acquired using this system on which aspects of population-level signals related to evidence accumulation are interdependent across brain areas.

Title: Anterior and posterior dorsal striatum play distinct roles in evidence accumulation

Authors: *A. G. BONDY[1], T. Z. LUO[2], C. D. BRODY[3];
[1]Princeton Neurosci. Inst., [2]Neurosci., Princeton Univ., Princeton, NJ; [3]Princeton Neurosci. Inst. and Dept of Mol. Biol., HHMI / Princeton Univ., Princeton, NJ

Abstract: Sensory-guided decision-making, in particular the accumulation of noisy sensory input across time, is a key cognitive function that remains the subject of intense study. Recent evidence suggests the dorsal striatum is a critical node in evidence accumulation. Firing rates of dorsal striatal neurons correlate strongly with the value of accumulated evidence in either rats integrating auditory evidence toward to a locomotor response or in monkeys accumulating visual evidence toward an eye movement response (Yartsev et al., 2018; Ding and Gold, 2013). Furthermore, optogenetic inactivation of two dorsal striatal subregions in rats, the anterior dorsal striatum (ADS) and posterior dorsal striatum (PDS), produces specific behavioral deficits in auditory evidence accumulation tasks (Yartsev et al., 2018; Znamenskiy and Zador, 2013). However, neuronal activity across the dorsal striatum during evidence accumulation has not been systematically characterized or directly compared. We therefore recorded from single neurons in ADS and PDS in rats performing a task requiring accumulation of competing streams of pulsatile auditory evidence generated by two sound sources . Task-modulated ADS neurons had firing rates that correlated with the value of accumulated evidence favoring a preferred choice during stimulus presentation, as well as strong choice-selective modulations of firing rate around the time of motor execution. By contrast, task-modulated PDS neurons showed less firing rate modulation related to accumulated evidence or choice. Instead, these neurons often responded vigorously and transiently to the individual auditory pulses with very short latencies, consistent with the area's auditory inputs. These pulse-aligned responses were spatially selective and thus can provide task-relevant sensory evidence for downstream brain areas.
We described these neuronal dynamics with a generalized linear model in which all task events, including the auditory pulses as well as motor actions, were used as covariates to predict neuronal spike times. Cross-validated variance explained on single trials was greater than 50% for some neurons, and the model fits captured the distinct relationships between sensory versus motor variables and neuronal spiking across the two areas. This approach will be expanded to

compare neuronal dynamics across many striatal, cortical and brainstem structures to distinguish their roles during auditory evidence accumulation.

Title: Neural basis of dynamic risk preferences in rats

Authors: *C. M. CONSTANTINOPLE[1], A. PIET[2], P. BIBAWI[3], A. AKRAMI[4], C. D. KOPEC[3], C. D. BRODY[5];

Abstract: Prospect Theory is the predominant behavioral economic theory describing decision-making under risk. We applied Prospect Theory's framework to rodents, using a task in which rats chose between guaranteed and probabilistic rewards. Like humans, rats distorted probabilities and showed diminishing marginal sensitivity, in which they were less sensitive to differences in larger rewards. They exhibited reference dependence, in which the valence of outcomes (gain or loss) was determined by an internal reference point reflecting reward history, and many rats exhibited loss aversion. However, Prospect Theory assumes stables preferences in the absence of learning, an assumption at odds with alternative frameworks such as animal learning theory and reinforcement learning. Rats also exhibited trial history effects, consistent with ongoing learning. A reinforcement learning model in which state-action values were updated by the subjective value of outcomes according to Prospect Theory reproduced rats' nonlinear utility and probability weighting functions, and also captured trial-by-trial dynamics. For example, rats exhibited a "risky win-stay" bias, in which they were more likely to gamble following risky rewards even though they were not more likely to win. Neurons in orbitofrontal cortex (OFC) encoded reward history and whether rats chose risky or safe options. Optogenetic inhibition of OFC eliminated the risky win-stay bias, but spared other sequential dependencies. These trial-by-trial dynamics, mediated by OFC, may reflect faulty inferences about reward contingencies or task states, which were stable but incorrectly inferred to be dynamic. We hypothesize that dynamic subjective preferences, including attitudes towards risk, may at times reflect suboptimal learning mediated by OFC.

Title: The medial and lateral subregions of the orbitofrontal cortex play dissociable and opposing roles in cue-guided risk/reward decision making

Authors: M. VAN HOLSTEIN[1], P. MACLEOD[2], ***N. L. JENNI**[1], S. B. FLORESCO[3]; [1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychology, Univ. of Britsh Columbia, Vancouver, BC, Canada; [3]Psychology, Univ. British Columbia, Vancouver, BC, Canada

Abstract: We often face decisions requiring a choice between options that vary in terms of reward magnitude and uncertainty. In some situations, the probabilities of obtaining a desirable outcome can be inferred from environmental cues. For example, an experienced Blackjack player knows the odds of winning a hand are better when the dealer is showing a “6” compared to an “ace”. Studies with humans, where subjects are often presented with explicit cues informing about the probabilities of winning a gamble, have revealed these types of risk evaluations are supported by the orbitofrontal cortex (OFC). Previous work from our group has implicated the medial subregion of the OFC in probabilistic discounting, where the odds of receiving the large reward change gradually across blocks of trials. Here, the mOFC tempers the urge to chase large/risky rewards when profitability is low. In contrast, lateral OFC inactivations did not affect choice on this task. This adds to mounting evidence that the OFC is made up of functionally heterogenous subregions. Another region known to modulate risky choice, at least in the context of losses, is the agranular insula. (AI). However, it is unclear how these regions contribute to cue-guided risky/reward decision making. To assess how the mOFC, lOFC and AI contribute to risky decision making when odds are explicitly cued, we used a novel “Blackjack” task. Rats were well-trained to choose between a certain 1 pellet or a large/risky 4 pellet reward. Critically, distinct auditory stimuli informed the rat of the probability of obtaining that large reward on a given trial: either 50% (good odds) or 12.5% (poor odds). mOFC inactivation reduced risky choice, and this effect was accompanied by an increase in sensitivity to feedback when the odds were good. This suggests that activity in the mOFC dampens the impact of the previous outcome on choice, specifically when choosing risky is the most advantageous strategy. In stark contrast, lOFC inactivation increased risky choice, accompanied by a reduction in the tendency to choose

the small/certain option after a recent loss. Thus, the lOFC may facilitate adaptation of choice strategy after negative feedback. AI inactivation had no effect on any decision variables measured. The mOFC and lOFC appear to play opposing roles in risky decision-making, specifically in situations where probabilistic odds are both previously learnt, and explicitly cued. These functions vary greatly compared to their role in risky choice guided by internal representations of changes in reward probabilities. These findings highlight novel roles for the m/lOFC and highlight the complexity with which the OFC functions to promote profitable choice.

Title: The abused inhalant toluene disrupts activity of medial prefrontal cortex (mPFC) glutamatergic neurons under conditions of uncertainty

Authors: *K. M. BRAUNSCHEIDEL[1], M. P. OKAS[1], M. HOFFMAN[1], P. J. MULHOLLAND[1], S. B. FLORESCO[2], J. J. WOODWARD[1];
[1]Med. Univ. of South Carolina, Charleston, SC; [2]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Volatile organic solvents like toluene cause intoxication and changes in brain function similar to those produced by classic drugs of abuse. For example, we previously demonstrated that toluene, applied acutely to medial prefrontal cortex (mPFC) brain slices, caused a long-lasting depression in glutamatergic synaptic transmission in deep-layer pyramidal neurons. The consequence of this effect is unknown, but would be expected to disrupt behaviors that require a functional mPFC. The present set of experiments used the mPFC-dependent probabilistic discounting task combined with *in vivo* fiber photometry to study decision making in the face of uncertain outcomes. In brief, Sprague-Dawley rats were trained to lever press for a reward (20% sweetened condensed milk): one lever delivered a small, certain reward (30 µl, 100% of the time) while a second lever delivered a large, uncertain reward (90 µl, reinforcement probability

shifts incrementally from 100% to 6.25%). We previously reported that the effect of toluene on this task depends on the order in which odds were presented, a pattern of responding that mimics pharmacological inactivation of the mPFC. It is not known, however, which portions of the task (e.g. generalized attention, choice selection, consumption encoding) depend on mPFC activity. To address this, we virally expressed the genetically encoded calcium sensor GCaMP6f in glutamatergic mPFC neurons and monitored calcium transients in real-time using *in vivo* fiber photometry. During free choice trials, mPFC activity peaked before either lever press. However, during forced choice trials, a peak only occurred when that lever produced an optimal outcome based on reward probabilities (shifting from risky lever to safe lever throughout the session). Toluene pretreatment caused a delayed and incomplete shift of this activity pattern. During reward consumption, mPFC activity decreased proportionally with time spent in the food well, and the depression following a risky win was larger than following a safe win. Following toluene exposure, mPFC activity also decreased during reward consumption, but it was not correlated with consumption time, resulting in no distinction between signal during safe vs risky wins. These results provide a physiological basis for the mPFC's theorized role in updating action - outcome contingencies and further implicate mPFC dysfunction in the behavioral flexibility deficits caused by toluene. More importantly, understanding this physiology may help guide the treatment of neuropsychiatric diseases marked by aberrant choice. Title: Mesocortical dopamine modulation of cue-guided, risk/reward decision making

Authors: *J. D. SCHUMACHER, M. VAN HOLSTEIN, S. B. FLORESCO;
Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The ability to make optimal choices between options that vary in terms of reward magnitude and uncertainty is a critical survival skill. Probabilistic decision-making paradigms often require human subjects to utilize external cues to guide decisions. On the other hand, studies of probabilistic decision making in rodents typically use tasks such as probabilistic discounting where choice is guided by internal representations of reward probabilities. Both in

human and rodent studies, probabilistic decision making relies on the medial prefrontal cortex (mPFC) and mesocortical dopamine transmission. However, it is unclear whether findings using probabilistic discounting assays are comparable to those obtained using cued tasks. Our group has recently developed a rodent operant assay which requires the use of explicit cues signaling the "odds" associated with various choices. In each trial of this "Blackjack task", rats choose between a small/certain option (1 pellet delivered with 100% probability) and a large/risky option (4 pellets) delivered in a probabilistic manner. On each trial, the odds of obtaining the large /risky reward (good - 50% or poor -12.5% odds) are signaled by distinct auditory cues. Previously, our group has revealed that the dorsal mPFC facilitates risky choice on good odds trials, whereas the ventral mPFC suppresses risky choice on poor odds trials. However, how PFC dopamine receptors modulate cue-guided probabilistic decision making is unknown. Here, we assessed the effect of blockade of dopamine D1, D2 and D4 receptors in the prelimbic cortex in rats well trained on the Blackjack task. Previous work by our group using probabilistic discounting tasks showed that dopamine D1 receptor blockade in the mPFC decreases risky choice whereas D2 blockade impairs adjustments in choice in response to changes in reward probabilities. In the present study, we show that blockade of D2 (but surprisingly, not D_1) receptors decreased risky choice on good odds trials - similar to the effect of prelimbic PFC inactivation. These data demonstrate a role for prefrontal dopamine receptors in cue guided risk/reward decision making that is distinct from their role in other types of risk/reward decision making.

Title: Increased corticotropin releasing factor signaling increases ventral tegmental area dopamine neuron activity

Authors: *C. A. BRYCE[1], M. TSE[2], S. B. FLORESCO[2];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychology, Univ. British Columbia, Vancouver, BC, Canada

Abstract: The neuropeptide corticotropin-releasing factor (CRF) is increased following episodes of acute stress and in patients with stress-related disorders, such as depression. Both stress and CRF alter motivational and effort-related decision making functions mediated by dopamine (DA)

function, which may be mediated by CRF-induced alterations in DA neural activity. However CRF/DA interactions are complex, with *in vitro* experiments reveal that CRF can increase or decrease excitatory and/or inhibitory transmission on DA neurons in the ventral tegmental area (VTA). Intracerebroventrical (ICV) CRF antagonism increases VTA DA neuron population activity, suggesting that CRF tonically inhibits spontaneous DA activity. However, intra-VTA CRF infusion reduces afferent input from the pedunculopontine tegmentum (PPTg), reducing motivation by blunting phasic DA release to reward. On the other hand, both ICV CRF and nucleus accumbens D_2 receptor stimulation reduce choice of larger rewards associated with greater effort costs (Bryce and Floresco, 2016, 2019), suggesting that increased central CRF reduces motivation by increasing mesoaccumbens DA release. Given these complex findings, we sought to clarify how excessive central CRF affects activity of VTA DA neuron physiology *in vivo*. Male rats received behaviorally-relevant doses of vehicle or CRF (1-3υg, ICV). Recording electrodes were lowered in the VTA to measure DA and GABA neuron activity, assessing overall population activity, basal firing rate, and burst firing. Both doses of CRF increased VTA DA and GABA firing rates, and 3υg CRF increased population activity, with no effects on burst firing. Together these findings suggest that excessive central CRF signaling increases tonic, but not phasic, DA neuron activity, serving to potentiate mesocorticolimbic DA release. Future experiments will investigate how excessive central CRF signaling alters afferent input to the VTA from the PPTg and prefrontal cortex. Understanding how CRF interacts with VTA DA signaling will help us elucidate how CRF hyperactivity may underlie symptom clusters common to various stress-related disorders characterized by altered DA function, such as depression.

Title: Oscillatory phase-locking within the primate anterior cingulate gyrus and basolateral amygdala in social decision-making

Authors: *C. C. J. CHU, O. DAL MONTE, N. A. FAGAN, S. W. CHANG;
Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: In social decision-making, different decisions linked to preference and agency need to be accurately differentiated. Currently, we understand little about the neural mechanisms underlying this process. Although we are beginning to comprehend fundamental spike-based codes used by multiple brain areas in social decision-making, our knowledge on other neural mechanisms is lacking. Phase-locking of local field potential activity (LFP) has been found to facilitate various cognitive functions. Oscillatory properties of LFP may become entrained to a particular stimulus or behavioral event and may help reset the communication between different frequency channels to enhance signal processing (e.g.,. see Taub, Perets, Kahana, Paz, 2018 for phase-locking in the anterior cingulate cortex with the amygdala spiking activity in theta frequency during conditional learning). It remains unknown whether LFP phase-locking is also implicated in social decision-making. Here, we investigated this question by examining LFP signals within the rostral ACC gyrus (ACCg) and the basolateral amygdala (BLA) during a social reward allocation task involving pairs of rhesus macaques. Behaviorally, actor monkeys preferred to deliver a juice reward to a conspecific (*Other*) over a juice collection bottle (*Bottle*), displaying a prosocial decision preference, but preferred to consume a juice reward alone (*Self*) over simultaneously with the conspecific (*Both*), displaying an antisocial decision preference. During these behaviors, we examined phase-locking of LFPs across trials within ACCg and BLA by computing the mean resultant vector length. We observed two types of phase-locking differences in the LFPs encompassing theta (4-8Hz) and beta (15-25) ranges. First, both ACCg and BLA exhibited more sustained phase-locking for choosing an option resulting in actor's received juice reward (*Self* or *Both*) compared to choosing an option resulting in no juice reward to the actors (*Other* or *Bottle*). Second, in ACCg, phase-locking patterns were further differentiated between *Other* and *Bottle* choices such that the phase-locking for *Other* emerged earlier prior to the time of decision and was more temporally widespread. These results suggest that phase-locking in both ACCg and BLA may differentiate one's received and forgone rewards during social decision-making. Moreover, phase-locking in ACCg may be further used to distinguish between prosocial and antisocial decisions. LFP phase-locking in these brain areas may thus contribute to social decision-making by selectively promoting neural communications among different choices.

Title: Exploring shared neural codes across social gaze and reward value in the primate brain

Authors: *O. DAL MONTE, S. FAN, N. FAGAN, C. C. J. CHU, S. W. CHANG;
Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: Social gaze interaction plays a dominant role in communicating information between individuals both in human and non-human primates. When we direct our attention to someone's eyes, for example, this decision is likely driven by the value associated with acquiring information from the eyes. However, it remains unclear whether neural codes used during social gaze interaction and non-social reward valuation are linked in any way within overlapping neurons in the primate brain. Previous single-neuron recording studies have found that neurons from several cortical and subcortical regions encode juice reward value as well as social value derived from various social information and social contexts (Azzi et al., 2012; Watson et al., 2012; Chang et al., 2013; Klein et al., 2013; Báez-Mendoza et al., 2013; Noritake et al., 2018). Particularly strong evidence for such relations came from the primate amygdala where identical subsets of neurons are found to encode juice value as well as social value such as conspecific's social status (Munuera et al., 2018). Here, we extend this line of work by examining neural codes used between social gaze interaction and non-social reward valuation in three distinct prefrontal areas and the amygdala. Across spontaneous social gaze interaction between pairs of macaques (Dal Monte et al., 2016, 2017) and non-social reward value association task, single-unit activity was recorded from a large number of neurons in the basolateral amygdala (BLA, n=564) and medial and orbital prefrontal structures - the rostral anterior cingulate gyrus (ACCg, n=249), the dorsomedial prefrontal cortex (dmPFC, n=236), and the orbitofrontal cortex (OFC, n=244). Based on a linear decoding analysis, neurons in all these areas discriminated juice value (small vs. large size) and social gaze region (e.g., eyes vs. non-eye region of the face) above chance. Upon applying cross-decoding analyses to directly test if overlapping neurons use generalizable neural codes for differentiating social gaze variables and juice reward value, we found that this generalizability depends on brain regions and specific social gaze variables. Overall, our findings indicate that reward valuation mechanism might be shared with computing social gaze variables in some but not all areas where reward value and social gaze signals are encountered.

Title: Neuronal coordination across primate prefrontal regions and the amygdala in spontaneous social gaze interaction

Authors: *S. FAN, O. DAL MONTE, N. A. FAGAN, C. C. J. CHU, S. W. CHANG;
Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: In primates, social gaze interaction serves an important function in communicating social information. Electrophysiological recording studies in non-human primates and neuroimaging studies in humans have shown that regions in the prefrontal cortex, the superior temporal sulcus, as well as the amygdala are implicated in social gaze processing. Yet, how different brain regions coordinate their neuronal activity during social gaze interaction remains elusive. We recorded single-unit and local field potential (LFP) activity from a large number of cells in three prefrontal regions—the rostral anterior cingulate gyrus (ACCg, n=249), orbitofrontal cortex (OFC, n=244), and dorsomedial prefrontal cortex (dmPFC, n=236)—and the basolateral amygdala (BLA, n=564) to examine the coordination of spiking and LFP between BLA and each of these prefrontal areas while pairs of rhesus macaques spontaneously interacted using gaze. We observed distinct spike-field coherence patterns across these three pairs of regions with respect to looking at the eyes of a conspecific compared to a non-social object. These coherence patterns were also frequency-specific depending on the spike contributor in a given pair. Specifically, spikes from BLA cells and LFP activity from ACCg (BLA[spikes]-ACCg[field]) showed enhanced synchrony in the beta frequency range (15-25Hz) immediately after looking at the eyes compared to an object. By contrast, ACCg[spikes]-BLA[field] coherence was enhanced in the gamma frequency band (45-70Hz) for the same comparison. Intriguingly, we recently observed enhanced spike-field coordination in the same two frequency bands across ACCg and BLA when monkeys expressed prosocial decision preference compared to antisocial decision preference in a social decision-making task (Dal Monte et al, 2019, BioRxiv). Moreover, while ACCg[spikes]-BLA[field] coherence was increased around and after looking at the eyes relative to an object in the gamma band, dmPFC[spikes]-BLA[field] coherence was enhanced mostly prior to looking at eyes in the gamma band, suggesting a possible role of dmPFC[spikes]-BLA[field] synchrony in social gaze planning. By contrast, we did not observe consistent coordination across OFC and BLA in either frequency band. These results demonstrate that social gaze is facilitated by specialized coordination of spiking and LFP activity in the primate prefrontal-amygdala network. Finally, the shared frequency channels utilized across ACCg and BLA between social gaze interaction and social decision-making imply that these coordination dynamics may be generalized across distinct social behaviors.

Title: Enriched environment restores cognition and reverses aging-associated transcriptional changes in the hippocampus of old c57bl/6 mice

Authors: *C. FRAHM[1], M. GÜNTHER[1], S. SCHMIDT[1], C. KALETA[2], O. W. WITTE[1]; [1]Hans Berger Dept. of Neurol., Univ. Hosp. Jena, Jena, Germany; [2]Inst. of Exptl. Medicine, Res. Group Med. Systems Biol., Christian-Albrechts-University Kiel (UKSH Campus), Kiel, Germany

Abstract: BACKGROUND: The decline of cognitive functions is currently among the greatest health threats of old age. Therefore, measures to maintain cognitive ability and prevent dementia are of substantial importance. An active lifestyle with social interactions and physical activity - even when initiated at old age - can increase brain plasticity and improve cognition. However, the underlying mechanisms are still largely unknown, so that targeted therapies are not available yet. Here we examined to what extent exposure of old mice to an enriched environment (EE) promotes cognition and whether aging-associated transcriptional changes in the hippocampus can be slowed or even reversed. METHODS: Mice at the age of 22 months were transferred to an EE. In parallel, a group of old mice was maintained in standard conditions. After 2 months mice were subjected to the Barnes Maze Test or the hippocampus was isolated for RNAseq. Differentially expressed genes were identified using DESeq and edgeR from the R package. In parallel, we assessed changes in the activity of individual molecular processes through mapping of gene expression data onto processes annotated in Gene Ontology and determining differentially active processes directly. RESULTS: After 2 months of EE, 24-month-old mice exhibited an improved cognition which was undistinguishable from that of five months old controls. On the transcript level, we identified 503 significantly age-regulated genes (DEGs, 24 vs. 5 months) and 551 DEGs in response to EE in 24-month-old mice compared to 24-month-old controls. 124 differentially expressed genes overlapped between aging and in response to EE. Genes induced during aging were down-regulated by EE and vice versa suggesting that EE led to a reversal of age-related changes on the molecular level. Similar changes could be observed on process level. We identified 851 processes that showed significant changes in activity with aging while 332 processes changed activity in response to EE. Of the 32 commonly regulated processes between aging and EE, 13 processes changed activity in the same direction while 19 showed opposing directions of regulation between aging and EE. CONCLUSION: An

intervention in the form of an EE with already aged mice improves cognition and leads to a reversal or slowing down of aging-associated transcriptional changes in the hippocampus on gene and functional Level.

Abstract: Alterations in glucose and energy metabolism have been associated with normal aging and the etiology of neurodegenerative diseases. Extracellular lactate, shuttled from astrocytes to neurons, has been shown to support spatial working memory in the hippocampus. Past studies have shown that glucose levels are diminished in the hippocampus in response to memory loads while lactate levels are increased. Additionally, inhibition of astrocytic glycogenolysis, which leads to lactate production, within the hippocampus has been associated with impaired performance on tasks of spatial memory. According to the multiple memory system theory, the striatum and the hippocampus have been shown to mediate dissociable types of learning. Response learning is correlated with physiological measures of activity in the striatum and place learning is correlated with physiological activation of the hippocampus. Additionally, prior research has suggested response learning improves with age while place learning declines. In the

current experiment, sensitive bioprobes (Pinnacle Technology) were used to measure extracellular brain lactate levels in the dorsolateral striatum or the dorsal hippocampus of young (age 3 months, n=15) or aged (age 24 months, n=11) male Fischer 344 rats in 1-sec intervals during spontaneous alternation, place learning, and response learning. Our prior data found lactate levels during learning and memory tasks were lower in aged rats compared to young rats. In this study, we explored the changes in lactate associated with discrete behaviors within the tasks. We observed brain region differences in extracellular lactate levels between old and young rats at the point of arm entries in the tasks. Increasing cognitive demands are correlated with greater declines in extracellular lactate in the hippocampus of young animals but not aged animals. Notably, we observed decreases in extracellular lactate levels in the striatum of aged rats after arm entries during tasks of spatial working memory and spatial learning, which are traditionally associated with the hippocampus. Our findings thus fit with the previous literature suggesting a shift in engagement and activity from the hippocampus to the striatum with age.

Title: Retinoic acid signalling differences in the hippocampus of aged rats with and without memory impairment

Authors: *M. U. WOLOSZYNOWSKA-FRASER[1], S. L. ROSSI[1], J. M. LONG[1], P. J. MCCAFFERY[2], P. R. RAPP[1];

Abstract: Retinoic acid (RA), a metabolite of vitamin A (retinol), has many key physiological functions, including roles in neuronal plasticity and homeostatic synaptic scaling in the hippocampus. Through binding to its receptor (RARα) and increasing dendritic synthesis of ionotropic glutamate receptors (GluR1), RA modulates synaptic efficacy in response to learning-induced changes. Retinol deficiency during adolescence causes memory impairments, and vitamin A supplementation can reverse these deficits. Although recent studies have expanded the understanding of RA function in memory processes, its role in neurocognitive aging has received

limited attention. Therefore, we asked if changes in RA signalling contributes to neurocognitive aging. Emphasising hippocampal dependent spatial memory, we used a well-established Morris water maze protocol and 24 male Long-Evans rats were characterized according to age and cognitive status, as either young (Y), aged unimpaired (AU) or aged impaired (AI). We measured serum levels of retinol binding protein (RBP4) and hippocampal protein levels of RA synthesizing (RALDH1; RALDH3) and catabolizing (CYP26A1; CYP26B1) enzymes. Additionally, RARα and GluR1 levels were measured in whole hippocampus lysates. We found significantly lower serum RBP4 in AU animals and decreased hippocampal protein expression of RALDH1 in aged rats, relative to Y ($p<0.05$), consistent with reports of decreased RA metabolism with age. However, serum RBP4, and protein expression of CYP26B1, and GluR1 in the whole hippocampus lysates were significantly increased in AI animals when compared with AU rats ($p<0.05$). Moreover, RARα expression was significantly increased in AI animals compared to Y ($p<0.05$). RALDH3 and CYP26A1 levels were unchanged. These results are indicative of increased RA metabolism in impaired aged rats, and overall, that altered hippocampal RA signalling is positioned to influence individual differences in the cognitive outcome of aging. Ultimately, our aim is to test whether exogenous manipulation of RA signalling in the hippocampus (stimulation or inhibition) affects the neurocognitive impairment in aging.

Abstract: Recent experiments have shown that sexual interactions can induce neurogenesis, particularly in the hippocampus, and thus enhance the memory process. Some studies suggest that sexual interactions prevented a reduction in neurogenesis caused by exposure to chronic stress. Also, sexual activity enhanced the expression of BDNF, TrkB and CREB in the adult hippocampus (Kim, 2013). On the other hand, in both humans and rodents, aging is associated with decreased memory and neurogenesis in the hippocampus. We hypothesized that adult-male rats with sexual interaction will show higher memory retention compared to control groups. Thus, the aim of the present study is to determine if sexual interaction facilitates the consolidation of memory in young and adult male rats. We used young (12 weeks of age) and adult (36 weeks of age) male Wistar rats. Experimental groups (young and adult) were exposed to sexual interaction with receptive females for four trials (each session for 30 min) to gain sexual experience, while control groups were kept undisturbed in their home cage. Once sexual interaction was concluded, rats were trained in an inhibitory avoidance task using a foot-shock of 0.6 mA. Results show that, compared to control groups, those exposed to sexual interaction enhanced consolidation of memory. Also, adult sexual interaction groups showed better retention in the memory task when compared to young sexual interaction groups. Overall, these results indicate that sexual interaction can revert the effects of aging, such as cognitive decline.

Title: Age-dependent changes in innate neuroimmunity affect hippocampal function

Authors: A. F. SMITH[1], A. ROT[2], *M. A. WHITTINGTON[1];
[1]hyms, Univ. of York, York, United Kingdom; [2]The William Harvey Res. Inst., Barts and The London, London, United Kingdom

Abstract: It is increasingly evident that the brain’s immune system is essential for normal cognitive function. When activated to excess, immune modulators are linked to pathology in

neurodegenerative disorders[1,2]. However, we know little of how baseline levels of these immune modulators shape normal neuronal function, nor how changes in neuroimmunity with age[3] relate to cognitive decline with normal senescence. Here we examine the effects of a subset of chemokine neuroimmune mediators on the activity of the hippocampus.
We took local field potential (LFP) recordings from subregions of hippocampal slices maintained *in vitro* following entorhinal cortex stimulation. Slices were prepared from mice at two age-points: Young adult (9-15 weeks old) and middle aged (25-35 weeks old). 3 genetic backgrounds were used: Wild-type controls (WT); mice lacking the chemokine receptor CCR5 ($CCR5^{-/-}$); mice lacking the atypical chemokine receptor ACKR1 ($ACKR1^{-/-}$). Enhanced chemokine signalling associated with neuroinflammation was, in part, modelled by bath application of the chemokine receptor ligand CCL5.
Slices from WT and $CCR5^{-/-}$ showed increased mean LFP response magnitude (area under stimulus-response curve) with age (WT young 13.8±1.9 vs aged WT 29.0±6.6, $P \leq 0.03$, and $CCR5^{-/-}$ young 12.2±4.7 vs aged $CCR5^{-/-}$ 31.0±6.2, $P \leq 0.03$) in dentate gyrus (DG, the main input subregion of the hippocampus) but not downstream area CA3. In contrast, slices from $ACKR1^{-/-}$ mice showed a decrease in mean LFP magnitude in the s*uprapyramidal* subregion of dentate gyrus (WT 1.1±0.5 vs $ACKR1^{-/-}$ -0.5±0.2, $P \leq 0.006$ and $ACKR1^{-/-}$ vs $CCR5^{-/-}$ 1.5±0.5, $P \leq 0.003$). This change was not affected by elevated CCL5 chemokine levels (10µg/ml) in young or older WT mice.
The data indicated a subregion-specific role for chemokine signalling for both age-related changes in DG function, and response to chemokine level increases associated with neuroinflammation. In both cases the age-related effects were profoundly altered in the absence of ACKR1, suggesting that changes in ACKR1-dependent chemokine signalling may play a pivotal role in normal cognitive decline and elevated susceptibility to neuroinflammation in senescence.

Title: Effects of age, diet and histone deacetylase inhibition on hippocampal memories

Authors: *G. GUILLAZO-BLANCH, A. VALE-MARTÍNEZ, M. PORTERO-TRESSERRA, M. MARTÍ-NICOLOVIUS;
Psychobiology and Methodology, Neurosci. Inst., Univ. Autónoma de Barcelona, Barcelona, Spain

Abstract: Variability in the trajectory of cognitive aging is due to genetic and environmental factors that affect our susceptibility or resilience to aging effects. Age-related cognitive decline correlates with decreased expression of hippocampal genes linked to synaptic plasticity and altered expression of immediate early genes. These transcription-signaling pathways interact with epigenetic mechanisms that may be modulated by environmental factors such as diet. For instance, a caloric restriction (CR) diet increases neurogenesis, improves memory, and protects from age-associated neurological disorders. The anti-aging value of CR has been proposed to act on epigenetic mechanisms, being histone acetylation and deacetylation two of the main players in these mechanisms. Since changes in histone acetylation have been linked to age-associated hippocampal memory decline, a recovery of their activity through histone deacetylase inhibitors -such as sodium butyrate (NaBu)- might delay the age-related hippocampal dysfunction. We assessed adult (3-month-old) and aged (24-month-old) male Wistar rats, with the goal to study the effects of both a life-long CR diet (25-30% of food intake reduction from 4-months-old) and administration of NaBu (1.2gr/Kg). The effects of both treatments were evaluated on two hippocampal-dependent learning tasks, the Morris water maze (MWM) and the object recognition task (ORT). The MWM task consisted of four daily acquisition trials for five days and a memory test conducted 72 h after the last acquisition session. The ORT entailed a 10-min acquisition session and two memory tests (24h and 72h). Immediately after each MWM and ORT acquisition session, rats received an intraperitoneal injection of saline or NaBu. The results revealed that both, post-training infusions of NaBu and CR diet prevented the deleterious effects of age on hippocampal memories. Animals fed ad libitum exhibited a lower performance when compared to old animals under CR, and aged NaBu-treated rats under CR did not differ from adult rats in the performance displayed in both tasks. These results cannot be attributed to alterations in sensory discrimination or locomotor activity. Our findings suggest that modulation of epigenetic factors may be a suitable strategy for the study of the mechanisms responsible for age-related cognitive decline and provide an effective approach to test new treatments aimed to alleviate memory deficits.

Title: Neuroprotective effects of thymoquinone on the learning and memory mechanisms and hippocampal neurogenesis in aged rats

Authors: *B. ELIBOL[1], S. TERZIOGLU-USAK[1], M. BEKER[1], S. EYUBOGLU[2];

Abstract: Thymoquinone (TQ) is the main active constituent of volatile oil from *Nigella sativa* seeds which has exhibited various beneficial properties in modern pharmacology including anti-inflammatory actions, suppression of oxidative stress-induced neuropathy, and neuroprotection. In this study, we aimed to investigate the effect of TQ on hippocampal neurogenesis of aged-rats both in functional and molecular perspectives. After determining blood-brain permeability of TQ by analyzing the presence of it in BOS by HPLC, TQ (10 mg/kg and 20 mg/kg, i.p.) was given to 15-month-old aged Long-Evans rats for 15 days. At the end of 15 days, the animals were subjected to some behavioral tests in terms of cognitive functions. There was no difference in the fear-conditioned memory determined by passive avoidance and the spatial memory determined by Morris water maze. On the second day of the spatial learning test, older rats receiving TQ showed better performance than their age-matched control group. From a molecular perspective, TQ increased the oxidative stress in elderly animals. In the high dose of TQ (20 mg/kg), the amount of IFNγ increased with no change in the levels of Ilα, Ilβ, and TNFα. However, low dose TQ decreased IFNγ level in the old animals. In parallel, an increase in the level of CORT and ACTH, which are stress indicators, was also detected. While there was no significant change in the level of DCX in old animals, it has been found that the expression of some neuroprotective proteins which are also related with synaptic plasticity (Klotho, prealbumin, clic6, BDNF, GDNF and NeuN) altered in elderly animals with TQ treatment. These results show that TQ administration in the elderly increases some neuroprotective properties by increasing synaptic plasticity, even if it made animals more stressed.

Title: Role of prefrontal-hippocampal interactions in age-related deficits in spatial working memory

Authors: *S. V. SRIVATHSA[1,2], S. O. KHATTAB[1,2], A. W. LESTER[1,2], C. A. BARNES[1,2,3]; [1]Evelyn F. McKnight Brain Inst., [2]Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Neural ensembles in hippocampus and mPFC play a crucial role in memory-guided navigation and decision making, a process susceptible to decline with age in mammals. These regions are connected via a unidirectional projection from the ventral hippocampus to the mPFC and damage or inhibition of this circuit leads to impairments in spatial alternation tasks (Wang et al, 2006). Rats with mPFC lesions show an impairment on spatial working memory tasks (Kim et al., 2009). On the other hand, rats with hippocampal lesions are impaired in both the spatial localization and spatial working memory components (Sapiurka et al., 2016). One task that was developed to test the interactions between these regions is a continuous spatial alternation task (Frank et al., 2000), which consists of two interleaved components: an "outbound" component (working memory) and an "inbound" component (spatial memory). Behavioral data from young (9-15 mo) and old (23-30 mo) rats tested on this task reveals that aged rats are slower in learning the inbound component and are unable to learn the outbound component (Kapellusch et al., 2018). The outbound component of the task requires coordination between the hippocampus and mPFC, suggesting that these interactions are impaired in aged rats. Here, we report data from an ongoing experiment studying the age-associated changes in the hippocampal-mPFC circuit that underlie the behavioral decline in spatial alternation in aged rats through simultaneous electrophysiological recordings in the ventral CA1 region of the hippocampus and in the dorsal ACC region of the mPFC. As disruption of hippocampal SWRs during awake rest leads to impairment of working memory performance (Jadhav et al., 2012) and CA1-mPFC synchronization is stronger during awake SWRs and enhanced in early stages of learning (Tang et al., 2017), several predictions of impact of age on these circuits can be offered. First, there may be a decrease in the synchronization between CA1 and mPFC unit activity during behavior in aged rats compared to young rats. This is likely to show a strong correlation with the age-related impairments in learning the outbound component. Second, since co-occurrence of hippocampal SWRs and spindles in the mPFC during sleep has been implicated in memory consolidation (Maingret et al., 2016), examining this relationship may provide insights into changes in memory consolidation with age. Furthermore, as increased coupling of the hippocampus and mPFC to the theta and gamma bands is correlated with spatial working memory (Jones et al., 2005; Tamura et al., 2017), we will study the disparities in this coupling during the working memory epochs of the task, between the age groups.

Title: Spatial eye-blink learning but not age predicts theta-gamma coupling in the CA1 region of the hippocampus

Authors: *L. CROWN[1,2,3], D. T. GRAY[2,3], L. A. SCHIMANSKI[6], C. A. BARNES[2,3,4], S. L. COWEN[5,2,3];
[1]Dept. of Psychology, Univ. Of Arizona, Tucson, AZ; [2]Evelyn F. McKnight Brain Inst., [3]Div. of Neural Systems, Memory and Aging, [4]Departments of Psychology, Neurol. and Neurosci., [5]Dept. of Psychology, Univ. of Arizona, Tucson, AZ; [6]Psychology, Simon Fraser Univ., Burnaby, BC, Canada

Abstract: Cross-frequency coupling (CFC) between theta- and gamma-band activity in the hippocampus has been linked to memory encoding and retrieval. Recent data suggest that the frequency of the gamma-band component of theta-gamma CFC differs as the relative contribution of entorhinal or hippocampal CA3 drive to mnemonic circuits within CA1 changes. While there are differing interpretations with respect to the generation of low gamma (25 - 50 Hz), one hypothesis is that it reflects drive from CA3 to CA1 while high gamma (75 - 90 Hz) denotes drive from medial entorhinal cortex (MEC) to CA1 (Colgin et al., 2009). Little is known about how activity in these frequency bands and their coupling changes with age; however, there are fewer functional Schaffer collateral synapses onto CA1 pyramidal cells and CA3 pyramidal cells show increased excitability. Given such alterations in these network properties, we hypothesized that high-gamma CFC associated with entorhinal input would be greater in aged animals. To examine this question, local field potential activity of 12 rats (n = 6 young, 9-12 mo, n = 6 old, 25-28 mo) was analyzed as they performed a spatial eye-blink conditioning task (Schimanski et al., 2013). We measured low-gamma power, high-gamma power, and theta-gamma phase-amplitude coupling (PAC) as animals approached and departed from the region of the maze associated with a brief eyelid stimulation. We observed no difference between young and old animals in 1) peak gamma frequency, 2) in CFC, or 3) the ratio of low- to high-gamma power. Interestingly, we observed that animals that did not develop reliable eye blink conditioning (n = 5), regardless of their age, showed greater low-gamma relative to high-gamma power than those (n = 7) that did consistently show conditioning (two-sample t-test, p = 0.01). This effect was apparent after 5 days of training, suggesting that eye blink training altered the

relative contribution of entorhinal drive to CA1. In addition, low-gamma PAC, but not high-gamma PAC, recorded as animals approached the eye-shock zone, was positively correlated with eye-blink learning in those animals that learned the task (one-sample t-test, $p < 0.01$), but not in animals that did not display learning, regardless of age. Taken together, these results suggest that age is a less important predictor of CA1 theta/gamma dynamics than is performance.

Title: Quantification of neuronal and astrocytic cells in the locus coeruleus of cognitively assessed, young and aged nonhuman primates

Authors: *W. PYON[1,2], D. T. GRAY[1,2], W. SCHNAPP[1], R. SCHWYHART[1,2], S. KHATTAB[1,2], N. M. DE LA PENA[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: The locus coeruleus is a small brainstem nucleus that is known for its role in supplying noradrenaline to various regions in the brain. The locus coeruleus is especially susceptible to age-related neurodegeneration and is one of the first regions to display Alzheimer's and Parkinson's pathologies (Mather and Harley, 2016), in part due to its high bioenergetic need. Whether differences in number of tyrosine hydroxylase (TH)-expressing neurons significantly contribute to age-related cognitive decline remains less clear. To investigate this, coronal brainstem sections from cognitively assessed rhesus macaques (N = 3 aged, mean 28 years; N = 3 adult, mean 11 years) were immunohistochemically labelled to visualize neuronal nuclei (NeuN), catecholaminergic neurons (TH), astrocytes (glial fibrillary acidic protein - GFAP) and vasculature (Solanum tuberosum lectin - STL). For this study, unbiased stereological techniques are used to quantify neuronal numbers. Astrocyte and vascular characteristics are also investigated. The preliminary results suggest a trend towards lower TH neuron density within the locus coeruleus of aged monkeys. There was also a trend for a

relationship between higher TH density and better object recognition memory (delayed nonmatching-to-sample) performance. This trend was not observed with performance on spatial short-term memory (delayed response) or object discrimination tasks. We are currently examining whether the volume of vasculature within the sampled region, or if properties of astrocytes within the region differ with age. Additionally, we are expanding the number of animals, assessing other neuronal cell types, and evaluating stereological estimates of volume to more thoroughly characterize age-related changes in the locus coeruleus.

Title: Perineuronal nets in the cerebral cortex of cognitively-assessed aged macaque monkeys

Authors: *D. T. GRAY[1,2], W. PYON[1,2], N. M. DE LA PENA[1,2], R. SCHWYHART[2,1], E. WALLACE[1,2], J. PUCHTA[4], W. HARTIG[4], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ; [4]Paul Flechsig Inst. for Brain Res., Univ. of Leipzig, Leipzig, Germany

Abstract: Perineuronal nets (PNNs) are specialized extracellular matrix structures that envelop specific neurons in the central nervous system and play critical roles in controlling plasticity and maintaining synaptic function (Sorg et al., 2016, J Neurosci). Alterations in the expression of different components of the extracellular matrix have been shown to occur in normative brain aging, as well as in several nervous system disorders. No studies have investigated PNNs across the lifespan of behaviorally characterized, aged nonhuman primates. Furthermore, the impact that potentially altered PNNs have on the manifestation of different aspects of age-associated cognitive decline is not clear. To these ends, the present study used fluorescence labeling and unbiased quantification of perineuronal net markers [Wisteria floribunda agglutinin (WFA) and the chondroitin sulfate proteoglycan aggrecan] on the brains from a colony of 30 rhesus macaque monkeys ranging in age from 7 to 32 years. All of these monkeys also underwent tests of spatial

short-term memory (delayed response), object recognition memory (delayed nonmatching-to-sample), and object discrimination, which allowed relationships between PNNs and cognition to be investigated. While there are interesting trends with respect to age, PNNs and parvalbumin (PV)-immunoreactive neurons, our preliminary results (N = 3 aged, mean 28 years; N = 3 adult, mean 11 years) suggest no age effect. The data do suggest that the strongest associations are found between the proportion of PV-immunopositive neurons with nets and behavior. Specifically, animals with more perineuronal nets surrounding PV-immunoreactive neurons tended to show worse behavior on all of our cognitive tasks. Furthermore, animals that exhibited fewer PNNs associated with PV-immunopositive cells tended to show better behavioral performance on our tasks. We are currently expanding the sample size, PNN markers, and the brain regions analyzed to more thoroughly characterize these nets across aging.

Abstract: 3D histology reconstruction brings cellular-level detail to 3D facilitating the ease of data analysis and enabling use of open-format brain atlases. These atlases facilitate automatic segmentation, 3D morphological analysis, and promote sharing across laboratories. Recently, a number of novel methods have been created to estimate the required spatial transformations that bring sections of histology into alignment with a 3D template without intermediate imaging steps such as block-face imaging. Although each section of tissue typically undergoes non-rigid

transformation when it is mounted, to date, no direct-to-template method has accounted for non-rigid terms during the optimization process. Instead, non-rigid transformations of each section of histology are estimated during a post-processing step after the sections have been localized to a specific plane of the template. Recently, we developed an artificial neural network-based 3D reconstruction method that utilizes "spatial transformer networks" to estimate non-rigid transformations thousands of times faster than traditional registration algorithms. The increase in computational speed allows us to include non-rigid transformations throughout the optimization process. Here, we compare a version of our method that uses rigid warps to the histology sections during optimization followed be a non-rigid post-processing step, to a version that includes non-rigid estimation throughout the optimization. We show that inclusion of the non-rigid estimation increases reconstruction accuracy as measured by target-registration error (TRE). Using the rigid version, we calculated a TRE of 1.7594 ± 1.3797 pixels (1.0996 ± 0.8623 mm), while using the non-rigid version we calculated a TRE of 2.1929 ± 1.6257 pixels (1.3706 ± 1.0161 mm). A paired t-test revealed that the rigid version had significantly higher TRE ($t(12) = 2.6879$ $p = 0.0197$) indicating lower (less accurate) reconstruction accuracy. Additionally, the non-rigid version of our algorithms produces the lowest TRE of any 3D histology reconstruction method that we are aware of, including block-face methods that utilize intermediate imaging to simplify 3D histology reconstruction. Thus, we show that direct-to-template methods are competitive with block-face methods without the added expense and effort involved in collecting and processing block-face images.

Abstract: Hypertension is associated with an increased risk of cardiovascular disease (CVD) and cognitive decline in aging humans (Keenan et al., 2011) with the onset occurring around middle-age (Wilkie et al., 1971). While prior research has suggested an association between CVD and cognitive decline in the elderly (Haring et al., 2013), it is also critical to investigate how this dynamic may evolve from middle to older age. In this study, Cyp1a1-Ren2 xenobiotic-inducible transgenic rats were used to model the gradual rate and age-of-onset observed in humans. In these transgenic rats, Ren2 expression in the kidney is driven by the Cyp1a1 promoter, which is activated by ingestion of indole-3-carbinol (I3C), causing elevated kidney angiotensin levels, increased arterial pressure, and reduced renal hemodynamics (Mitchell et al., 2006). Fifteen month old male rats were assigned to either control or treatment diet groups, and given a battery of behavior tests to establish baseline cognition measures. Following these tests the treatment group received a diet with 0.015% I3C while control rats received a global 18% protein rodent diet. Post-treatment, the same behavioral battery was given to assess the effect of hypertension on cognition. Gradual onset of hypertension was confirmed through systolic and diastolic blood pressure changes. Postmortem heart and kidney analysis replicated and expanded on recent studies (Willeman et al., 2019). The behavioral battery includes spatial and cued versions of the Morris watermaze, spontaneous object recognition (SOR) and a delayed matching- to-place working memory task. Analysis of the hippocampal-dependent spatial watermaze, the perirhinal cortex-dependent SOR, and the prefrontal cortex-dependent working memory task, suggest that these hypertensive rats maintain high performance levels on each behavioral task. While the treated group in this study did show significant cardiac and renal end organ damage as in the Willeman et al. (2019) study, we did not replicate the impairment observed in spatial memory in this larger cohort. Further studies, including those that assess vascular damage in relevant brain regions, are needed to determine if the molecular and cellular changes observed in these animals are similar to those seen in the peripheral vasculature. For example, the persistence of normal cognition after hypertension may be due to compensatory mechanisms such as local modulation of vascular tone and arteriole diameter by neurons and glial cells.

Title: Effects of NPTX2 knockout on behavior, brain volume by MRI and CA1 hippocampal single unit properties

Authors: *A. TERRAZAS[1,2], W. PYON[1,2], M. ZEMPARE[1,2], K. F. YOUNG[1,2], A. DALMENDRAY[1,2], L. DO[3], B. DAVID[1,2], K. M. BOHNE[1,2], N. J. CAREY[1,2], M. K. CHAWLA[1,2], T. P. TROUARD[1,3], J. ZHOU[5], P. F. WORLEY[5], C. A. BARNES[1,2,4];

Abstract: Long-term memory is dependent on rapid, de novo protein synthesis, and we have studied immediate early genes (IEG) that act at excitatory synapses to understand the molecular basis of memory. IEGs Arc, Homer1a, and NPTX2 each play a unique and essential role in homeostatic restoration of activity levels of pyramidal neuron-inhibitory interneuron circuits in culture (1) (2) (3). Here, we examine NPTX2, which is induced by patterned activity that induces synaptic plasticity (4), is trafficked along axons, secreted from presynaptic elements, and selectively accumulates at excitatory synapses on PV-interneurons (3). This synaptic NPTX2 binds postsynaptic AMPAR (GluA1 and GluA4) and strengthens excitatory drive of PV-interneurons. Sprague Dawley CRISPR-Cas9 NPTX2 knockout (KO) rats were compared to their wildtype (WT) littermates on 1) a battery of behavioral tasks (spatial and working memory on the watermaze, spontaneous object recognition memory and a test of anxiety), 2) MRI brain regional volumetric analysis, and 3) multiple single unit electrophysiological recordings in area CA1 of the hippocampus while rats traversed a 65 cm track for reward. The NPTX2 KO (n=7) rats exhibited similar performance to WT rats (n=5) on these tasks. Furthermore, regional brain volumes were not significantly different between KO and WT rats. Place-specific firing of CA1 single units, however, was strikingly different between groups. Compared to WT rats (n=2), KO rats (n=3) (8 to 15 mo) exhibited significantly lower spatial information content per spike and information per second (for KO and WT respectively, number of single units =142 and 63, mean information per spike +/- std = 0.66 +/- 0.52 and 1.10 +/- 0.72, $t=-4.30$, $p<0.0005$; mean information per second = 0.59 +/- .79 and 1.06 +/- 0.93, $t=-3.48$, $p< 0.005$.) Firing rates of pyramidal cells were assessed while rats were on the maze and during pre- and post-maze sleep periods. There was a trend for the firing rates of hippocampal place cells to be higher in KO rats for all behavioral conditions, and this reached statistical significance in post-behavior sleep sessions (mean rate in Hz 0.84 +/- 1.14 compared to 0.54 +/- 0.60 for WT, $t=2.40$, $p<0.05$). Surprisingly, the reduction of information content and spatial tuning of place cells is not manifest as deficits in the standard behavioral tasks used. NPTX2 is required for developmental plasticity in the visual cortex to refine tuning properties of excitatory neurons (5), and a similar role in the hippocampus might create circuits capable of optimal information processing. In fact it is possible that, during development, NPTX2 sets the spatial tuning parameter space for hippocampal networks.

Title: Age-related, specific changes in expression of several central melanocortin receptor subtypes in the rat

Authors: *M. K. CHAWLA[1,2], M. ZEMPARE[1,2], V. HRUBY[3], C. A. BARNES[1,2,4], M. CAI[3]; [1]Evelyn F. McKnight Brain Inst., [2]Div. of Neural Systems, Memory and Aging, [3]Dept. of Chem. & Biochem., [4]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: The five melanocortin receptors cloned so far (MCR1-5) have been associated with control of inflammatory disorders, immunomodulation, antipyretic effect and prevention of brainstem ischemia and reperfusion injury (Schimolli et al. 2009). It has been reported that the human melanocortin 4 receptor (hMC4R) is involved in neurodegenerative disease (Shen et al., 2016). Melanotropins may protect against the progression of Alzheimer's disease (Giuliani et al., 2014). Furthermore, administration of α-MSH or its more stable analog [Nle4,D-Phe7]-α-MSH (NDP-α-MSH) has been observed to enhance learning and memory (Beckwith, et al. 1975). However, the impact of age with respect to melancortin receptor expression remains unexplored. Previously we have shown that the total expression of melanocortin receptor is reduced in the aged rats in four of the six brain regions studied. In the present study, we systematically investigated the expression of 5 different subtypes of melanocortin receptors in brain of young (9 months) and aged (23 months) rats that were assessed for their cognitive status in memory tasks. Spatial memory and visual discrimination ability were assessed using the Morris watermaze task. Six regions of the brain were extracted from each animal, including the frontal cortex + anterior midbrain, parietal cortex, cerebellum, posterior midbrain, hippocampus and occipital lobe. We collected the membrane fragments from each region of all animals in each age group, then ran a specific binding assay using iodine labelled NDP-α-hMCHR1-5 on a high throughput Micro Beta II radiation counter. Six samples were measured from each animal for each region, and then averaged to produce a single count for each animal in each region. All measurements were collected in a blind fashion. We then ran a linear regression analysis with spatial learning

behavior and specific receptor binding for hMCHR1-5 receptors using Graph-pad Prizm software. A significant correlation was found between spatial memory and two receptor subtypes MCH-1R ($p = 0.048$) and MCH-3R ($p = 0.049$) in old animals. This finding potentially opens a new window of discovery for exploring and developing new treatments for cognitive changes that arise in normative aging and in neurodegenerative disease.

Title: A computational model of aged head direction network updating in the presence of sudden spatial cue mismatch

Authors: *A. W. LESTER[1,2], A. J. KAPELLUSCH[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: As with older adults, aged rats show pronounced impairments on a number of different spatial navigation tasks as well as a bias toward relying on self-motion (i.e., idiothetic) over environmental (i.e., allothetic) cue-based navigation strategies (Lester et al., 2017). Rosenzweig et al. (2003) found that, when exposed to conflicting allothetic and idiothetic feedback, aged rats were impaired in navigating to an allothetic cue-aligned goal location and the place cell networks of aged rats were delayed in realigning their firing fields to match the spatial information relayed by the allothetic cues. The Instantaneous Cue Rotation (ICR) task used here requires animals to navigate to a reward location that is always aligned to the projected visual cues in the environment (Lester et al., 2018). We previously reported that, when young and aged rats were tested on the ICR task, allothetic cues were found to exert a less pronounced influence on the running behavior of aged rats following sudden cue rotation. The overall pattern for young rats, in contrast, suggested a reliable although incomplete control by allothetic cues, which may reflect a greater tendency for young animals to resolve conflicting allothetic-idiothetic feedback by integrating information from both. A continuous attractor neural network model was created to assess how a sudden rotation of visual cues may affect the spatial tuning of head direction cell networks and how the behavior of these networks may be altered in the presence of erroneous

self-motion feedback (i.e., idiothetic error). The model incorporates a head direction (HD) and angular head velocity (AHV) network, the tuning of which depend on both angular movement and visual cue inputs. In the absence of any idiothetic error, the HD and AHV networks collectively undergo a gradual but reliable realignment of their directional firing after visual cue rotation. In contrast, the introduction of idiothetic errors either amplifies or diminishes visual cue control over HD-AHV alignment depending on the degree and direction of drift these errors induce in the network's directional firing. As a consequence, visual cues exert less reliable control over directional tuning and often lose control over the networks directional tuning following visual cue rotation. Considered in the context of known age-related changes in vestibular function as well as deficits in self-motion perception and path integration, the findings from this computational model suggest a plausible mechanism that could contribute to impaired integration of conflicting spatial signals in aged spatial networks.

Title: Rna stress granule components are dynamically expressed during aging and stress conditions in rats and fruit flies

Authors: R. ECK[1], M. K. CHAWLA[2,3], B. BAGEVALU SIDDEGOWDA[1], N. J. CAREY[2,3], M. ZEMPARE[2,3], C. NGUYEN[2,3], D. BILLHEIMER[4], *C. A. BARNES[2,3,5], D. C. ZARNESCU[6,1];

Abstract: During times of cellular insult, non-membrane bound organelles called RNA stress granules form to sequester mRNAs, translation initiation factors and proteins into dense cytoplasmic structures, halting translation. Dysfunction in the dynamic assembly and disassembly of RNA SGs has been linked mechanistically to age-related neurodegenerative

diseases. It is not known, however, how these mechanisms are affected during aging. To understand the molecular mechanisms that underly these links, we profiled the dynamic changes of RNA SGs during aging and their relationship to stress resiliency through examining the expression of genes critical to translation initiation and RNA SGs formation in behaviorally characterized young (6-10 mo, n=11), middle-aged (15-19 mo, n=11), and old rats (23-25 mo, n=13). These rats were assessed for their spatial memory, working memory, and motor function using the Morris water maze. Some of the genes profiled were G3BP1, necessary for RNA SGs formation, FMRP, a modulator of mRNA association with RNA SGs, EIF2alpha, a translation initiation factor whose phosphorylation indicates RNA SG formation, and PABP and TIAR among others. Western blots and real-time PCR found region-specific expression of these critical genes in the hippocampus, pre-frontal cortex, and cerebellum throughout aging. Using regression models, we sought to determine if these region-specific expression changes can account for variation among rats in behavioral performance, when taking age into account. We used Principle Component Analysis to determine if the variations among critical protein and transcript expression levels reveal differences or similarities between rats that relate to age or behavioral performance. The levels of key proteins and transcripts, along with other analysis trends, will be compared between young and old rats who received maximum electro-convulsive shock treatment (shock duration = 1 second, current intensity = 85mA, 1 hour recovery) and those who did not. In fruit flies, the dynamic response of RNA SGs under stress conditions appears to vary with age compared to the non-stressed control condition. Future investigation will focus on isolating RNA SGs from fruit flies to examine how components associated with RNA/protein structures change during aging and in response to multiple stress conditions.

Title: Sex differences in exercise-induced extracellular vesicle release and cognitive enhancement

Authors: *B. YEGLA[1], K. ESSER[2], T. C. FOSTER[1,3];
[1]Dept Neurosci., Evelyn F. and William L. McKnight Brain Inst. Univ. of Florida, Gainesville, FL; [2]Dept. of Physiol. and Functional Genomics, Myology Inst., Univ. of Florida, Gainesville, FL; [3]Genet. and Genomics Program, Univ. of Florida, Gainesville, FL

Abstract: Aging is characterized by a substantial loss of muscle mass and strength, which is associated with higher mortality. Exercise can not only mitigate age-related frailty and muscle weakness but also improve metabolic, cardiovascular, and cognitive function. The mechanism by which exercise exerts these effects remains to be elucidated. Thus, this study examines age- and sex-related differences in exercise-induced intercellular signaling, specifically extracellular vesicles (EV) and their miRNA content, and how this relates to changes in muscle, cognition, inflammation, and redox state in multiple organs with exercise. One cohort of young and aged (6 & 24 mo) male and female Fischer-344 rats (N=4/group) underwent treadmill running for a single bout of exercise at 70% VO_{2max} to determine maximal plasma EV release post-exercise (<15, 90, 180min after). A second cohort ran on treadmills for two months on a progressive workload schedule to elicit 70% VO_{2max}. Following exercise rats were evaluated for physical and cognitive changes compared to sedentary controls. After a final bout of exercise, rats were euthanized, and blood, muscle, liver, kidney, brain, and fat were collected to examine the impact of age, sex, and exercise on EV-derived miRNA expression, redox levels, and inflammatory markers. For the first cohort, CD-63+ EVs displayed a relative increase 90min after acute treadmill running (z-score; control: -0.24±0.22; <15min: 0.04±0.28; 90min: 0.30±0.29; 180min: -0.10±0.20). This timepoint was utilized for euthanizing the second cohort. Interestingly, young females released significantly more EVs after exercise than young and aged males (p<0.02) and aged females released more than young males (p=0.01). For behavioral measures, repeated exercise elicited sex-specific effects in open field measures ($F_{1,20}$=5.21, p=0.03), where female runners moved more than other rats (p<0.05). They also froze less during contextual fear conditioning (p<0.05) and throughout cued extinction (p<0.01) compared to controls. Exercise enhanced cognitive performance on a hippocampal task (context-object discrimination; $F_{1,19}$=4.69, p=0.04), with all runners exploring a context-incongruent object more than controls. Next-generation sequencing of EV miRNA and inflammatory quantification are currently being conducted. It is predicted that continued exercise will shift the aging secretome to resemble a younger profile. Overall, these data are the first to demonstrate a sex-specific effect of exercise on EV release and physical and cognitive measures, which may allude to differential exercise-induced EV content in males and females.

Title: Impaired pattern separation during aging is associated with altered hippocampal gene transcription

Authors: *G. SMITH[1], A. RANI[1], A. KUMAR[1], T. C. FOSTER[2];
[1]Dept. of Neuroscience, McKnight Brain Institute, Univ. of Florida, Gainesville, FL; [2]Dept. of Neuroscience, McKnight Brain Inst. and Genet. and Genomics Program, Univ. of Florida, Gainesville, FL

Abstract: Previous studies of age-related transcriptional changes indicate that cognitive impairments are associated with differentially expressed genes (DEGs) linked to defined neural systems (e.g. episodic memory-CA1, executive function-prefrontal cortex). These findings provide information on possible molecular mechanisms for age-related cognitive decline. Aging is also associated with a deficit in pattern separation (PS), the generation of distinct mnemonic representations from overlapping experiences. The dentate gyrus (DG) is implicated in PS and exhibits several age-related changes (e.g. decrease in neurogenesis, impaired synaptic plasticity, and loss of afferent input) that could impair PS performance. We hypothesize that aged animals with impaired PS ability will express a distinct transcriptional profile relative to unimpaired animals, specifically within the DG and not in other hippocampal subregions. We used a modified water maze beacon discrimination task to characterize PS in young (5 mo, n=12) and middle-age (12 mo, n=16) F344 male rats. This was followed by a reference memory task. Middle-age rats showed deficits in discriminating two identical beacons compared to young, when trials began with the rat positioned equidistant between the two beacons (p=0.005). Reference memory performance between these two age groups was not significantly different (p=0.2); however, older animals appeared to compensate for impaired for PS though greater reliance on reference memory. Following behavioral testing, mRNA sequencing was performed on hippocampal subregions DG, CA1, and CA3. The DG exhibited more age-related DEGs compared to CA1 and CA3. Likewise, middle-age rats impaired on the PS task showed more DEGs in the DG than in CA1 or CA3, compared to age-matched unimpaired rats. Functional

annotation clustering of impaired animals highlighted dysregulation of genes related to RNA processing and protein folding in the DG, downregulation of inflammation-related genes in CA1, and no significant cognition-related gene dysregulation in CA3. These results suggest: 1) the beacon task is sensitive to age-related PS impairment, 2) the three hippocampal regions age independently, and 3) regional differences are reflected in differential use of strategies to solve the task.

Title: Age and sex influence the hippocampal response and recovery following sepsis

Authors: *J. D. BARTER[1], A. KUMAR[1], J. STORTZ[2], M. HOLLEN[2], D. NACIONALES[2], P. EFRON[1], L. MOLDAWER[1], T. C. FOSTER[3];

Abstract: Although in-hospital mortality rates for sepsis have decreased, survivors often experience lasting physical and cognitive deficits. Sex and age are major factors contributing to variability in the response to sepsis. Many studies in humans and rodents have demonstrated decreased mortality following sepsis for females and the incidence of sepsis and associated complications increase with advancing age. We employed a murine model to examine the influence of age and sex on the brain's response and recovery following sepsis. Young (~4 months) and old (~20 months) mice (C57BL/6) of both sexes underwent cecal ligation and puncture (CLP) with restraint stress. The hippocampal transcriptome was examined in age and sex-matched controls at 1 and 4 days post-CLP. A considerable number of hippocampal genes were altered in a similar manner across all sex and age groups on day 1. In general, immune and

stress-related genes increased while neuronal, synaptic, and glial genes decreased one day after CLP-induced sepsis. However, specific age and sex differences were observed for the initial responsiveness to sepsis as well as the rate of recovery examined on day 4. Young males differentially expressed a substantial number of genes 1 day after sepsis, but recovered normal gene expression profile 4 days after sepsis. Young females were the least responsive group across the four days of sepsis, exhibiting the fewest number of altered genes and gene ontology clusters. Old females exhibited a robust shift in gene transcription on day 1 and, while most genes recovered, genes linked to neurogenesis and myelination continued to be downregulated by day 4. In contrast, old males exhibited a more delayed or prolonged response to sepsis, such that neuronal and synaptic genes continued to decrease while immune response genes continued to increase on day 4. The genes that were altered on day 4 in older animals may shed light on the mechanism for sepsis-induced cognitive impairment, which is particularly evident in older individuals. These results suggest that aging is associated with delayed recovery from sepsis, which is particularly evident in males.

Abstract: Variability in cognitive decline during aging is related to biological factors (e.g. sex) and the history of experience (e.g. environmental enrichment, previous testing) and lifestyle factors (diet, exercise). In order to understand the contribution of these factors and underlying mechanisms, longitudinal studies are required to define when cognitive decline first emerges. An important caveat for longitudinal studies is the need to control for practice and carry-over effects, associated with multiple testing, which could mask the effects of aging. The current longitudinal study was designed to examine the role of biological and behavioral factors that might predict the variability in age-related cognitive decline. Fischer-344 male (n = 10) and female (n = 10) rats were first characterized at 6 months. Behavioral tests included physical ability (grip strength, Rotarod, and activity wheel), anxiety (neophobia and open field activity), episodic memory (water maze delayed match to place and novel object recognition), and a circadian stress test of resiliency. These measurements were repeated at 12 and 18 months. Sex differences were observed as increased grip strength for males (6 mon: $p < 0.01$, 12 mon: $p < 0.005$, 18 mon: $p < 0.005$). Females exhibited increased activity (6 mon: $p < 0.001$, 12 mon: $p < 0.0001$, 18 mon: $p < 0.0001$). Females also exhibited better Rotarod performance ($p < 0.01$) at 12 mon. In general, neophobia and open field activity declined across testing sessions in the absence of a consistent sex difference. A decline in episodic memory for longer delays (30 and 120 min) emerged at 12 month, particularly for males. Within sex comparisons confirmed that males exhibited a decline in episodic memory during aging. Functional magnetic resonance imaging measures indicated impaired memory was associated with changes in functional connectivity, which suggest compensatory mechanisms. Currently, analysis is focused on the circadian stress test of resiliency and other biological measures. The results of the current study demonstrate sexual dimorphism in the onset and trajectory of cognitive decline.

Title: Does systemic inflammation contribute to the senescent synapse?

Authors: *A. KUMAR[1], J. BARTER[1], A. RANI[1], T. C. FOSTER[2];
[1]Neuroscience, McKnight Brain Inst., Univ. of Florida, Gainesville, FL; [2]Dept. of Neuroscience-McKnight Brain Institute, and Genet. and Genomics Program,, Gainesville, FL

Abstract: Low-grade chronic systemic inflammation during aging is associated with poorer cognitive performance. The current study was design to address the question of whether systemic inflammation contributes to a decrease in hippocampal synaptic transmission and redox mediated decline in NMDA receptor function, which are characteristic of aged-memory impaired animals. Young (5-6 months) Fischer 344 X Brown Norway hybrid rats were injected once a week, for six weeks, with either lipopolysaccharide (LPS) (1 mg/kg, i.p.) or vehicle. Starting 72 hr after the final LPS/vehicle injection, we performed *in vitro* slice electrophysiological recording from CA3-CA1 hippocampal synapses. An input-output curve was generated for total synaptic response across different stimulation intensities for vehicle (n=7/4 slices/animals) and LPS (n=8/4 slices/animals) treated animals. A repeated-measures ANOVA across stimulation intensities indicated an interaction of treatment by stimulation intensity [$F(8,104)=4.029$, $p<0.001$] due to a decrease total synaptic response in slices from LPS animals. Following assessment of total synaptic responses, the NMDA receptor mediated synaptic component was pharmacologically isolated, and input-output curves were generated from vehicle (n=7/4 slices/animals) or LPS (n=7/4 slices/animals) treated animals. A repeated-measures ANOVA across stimulation intensities indicated an interaction of treatment by stimulation intensity [$F(8,96)=3.3$, $p<0.01$], due to a decrease in the NMDA receptor response for LPS-treated animals. The role of redox stress in the decline of the NMDA receptor mediated synaptic component was also tested. After collection of baseline responses, the reducing agent, dithiothreitol (DTT) was added to the bath and responses were measured for 60 minutes. No group differences were observed following addition of DTT, which increased the NMDA receptor synaptic response by 127±10% (3/6 animals/slices) in the vehicle control group and 123±3% (4/7 animals/slices) in the LPS group, indicating no redox effects at this time point. We suggest that synapse elimination underlies LPS-mediated decrease the total and NMDA receptor synaptic transmission. However, transcriptional evidence indicates that younger animals exhibit considerable recovery at the 72 hr time point. Preliminary results suggest that a redox mediated NMDA receptor hypofunction may be present within 24 hr after LPS treatment.

Title: Effect of age and estrogen on whole genome DNA methylome profiling of CpGs in CA1 region of the hippocampus

Authors: *P. SINHA[1], A. KUMAR[1], A. RANI[1], T. C. FOSTER[2];
[1]McKnight Brain Institute, Univ. of Florida, Gainesville, FL; [2]Dept. of Neurosci. McKnight Brain Inst. & Genet. and Genomics Program, Univ. of Florida, Gainesville, FL

Abstract: The ability of estradiol (E2) to improve hippocampal-dependent memory declines with advanced age and prolonged E2 deprivation, indicating a closing of the E2 therapeutic window. Similarly, the ability of E2 to induce transcription of synaptic plasticity genes in the hippocampus deteriorates with advanced age. We hypothesize that during aging, epigenetic modification through DNA methylation renders these genes unresponsive to E2. Estrus cycle was checked by vaginal lavage before and after ovariectomy (OVX) to confirm the loss of E2. Young and middle aged (MA) rats were cycling at regular intervals while two out of six aged animals had an irregular estrus cycle prior to OVX. Six weeks following OVX, two injections of E2 (10 µg: young, n = 4; MA, n = 3; aged, n = 4) or oil (young, n = 2; MA, n =2; aged, n = 2) were given 24 hours apart. The hippocampal CA1 region was collected 6 hours following the second E2/Oil injection and flash frozen. Genomic DNA was isolated. Following sodium bisulfite conversion of genomic DNA, whole genome bisulfite sequencing (WGBS) was performed. WGBS libraries were constructed with the Illumina Truseq DNA Methylation kit, and libraries were paired-end sequenced with the Illumina HiSeq3000 (2X150 cycles). Data analysis was performed using the differential methylation analysis pipeline to detect differentially methylated regions (DMRs) as well as the differential CpG methylation in promoters and gene bodies. The majority of identified CpG sites (> 90%) were found in gene body regions. Methylation analysis of E2-treated relative to age matched oil-controls indicated decreasing effect of E2 on differential CpG methylation with advancing age, particularly for hypomethylation following E2 treatment: young (hyper/hypo-653/660 sites), MA (hyper/hypo-555/485 sites), and aged (hyper/hypo-553/291 sites). Similarly, DMRs for E2 treatment were 113, 59 and 45 in young, MA, and aged treated groups, respectively. The results support a decrease in E2 induced differential methylation with advanced age. Gene ontology (GO) was used to examine gene clustering for hypermethylated and hypomentylated genes in E2 treated versus controls within each age group. A treatment associated enrichment was observed for MA hypomethylated genes (cAMP signaling pathway) and hypermethylated genes for aged animals (calcium-dependent membrane targeting). Comparisons between control groups indicated hypermethylation of synaptic signaling genes in MA relative to young control. The results are consistent with hypermentylation contributing to an age-related **1)** decreased expression of synaptic genes and **2)** decreased E2-responsive transcription.

Title: Low dose of THC improves age-related cognitive impairments

Authors: *R. DORON[1], R. TOLEDANO[1], L. RACHMANY[2], E. SASSON[2], Y. SARNE[2];
[1]The Open Univ., Ra'Anana, Israel; [2]Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel

Abstract: The world's population is ageing. Population ageing is poised to become one of the most significant social transformations of the twenty-first century. a variety of insults In the present study we evaluated the effect of the same ultra-low dose of THC on reversing age-related cognitive decline in mice. As was expected, the cognitive prefomance of Old (18-24 months) mice were found to be weaker then the performance young ones (3-4 months). The important finding was that we showed that a single injection of an ultra-low dose of THC (0.002mg/kg) ameliorated cognitive functioning of old (but not of young) mice, as was evaluated by six different assays that measured various aspects of memory and learning. The assays that were used were: Morris Water Maze, Active and Passive Avoidance, Y maze, Object Recognition and Place Recognition tests. The old mice were found to preform the tasks similarly to young mice. The behavioral results were consistent with Magnetic Resonance Imaging (MRI) findings that demonstrated a larger volume and higher tissue of entorhinal cortex, prefrontal cortex and posterior hippocampus. In addition higher density in various regions of the brain (including the entorhinal cortex, amygdala, cingulate cortex and caudate/putamen) following ultra-low-THC treatment Sirtuin 1 (SIRT1) is an NAD-dependent protein deacetylase that has been previously shown to be involved in neuroprotection and neuroplasticity. It was found to mediate the protective effects of resveratrol, of melatonin and of caloric restriction, and was suggested to take part in the pathology of various neurodegenerative diseases. In the current study we showed that the same treatment elevated the level in the brain of SIRT1 at least for 7 weeks. These behavioral, biochemical and structural effects lasted for at least seven weeks following a single injection of ultra-low-THC. The harmful effect of THC on young brains has long been known, but the present study suggests that a minimal dose of THC can be an effective pharmaceutical treatment for age related cognitive impairment.

Title: Steady stream of complex traveling waves underlying cortical up-down states in sedated mice

Authors: *Y. LIANG[1], C. SONG[2], L. MIANXIN[4], T. KNOPFEL[3], P. GONG[6], C. ZHOU[5]; [1]Hong Kong Baptist Univ., Hong Kong, Hong Kong; [2]Med., [3]Imperial Col. London, London, United Kingdom; [4]HKBU, Hong Kong, China; [5]HKBU, Hong Kong, Hong Kong; [6]The Univ. of Sydney, Sydney, Australia

Abstract: Up (high neuronal firing probability) and Down (low firing probability) states have been widely observed in the cerebral cortex, which play important functional roles such as memory consolidations. However, the dynamical mechanism of Up-Down transitions and their spatiotemporal organization properties and principles remain unclear. We investigated the dynamical properties of various waves and their interactions using high spatiotemporal resolution optical voltage imaging of the upper cortical layers in sedated mice.
Our analysis based on phase velocity fields revealed that there are only a small number of large-scale, cortex wide plane wave and synchrony (standing wave) patterns during Up-Down states. During transition of Up to Down state, a large plane wave swept across the whole cortex. Interactions of local sources and sinks can generate saddles and interactions of local wave patterns with large plane waves can induce a change of their wave propagating direction. Local wave patterns emerge at preferred spatial locations. Specifically, sources are predominantly found in cortical regions with high cumulative input through the underlying connectome. Our findings reveal the principled spatiotemporal dynamics of Up-Down states and associate them with the large-scale cortical connectome.

Title: The medial septum enhances cognitive flexibility via actions on ventral tegmental area and substantia nigra dopamine neurons

Authors: *D. M. BORTZ, K. L. GAZO, A. A. GRACE;
Neuroscience, Psychiatry, and Psychology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cognitive flexibility deficits are one of the most pervasive symptoms across psychiatric disorders, making continued investigation of the circuitry underlying this function a top priority. One brain area that has emerged is a sub region of the basal forebrain called the medial septum (MS). The MS has a well-established role in learning and memory processes, specifically in behaviors that require inhibition of prior learned information in order to learn a new rule. Furthermore, the MS potently regulates dopamine (DA) neuron activity in both the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc), which are known to be involved in reward learning, both in general and in the context of cognitive flexibility tasks. Despite this, a role for the MS in cognitive flexibility circuitry has never been examined. To test this hypothesis, we activated the MS of male and female Sprague-Dawley rats with designer receptors exclusively activated by designer drugs (DREADDs) and measured their performance on a T-maze spatial reversal-learning task, an operant-based strategy shifting task, and an operant-based non-spatial reversal learning task. Next, we determined if the effects of MS activation on both cognitive flexibility and midbrain DA activity were mediated via the same pathway. Finally, we determined whether DA transmission at D1 receptors was necessary to produce the MS's effects on cognitive flexibility. DREADD activation of the MS via systemic and intra-ventral subiculum (vSub) CNO improved performance on the cognitive flexibility tasks compared to the control groups. Intra-vSub CNO also increased (78%) the number of spontaneously active DA neurons in the VTA, and decreased (31%) the number of active DA neurons in the SNc, revealing that the MS's regulation of cognitive flexibility and DA activity both occur via the specific MS to vSub pathway. Finally, co-injection of the D1 antagonist SCH23390 completely prevented the enhancement in cognitive flexibility performance seen in the DREADD/CNO rats, suggesting the MS's effect on DA transmission is necessary for its enhancement of cognitive flexibility. In conclusion, these data add substantially to the known circuitry involved in cognitive flexibility, demonstrating a key role for the MS to vSub pathway.

They also provide evidence to suggest that this pathway's regulation of VTA and SNc DA activity could be the mechanism by which strategy-switch signals, precipitated during cognitive flexibility tasks, could be enacted downstream. Taken together, these data provide a first step towards developing novel, more effective therapies to treat cognitive flexibility deficits.

Title: Mechanisms of stress-induced memory generalization

Authors: *L. Y. REN[1], J. M. RADULOVIC[2];
[1]Northwestern Univ. - Chicago, Chicago, IL; [2]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Episodic memories must be encoded and maintained with specificity so that information about different situations is not generalized to unrelated novel situations. Stress is known to promote generalization of memories, and this effect likely relies on stress-induced neurobiological changes that bias memory systems towards increased generalization. A promising locus for these stress-induced changes is the dorsal hippocampus given that (1) excitatory neurotransmission in the dorsal hippocampus is crucial for associative learning, contextual memory, and episodic memory and (2) abnormal hippocampal function contributes to generalization of memories in rodents and humans. Thus, we sought to explore the role of the dorsal hippocampus in stress-induced generalization of memories. As dorsal hippocampal excitatory efferents contain either vesicular glutamate transporter 1 (vGlut1) or 2 (vGlut2), we used vGlut1- and vGlut2-Cre mice to investigate their roles in stress-induced generalization of context memories. After training mice to associate a context with a fear-provoking stimulus, we exposed mice to social defeat stress. Under these conditions, mice that normally acquired fear responses began to show generalization during testing in a novel context, thus providing a model

of stress-induced generalization of fear memory. Using this model, we found that chemogenetic inhibition of vGlut1-expressing dorsal hippocampal neurons before memory tests prevented generalization of the context fear memory, whereas inhibition of vGlut2-expressing dorsal hippocampus neurons did not have this effect. Additionally, inhibition of muscarinic acetylcholine receptors in the dorsal hippocampus before memory tests also prevented stress-induced generalization of the context fear memory. Next, we sought to explore the role of vGlut1-expressing dorsal hippocampal projections to the retrosplenial cortex in stress-induced generalization of memories, as these projections play a role in processing of recent contextual memories. We found that chemogenetic inhibition of these outputs prevented generalization of context fear. These results suggest that fear memory generalization is promoted by social defeat stress, and this effect is mediated through cholinergic mechanisms in the hippocampus and a glutamatergic output from dorsal hippocampus to retrosplenial cortex.

Title: Mechanisms underlying sharpening of visual response dynamics with familiarity

Authors: *S. LIM;
New York Univ. Shanghai, Shanghai, China

Abstract: Experience-dependent modifications of synaptic connections are thought to change patterns of network activities and stimulus tuning with learning. However, only a few studies explored how synaptic plasticity shapes the response dynamics of cortical circuits. Here, we investigated the mechanism underlying sharpening of both stimulus selectivity and response dynamics with familiarity observed in monkey inferotemporal cortex. Broadening the distribution of activities and stronger oscillations in the response dynamics after learning provide evidence for synaptic plasticity in recurrent connections modifying the strength of positive feedback. Its interplay with slow negative feedback via firing rate adaptation is critical in sharpening response dynamics. Analysis of changes in temporal patterns also enables us to disentangle recurrent and feedforward synaptic plasticity, and provides a measure for the strengths of recurrent synaptic plasticity. Overall, this work highlights the importance of analyzing changes in dynamics as well as network patterns to further reveal the mechanisms of visual learning.

Title: There and back again: Identification of distinct neural circuits for associative recognition memory encoding and retrieval

Authors: *G. R. I. BARKER, Z. I. BASHIR, E. C. WARBURTON;
Physiology, Pharmacol. & Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Associative recognition memory, the ability to associate an object with its location or position in a sequence, is critically dependent upon a neural network which includes the medial prefrontal cortex (mPFC), hippocampus (HPC) and nucleus reuniens (NRe) of thalamus (Barker & Warburton 2011, 2018) which are anatomically interconnected. While the key nodes for associative recognition memory have been identified, how these brain regions interact during the different stages of memory formation is poorly understood. This study aimed to investigate how information moves between these brain regions during the encoding and retrieval of associative recognition memory by deactivating specific anatomical projections between these brain regions. Projection specific deactivation was achieved using either optogenetic or chemogenetic approaches in male lister-hooded rats. The following projections were deactivated using an optogenetic approach intermediate CA1→mPFC, NRe→mPFC and mPFC→NRe. Thus an AAV vector expressing the inhibitory opsin ARCH3.0 was injected into the somatic site of the projection and optrodes were implanted into the axonal target, The NRe→HPC projections were investigated via chemogenetic manipulation through injection of an AAV vector expressing the inhibitory DREADD receptor (hMDi4) in NRe combined with guide cannula implantation into both the dorsal and intermediate HPC. Associative recognition memory was tested using a range of different spontaneous preferential exploration tasks with deactivation of the projections during either memory encoding or retrieval. Performance in associative recognition memory tasks was compared using a two-way or one-way ANOVA and post-hoc comparisons used a Bonferroni correction.
Deactivation of iCA1→mPFC and NRe→mPFC projections selectively impaired associative recognition memory encoding but not retrieval, in contrast deactivation of mPFC→NRe projections selectively impaired memory retrieval but not encoding. Deactivation of NRe→HPC projections impaired both the encoding and retrieval of associative recognition memory but with distinct anatomical loci in dHPC and iHPC between encoding and retrieval. Further when

animals were simultaneously encoding and retrieving object associations deactivation of NRe→mPFC projections selectively impaired encoding and deactivation of mPFC→NRe projections selectively impaired retrieval. Thus, this study has revealed distinct networks which are critical for associative recognition memory encoding and retrieval.

Title: Cortical and subcortical information processing during a context-association task

Authors: *M. MOAZAMI GOUDARZI, E. K. MILLER;
MIT, Cambridge, MA

Abstract: Learning associations based on context is a fundamental hallmark of intelligence. Multiple cortical and subcortical brain regions have been implicated in context-association behavior, but the flow of information between these areas for underlying neuronal computations remains unclear. To address this question, we simultaneously recorded spiking and local field potential (LFP) activity from up to 104 electrodes in the prefrontal cortex (PFC), hippocampus (Hpc), and caudate (Cd) of monkeys. During recording, monkeys performed a context-specific rule-switching task. In each trial, one of four object cues was shown in one of four locations. Two of the objects mandated a leftward saccadic response following a brief delay when presented in the upper right or bottom left quadrants of the screen, and a rightward saccadic response when in the other two quadrants. This mapping was reversed for the other two objects. Thus, this task required monkeys to adjust their decisions based on the integration of both object identity and its spatial context. We investigated how information about the object identity, spatial context, and behavioral response was represented in multiunit spiking activity (MUA) within each area. First, we found strong information about object identity and spatial context in PFC and Cd in MUA during the sample period, with shorter latency in the Cd. This information decayed more slowly during the delay period in PFC. Interestingly, information about the behavioral response was only manifested in PFC. In contrast, the Hpc represents object identity, spatial context, and behavioral response only in its LFPs. Second, we examined the LFP Granger causality between Cd, Hpc, and PFC. We found that during the sample period the Cd and Hpc influence PFC in beta frequency bands. These results suggest that the Cd processes object

identity and spatial context and passes them to PFC to integrate them and guide the behavioral response.

Title: Tracing of glutamatergic afferents and efferents of dorsal hippocampus and retrosplenial cortex

Authors: *P. GAO[1], M. MEYER[3], L. Y. REN[3], J. M. RADULOVIC[2];
[2]Psychiatry & Behavioral Sci., [1]Northwestern Univ., Chicago, IL; [3]Northwestern Univ. - Chicago, Chicago, IL

Abstract: The dorsal hippocampus (DH) and retrosplenial cortex (RSC) play important roles in contextual memory processing. In particular, glutamatergic neurotransmission in these regions is crucial for these functions. DH and RSC glutamatergic neurons express either vesicular glutamate transporter 1 (vGlut1) or 2 (vGlut2), and these contribute differentially to processing of contextual fear memories. Given this, a map of vGlut1-expressing and vGlut2- expressing DH and RSC afferents and efferents would help further our understanding of memory circuits. We performed cre-dependent AAV-mediated tracing to identify brain areas projecting to and receiving innervation from DH and RSC. Analyses were performed separately for vGlut1-expressing and vGlut2-expressing projections, and for males and females. The identified brain areas will improve our understanding of memory networks and their interactions during contextual memory processing.

Title: New non-canonical circuit connections between the subicular complex and hippocampal CA3

Authors: *X. LIN[1], R. TAFLA[1], C. BLANTON[1], Y. WU[1], D. A. NITZ[2], X. XU[1];
[1]Univ. of California Irvine, Irvine, CA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: The hippocampal formation is traditionally viewed as having a feedforward, unidirectional circuit organization. However, recent studies (Sun et al., 2014; 2018) using genetically targeted rabies tracing show a significant backprojection pathway from the subiculum (SUB) and other parts of the subicular complex to hippocampal CA1 in the mouse as previously suggested in other mammalian species using less strict mapping methods. We refer to this circuit as 'non-canonical' in that it runs opposite the prominent pathway leading from CA1 to SUB. Furthermore, theta rhythms generated in the rat subiculum are reported to flow backward to actively modulate spike timing and local network rhythms in CA1 and CA3 (Jackson et al., 2014). This suggests an even larger, non-canonical circuit networks involving the subicular complex and hippocampal CA3. Thus we address whether hippocampal CA3 participates in these non-canonical circuit connections and investigate if CA3 excitatory neurons receive significant direct synaptic inputs from SUB and its associated structures including presubiculum (PrS), poststubiculum (PoS) and parasububium (PaS). We used our established monosynaptic rabies tracing approach to map brain-wide inputs to CA3 excitatory neurons in the mouse. As expected, the rabies-mediated input mapped regions include the dentate gyrus, medial septum, entorhinal cortex and contralateral CA3. Interestingly we also find that a significant number of rabies labeled neurons are present in the PrS, PoS and PaS, following rabies tracing from excitatory neurons in CA3 subregions. Reciprocally, we confirmed a direct projection of the subicular complex to hippocampal CA3 using anterograde directed herpes simplex virus (H129) mapping. Together, our data demonstrate the existence of new non-canonical circuit connections between the subicular complex and hippocampal CA3, which offers the anatomical circuit basis to consider the largely unexplored role of the subicular backprojection to the hippocampus.

Title: The lateral septum drives sex differences in fear memory encoding

Authors: *S. BASU, E. K. LUCAS;
North Carolina State University, Col. of Vet. Med., Raleigh, NC

Abstract: Fear-based psychiatric conditions, such as post-traumatic stress and anxiety disorders, are the most prevalent mental illnesses worldwide, affecting 18% of the population annually. These illnesses are thought to arise from enhanced encoding of cues associated with aversive outcomes, leading to maladaptive fear responses that persist in the absence of threat. Women are twice as likely as men to be diagnosed with fear-based mental illness, suggesting that the mechanisms underlying associative fear memory differs between the sexes. One possibility is that females encode fear memories through different neural networks than males. To explore this possibility, we quantified expression of the neural activity marker c-fos throughout selected forebrain regions in auditory fear conditioned and naïve male and female littermates. While both sexes equally engaged canonical regions of cued fear circuit, such as basolateral and central amygdala, we found a robust female-specific increase of c-fos expression in the lateral septum (LS). We next used designer receptors exclusively activated by designer drugs (DREADDs) to determine if sex-specific LS activation is causally related to sex-specific memory encoding. We bilaterally infused adeno-associated viruses encoding $hM3D_{Gq}$ (excitatory DREADD), $hM4D_{Gi}$ (inhibitory DREADD), or eYFP (empty-vector control) into the LS of male and female mice, injected clozapine-*N*-oxide 30 minutes prior to auditory fear conditioning, and assessed fear memory encoding and persistence. LS activation enhanced fear memory in females but impaired memory formation in males. Conversely, LS inhibition enhanced fear memory in males but rendered female fear memory more pervious to degradation. To reveal the neurons of the LS memory ensemble, we employed a viral vector approach for permanent eYFP labeling of neurons active during fear memory acquisition. Consistent with our c-fos data, we observed more tagged neurons in fear-conditioned females than fear-conditioned males or naïve animals of either sex. Analyses of eYFP-positive terminals revealed that female LS ensemble neurons mainly project to the lateral hypothalamic area, periaqueductal gray, and ventral hippocampus. Taken together, these data suggest that sex-specific engagement of the lateral septum during associative fear learning enhances fear memory in females through canonical mediators of fear-evoked responses. This in turn might be a contributing factor for the increased prevalence of fear-based psychiatric disorders observed in women.

Title: The primate subthalamic nucleus encodes both current and historical values of visual objects in the experience-based learning

Authors: *H. JIANG, H. F. KIM;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The basal ganglia play a crucial role in value-guided decision making through three pathways: Direct, indirect and hyperdirect pathway. The hyperdirect pathway transmits the cortical signal to motor output structures in the basal ganglia through the subthalamic nucleus (STN), contributing fast inhibition of motor responses. Neurons in the STN showed responses for behavioral switching and canceling in instructive cue-driven choice tasks. In real life, however, the cue is often not clear, and animals have to discriminate the object values and recognize their changes to choose the best one by trials and errors. The STN in hyperdirect pathway may have a role to suppress the unnecessary movement based on the experience of object values.
To test the value process in the STN neurons during the experience-based learning, we recorded the STN neurons while a monkey learned value changes of visual objects without an instructive cue. The object-reward value contingency was reversed across the blocks, and the monkey made quicker saccades to rewarded objects in current blocks than no rewarded ones. Among 125 visually responsive neurons, 14 neurons (11.2%) showed discrimination activity to flexibly changed values of objects (current value-coding neurons). These neurons negatively encoded the current values: higher activity to no rewarded objects than rewarded ones. Next, the STN neurons were tested during stable-value learning task, where the object-value contingency was sustained across whole sessions. During the first day of learning, the STN neurons gradually developed the value discrimination activity: higher response to no rewarded objects.
We further tested whether the STN neurons memorize previously learned object values. Behaviorally, the monkey showed a gaze preference to the previously rewarded objects in free viewing task after long-term value learning. The STN neurons encoded learned object values: 15 of 125 visual neurons (12%) responded higher to previously no rewarded objects than rewarded

ones (historical value-coding). 12 of 15 (80 %) stable value-coding neurons also encoded flexible value, indicating that most of value-coding neurons in the STN encoded both historical and current values.
Our data indicate that the STN neurons negatively encoded object values in trials and error-based learning. The neural excitation to no rewarded objects in the STN can directly increase the neural activity in the substantia nigra pars reticulata (SNr). Consequently, the superior colliculus neurons are inhibited by no rewarded objects, leading to the gaze suppression on no rewarded objects.

Title: A two-stage model of landmark processing in retrosplenial cortex

Authors: Y. YAN, *A. BICANSKI, N. BURGESS;
UCL, London, United Kingdom

Abstract: Electrophysiology studies in rodents and imaging studies in humans suggest a role for the retrosplenial cortex (RSC) in spatial memory and navigation. In particular, the existence of head direction coding in RSC is well established. However, theoretical models have only recently begun to address the functional role of this head direction signal (Bicanski and Burgess 2016; Page and Jeffrey 2018), with RSC hypothesized to be a key gateway for visual landmark information that can stabilize head direction signals against drift. Recent empirical data suggest separate populations of landmark and head-direction dominated neurons in RSC. In addition, the role of theta modulation in a subset of head direction cells along Papez' Circuit is so far unaccounted for. Here, we propose a two stage model of visual processing in RSC to account for these phenomena within a single theoretical framework. In the first stage, combinations of visual inputs generate a stable unimodal landmark bearing signal even in complex environments composed of multiple landmarks with differing directional specificity and stability. In the second stage, this representation is associated with the retrosplenial head direction signal (inherited from thalamic head direction cells), in order to convey feedback to the generative circuitry of the head direction system. We explore different algorithmic solutions, investigate the capacity of the

system to map distinct environments, and suggest a neural implementation which may account for the difference between head direction cells with and without theta-modulation. In summary, this theoretical framework integrates numerous empirical findings to provide a coherent account of the role of RSC in spatial cognition, and makes predictions for future experimental studies.

Title: The role of VTA-infralimbic circuits in mediating estrous-dependent fear extinction learning

Authors: *P. RUBIO ARZOLA[1], N. SHEPARD[2], R. SHANSKY[3];
[1]Psychology, Northeastern Univ., Boston, MA; [2]Psychology, Northeastern Univ., Bostonq, MA; [3]Behavioral Neurosci., Northeastern Univ., Boston, MA

Abstract: Post-traumatic stress disorder (PTSD) is characterized by excessive fear to stimuli that no longer predict an aversive situation and is more than twice as likely to occur in women than in men. Extensive research has been done to understand fear extinction in rodents, yet most of these studies have only used male rodents. The few relevant studies that do include female subjects have revealed that there are clear sex differences in fear extinction. Considering that PTSD is more prevalent in women, it is imperative to investigate the neural circuits underlying fear extinction in females. Several studies have revealed that estrogen has an effect on learning. Specifically, estradiol has been shown to facilitate extinction through estrogen receptor ER-β activation and elicits an increase of c-fos in the infralimbic cortex (IL). However, whether estrogen affects extinction through direct actions in the IL or through upstream brain regions that target the IL has not been investigated. One intriguing possibility is that estrogen might have a modulatory effect on the IL through its interactions with dopamine (DA). Previous studies in our lab have shown that administering a D1 receptor agonist improved the extinction of females with low estrogen. Furthermore, it has been noted that DA VTA cells projecting to the prelimbic cortex (PL) contain estrogen receptors ER-β but not ER- α, yet no one has looked at estrogen receptor expression in VTA projections to IL. We hypothesize that estrogen promotes fear extinction by selectively activating dopaminergic VTA neurons that project to the IL (VTA-IL). We further predict that this activation occurs via actions at ER-β. To test this, we first injected CTB-555 bilaterally into IL and, after 2 weeks, began a 2-day fear conditioning and extinction paradigm. After fear extinction, rats were sacrificed and VTA slices were collected and used immunofluorescence to co-labeled for c-fos and tyrosine hydroxylase (TH) to identify activated

dopaminergic neurons. We then used fluorescent microscopy to examine overlap between these markers and CTB-555 and quantified the relative recruitment of VTA-IL neurons. Additionally, we assessed which estrogen receptor was necessary for this by implanting bilateral cannulae into VTA and infusing with an ER-β antagonist before undergoing fear extinction. The following day, rats were tested on an extinction retrieval paradigm to assess the effects of the antagonist on extinction recall. Taken together, these data will help elucidate how estrogen and dopamine interact to improve fear extinction in females.

Title: Functional connectivity between the nucleus basalis and the dorsolateral prefrontal cortex during visual-motor associative learning

Authors: *N. J. KILLIAN, E. N. ESKANDAR;
Leo M. Davidoff Dept. of Neurolog. Surgery, Albert Einstein Col. of Med., Bronx, NY

Abstract: The nucleus basalis of Meynert (NBM) and dorsolateral prefrontal cortex (dlPFC) have a multimodal involvement in associative learning, dynamically encoding novelty, reward, and learning state. The NBM is known to degenerate in Parkinson's disease dementia (PDD) and Alzheimer's disease (AD), contributing to impaired learning. However, manipulations of the NBM with deep brain stimulation (DBS) in PDD and AD patients have had mixed results (Kuhn et al., 2015). A better understanding of the functional circuitry of the NBM may improve attempts to compensate for impaired learning in pathological states. The NBM provides the primary source of cholinergic efferents to the dlPFC, which does not reciprocate these connections. The NBM has reciprocal connections with limbic and paralimbic areas, which are also reciprocally-connected with the dlPFC. To examine how this circuitry influences learning, we inferred functional connectivity from simultaneous single-electrode recordings of the NBM and dlPFC (N = 25) in two monkeys (*Macaca mulatta*) as they performed an associative learning task. In this task, the animal learns visual-motor associations between specific novel visual images and a saccade to one of four target locations. In a given trial, an image is first viewed (*viewing phase*), and then the animal is forced to make a saccade to a target (*choice phase*). Saccades to the correct location are rewarded, and visual feedback is given to indicate whether the decision was correct or incorrect. We analyzed connectivity by applying Granger causality (GC) statistics to the local field potentials. Consistent with anatomical connectivity, we observed no GC influence of the dlPFC on the NBM. The GC influence of the NBM on the dlPFC

occurred in two distinct bands, theta-alpha (5 to 15 Hz) and high-gamma (100 to 170 Hz). The NBM drove theta-alpha power in the dlPFC during both the viewing phase and the choice phase. Additionally, during the choice phase, the NBM drove high-gamma power (100 to 170 Hz) in the dlPFC ($p < 0.025$, cluster-based permutation test). These results suggest that the NBM modulates cortical activity using separate frequency bands for different stages of learning, consistent with recent findings (Martinez-Rubio et al., 2018). Strategies for DBS of the NBM might be improved by differentially stimulating to induce distinct oscillations based on learning state estimates.

Title: Transformation of motor memory

Authors: *G. SULLENS[1], K. GILLEY[2], M. J. SEKERES[3];
[2]Psychology, [3]Psychology & Neurosci., [1]Baylor Univ., Waco, TX

Abstract: In both humans and rodents, episodic and episodic-like memories may undergo a process of transformation, in which a memory that is initially context-specific strongly engages the hippocampus. Over time, hippocampal activity may decline as the memory trace reorganizes and becomes represented in prefrontal cortical regions. The hippocampus is not critical for the acquisition of motor memory, but if intact, the hippocampus may participate in the episodic-like encoding of the task event. Over time, as the task becomes highly familiarized, and less bound to the context in which the task was acquired, we predict that hippocampal engagement will decrease, and increasingly engage regions within the prefrontal cortex and striatum. To test this idea, three-month-old male C57BL6 x 129 hybrid mice learned a straight alley motor task. Mice were assigned to one of six conditions: homecage control; 1 training day in Context-A; 1 training day in CXT-B; 20 training days in CXT-A; 19 training days in CXT-A with 1 additional day in a novel Context-B; and 1 training day in CXT-A prior to 18 days of homecage control rearing followed by one final training day in CXT-A. Latency to mount the hidden platform revealed decrease time across training exposure, which is indicative of motor learning. Immediate early gene expression (IEG) of c-Fos is being used to assess the neural activation at the time of the last training session, which will identify how motor memory networks reorganize over time, exposure, and across contexts in the intact mouse brain. We predict that motor memories will engage an altered network as the task becomes highly familiarized.

Title: Effects of amygdala lesions on stimulus vs. action based learning

Authors: *B. H. HARRIS[1], N. MANEM[2], C. A. TASWELL[2], E. A. MURRAY[2], B. B. AVERBECK[2];
[1]Natl. Instituteof Hlth., Bethesda, MD; [2]NIH/NIMH, Bethesda, MD

Abstract: Reinforcement learning (RL), is the process of associating values with objects and actions. Work in our lab has been dissecting the neural circuitry that underlies visual stimulus-based vs. action based RL. We have developed a task that interleaves blocks of trials in which animals have to learn to associate rewards with actions or with visual stimuli. In previous work, we found evidence that animals with lesions of the ventral striatum were impaired on visual stimulus based, but not action based learning (Rothenhoefer, K, et al., 2017). In the present study we examined the effects of lesions of the amygdala on the same task. Specifically, we trained unoperated control monkeys (n = 6) and monkeys with bilateral excitotoxic amygdala lesions (n=4) on a probabilistic two-arm bandit reversal learning task. The task had two conditions, which were run in randomly interleaved blocks of 80 trials. In the What condition, the monkeys had to learn which of two images was more frequently rewarded. In the Where condition, they had to learn which of two saccade directions was most frequently rewarded. At the beginning of each block of 80 trials, two new images were introduced. In a What block, a high reward probability was assigned to one image and a low reward probability was assigned to the other. In a Where block, a high reward probability was assigned to one of the saccade directions (left or right) and a low reward probability was assigned to the other. In each trial the animals made a saccade to one of the images to indicate their choice. Following their choice, they were stochastically rewarded. In addition, on a randomly chosen trial between 30 and 50, the choice-outcome mappings were reversed, so the opposite choice within the same condition became more frequently rewarded. Compared with controls, amygdala lesioned monkeys showed deficits in both stimulus-based and action-based learning.

Title: Fast cholinergic prediction errors track conditioned behavior during reversal learning

Authors: *J. F. STURGILL[1], A. SIEBELS[1], S.-J. LI[1], B. HANGYA[2], A. KEPECS[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Dept. of Cell. and Network Neurosci., Inst. of Exptl. Med., Budapest, Hungary

Abstract: The cholinergic basal forebrain (CBF) projects throughout pallium-derived structures such as cortex, and, by modulating plasticity, may support learning. Yet the principles governing CBF activation, and the precise relationships of CBF signals to learning have remained unclear. Recent work from our lab revealed that CBF neurons respond rapidly to reinforcers (reward, punishment) and are modulated by reinforcement expectation or surprise, similar to dopaminergic reward prediction error (RPE). Therefore we hypothesized that the CBF provides a valence-free counterpart to dopaminergic RPE. Confirming this hypothesis we show that: 1) the CBF encodes a quantitative prediction error signal that is conveyed to cholinergic terminal fields 2) CBF predictions adapt as quickly with learning as their dopaminergic counterpart 3) overlapping afferent circuitry and correlated activities indicate a global, distributed circuit for computing reinforcement prediction errors.
To relate CBF signals to reinforcement expectation, we used fiber photometry to record CBF activity in a cued, probabilistic outcome task to manipulate reinforcement expectations. Consistent with an unsigned signal, our data confirm that the CBF responds alike to reward and punishment. With learning, the CBF acquires responses to outcome predictive stimuli. These responses precede and predict the degree of anticipatory licking, as well as are modulated by expected outcome value. Furthermore, CBF neurons show diminished responses to expected outcomes, a hallmark of a prediction error signal.
A key, outstanding question is how the activities of neuromodulatory systems, including the CBF, are coordinated during learning. Using dual fiber recordings we simultaneously recorded dopaminergic and cholinergic signals in a serial reversal learning paradigm. We found that cholinergic responses to positive valence cues emerge at least as quickly following reversals as dopaminergic responses and track the acquisition of conditioned behavior. At a finer timescale, noise correlations to cue and reinforcement delivery and coherent activity even in spontaneously behaving mice suggest that the CBF and dopaminergic systems are driven in part by common

upstream circuits. These data indicate the CBF's involvement in reinforcement learning in parallel to dopamine and are consistent with emerging evidence that the prediction error circuits governing learning are more distributed and diverse than originally appreciated.

Title: Synaptic correlates of contextual fear memory consolidation in prefrontal neocortical circuit

Authors: W. KIM, E. PARK, ***J.-H. CHO**;
Univ. of California, Riverside, Riverside, CA

Abstract: In contextual fear learning, experimental subjects learn to associate a neutral context with an aversive stimulus and display fear responses to a context that predicts danger. Exposure to a context activates a subset of hippocampal neurons, which convey contextual representations to the amygdala and medial prefrontal cortex (mPFC). The contextual information is then integrated with aversive signals for fear memory formation. Once encoded, contextual memories progressively mature to a stabilized form during systems consolidation. Although it has long been proposed that permanent storage of contextual memories involves strengthening of neocortical circuits, this hypothesis has not been thoroughly tested. To test the hypothesis, we employed a combined approach of neural activity-dependent labeling, optogenetics, and electrophysiology in a mouse model of contextual fear conditioning. With this approach, we labeled mPFC neurons active during contextual fear learning and found that they were reactivated during the recall of a remote contextual fear memory. Moreover, consolidation of a contextual fear memory was associated with selective strengthening of excitatory connections between mPFC engram cells active during fear learning. Our study suggests that strengthening of connections between memory engram cells plays pivotal roles in permanent storage of contextual fear memories in prefrontal neocortical circuits.

Title: Specific reorganization of striatal network dynamics during habit formation

Authors: *N. BADREDDINE[1,2], G. ZALCMAN[1,2], F. APPAIX[1,2], G. BECQ[3], N. TREMBLAY[3], F. SAUDOU[1,4], S. ACHARD[3], E. FINO[1,5];

Abstract: Procedural memory, the memory of habits, is formed by the repetition of a given action. The neural substrates underlying this memory are the basal ganglia, long known to be critical for normal motor control, but now also recognized as influencing cognitive and motivational aspects of behavior. The striatum, the input stage of basal ganglia, relays information between the cortex and other subcortical structures, thus ensuring the selection and integration of cortical information by forming functional parallel loops (associative, sensory-motor and limbic). The associative loops include the dorsomedial striatum (DMS) and mediate the first phase of procedural learning (goal-directed behavior). The sensorimotor loops include the dorsolateral striatum (DLS) and mediate habit formation. Although the anatomy of the circuits involved in procedural learning has been well described, little is known about the dynamics of the striatal networks responsible for the engram of procedural memory. The goal of our study is to characterize the dynamics of the striatal networks involved in the different phases of procedural learning. For this purpose we are using a behavioral paradigm to form procedural memory and anatomical and functional approaches (ie. tracing and two-photon calcium imaging). This will allow us to characterize the networks' activity and properties in relation to memory formation.

Title: Medial septum cholinergic signaling regulates gastrointestinal-derived vagus sensory nerve communication to the hippocampus

Authors: *A. N. SUAREZ[1], C. M. LIU[2], A. M. CORTELLA[1], E. N. NOBLE[1], S. E. KANOSKI[1];
[1]Integrative and Evolutionary Biol., [2]Neurosci. Grad. Program, USC, Los Angeles, CA

Abstract: The vagus nerve delivers bi-directional communication between feeding-relevant gastrointestinal (GI) signals and the brain. Vagal sensory-mediated GI satiation signals, including gastric distension and intra-gastric nutrient infusion, activate neurons in the hippocampus (HPC). Recent work from our lab revealed that selective GI-derived vagal sensory signaling is required for HPC-dependent episodic and visuospatial memory, effects accompanied by reduced dorsal HPC (dHPC) expression of neurotrophic and neurogenic markers. To investigate the neural pathways mediating gut regulation of hippocampal-dependent memory, here we investigate the hypothesis that GI-derived signals communicate to dHPC neurons via cholinergic input from the medial septum, a memory-promoting pathway that is vulnerable to disruption in various degenerative dementia diseases. To explore this putative gut-to-brain pathway, we administered 192IgG-saporin, a neurotoxin that selectively kills cholinergic neurons via apoptosis, in the medial septum to determine whether septal cholinergic neurons regulate vagally-mediated neuronal activation in dHPC. Results revealed that elimination of cholinergic neurons in the MS reduced peripherally-administered cholecystokinin (CCK)-induced c-Fos expression in the dHPC, suggesting that cholinergic inputs from the MS transmit GI-derived signaling to the dHPC. Consistent with this interpretation, dHPC protein expression of vesicular acetylcholine transporter (VAChT), which promotes memory function and acetylcholine release without disrupting other co-released molecules, was significantly reduced in rats with GI-specific vagal sensory ablation via nodose ganglion injections of CCK conjugated to saporin. Collectively these results suggest that GI-derived vagal sensory signaling influences memory function via enhancement of MS cholinergic signaling to the dPHC.

Title: The role of coordinated activation between insular cortex and basolateral amygdala during taste-aversion association learning to recruit a memory trace

Authors: *K. ABE[1], M. KURODA[1], Y. NARUMI[1], Y. KOBAYASHI[2], S. ITOHARA[2], T. FURUICHI[1], Y. SANO[1];
[1]Dept. of Applied Biol. Sci., Tokyo Univ. of Sci., Noda, Chiba, Japan; [2]RIKEN Ctr. for Brain Sci., Wako, Japan

Abstract: Memory is thought to be stored in a subset of neurons activated during learning. These neurons are reactivated during memory retrieval. In the amygdala and hippocampus, it has been shown that the selection of this subset of neurons is regulated by neural excitability and CREB (cAMP response element binding protein) activity during learning. We previously showed that insular cortical neurons with virally transduced CREB are preferentially activated after taste memory retrieval and memory retrieval was impaired by selectively silencing those neurons. However, it is not well known about cellular mechanisms of memory allocation in the cortex. Conditioned taste aversion (CTA) is associative learning in which a taste (such as saccharine; conditioned stimulus [CS]) with the experience of malaise (in this experiment, it was induced by i.p. of LiCl; unconditioned stimulus [US]). It is believed that the insular cortex (IC) and basolateral amygdala (BLA) are required for formation and retrieval of CTA memory. First, we tested whether it is possible to recruit the encoding of an taste memory to a subset of IC neurons with increased excitability. We manipulated neural excitability using Gq-DREADD (hM3Dq receptor). Contrary to previous findings about mechanism of fear memory allocation in the amygdala, increased neural excitability during learning did not bias c-fos expression following retrieval in IC when neural activity was only manipulated in IC. While highly excitable neurons during conditioning were preferentially expressed c-fos following CTA memory retrieval in BLA. Interestingly, IC neurons with higher excitability during learning were preferentially expressed c-fos following memory retrieval when both of IC and BLA was manipulated during

learning. These findings probably suggest that coordinated activation of IC and BLA determines which subset of neurons recruits a taste memory trace in the insular cortex.

Title: Prefrontal neural ensembles develop selective code for event associations within minutes of novel experiences

Authors: *K. TAKEHARA-NISHIUCHI[1,2], M. D. MORRISSEY[1], M. PILKIW[2];
[1]Psychology, [2]Cell and Systems Biol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Prevailing theories posit that the hippocampus rapidly learns stimulus conjunctions during novel experiences, whereas the neocortex learns slowly through subsequent, off-line interaction with the hippocampus. Recent studies, however, show that at the time of encoding, the medial prefrontal cortex (mPFC, a critical node of the neocortical network supporting long-term memory storage) undergoes rapid modifications of synaptic structure and physiology (Bero et al., 2014) as well as tagging of memory-bearing “engram” cells (Kitamura et al., 2017; see also Lesburgueres et al., 2011). These observations, along with impaired learning with disrupted mPFC (Weible et al., 2000; Takehara-Nishiuchi et al., 2005; Barker and Warburton, 2008; Gilmartin et al., 2010; Bero et al., 2014), suggest that mPFC neurons may exhibit rapid neural plasticity during novel experiences; however, direct empirical evidence is lacking. With chronically implanted an array of tetrodes, we recorded spike activity of cells in the prelimbic region of the mPFC while four naïve, male Long-Evans rats received a sequence of neutral sensory stimuli and aversive eyelid shock for the first time. Moment-to-moment tracking of neural ensemble firing patterns revealed that prefrontal network exhibited an abrupt transition upon the first presentation of an aversive, but not neutral, stimulus. This network-level change was driven by ~20% of putative excitatory neurons that acquired firing responses to the aversive and the preceding neutral stimulus within a few instances of their pairings. When a new sensory stimulus was paired with the same aversive event, these neurons immediately generalized firing responses to the new stimulus association. These results suggest that mPFC neurons are capable

of developing firing selectivity for novel relevant events on the fly, which may facilitate selective gating of those events into long-term storage.

Title: Event-locked cholinergic signal in the medial prefrontal cortex has opposing effects on temporal associative learning depending on event types

Authors: *G. TU[1,2], S. GILLMAN[3], X. YU[3], A. HALAWA[4], K. TAKEHARA-NISHIUCHI[1,2,3]; [1]Psychology, [2]Collaborative Program in Neurosci., [3]Cell and Systems Biol., [4]Human Biol., Univ. of Toronto, Toronto, ON, Canada

Abstract: The basal forebrain (BF) cholinergic system plays an important role in higher cognitive function, including learning and memory, sleep-wake regulation and attention. Recent studies found that BF cholinergic neurons respond to reward and punishment with millisecond precision (Hangya et al., 2015). Additionally, the cholinergic activity increases in response to sensory cue (Parikh et al., 2007) and stimulating BF cholinergic neurons enhances cue detection (Gritton et al., 2016). These findings led us to hypothesize that the transient, event-locked cholinergic signal improves cortical neural responses to the events and in turn facilitates encoding of event memories. Among various targets of BF cholinergic innervation, the prelimbic subregion (PrL) of the medial prefrontal cortex (mPFC) plays a key role in associating temporally discontinuous events. We thus optogenetically manipulated cholinergic terminals in PrL in trace eyeblink conditioning task, where mice associate a neutral tone (conditioned stimulus; CS) with a mild eyelid shock (unconditioned stimulus; US) over a stimulus-free trace interval. Male ChAT-IRES-Cre mice (C57B6J) were injected with adeno-associated viral vectors carrying archaerhodopsin (Arch), or channelrhodopsin (ChR2), or green fluorescent protein (Control) in a Cre-recombinase-dependent manner. Over ten days of conditioning, photo-inhibition of cholinergic terminals in PrL during the CS impaired associative learning (Control, n=13; Arch n=11); while the same manipulation during the US facilitated the learning (Control, n=13; Arch n=11). Conversely, photo-stimulation of cholinergic terminals during the US impaired the learning (Control, n=8; ChR2 n=8). In parallel, cholinergic inhibition during the

US, but not the CS, increased the expression of neuronal activity marker, c-Fos in somatostatin-positive interneurons and excitatory neurons in PrL while cholinergic excitation during the US decreased c-Fos expression in these neuron types. These findings support the proposed role of transient cholinergic signal in cue detection (Parikh et al., 2007; Howe et al., 2013; Gritton et al., 2016) but contradict with its role in signaling reinforcement surprise (Hangya et al., 2015). Rather, the reinforcer-locked cholinergic signal may modulate the level of recurrent excitation in mPFC network, thereby controlling the degree to which the network integrates information across days.

Title: Excitation of medial prefrontal cortex during conditioning enhances fear memory formation

Authors: N. SHIBANO[1], M. YAMAZAKI[1], M. KURODA[1], K. ABE[1], T. ARIMA[1], Y. KOBAYASHI[2], S. ITOHARA[2], T. FURUICHI[1], ***Y. SANO**[1];

Abstract: Memories of fearful events can be remembered for a long time, which allow animals to predict danger and is important for their survival. While the formation of strong fear memory can drive neuropsychiatric disorders, such as posttraumatic stress disorder. Contextual fear memory is initially encoded and consolidated in the hippocampus and gradually consolidated in multiple brain regions over time including the medial prefrontal cortex (mPFC). In mPFC, a subset of neurons are tagged for a given memory at early phase of learning and become functionally mature as engram cells with time. However, it is not well known how mPFC neurons contribute to fear memory formation at early phase. Previously, we and other groups showed that neural excitability biases the allocation of fear memory. Here, we have tested

whether it is possible to recruit the encoding of fear memory to a subset of mPFC neurons with increased excitability at recent time point. We manipulated neural excitability in a small or large population of mPFC neurons using Gq-DREADD (hM3Dq receptor) during contextual fear learning. Next day, retrieval test was implemented and analyzed c-fos expressing neurons which were activated by memory retrieval. In both of manipulation in a small and large neural population, increased neural excitability during learning did not bias c-fos expression following fear memory retrieval. But contextual fear memory formation was significantly enhanced when neural excitability was manipulated in a large but not small subset of neurons. Interestingly, a size of cell assembly involved in memory retrieval was significantly increased in the basolateral amygdala (BLA) but not in mPFC. The number of c-fos expressing neurons was correlated with the amount of freezing behavior. We have also tested which neuromodulator is involved in fear memory formation. A weak fear memory was strengthened by increasing noradrenergic activity in mPFC. Taken together, our results suggest that neural excitability in mPFC during learning modulates fear memory formation via activation of BLA neurons, which could be independent of recruiting mPFC neurons into a memory trace. And strong input from noradrenergic neurons to mPFC could augments fear memory formation.

Title: *Danionella translucida:* A novel fish species for systems neuroscience

Authors: *A. PENALVA-TENA, A. D. DOUGLASS, J. BEDKE, J. P. BARRIOS, E. P. L. BERTRAM, W.-C. WANG, E. S. B. COOK;
Univ. of Utah, Salt Lake City, UT

Abstract: A central goal of systems neuroscience is to understand how the coordinated activities of many single neurons determine behavior. The small size and optical transparency of the larval zebrafish (*Danio rerio)* enable the recording and manipulation of neural activity throughout its brain, but larval zebrafish have a rudimentary behavioral repertoire, and complex social and learning behaviors do not appear until adulthood when they are no longer optically transparent.

Here we establish miniature fish species *Danionella translucida* as a laboratory model that overcomes these limitations, demonstrating the genetic, optical, and behavioral advantages of this novel fish model during its adult stages.
Adult *Danionella* retain a small size and optical transparency during adulthood, allowing for whole-brain imaging techniques. We demonstrate the use of two-photon microscopy to image deep within the brain of adult *Danionella* at a high optical resolution, a feat not achievable in adult zebrafish. The close phylogenetic relationship between *Danionella* and zebrafish has also allowed us to use zebrafish-derived enhancer elements to drive the expression of foreign transgenes in specific cells within *Danionella.*
We demonstrate the complex behavioral repertoire of *Danionella* by reliably developing a social preference and reinforcement assay for this fish species. We show *Danionella* exhibit an innate preference for social interaction, which acts as a behavioral reinforcer in a conditioned place preference paradigm. These innate social responses are species and gender-specific, and are mediated by visual and olfactory cues. In addition, the introduction of antagonists to the oxytocin receptor, a peptide implicated in social reward, diminishes these behaviors.
The optical, genetic, and behavioral tractability of *Danionella* provides a new model to interrogate the neural circuitry of complex social and learning behaviors.

Title: Cognitive enhancement of perceptual decision making through vagus nerve stimulation

Authors: *N. SUBRAMANIAN[1], B. GOOLSBY[2], H. KIM[1], P. NAVARRO[1], M. BRODSKY[2], M. MANSY[2], K. OWEISS[1,2,3];

Abstract: The vagus nerve innervates the Nucleus Tractus Solitarius (NTS), which in turn relays much of the information received to the reticular formation, the Locus Coeruleus (LC) and Basal forebrain (BF) which directly innervate the medial prefrontal cortex (mPFC). Previous studies from our group have demonstrated that reversible optogenetic suppression of mPFC neurons

degrades performance in a delayed response task requiring animals to perceive auditory cues for rewarded choice. Herein, we hypothesized that vagus nerve stimulation (VNS) would enhance perceptual decision making when the task required animals to accumulate evidence from a mix of salient and non-salient cloud of tones. We varied the task complexity by increasing the degree of tone overlap between the low and high frequency categories. We found significant improvement in behavioral performance in the VNS group compared to the sham and untrained control groups. Furthermore, VNS significantly shortened decision time and increased performance accuracy for complex task (20% tone overlap between tone categories) compared to the basic task (no tone overlap). Using fiber photometry, VNS stimulation increased the rate of Ca^{2+} transients in GCaMP6f+ mPFC neurons, suggesting that VNS might enhance attentional mechanisms through increased synchrony between neurons in the neuromodulatory pathways of both LC and BF that permits deciphering salient and non-salient cues.

Title: All-optical functional mapping of association cortex subserving working memory and perceptual decision making

Authors: B. GOOLSBY[1], H. J. KIM[2], J. CANZANO[3], *K. G. OWEISS[1,2,3];
[1]Biomed. Eng, [2]Electrical & Computer Eng, [3]Col. of Med., Univ. of Florida, Gainesville, FL

Abstract: The posterior parietal cortex (PPC) is part of association cortex that reciprocally projects to primary sensory areas, thalamus and striatum. It has been implicated in a number of higher order cognitive processes, including decision making (DM), working memory (WM) and motor planning (MP). The extent to which PPC neurons simultaneously contribute to these processes, however, remains elusive. Here we trained head fixed mice on a delayed response task that required animals to discriminate a sequentially presented 'cloud of tones' sampled randomly from high and low frequency bands to earn water reward through corresponding left or right lick ports after a delay period. Mice learned to perform the task at 90% correct at one second delay and maintained up to 70% performance through a five second delay. Two-photon Ca^{2+}imaging of the genetically encoded Ca^{2+} indicator GCaMP6f revealed differential engagement of GCaMP6f^{+} PPC neurons during multiple task epochs. Individual spikes from Ca^{2+}dynamics were inferred

and used to estimate the extent of temporal correlation with behavioral task variables using a generalized linear model, permitting individual neurons to be characterized by their weights in each behavioral epoch with high temporal precision. We found that neuronal population activity significantly encodes task variables with different degrees across time, suggesting dynamic contributions to DM, WM and MP. Within behavioral epochs, neurons were differentially tied to tone, delay, and behavioral response epochs, including choice outcome in each trial. Inferring functional connectivity between these task-dependent neurons using Bayesian graphical models allowed us to study the extent to which specific network states during each behavioral epoch are critical to maintain in the next epoch for correct choice, thereby contributing to a sequential - rather than a persistent - activity coding model of task variables. Furthermore, event-triggered targeted photostimulation of a subset of graph-derived influential neurons using the redshifted opsin C1V1 permits establishing causal contribution of subpopulations of PPC neurons to both network dynamics and choice behavior.

Title: Simultaneous two-photon calcium imaging and cell-targeted optogenetic stimulation shapes somatosensory cortex plasticity

Authors: N. SUBRAMANIAN[1], ***J. S. CANZANO**[2], B. GOOLSBY[3], H. KIM[1], P. NAVARRO[1], R. CASTRO[1], K. G. OWEISS[1,3,2];
[1]Electrical & Computer Engin., [2]Col. of Med., [3]Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Somatosensory feedback is a fundamental component of motor learning. Subjects with disembodied limbs rely on artificially induced somatosensation to guide motor control, yet despite advances in stimulation strategies that measure perception in these subjects, successful integration into moment-to-moment movement trajectories remains largely unexplored. In the intact system, sensory-evoked population activity in primary somatosensory cortex (S1) could be viewed to arise from a low-dimensional latent dynamic system in which implicit latent variables drive the evoked high dimensional neural activity. Thus, neurons with the highest weight in this low dimensional space would theoretically be the most influential in driving local population activity towards desired states associated with ongoing motor encoding populations in primary

motor cortex (M1). Herein we developed a platform for interrogating S1 populations in head-fixed behaving mice via two-photon volumetric calcium imaging and simultaneous cell-targeted optogenetic stimulation. The platform benefits from close proximity of the M1 and S1 regions of the caudal forelimb area (CFA) and therefore simultaneous imaging and stimulation of both regions is possible. Mice chronically implanted with cranial windows and virally-induced to co-express the calcium indicator GCaMP6f and redshifted opsin C1V1 in the CFA are trained to perform a simple sensory-guided motor task. The apparatus consists of mice locomoting on a floating ball capable of delivering vibrotactile feedback during virtual navigation. M1 and S1 CFA responses to passive and active forepaw touch are first analyzed to functionally tag GCaMP6f+, C1V1+ neurons. Estimating latent variables to identify neurons with high weights in the low-dimensional latent space is then achieved through a Bayesian graphical model. These ensembles are then photostimulated conditioned on behavioral events in the virtual maze to achieve S1 activity dynamics that inform motor planning. Preliminary results show as little as 30 trials of timelocked vibrotactile + optogenetic stimuli delivered to an individual CFA neuron is sufficient to introduce a significant change in receptive field and a transient calcium response (crossing 3xSD threshold of baseline during post-stim period, n=10 trials). These results will help describe 1) cortico-cortical information transmission between S1 and M1 in response to natural tactile stimuli during ongoing movements 2) cortical responses to cell-targeted optogenetic stimulation and its capacity to inform motor output 3) the capacity for cell-targeted optogenetic stimulation to drive local circuit plasticity.

Title: Differential task coding between the prelimbic and rostral anterior cingulate cortices during spatial working memory

Authors: *J. J. STOUT, Jr[1], A. L. GRIFFIN[2];
[1]Psychological and Brain Sci., Grad. Student, Newark, DE; [2]Univ. Delaware, Newark, DE

Abstract: The medial prefrontal cortex (mPFC) is composed of distinct sub-regions defined by anatomical connectivity and behavioral correlates. The prelimbic sub-region (PrL) of the mPFC receives dense innervation from the hippocampus with converging findings of spatially

modulated neuronal firing-patterns during spatial working memory. Alternatively, the anterior cingulate sub-region (ACC) receives less input from hippocampus and has been shown to be more involved in attention and reward-related processes. To better understand how neuronal activity in these prefrontal sub-regions supports memory and decision-making, we conducted *in vivo* single-unit recordings as rats performed a delayed non-match to position task (DNMP) on a T-maze. This paradigm teases apart encoding, maintenance, and decision-making processes via the distinct sample, delay, and choice-phases of the task. We sought to understand how neurons represent and integrate goal-relevant spatial information within the context of DNMP task-phase. First, by comparing the correlation-coefficients between firing-rates from each maze-location, we find spatially-influenced firing-patterns such that neurons increase, or decrease, their activity while traversing locations of the maze. Next, we report that a task-phase code is integrated into this spatially-influenced activity, with both sub-regions exhibiting a decision-accuracy-dependent increase in firing-rate at the sample-phase T-junction. Lastly, training a linear classifier to distinguish population firing-patterns during the sample and choice-phases of the task, we find that both sub-regions were predictive of task-phase at the T-junction. However, ACC showed selective prediction of task-phase at stem and goal-zone, while PrL showed selective prediction of task-phase on the goal-arms. Given the overlap of sample-phase preference among the sub-regions, it is likely that stronger limbic connections support PrL's shared importance with infralimbic for DNMP performance. Finally, our classification findings support ACC's roles in attentional and reward-related processes, while suggesting that PrL continues to exhibit a representation linked to decision-making after T-junction occupancy. These results establish a multiplexed code for location and task-phase, while supporting a subtle heterogeneity among the sub-regions.

Title: Odor preference training in week-old rat pups is associated with changes in protein and non-protein coding messenger ribonucleic acids in odor-encoding mitral cells

Authors: *C. W. HARLEY[1], M. N. NARTEY[2], L. PEÑA-CASTILLO[3], M. LEGROW[2], J. DORÉ[2], A. DARBY-KING[2], S. J. CAREW[2], Q. YUAN[2], J. H. MCLEAN[2];

Univ. of Newfoundland, St. John's, NL, Canada; [3]Dept. of Computer Sci., Mem. Univ. of Newfoundland, St.John's, NL, Canada

Abstract: Odor preference learning in the week-old rat pup captures the main features of associative mammalian learning. Odor learning requires the cAMP/PKA/CREB cascade. NMDA receptors are needed for its initiation, and memory is supported by AMPA receptor insertion. A ten-minute pairing of odor with stroking produces a 24-hour long-term memory. Protein translation and transcription within the first hour post-training are required for 24-hour memory. Here pups were trained with peppermint odor and stroking for 10 min, tested for associative learning at 30 min and sacrificed at 50 min for laser micro-dissection of the dorsal olfactory bulb peppermint-encoding mitral cells. Control tissue was taken from rat pups not given stroking during the 10 min odor exposure. Microarray analysis revealed changes in 11 protein-coding mRNAs and 13 non-protein coding mRNAs. Among the protein-coding mRNAs, Sec23b, Clic2, Rpp14, Dcbld1, Magee2, Mstn, Fam229b, RGD1566265, and Mgst2 were up-regulated, while Gng12 and Srcg1 were down-regulated. MicroRNA23b was also down-regulated. Sec23b, Clic2, and Dcbld1 proteins were confirmed, using immunocytochemistry, to be increased in the mitral cell layer 50 min post training using odor and stroking with single naris occlusion. Thus, neither odor nor stroking alone is responsible for increases in these pathways. The protein-coding changes are consistent with extracellular matrix remodeling and ryanodine receptor mediation in odor preference memory, and with a role for CREB and AP1 in regulating memory-related mRNA changes. The majority of the mRNA changes (13) were in nucleolar and nuclear non-coding RNAs. The non-coding changes suggest splicing alterations in early olfactory memory and are consistent with evidence that changes in t-mRNA fragments occur with olfactory learning. While a number of the mRNA changes identified correlate well to models of learning and memory that depend on circuitry change, the roles of others are unknown and may point to novel supporting elements. The relatively small number of gene changes in the input/output link for learning in this model, the mitral cells, offers an opportunity to thoroughly characterize learning's remodeling and structural support after training.

Title: Cornichon homolog-3 (CNIH3) modulates hippocampal synapses and memory in female mice

Authors: *H. E. FRYE[1], C. TROUSDALE[1], J. D. DOUGHERTY[2], E. C. NELSON[3], J. MORON-CONCEPCION[1];
[1]Anesthesiol., [2]Genet. and Psychiatry, [3]Psychiatry, Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Cornichon homolog-3 (CNIH3) is an AMPA receptor (AMPAR) auxiliary protein highly expressed in the hippocampus. While AMPARs are critical actors for hippocampal synaptic plasticity and memory formation and maintenance, little is known about the role of CNIH3 in these processes. We hypothesize that CNIH3 modulates learning and memory through regulation of AMPAR activity and synapse stability in the hippocampus. Using C57BL/6 *CNIH3* knockdown (KD) mice obtained from the Knockout Mouse Project, we generated *CNIH3* full knockout (KO) male and female mice for use in this study. Western blot analysis in sub-cellular fractions demonstrate that female *CNIH3* KD mice have reduced PSD-95 expression, an excitatory post-synaptic scaffolding protein, at hippocampal post-synaptic densities (PSD). As synaptic stability plays a critical role in learning and memory, we utilize the Barnes Maze assay to assess the impact of *CNIH3* expression on AMPAR-mediated spatial memory. In this task, *CNIH3* KO females show impaired learning processes compared to wild-type (WT) controls, as observed through increased primary errors, reduced path efficiency, and higher latency to locate the target. Interestingly, no deficits are observed in *CNIH3* KO male mice. To determine if increased *CNIH3* expression in the dorsal hippocampus (dHPC) improves spatial memory, we injected an AAV5-CAMKII-myc-CNIH3-t2A-GFP virus into the dHPC of WT mice to induce local *CNIH3* overexpression (OE). *CNIH3* OE in the dHPC significantly improves spatial memory compared to sham injected controls in female mice, but not in male mice. We hypothesize that we can rescue the spatial memory deficits in *CNIH3* KO females with *CNIH3* OE in the dHPC. This study establishes CNIH3 as a key component in the maintaince of hippocampal synaptic structure and spatial memory in female mice. Future studies will assess the role of CNIH3 on hippocampal synapse formation and density within the dHPC of *CNIH3* KO mice, and investigate how sex impacts the role of CNIH3 in these processes.

Title: Conditional deletion of CC2D1A impairs hippocampal synaptic plasticity and cognitive function through Rac1 hyperactivation

Authors: *C.-Y. YANG[1], T.-H. YU[1], W.-L. WEN[2], P. LING[3], K.-S. HSU[1,2];
[1]Inst. of Basic Med. Sci., [2]Dept. of Pharmacol., [3]Dept. of Microbiology & Immunol., Col. of Medicine, Natl. Cheng Kung Universit, Tainan, Taiwan

Abstract: Coiled-coil and C2 domain containing 1A (CC2D1A) is a protein recently identified as nuclear factor-κB activator. Human studies have shown that, Mutation of CC2D1A result in nonsyndromic intellectual disability. However, it remains unclear how *cc2d1a* mutation alters brain functions. We used Cre/loxp recombinase-based strategy to conditional delete CC2D1A in excitatory neurons to explore its role in hippocampal synaptic plasticity and cognitive function. We have confirmed the expression pattern of CC2D1A in hippocampus from embryonic stage to adulthood and it expresses in both excitatory and inhibitory neurons. Conditional deletion of CC2D1A (cKO) in excitatory neurons leads to spatial memory impairment and anxiety-like behavior. Consistently, cKO mice exhibited impaired long-term potentiation (LTP) maintenance in hippocampal CA1 region. We also discovered that, cKO mice have decreased complexity in apical and basal dendritic arbors of CA1 pyramidal neurons. An enhanced basal Rac1 activity was observed in cKO mice. This enhancement was mediated by reduced SUMO-specific protease 1 (SENP1) and SENP3 expression, thus increasing the amount of Rac1 SUMOylation. Partial blockade of Rac1 activity by NSC23766 rescued the impairment of cognitive function and LTP maintenance in cKO mice. Altogether, our results implicate Rac1 hyperactivity in synaptic plasticity and cognitive deficits observed in *Cc2d1a* cKO mice and reveal a novel role for CC2D1A in regulating hippocampal synaptic function. Such insights may have implications for the utility of Rac1 inhibitors in the treatment of intellectual disability caused by Cc2d1a mutations in human patients.

Title: Pin1 gene deficient mice impair spatial memory and show small brain volume

Authors: *H. OHTAKI[1], Y. TANAKA[1], T. UCHIDA[3], K. KIRIYAMA[1], K. ONO[2], K. HONDA[4];
[1]Anat., [2]Neurol., Showa Univ. Sch. of Med., Tokyo, Japan; [3]Mol. Cell Sci., Tohoku Univ., Sendai, Japan; [4]Anat., Showa Univ., Tokyo, Japan

Abstract: Pin1 is a ubiquitous peptidyl-prolyl cis/trans isomerase (PPIase) and has been shown to be necessary for cell growth and apoptosis. While pin1 deficient (-/-) mice are suggested the contribution of the age-dependent neurodegeneration, the relation between behavior and pin1 deficient has not been clarified in detail. The purpose of study is to determine the relationship between pin1 gene and spatial memory. Pin1 homozygous gene deficient (-/-) and the wild-type mice were obtained as a littermate by breeding from the heterozygous gene deficient (+/-) mice. Battery of behavioral tests were performed age-matched Pin1 (-/-) and wild mice at 12 month old. The tests were involved in Y-maze, open-field spontaneously motor activity, new objective recognition and Morris water maze to examine the recognition, learning and memory function. Another group of animals was examined light/dark transition to determine the anxiety-like behavior at 13 month. To determine morphology of the brain, the animals were also measured T2-weight MRI (ICON 1T, Burker) coronal images in the brain every 3 month for 15 month, and semi-quantified the area of coronal plate by manually tracing with Osirix software. No significantly differences were recognized in the body weight during the experiment. Y-maze score, and open-field spontaneously motor activity between Pin1 (-/-) mice and the wild-type (+/+) mice also recognized no difference between the littermate. However, the Pin1 (-/-) mice impaired the score in the new objective recognition and Morris water maze. Although there were no differences to the total sojourn time in light/dark room for 3 days (6-trials), the Pin1 (-/-) mice significantly frequent passing number of gate after 3rd trial, suggesting the mice was restless. The brain volume in the Pin1 (-/-) KO mice was significantly smaller than the wild-type mice, especially in the frontotemporal plane. These results suggest that Pin1 (-/-) mice impaired spatial cognitive function with frontotemporal atrophy.

Title: Synaptogenesis and neuronal activation dependent on MeCP2/CaMK2A phosphorylation signaling pathway

Authors: *L.-C. LEE[1], M.-T. SU[2], H.-Y. HUANG[1], Y.-C. CHO[3], T.-K. YEH[1], C.-Y. CHANG[1]; [1]Sci. Educ. Center, Natl. Taiwan Normal Univ., Taiper, Taiwan; [2]Dept. of Life Sci., [3]Grad. Inst. of Sci. Educ., Natl. Taiwan Normal Univ., Taiper, Taiwan

Abstract: Calcium/Calmodulin-dependent protein kinase II (CaMKII) plays fundamental roles in synaptic plasticity that underlies learning and memory. The auto-phosphorylation of CaMK2A (CaMKII alpha) works as a 'molecular memory' for a transient calcium activation, thereby accelerating learning. From previous study, we proposed and evidenced that microRNAs and MeCP2 homeostatic regulation are involved in the same molecular signaling pathways as disease development and normal synaptic plasticity in learning. Bridging perception and cognition, we decide to investigate the synaptogenesis and neuronal activation. How it dependent on MeCP/CaMK2A phosphorylation and de novo variants in CaMK2A cause impairment perception or cognitive ability. Neuronal human derived neuroblastoma cell line (SH-SY5Y) cells with inducible MeCP2 overexpression gain-on-function will dramatically increase phosphorylated MeCP2 (phosphor Ser80). Then it positivity affected phosphorylated CaMK2A (phosphor Thr286) and CaMKII-PP1 signaling pathway, which CaMK2A is simultaneously bound by Ca^{2+}/CaM following a Ca^{2+} influx initial phosphorylation and neuronal activation. Furthermore, the negative regulation CaMK2A phosphorylation by microRNA will be investigated either. De novo variants in CaMK2A predict perception or cognitive ability in human adolescent. CaMK2A-rs2241694 was significantly associated with perceptual speed and accuracy in this 832 tenth-grade Taiwanese volunteers' cognitive ability study. The others de novo variants has been assay by a cell- and single molecule-based methods to monitor conformational signaling required for synaptic plasticity. Our data established the importance of CaMK2A and its auto-phosphorylation in human cell based model for neuronal plasticity and this molecular memory mechanism was associated with human adolescent's perception or cognitive ability.

Title: Mice deficient in Akain1, a novel protein kinase A-binding protein, exhibit decreased pain sensitivity and impaired context discrimination

Authors: K. FUJII[1,2], Y. KOSHIDAKA[2], M. ADACHI[2], Y. YANAGIBASHI[2], M. MATSUO[2], H. NISHIZONO[2], Y. AIZAWA[3], *K. TAKAO[1,2];

Abstract: Cyclic AMP (cAMP) -dependent protein kinase (PKA) is a ubiquitous serine/threonine kinase. PKA plays a key role in the signaling of many G protein-coupled receptors through the consequent production of cAMP. The specificity of PKA actions is achieved by controlling its cellular localization through a family of A-kinase anchoring proteins (AKAPs). AKAPs localize PKA to specific intracellular sites and spatially restrict intracellular signaling events. AKAP-PKA interactions control various cellular processes, including the regulation of neuroplasticity. A-kinase anchor inhibitor 1 (Akain1) is a novel PKA-binding protein with a unique function in PKA signaling. Akain1 competes with other AKAPs (e.g., AKAP1 and MAP2) for PKA binding and seems to cancel intracellular localization of PKA. In particular, Akain1 is preferentially expressed in neural tissues. How Akain1 affects brain function and behavioral characteristics, however, is unclear. To elucidate the function of Akain1, we generated Akain1 knockout (KO) mice on the C57BL/6J background using the CRISPR/Cas9 genome editing system. Akain1 KO mice were subjected to a comprehensive battery of behavioral tests. In the hot plate test, the latency to the first hind paw response on the hot plate was significantly longer in Akain1 KO mice than in their wild-type (WT) litter mates, suggesting that Akain1 KO mice have decreased pain sensitivity compared with WT mice. In the pattern separation test, Akain1 KO mice exhibited impaired performance in distinguishing between two similar contexts. In the Barnes maze test, Akain1 KO mice and WT mice learned the fixed escape box position at the same rate. For reversal learning, in which the target was moved to the opposite side of the maze, the Akain1 KO mice and WT mice learned the new escape box position at similar rates. While the time spent investigating the new target was significantly longer than the original target, there was no significant difference in Akain1 KO mice, suggesting that Akain1 KO mice had deficits in behavioral flexibility. These findings suggest that Akain1 has a critical role in pain sensitivity and discrimination of similar contexts.

Title: miR-195 affects cognitive function in the aging-associated changes by targeting semaphorin 3A

Authors: *Y.-M. CHAO, J. Y. H. CHAN;
Inst. for Translational Res. in Biomedicine, Kaohsiung Chang Gung Mem. Hosp., Kaohsiung, Taiwan

Abstract: MicroRNA-195 (miR-195), a member of the miR-16/15/195/424/497 family, is abundantly expressed in normal tissue, including the brain. Recently, an anti-aging role of miR-195 was reported. However, its significance in the change of cognitive function, in particular in the whole animal system, has not been properly characterized. Using a tamoxifen-inducible miR-195 knockout (miR-195 /- KO) mice based on the *Cre-loxP* system, we compared in this study temporal profiling of cognitive functions in the KO mice at age of 3, 6, 12, 18 or 24 months to their wild-type (WT) control. The Morris water maze was performed for the evaluation of cognitive function. In both WT and miR-195 /- KO mice, the learning ability was age-dependent but there was no significant difference between the two groups to learn the location of a hidden platform in the water maze for 5 consecutive days. After training, both groups of mice were subjected to probe trials at 24 h, or in 1 and 2 weeks after the last training session, in which the hidden platform was removed from the water maze. At age of 3, 6 and 12 months, not an only preference in the target quadrant was less but also the time spending in the target quadrant was shorter in miR-195 /- KO mice, compared to the WT mice. Semaphorin 3A (Sema 3A) as a potential target gene downregulated by miR-195. So, we overexpressed Sema 3A by lentivirus microinjection into hippocampus and Rapamycin intervention by microinjection into the dorsal third ventricle, the mice which administrated rapamycin reversed the disrupted learning and memory induced by overexpressed Sema 3A. Taken together, these data indicated that while miR-195 targeting gene Sema 3A may play a permissive role in consolidating the spatial working memory, its role in age-associated memory impairment.

Title: Neuronal cannabinoid receptor 2 plays a role in anxiety and memory

Authors: J. KOMOROWSKA, A. BILKEI-GORZO, A. ZIMMER, *B. SCHURMANN; Univ. of Bonn, Bonn, Germany

Abstract: The Endocannabinoid system is a neuromodulatory system that influences a majority of vital physiological functions. It consists of endocannabinoids, their synthesizing and degrading enzymes and receptors. The main receptors are CB1 (cannabinoid receptor 1, localized primarily on neurons) and CB2 (cannabinoid receptor 2, localized primarily on glial and immune cells). Contrary to the common believe, recent publications showed the presence of the CB2 receptor on hippocampal neurons and its functional relevance specifically in the CA2/3 area (Stempel et al., 2016). A long-lasting activity driven hyperpolarization depends on neuronal CB2 in CA2/3 pyramidal neurons. CB2 signaling in turn alters the input/output function of CA3 PCs and changes gamma oscillations *in vivo*.
To assess the behavioral consequences of the CB2 deletion we tested constitutive (*Cnr2* d/d) and neuron-specific (*Cnr2* fl/fl Syn-Cre wt/tg) knock-out mice in two sets of behavioral paradigms. We analyzed social (Partner Recognition test) and spatial (Novel Object Location Recognition and Morris Water Maze) memory as well as anxiety (Light-Dark test and O-maze test) in 3 months old male mice. Constitutive deletion of the receptor affects social memory and memory retrieval in the Probe trial of Morris Water Maze. For the most part these phenotypes depend on neuronal Cnr2 as we observed similar behavioural phenotypes in neuron specific conditional knock out animals. Both constitutive and conditional knock-out mice display alterations in anxiety-related behaviours. Altogether our results clearly show that the neuronal cannabinoid receptor 2, despite its low expression, has an impact on mice behaviour playing a role in memory and anxiety.

Title: Subregion-specific expression of the endogenous nicotinic receptor modulator Lynx1 and relation to cognitive function in mice

Authors: *Y. SHERAFAT[1], M. BAUTISTA[2], J. FOWLER[2], C. D. FOWLER[3];
[1]Univ. of California of Irvine, Irvine, CA; [3]Neurobio. and Behavior, [2]Univ. of California Irvine, Irvine, CA

Abstract: Nicotinic acetylcholine receptors (nAChRs) have been implicated in various aspects of cognitive function, including learning, memory and sensory processing. However, little is known about the endogenous modulators that alter the function of nAChRs and the resulting impact on behavior. Here, we examined the role of the nAChR endogenous protein modulator, Lynx1, in a knockout mouse model. The expression of Lynx1 was first assessed in various brain regions, and interestingly, we found subregion specific expression of the gene within relevant brain regions, such as the hippocampus and cortex. Thus, we then probed for differences in nAChR-mediated neuronal activation patterns between Lynx1 knockout and wildtype mice. Thereafter, to test the effects of Lynx1 on sensory processing, Lynx1 knockout mice and their wildtype littermates were examined in the prepulse inhibition test. To examine the effects on learning and cognitive flexibility, Lynx1 knockout and wildtype mice were trained to press a lever to receive food reward under a fixed ratio schedule of reinforcement. After acquisition, mice were then assessed in a lever reversal task. Together, these findings further define the function of Lynx1 proteins in cholinergic signaling mechanisms in the brain.

Title: The E3 ubiquitin ligase ITCH is critical for learning and memory

Authors: *Y. DU[1], R. ZHENG[2], J. XU[2], J. LUO[2];
[1]Zhejiang Univ. Sch. of Med., Hangzhou, China; [2]Zhejiang Univ. Sch. of Med., Zhejiang, China

Abstract: It is wildly accepted that memory formation and consolidation needs protein synthesis which is required for synaptic plasticity changes in neurons, while whether memory requires protein degradation is not well known. ITCH, an E3 ubiquitin ligase, is involved in the controlling of many aspects of immune responses, tumorigenesis, development, and stress responses. However, few findings indicated the role of ITCH in nervous system. Here, we reported that nestin-cre induced conditional knockout of ITCH in brain impaired multiple forms of memory but had no influence on the anxiety level or the social ability of mice. It suggested that ITCH maybe specifically important for memory through mediating the degradation of related proteins. ITCH might be crucial elements of memory modulation and therefore also of intervention.

Title: Acute administration of methamphetamine impairs higher cognitive functions in C57BL/6J mice through cortico-striatal circuits

Authors: *J. LIAO[1], T. NAGAI[2], B. WULAER[2], T. NABESHIMA[3], K. YAMADA[2];
[1]Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [2]Nagoya Univ. Grad Sch. Med., Nagoya, Japan; [3]Fujita Hlth. University, Grad. Sch. of Hlth. Sci., Toyoake, Japan

Abstract: Touchscreen-based cognitive tasks have been developed for rodents to provide a better translational approach across species for further understanding of the cognitive impairments observed in various neuropsychiatric disorders. METH is one kind of highly addictive drugs, and METH-treated animals have been widely used as a pharmacological animal model of schizophrenia for the screening of compounds with antipsychotic properties. In the

present study, we aimed to explore the effect of methamphetamine (METH) on higher cognitive functions by a touchscreen-based visual discrimination task. Mice were initially trained to discriminate between a pair of stimuli. On the testing day, mice were treated saline or METH (0.3 or 1 mg/kg, i.p.). METH significantly reduced the accuracy in the visual discrimination task. To clarify the mechanism underlying the METH-induced cognitive deficits, we also analyzed the changes in neuronal activity by METH treatment using c-Fos immunostaining. METH treatment markedly increased the number of c-Fos-positive cells in the medial prefrontal cortex, dorsomedial striatum and thalamus. We demonstrated that acute METH treatment induces cognitive dysfunction by using the translatable visual discrimination task, possibly through the activation of cortico-striatal-thalamic circuits.

Title: Alpha lipoic acid and metformin alleviates experimentally induced insulin resistance and cognitive deficit by modulation of TLR2 signalling

Authors: *A. UNIYAL[1], S. P. SAH[2];
[1]Dept. of Pharmaceut. engineering and Technol., Indian Inst. of Technol., Varanasi, India; [2]Univ. Inst. of Pharmaceut. Sci., Panjab Univ., Chandigarh, India

Abstract: Background: Obesity is commonly found to be co-morbid with type 2 Diabetes Mellitus. In obese diabetic patients, TLR-2 receptor induced inflammation leads to the development of insulin resistance (IR). Furthermore, the IR is considered to be the most important cause for promoting cognitive decline which is evident in brain of patients with Alzheimer's disease related dementia (ADRD). **Methods:** In this study, the effect of α-lipoic acid (ALA) has been examined in rodent model of zymosan induced insulin resistance and cognitive deficits, targeting at TLR-2 signalling. TLR-2 agonist, Zymosan initiates inflammatory cascade, resulting in IR and cognitive dysfunction. Zymosan (50 mg/kg *ip*) was given to mice on 1st, 8th, 15th and 22nd day to induce IR which was confirmed by hyperglycaemia, hyperinsulinemia, hyperlipidimea, increased glycated haemoglobin and HOMA-IR. Further the cognitive performance was assessed in Morris water maze revealing cognitive deficit in zymosan treated mice. **Results:** Daily treatment with ALA for 28 days (50, 100, 200 mg/kg *ip*) significantly improved insulin sensitivity and cognitive performance in mice by decreasing insulin resistance, corticosterone, IL-6 levels, acetylcholinesterase enzyme activity and oxidative

stress in liver, cortex and hippocampus. ALA also increased adiponectin level and reduced body weight. Combination of ALA (100 mg/kg, *ip*) with metformin (100 mg/kg, *ip*) exhibited a potentiating effect in improving cognitive performance and insulin signalling.

Title: Centrally administered scopolamine impairs spatial memory retrieval and alters hippocampal matrix metalloproteinase levels

Authors: *M. L. OLSON, A. BENSON, C. BUCHING, H. GLEWWE;
Concordia Col., Moorhead, MN

Abstract: The accurate formation and retrieval of memories is an important function of the brain, and the forebrain cholinergic system has been widely studied for its role in spatial memory formation. Morphologically, the structural alteration of synaptic connections that underlies spatial memory appears to also require reorganization of the extracellular matrix (ECM). A family of enzymes known as matrix metalloproteinases (MMPs) are known to play an important role in restructuring the ECM. Our study sought to determine whether the cholinergic antagonist scopolamine affects spatial memory retrieval in a standard circular water maze paradigm. We also tested whether scopolamine affects learning-induced changes in hippocampal MMP-3 and MMP-9. Male Sprague-Dawley rats were trained in the circular water maze for 5 days and then underwent cannulation surgery. Scopolamine was administered prior to retrieval testing and hippocampi were dissected and analyzed for levels of MMP-3 and MMP-9. Our results indicate that scopolamine impairs spatial memory performance on testing trials and on post-test probe trials. Our results also indicate a relationship between hippocampal MMP-3 and MMP-9 levels and spatial memory formation, and suggest that regulation of these proteins may be important in mediating the activity-induced neuronal plasticity which is thought to underlie memory formation.

Title: GR receptor activation in dorsolateral striatum enhanced extinction of a response memory

Authors: A. FUENTES-IBAÑEZ, N. SERAFÍN, R. A. PRADO-ALCALÁ, *G. L. QUIRARTE;
Dept. de Neurobiología Conductual y Cognitiva, Inst. de Neurobiología-UNAM, Querétaro, Qro., Mexico

Abstract: Extinction has been used as therapeutic method to treat neuropsychiatric disorders such as posttraumatic stress disorder and addictions. These kinds of disorders have been associated with deficiencies in the mnemonic functions of several brain structures, including the dorsolateral striatum (DLS). DLS is a cerebral region involved in acquisition, consolidation and extinction of tasks acquired through operant conditioning procedures such as stimulus-response associations, skills, and habits. On the other hand, glucocorticoids (GCs), such as corticosterone (CORT) in rodents, are hormones that modulate the acquisition and use of response strategies and could modulate extinction as well. In this context, we wondered if the administration of CORT to EDL could facilitate extinction when activating the GCs receptor. To study this issue male Wistar rats were trained in a DLS-dependent response task using the Tolman maze. Once this behavior had been acquired, three extinction sessions were given. Immediately after the first extinction session, CORT (5, 10 or 30 ng/0.5 μL) or vehicle was bilaterally administered to the DLS. The second and third extinction sessions took place 24 and 48 h after the first one, respectively. The latencies to reach the reinforcer and the number of conditioned responses were recorded. The statistical analysis showed no differences between groups regarding the number of conditioned responses or latencies in the first extinction session. In the second and third extinction sessions, the CORT 30 ng group exhibited more efficient extinction. Administration of RU486, a selective antagonist to GR receptor, before the administration of CORT blocked this effect. Importantly, CORT (30 ng) administered 90 min after of the first extinction session had no effect on the parameters measured. These results suggest that striatal glucocorticoids enhance extinction; this effect may be attributed to an effect on consolidation of the extinction memory which may be mediated by GCs receptor activation. We thank Cristina Medina, Martin García, Alejandra Castilla, Deisy Gasca, Nuri Aranda, Lourdes Lara, Ramón Martínez and Omar

González for technical support. Funded by CONACYT (Grant 251634, and Scholarship 419800 to AFI) and PAPIIT-UNAM IN204118.

Title: 5-HT_6 receptor and forgetting process

Authors: *A. MENESES[1], I. PAZ[2,3], K. GRYCHOWSKA[3], V. CANALE[3], P. ZAJDEL[3]; [1]Cinvestav - IPN, Mexico City, Mexico; [2]Cinvestav - IPN, Mexico, Mexico; [3]Medicinal Chem. Dep, Jagiellonian Univ. Med. Col., Krakow, Poland

Abstract: Forgetting is a physiological process seldom investigated as a therapeutic target for memory disorders. In a decay forgetting paradigm there are two-time points to study this process, when forgetting is forming (e.g., 48-h following the interruption period) and/or before the retrieval of memory (e.g., 168-h). We know that forgetting occurs one week of interruption following autoshaping training/testing sessions, showing decreased conditioned responses (CR%). In this work, the partial 5-HT_6 receptor agonist EMD-386088 (5.0 mg/kg, *ip*) partially reversed forgetting or facilitated retrieval (administration -168-h); however, when this compound was administered before forgetting formation and retrieval, the latter process was even more importantly facilitated. The 5-HT_6 receptor inverse agonist PZ-1444 (3.0 mg/kg, *ip*) had an anti-forgetting effect and facilitated retrieval. When PZ-1444 was injected at 48- and 168-h from the interruption, it produced minor facilitation of retrieval. However, a higher dose of PZ-1444 (5 mg/kg, *ip*) produced a minor anti-forgetting effect or less retrieval. Moreover, the 5-HT_6 receptor antagonists SB-399885 (5.0 mg/kg, *ip*) and CPPQ (3.0 mg/kg, *ip*) partially prevented forgetting and retrieval when were injected previously to forgetting formation or retrieval; however, these effects disappeared when injected at 48- and 168-h from the interruption period. In the case of CPPQ, its anti-forgetting effects are in line with evidence reported by Grychowska *et al* (2016), finding that CPPQ administration facilitated performance in the novel object recognition task. In contrast, a higher dose of CPPQ (5 mg/kg, *ip*) had no effect in any time of administration in our model. Summing up, these findings suggest that the pharmacological manipulation of the 5-HT_6 receptor represents an important therapeutic target in the treatment of forgetting alterations (e.g., PTSD), and further studies with inverse agonists as well as agonists and antagonists are warrant.

Title: Bradykinin B2 receptor, a novel drug target for vascular dementia: *In-silico* and *in-vivo* evidence

Authors: *S. KUMAR[1], S. IVANOV[3], A. LAGUNIN[3], R. K. GOEL[2];
[2]Dept. of Pharmaceut. Sci. & Drug Res., [1]Punjabi Univ., Patiala, India; [3]Dept. of Bioinformatics, Inst. of Biomed. Chem., Moscow, Russian Federation

Abstract: Vascular dementia is attributable to several risk factors such as hypertension, diabetes, hyperlipidemia, atherosclerosis, obesity, and hyperhomocysteinemia, etc. A network pharmacology approach was adopted for collective analysis of genetic interactome of these risk factors with an aim to find a new drug target for the development of specific therapy because available drugs such as cholinesterase inhibitors (donepezil, galantamine, rivastigmine) and memantine are symptomatic in nature i.e. do not alter the underlying disease trajectory. Bradykinin B2 receptor evolved as a new drug target and its antagonism may trigger several downstream pathways that are relevant for the treatment of vascular dementia (viz. protection against atherosclerosis, blood-brain barrier dysfunction, oxidative stress, neuronal death along with cognitive enhancement by acetylcholine synthesis and neurogenesis). Experimental validation of bradykinin B2 receptor antagonism involved a total of six animal groups (n=7) i.e. naïve, control, donepezil 5mg/Kg, and icatibant (bradykinin B2 receptor antagonist) treated 5,10,20 nmol/Kg. Vascular dementia was induced through mild chronic cerebral hypoperfusion in adult Swiss albino mice of either sex. The discrimination, recognition, emotion, spatial and fear-motivated learning, and memory impairments were assessed by object recognition task, step-through, water maze task and elevated plus maze task, respectively. These learning and memory impairments were significantly ($P < 0.05$) attenuated by icatibant treatment, along with significant ($P < 0.05$) attenuation of oxidative stress, cholinergic dysfunction and glutamate-induced excitotoxicity in critical brain areas (viz. cerebral cortex and hippocampus) than available standard drug donepezil. All these behavioral, biochemical and histological evidence agreed well with the pre-experimental in-silico predictions. Collectively, these findings infer that antagonism of the bradykinin B2 receptor may ameliorate learning and memory impairment

associated with mild chronic cerebral hypoperfusion that mimics the core features of vascular dementia.

Title: Vitamin E prevents the cognitive impairments in post-traumatic stress disorder rat model: Behavioral and molecular study

Authors: *K. H. ALZOUBI[1], M. AHMED[2], O. F. KHABOUR[3];
[1]Jordan Univ. of Sci. & Technol., Irbid, Jordan; [2]Sorbonne Univ., Paris, France; [3]Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: Post-traumatic stress disorder (PTSD) is a psychiatric disorder developed after an exposure to severe traumatic events. Patients with PTSD suffer from different symptoms including memory impairment. In addition, PTSD is associated with oxidative stress. Vitamin E. A fat-soluble vitamin, possesses cognition protective effects via its antioxidative properties. In this study, the impact of vitamin E on memory impairment induced by PTSD was tested using rat model and the radial arm water maize (RAWM) learning and memory paradigm. Rats were divided into 4 groups: control, vitamin E, PTSD and Vitamin E + PTSD. In the learning phase, results showed no significant differences among all groups, indicating that PTSD did not impair learning ability. However, memory tests in RAWM showed that PTSD impairs both short-term and long-term memories. Vitamin E, on the other hand, prevented these impairments of memory. With respect to oxidative stress, significant decreases were detected in GSH/GSSG ratio, GPx and catalase enzyme activities, global histone 3 acetylations, and BDNF levels in the PTSD group compared with other groups ($P<0.05$). Vitamin E prevented these oxidateve stress biomarkers, global histone 3 acetylations, and BDNF. In conclusion, vitamin E prevents memory impairments associated with PTSD, probably via its antioxidative properties, and preservation of epigenetic changes induced during PTSD.

Title: Exploring the persistence of learned sexual behavior in male Japanese quail conditioned on a Pavlovian partial schedule: Behavioral and opioid antagonist effects

Authors: T. K. BAK, R. L. FISHER, J. M. GRANATO, D. R. C. HAGOOD, L. M. PRICE, B. A. SULAMAN, ***K. S. HOLLOWAY**;
Vassar Col., Poughkeepsie, NY

Abstract: Male Japanese quail will approach and remain near an arbitrary conditional stimulus (CS) that predicts the arrival of a quail hen. This behavior has been demonstrated to be remarkably persistent. We explored the persistence of this behavior in two experiments, one utilizing a behavioral manipulation and one utilizing a pharmacological manipulation. In the first experiment, subjects acquired approach to a CS paired with a quail hen on either a continuous or partial schedule in a Pavlovian conditioning procedure. In a subsequent extinction phase, during which the CS was presented by itself, the approach behavior of subjects trained under a continuous schedule of reinforcement extinguished more rapidly than that of subjects trained under a partial schedule. In the second experiment, we explored the effect of naloxone administration during extinction trials following Pavlovian sexual approach conditioning under both continuous and partial schedules of reinforcement. Confirming earlier findings, naloxone injections (30 mg/kg, i.m.), administered 15 minutes prior to each extinction trial, facilitated the extinction of approach responses of subjects trained under a continuous schedule of reinforcement as compared to subjects that received saline vehicle injections. Extending these findings, naloxone administration also facilitated extinction of responses of subjects conditioned under a partial schedule. The results of these two experiments are discussed as factors contributing to the persistence of learned behaviors.

Title: The serotonin 1A1B receptor agonist RU24969 on behavioral flexibility in mice

Authors: B. OLIVER, A. PAHUA, S. PETERSON, S. SANCHEZ, R. POSADAS, *D. A. AMODEO;
California State Univ. San Bernardino, San Bernardino, CA

Abstract: Obsessive compulsive disorder (OCD) is defined as insistent urges, persistent thoughts, and/or repetitive behaviors that are difficult to inhibit (DSM-5, 2013). Pharmacological alterations to the serotonergic system have shown to induce OCD-like behaviors in mouse models (Shanahan et al., 2009; Ho et al., 2015). Moreover, the serotonin-1B/1A receptor (5-HT1B/1A) agonist RU24969 has been shown to induce OCD-like behavior in rodents (Ho et al., 2015; Shanahan et al., 2009; Woehrle et al., 2013), and induce deficits in working memory as evidenced by impaired performance on the delayed alternation task (Woehrle et al., 2013). Much of the current literature has modulated other serotonergic receptor cites in attempts at rescuing OCD-like behaviors induced by RU24969 treatment such as increased locomotor stereotypy (Ho et al., 2015; Shanahan et al., 2009) and deficits in pre-pulse inhibition (Shanahan et al., 2009; Thompson & Dulawa, 2019). Many studies examining increased 5-HT1B/1A activation use relatively high dosages of RU24969 anywhere from 1 to 10 mg/kg (Ho et al., 2015; Shanahan et al., 2009; Thompson & Dulawa, 2019; Woehrle et al., 2013). OCD's symptomology includes excessive habit formation that can impact goal-directed learning (Gillan & Robbins, 2014) and cognitive flexibility (Grutter & Pitteger, 2017). The current study examines the effects of systemic 5-HT1B/1A receptor agonist RU24969 (0.01 or 0.1 mg/kg) treatment on behavioral flexibility testing C57BL/6 mice in the spatial 80:20 probabilistic reinforcement reversal learning task. Before acquisition, all mice were treated with vehicle. Before the reversal phase, mice were injected with RU24969 (0 mg/kg, 0.01 mg/kg, or 0.1 mg/kg) and the reinforcement contingencies were reversed to examine how many trials were required for mice to reach learning criterion. Learning criterion was met when mice made six consecutive correct choices. As we have previously demonstrated, all groups performed similarly on acquisition of the initial spatial discrimination. On reversal, mice treated with 1.0 mg/kg RU4969 required significantly more trials to reach criterion. This impairment was driven by a specific increase in regressive type errors, suggesting RU24969 treatment impaired the ability to maintain a new choice pattern during reversal. Further analysis show that neither dose of RU24969 increased trials per minute demonstrating that RU24969 was not sedative. In sum, these findings indicate that acute systemic 5-HT1B/1A receptor activation significantly impaired reversal learning performance.

Title: Investigating the effects of methylphenidate on cue salience and strategy set-shifting: Role of D_2 receptors

Authors: *M. MCWATERS[1], A. L. BLAKER[2], S. B. FLORESCO[3], B. K. YAMAMOTO[2], L. MATUSZEWICH[1];
[1]Northern Illinois Univ., Dekalb, IL; [2]Pharmacol. and Toxicology, Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Healthy individuals worldwide are using cognitive enhancing drugs in an attempt to remain competitive in society for education, careers, and athletics. Commonly, these individuals are using prescription stimulants, such as methylphenidate (MPH), due to their known acute neuroenhancing effects. While these neuroenhancing effects have been established using a variety of learning, memory, and attention tasks in ADHD-diagnosed humans and rodents, little research has investigated the effects of MPH on set-shifting, which is a higher-level cognitive function with many clinical implications. Previous research indicates that MPH enhances set-shifting task performance in ADHD-diagnosed individuals (Cao et al., 2012; Mehta, Goodyer, & Sahakian, 2004), however, the effect of MPH in healthy individuals and potential mechanisms underlying its cognitive enhancing effects on strategy set shifting remain elusive. Recent evidence suggests that association learning and set-shifting are dopamine-dependent (Flagel et al., 2011; Floresco, Magyar, Ghods-Sharifi, Vexelman, & Tse, 2006). Cue salience, one type of association learning, is related to D_2 function. Therefore, the purpose of the current study was to investigate: 1) MPH's influence on cue salience in rats using the Pavlovian Conditioned Approach (PCA) Index; 2) whether cue salience affected the set-shifting task in healthy rats and 3) whether D_2 receptor function affects set-shifting. Rats received MPH or saline daily 20 minutes prior to each autoshaping session for 5 days to measure PCA Index (Meyer et al., 2012). Rats were then trained on a strategy set-shifting paradigm (Brady & Floresco, 2015) and administered either the D_2 antagonist raclopride (0.2 mg/kg i.p.) or vehicle 30 minutes prior to the set-shift test. MPH decreased PCA Index Scores, however PCA Index was not a significant covariate on the set-shifting task. There was no effect of MPH exposure on the set-shift. When administered raclopride, rats in the MPH condition had poorer performance on the set-shift compared to saline rats. However, raclopride alone did not affect set-shifting. Western blot

analysis showed D_2 receptor immunoreactivity in the striatum was increased following MPH treatment compared to rats injected with saline. Future research will further explore the effects of MPH on the dopaminergic system and assess the impact of this alteration in other learning tasks, as this may have clinical implications for cognitive enhancement use in healthy individuals.

Title: Addiction potential in methylphenidate treated rats after chronic drug exposure

Authors: S. D. GEORGE, P. B. YANG, *D. J. FELLEMAN, N. DAFNY;
McGovern Med. Sch. -UTHealth, Houston, TX

Abstract: Methylphenidate, commonly known as Ritalin, is a psychostimulant prescribed for behavioral disorders. Its use is widely accepted to treat young children and adults exhibiting attention-deficit/hyperactivity disorder (ADHD) symptoms. Methylphenidate (MPD) consumption has increased in popularity as a cognitive enhancer and recreational drug among multiple age groups. Due to the close chemical profile it shares with cocaine and amphetamines there is concern for the compound's potential to elicit dependence and abuse. The objective of this study was to test whether chronic MPD exposure in three different rat genetic strains, including an ADHD model, would express symptoms of drug dependence in young and adult, male and female rats. Three hundred and eighty-four rats composed of adult, adolescent, male, female, and three different genetic strains were used for this experiment. The three strains of rats studied in the experiment were Sprague Dawley (SD), Wistar-Kyoto (WKY), and Spontaneous Hyperactive (SHR). Forty-eight groups of rats were used, each with an N=8. Control groups were treated with saline, and experimental groups were treated with acute and chronic dose responses (0.6, 2.5, and/or 10 mg/kg i.p.) of MPD. An open field assay was used to record and monitor behavioral activity of the animal before and after acute and chronic psychostimulant exposure. Total distance traveled, horizontal activity, and the number of stereotypic repetitive purposeless activity were quantified with an Accusan analyzer to detect changes in locomotor

activity. Data was collected at baseline (Day 1), followed by daily MPD doses for 6 consecutive days (Day 2-7), 3 subsequent washout days (Day 8-10), and rechallenge doses of MPD at Days 11, 27, and 32. The chronic effect of MPD exposure in rats demonstrates behavioral tolerance in some animals while behavioral sensitivity in others. Differences between animals of different age, sex, and strain were observed. The changes in behavioral activity following chronic MPD use suggest its potential to cause drug dependence, in adolescent, adult, male, and female rats.

Title: Delta-9-tetrahydrocannabinol regulates memory, anxiety, and sensorimotor gating via dissociable modulation of the Wnt and mTOR signalling pathways in the nucleus accumbens shell

Authors: *C. NORRIS[1], R. M. HUDSON[2], H. J. SZKUDLAREK[3], D. KHAN[1], W. J. RUSHLOW[4], S. R. LAVIOLETTE[1];
[2]Neurosci., [3]Dept. of Anat. & Cell Biol., [4]Dept of Anat. and Cell Biol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Exposure to Δ^9-tetrahydrocannabinol (THC), the primary psychoactive compound in cannabis, is associated with psychotomimetic side-effects and an increased risk of serious neuropsychiatric disorders, such as schizophrenia. The nucleus accumbens shell (NASh) is involved in the neuropathological phenotypes associated with schizophrenia and anxiety-related disorders. Given previous evidence also indicating a functional division between the anterior NASh (aNASh) and posterior NASh (pNASh), we evaluated the effects of direct infusions of THC in the NASh on the levels of signaling proteins associated with psychiatric illness, the formation of associative fear memory, pre-pulse inhibition (PPI) and facilitation (PPF) of the acoustic startle response, object recognition memory, and anxiety in the elevated-plus maze (EPM). Our results indicated that THC infused in the pNASh decreased levels of phosphorylated GSK3α and increased levels of β-catenin but had no significant effect on pGSK3β, or total GSK3. THC infused into the aNASh, however reduced levels of the Ser473 isoform of phosphorylated Akt and phosphorylated mTOR but not Thr308 phosphorylated Akt, total Akt, or total mTOR. Next, we examined the role these molecular signaling compounds played in the

behaviour effects of THC by co-administering THC into the pNASh with SB216763, a GSK3 inhibitor, and into the aNASh SC-79, an Akt promoter. We demonstrated that intra-pNASh infusions of THC produced GSK3 dependent potentiation of fear memory salience; induced anxiogenic effects and impaired PPI and PPF; and pNASh THC exposure induced object recognition memory deficits. In contrast, intra-aNASh THC blocked the encoding of normally supra-threshold associative fear memory and produced anxiolytic effects. When THC was co-administered with SC-79, the formation of associative fear memory was restored, time in the open arms during EPM increased, PPF was impaired and object recognition memory was reduced. Our findings provide several novel mechanisms for how THC differentially modulates CB_1 signalling pathways and provide new insight into the underlying molecular mechanisms of THC in distinct regions of the NASh and how they may underlie both the affective and cognitive side-effects of cannabis exposure.

Title: Influence of habituation and NMDA receptor antagonism on novel object recognition and object location tasks in zebrafish

Authors: K. V. GASPARY, G. K. REOLON, D. GUSSO, ***C. D. BONAN**;
Pontificia Univ. Catolica Rio Grande do Sul, Porto Alegre, Brazil

Abstract: This study aims to establish a protocol for evaluating the object recognition memory and object location tasks in zebrafish. We evaluated the novel object recognition memory and analyzed the exploration time of the objects during training and testing. Zebrafish explored more the new object in comparison to the familiar object (61% of exploration time during test session). We also tested the object location task and measured the exploration time of each object in the familiar and novel object location. There was a preference to explore the object in the novel location (63% of exploration time during test session). The effect of the non-competitive NMDA receptor antagonist MK-801 was investigated on the object recognition and object location memory. Control (water only) and treated animals (5 μM MK-801) presented a significant preference in exploring the familiar object in comparison to the new object (66 and 68% of

exploration time, respectively); however, 10 μM MK-801-treated animals did not show differences in the exploration time of the objects. In the object location task, the animals treated with the 5 or 10 μM MK-801 did not show a preference for the familiar or novel location whereas the control group had a higher preference in exploring the object in the familiar location (64% of exploration time during test session). Considering the different responses of the control group between original task and in the regimen treatment, we evaluated the impact of habituation on cortisol levels of animals in three different protocols: (1) habituated at the experiment apparatus for 3 days (C1 condition), (2) habituated at the experiment apparatus for 3 days plus treatment tank exposure at fourth day (C2 condition), (3) habituated at the treatment tank and experiment apparatus for 3 days and exposed to treatment tank again at fourth day (C3 condition). The results showed higher levels of cortisol in animals submitted to C2 and C3 conditions compared to animals submitted to C1. Treatment tank exposure induced a different performance in object recognition and object location memory due to stress responses. These tasks are prone to evaluate memory in physiological and pathological conditions, but its use is limited due to sensitivity to stress caused by manipulation.

Title: Potent, highly selective and brain penetrant adrenergic alpha 1a antagonists for improvement of cognition in neuropsychiatric disorders and Alzheimer's disease

Authors: *H. H. SCHIFFER[1], S. KIKUCHI[1], J. RUSSO[1], Y. CHEN[1], J. BLIESATH[1], B. LAM[1], S. OLSEN[1], K. MA[2], S. SAILLET[2], J. J. PALOP[2], J. RAY[1], H. MONENSCHEIN[1], S. HITCHCOCK[1];
[1]Takeda California Inc., San Diego, CA; [2]Gladstone Inst. and Univ. of California San Francisco, San Francisco, CA

Abstract: The role of adrenergic alpha 1a receptors in cognitive functions in health and disease is not fully understood due to the lack of brain penetrant highly selective alpha1a ligands. We have developed nM potent and highly selective (>1000x selective over adrenergic alpha 1b and d) adrenergic alpha1a receptor antagonists, which enabled us for the first time to study the biological role of antagonizing alpha 1a receptors in health and disease mouse models *in vivo*. BacTRAP data and *in situ* hybridization studies show that alpha 1a receptor expression is highly enriched in cortical and hippocampal neuropeptide (NPY) inhibitory interneurons. Axonal sprouting of neuropeptide Y (NPY) interneurons and reduced expression of Fos in hippocampal

granule cells have been observed in the human hippocampus in Alzheimer patients and in preclinical Alzheimer disease mouse models (e.g. J20). It has been hypothesized that axonal sprouting is a compensatory mechanism of hippocampal hyperexcitability leading to aberrant circuit inhibition, which might contribute to cognitive impairment in AD [1]. Selective alpha 1a blockade dose-dependently increased the levels of Fos expression in the cortex and hippocampus in wild-type mice and partially restored the number of Fos-positive granule cells in the J20 mouse model of AD model, suggesting that alpha 1a blockade prevents the aberrant inhibition of the granule cells. Importantly, selective alpha 1a blockade also normalized the abnormal hyperlocomotion and disinhibition phenotypes during exploration of a novel environment, indicating that slight disinhibition might be therapeutic in AD. Our highly selective adrenergic alpha 1a antagonists demonstrated a robust procognitive efficacy profile in both rats and mice, including improved recognition memory (novel object recognition test), spatial memory (spatial recognition test), and increased attention (two-choice visual discrimination test). In addition, alpha 1a blockade reversed scopolamine-induced working memory deficits in the Morris water maze task. Using microdialysis, we determined that our alpha 1a antagonist increased extracellular acetylcholine in the cortex and hippocampus in rats. Additional studies in wild type rats suggested alpha 1a blockade increased wakefulness. Our results show that selective inhibition of adrenergic alpha 1a receptors provides procognitive benefit in health and disease mouse models of AD and suggest that adrenergic alpha1a inhibition should be considered as therapeutic treatment of cognitive deficits in neuropsychiatric disorders and potentially AD. Title: Role of α7nAChR agonist (GTS-21) on ICV-STZ induced altered central insulin signaling leading to cognition deficits

Authors: *Y. PERUMAL[1], R. RAY[1,2], K. CHOPRA[1];
[1]Univ. Inst. of Pharmaceut. Sci., Chandigarh, India; [2]Indian Pharmacopoeia Commission, Ghaziabad, India

Abstract: Central insulin resistance is a pathological condition in which brain cells fails to respond normally to insulin. Central insulin resistance evokes pathological hallmarks of Alzheimer's disease (AD), such as formation of amyloid plaques and neurofibrillary tangles (NFT). Intracerebroventricular administration of streptozotocin (ICV-STZ) leads to central insulin resistance leading to cognitive deficits in mice. The aim of our study is to determine the effect of α7nAChR agonist (GTS-21) on ICV-STZ-induced central insulin resistance leading to cognition deficits. α7nAChR agonist (GTS-21) was administered for 21 days following the ICV-STZ administration (3 mg/kg). Neurobehavioral assessment such as morris water maze and novel object recognition were performed to determine cognitive deficits. Oxidative stress markers (MDA, nitrite and GSH) and inflammatory markers (TNF-α and IL-1β) were estimated in the hippocampus and cortex. Acetylcholine esterase and choline acetyltransferase were determined to evaluate the level of acetylcholine in the hippocampus and cortex. Insulin and glucose levels were also assessed in the hippocampus and cortex. ICV-STZ administration-induced memory impairment in neurobehavioral assessments, coupled with oxidative stress and increased inflammatory markers. Our results demonstrated that α7nAChR agonist (GTS-21) was effective against memory impairment, decreased oxidative stress and subsequently decreased inflammatory markers in hippocampus and cortex. Furthermore, we found that insulin and glucose levels were altered after ICV-STZ administration which were restored by α7nAChR agonist (GTS-21) treatment. Therefore, α7nAChR might be the potential target for the prevention of central insulin resistance induced cognition deficit.

Title: Fractionating aberrant salience in rodent models of psychosis

Authors: *T. BLACKMORE[1], L. B. STAHR[1], V. SAMBORSKA[1], G. GILMOUR[2], M. E. WALTON[1], D. M. BANNERMAN[1], M. C. PANAYI[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Eli Lilly & Co. Ltd., Windlesham, United Kingdom

Abstract: Psychosis is a prominent feature of a number of neurological and psychiatric disorders. Aberrant salience to sensory stimuli likely contributes to the generation of psychotic symptoms, but this is a diverse phenomenon with many potential contributing factors. While many rodent models of aberrant salience exist, they may have different underlying psychological or neurobiological substrates. Hyperactivity commonly reported in these models reflects enhanced exploratory attention to sensory stimuli, similar to aberrant salience in humans. This may be due to impaired habituation and/or hyperarousal, but the exact mechanisms remain poorly specified. The current study investigates the relationship between habituation, attention and locomotor activity in three mouse models of psychosis to shed light on the heterogeneity of symptoms seen in human patients.
Two pharmacological (2.5mg/kg amphetamine i.p., 0.2mg/kg MK-801 i.p.) and one genetic (*Gria1*$^{-/-}$, encoding GluA1 AMPA receptor subunit) knockout mouse model were tested in three assays of short-term habituation and locomotor activity; open-field, spatial novelty Y-maze, and novel context recognition.
All models tested displayed a significant hyperactive phenotype, consistent with the literature. However, the nature of this hyperactivity differed between these models. Increased dopamine levels in amphetamine-treated mice led to 'hyperarousal', defined by significantly increased locomotor activity, but were capable of short-term habituation. The NMDA receptor antagonist MK-801 induced significant hyperactivity and impaired short-term habituation; however, animals started off unexpectedly hypoactive to novelty. These deficits may reflect an inability to maintain attention to specific stimuli, where instead stimuli cycle rapidly in and out of focus; 'butterfly attention'. GluA1$^{-/-}$ mice displayed a stimulus-specific form of hyperactivity, with exploratory attention initially similar to wild-types but failing to habituate and ramping up over time; 'sticky attention'. Thus, whilst all models showed hyperactivity, the aetiology and psychological underpinnings were markedly different following manipulation of dopamine, NMDA or AMPA receptor function. This finding may help to explain the heterogeneity of symptoms in schizophrenic populations.

Title: CART peptide protects the behavioral deficits in rat model of Huntington's disease

Authors: *M. A. UPADHYA[1,2], H. M. UPADHYA[2], N. SUBHEDAR[1], D. KOKARE[2]; [1]Dept. of Biol., Indian Inst. of Sci. Educ. and Res., Pune, India; [2]Pharm., Dept. of Pharmaceut. Sci., Nagpur, India

Abstract: Huntington's disease (HD) is an inherited progressive neurodegenerative disorder, characterized by severe degeneration of GABAergic neurons in the striatum and cerebral cortex, exhibiting motor abnormalities, impaired cognitive functions and emotional disturbances. A neuroprotective peptide cocaine and amphetamine regulated transcript (CARTp) closely interacts with the GABAergic system. Although its expression in striatum is altered in HD like conditions, there is no information on the neuroprotective activity of CARTp with reference to this condition. The present study was designed to elucidate the role of CART in 3-nitropropionic acid (NP)-induced animal model of HD in rats. The effect on walking pattern, learning and memory, and locomotion was assessed using foot print analysis technique, Morris water maze and actophotometer, respectively. Rats treated with 3-NP showed significant decrease in the stride length and foot print length as compared to that of the rats treated with aCSF. The actophotometer count, taken as an index of locomotion, was decreased significantly in these rats. In addition, the escape latency was significantly increased in 3-NP treated rats, which may be attributed to retarded swimming speed or dementia like condition as compared to normal rats. Intracerebroventricular CART treatment prior to 3-NP for four days prevented all the motor deficits as observed in gait analysis and altered swimming pattern in rats. CART-immunoreactivity was decreased significantly in Dentate gyrus of hippocampus, striatum and LC. In view of this evidence and that CART positively modulates GABAergic neurons directly or indirectly via dopamine, it seems that endogenous CART might play a pivotal role in the HD like conditions. Further, activation of CART system in striatum might help to improve the symptoms related to neurological ailments like HD.

Title: Inhibition of cellular palmitoylation impairs the formation and maintenance of spatial memory and synaptic plasticity

Authors: *O. URREGO MORALES[1], I. DELINT-RAMÍREZ[2], F. BERMUDEZ-RATTONI[3]; [1]Inst. De Fisiologia Celular - UNAM, Ciudad de México, Mexico; [2]UT Southwestern Med. Ctr., Dallas, TX; [3]UNAM, Mexico City DF 04510, Mexico

Abstract: Protein palmitoylation (addition of lipid palmitate) is a post-translational modification that changes the hydrophobicity of proteins. This process allows the interaction of proteins with the lipids of the cell membrane and the subcellular membranes, regulating the location and function of these proteins. In the nervous system, palmitoylation regulates vesicular trafficking and the localization of neurotransmitter receptor proteins in processes of synaptic plasticity. Genetic and pharmacological approaches in murine models have reported the participation of palmitoylation in spatial memory processes. However, these approaches have not evaluated the effects of palmitoylation during the different phases of spatial memory; that is, acquisition, consolidation and retrieval. Therefore, in this work, we studied the participation of palmitoylation during the three phases of memory to understand a possible regulatory mechanism of the proteins involved on memory processes. For this, we evaluated the effect of the inhibition of the palmitoyl acyltransferase enzymes in the dorsal hippocampus with the irreversible 2-bromopalmitate inhibitor. The drug was administered to different groups of animals during the three phases of memory in two different behavioral models of spatial memory that depend on the activity of the hippocampus. The results showed that the inhibition of palmitoylation affected the acquisition and consolidation, but not spatial memory retrieval. In addition, the inhibition of the protein palmitoylation prevented the induction but did not affect the maintenance of the *in vivo* long-term potentiation in the CA1 of the hippocampus. In conclusion, palmitoylation of proteins mediated by palmitoyl acyltransferase enzymes participates in the formation and maintenance of spatial memory throughout plastic changes in the hippocampal synapses, possibly through AMPA and NMDA receptors.

Title: Neuroprotective effects of chronic memantine treatment on okadaic acid (ICV) induced neurotoxicity at behavioral, structural and molecular level in rats

Authors: *G. BESELIA[1,2], M. DASHNIANI[1], M. BURJANADZE[1], N. CHKHIKVISHVILI[1], L. KRUASHVILI[1];
[1]Lab. of Behavior and Cognitive Functions, I. Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia; [2]Dept. of Behavioral Sci., Petre Shotadze Tbilisi Med. Acad., Tbilisi, Georgia

Abstract: In the present study, intracerebroventricular (ICV) injection of okadaic acid **(**OA) in rats was used as a memory impairment and hippocampal neurodegeneration animal model. The possible beneficial effect of memantine - NMDA (N-methyl-D-aspartate) receptor antagonist on the OA-induced spatial memory impairment was examined in Morris water maze (MWM). The neuroprotective potential of memantine on OA-induced structural and molecular changes in the hippocampus and medial septum (MS) was evaluated by immuno and Nissl staining. The OA induced neurotoxicity and neuroprotective effects of chronic memantine treatmentat behavioral, structural and molecular level was evaluated in 4 groups of animals: control rats injected i.p. with saline or memantine and **OA injected rats** treated i.p. with saline or memantine. OA was dissolved in artificial cerebrospinal fluid (aCSF) and injected ICV 200 ng in avolume of 10 µl bilaterally. Vehicle control received 10 µl of aCSF ICV bilaterally. Memantine (5 mg/kg, i.p) or saline were given daily for 13 days starting from the day of OA injection. Experimental protocol was approved by Animal Studies Committee of I. Beritashvili Center of Experimental Biomedicine. The results described in this chapter showed that bilateral injection of OA causes a deficiency of spatial memory and loss of hippocampal cells in this model and demonstrated for the first time, to our knowledge, reduces the number of cholinergic and GABAergic medial septal neurons. These changes are observed in patients with Alzheimer's disease and, therefore, reinforce the importance of this model for the investigation targets of new therapeutic strategies. The results have shown that the chronic exposure of memantine can prevent a deficiency of spatial memory and that an improvement in memory function correlates with the prevention of OA-induced neuropathological changes in the hippocampus and MS. This fact, on the one hand, points to the involvement of neuropathological processes developed in the hippocampus and MS in memory impairment caused by OA, and, on the other hand, the involvement of NMDA receptors in the neurotoxicity of OA.

Title: Influence of maternal deprivation on recognition memory and global DNA methylation in adult rats: How epigenetics modulation can contributes to vulnerability or resilience to stress

Authors: *M. N. M. DE LIMA[1], B. S. DE FREITAS[1], K. C. R. RAPACH[1], M. A. FREYMUTH[1], R. B. M. SILVA[1], N. SCHRODER[2];

Abstract: Exposure to stress early in life may negatively impact nervous system functioning, including increasing the proneness to learning and memory impairments later in life. Maternal deprivation, a model of early stress, impairs memory in adult rats in a very heterogeneous way between individuals, resulting from either greater vulnerability or resilience to stress. It has been suggested that maternal care influences DNA methylation, a well-studied form of epigenetic regulation of gene expression, in hippocampus. Thus, the aim of the present study was to investigate if DNA methylation is underlying recognition memory impairment of adult maternally deprived rats. Maternally deprived animals were submitted to object recognition memory task (NOR1) in order to discriminate the `inferior learners' and the 'superior learners' in comparison to controls. After fifteen days of washout, they were submitted one more time to object recognition memory task (NOR2) receiving a methyl group donor (l-methionine), or vehicle, 1h prior to training session or a DNA methyltransferase (DNMT) blocker (5-Aza-2´-deoxycytydine), or vehicle, immediately after the training session. Results showed that acute administration of the methyl group donor improved recognition memory in inferior learner subjects, whereas DNA methyltransferase (DNMT) blockade had no effect. Global DNA methylation in hippocampus was measured 3h after the training session (to determine if there was alterations in DNA-methylation during this critical period for memory consolidation) and 24h after the LTM test (to determine if these alterations were persistent). Data were analyzed to verify the relationship between DNA-methylation status and cognitive performance among these individuals. The better comprehension of the mechanisms related to persistent alterations observed in adult life induced by early stressful circumstances could contribute to develop novel therapies to improve cognitive performance in subjects more vulnerable to stress.

Title: Effect of lateral cerebellar nucleus inactivation on supra-second interval timing performance across changing task demands in rats

Authors: *K. A. HESLIN, B. J. DE CORTE, S. J. FARLEY, H. HALVERSON, K. L. PARKER;
Univ. of Iowa, Iowa City, IA

Abstract: The cerebellum is necessary for the acquisition and proper timing of sub-second Pavlovian conditioned responses (e.g., eyelid closures in eyeblink conditioning). However, reports conflict on whether the cerebellum is necessary for successful supra-second interval timing (i.e., timing in the seconds to minutes range). Some past findings indicate that, under certain task demands, the dentate nucleus (homologous to the rodent lateral cerebellar nucleus) may be necessary for supra-second interval timing. Therefore, we evaluated the necessity of the lateral cerebellar nucleus to interval timing across a variety of operant task demands. One cohort of rats was trained in a standard 'peak interval procedure', in which the onset of a stimulus (light) cued rats to make an operant response after a specific time interval elapsed (12 seconds). A second cohort was trained in a variant of the same task, in which they were required to self-initiate each trial. Once trained, we evaluated the effects of reversibly inactivating the lateral cerebellar nuclei with bilateral Muscimol (GABAA agonist) infusions on baseline task performance. Following this, the duration associated with the learned cue was shifted from 12 seconds to 24 seconds in both cohorts. Half of subjects underwent lateral cerebellar nuclei inactivations during the new duration acquisition phase, while the remaining half was infused with vehicle. Preliminary results suggest that the lateral cerebellar nucleus may play a subtle role in the performance of supra-second interval timing, depending on task demands.

Title: The effects of nutritional supplementation on memory in adolescent male rats exposed to cannabinoids

Authors: *L. M. BUYNACK[1], L. M. PACK[1], H. M. PARRISH[1], C. E. YULE[1], R. D. LUNDY, III[2], G. D. MEDLEY[1], D. M. HAYES[1], P. A. JACKSON[2];
[1]Psychology, [2]Radford Univ., Radford, VA

Abstract: Many developmental changes occur during adolescence that are critical for cognitive functioning including neuroplastic shaping, reorganization of synapses, and neurochemical transformations (Spear, 2000). Adolescent rats that are exposed to cannabinoids experience negative brain development repercussions (Lubman, et al., 2014) that often leads to memory deficits during adulthood (O'Shea et al., 2004). Rats exposed to cannabinoids in adulthood exhibited little or no impairment of memory during an object location recognition (OLR) task. However, a different explanation for these cognitive deficits is that rats display a reduction in both food intake and body weight during the period of injections although they recover once injections cease (Biscaia et al., 2003; Schneider, 2009). Impaired weight gain during this period that is critical for neural development may result in behavioral changes separate from those caused by cannabinoids. The current study included multiple litters of male siblings, semi-randomly assigned to each of ten groups. On postnatal day (PND) 35 through PND 48, Long-Evans male rats were administered intraperitoneal injections of either vehicle or a synthetic cannabinoid (CP55,940) at 0.35 mg/kg. Starting on PND 34 and ending on PND 50, food intake was observed and altered such that ten conditions were created to manipulate drug exposure and food consumption. The conditions included drug, yoked control, and supplement-yoked control with each individual condition receiving no supplementation, a small supplementation, or a large supplementation. Yoked controls were matched for food and supplement to drug matched siblings, whereas supplement-yoked rats received free-food but were matched for amount of supplement. One group of untreated control rats did not receive injections nor did they receive any supplement. A battery of behavioral tasks was conducted, however, the current report is on an OLR memory task. Rats were habituated to the open field apparatus for four days prior to the task. The OLR task consisted of two 5-minute trials that occurred 10 minutes apart. In the first trial two identical objects were placed on the open-field and the rat could explore both objects. In

the second trial, one object from the previous trial remained in the same location, but the second object was placed in a new location. Results indicate that food supplementation may be beneficial to performance in drug groups compared to yoked conditions.

Title: Development of novel and selective Kv3.1/3.2 channel modulators with improved potency for the treatment of social and cognitive deficits in schizophrenia

Authors: *N. IDRIS[1], J. C. NEILL[1], B. GRAYSON[1], G. PODDA[1], M. BURGESS[1], L. WATSON[1], S. MUNNI[1], A. MARASCO[2], G. ALVARO[2], C. LARGE[2];
[1]Div. of Pharm. and Optometry, Fac. of Biology, Med. and Hlth., Univ. Of Manchester, Manchester, United Kingdom; [2]Autifony Therapeut. Ltd, Stevenage, United Kingdom

Abstract: Introduction: Cognitive dysfunction and negative symptoms remain a major clinical unmet need in schizophrenia and have been associated with NMDAR hypofunction at cortical, parvalbumin (PV) -positive, fast-spiking interneurons. The voltage-gated potassium channel, Kv3.1 is predominantly localized in PV-positive interneurons, and is reduced in un-medicated schizophrenia patients (Yanagi et al. Mol Psychiatry 2014; 19: 573-579). Sub-chronic treatment of rodents with the NMDAR antagonist, phencyclidine (scPCP) impairs cognition and reduced expression of the calcium binding protein, PV in fast spiking GABAergic interneurons (Cadinu et al. Neuropharm 2018;142:41-62). We shave shown that the novel Kv3.1/Kv3.2 channel modulator, AUT6, reverses cognitive and social deficits in scPCP rats, and reverse the decrease in PV expression, confirming the importance of this target for the treatment of schizophrenia. Here we aim to compare the efficacy of novel high potency Kv3.1/3.2 modulators in cognitive and social behaviour tests in the scPCP rodent model. **Methods:** Four cohorts of adult female Lister Hooded rats (240 in total) received PCP (2 mg/kg, i.p.) or saline i.p. for 7 days, followed by 7 days washout. Rats were then treated acutely with Kv3.1/3.2 channel modulators, AUT6 (3.0, 10, 30 mg/kg), AUT15 (1.0, 3.0, 10 mg/kg,), AUT16 (3.0, 10, 30 mg/kg,) or vehicle, orally 90 min prior to testing in novel object recognition (NOR), social interaction (SI) and reversal learning (RL) tasks. Data were analysed by ANOVA and post-hoc LSD test or a paired Student t-test. **Results:** scPCP significantly impaired behaviour in these tests. See table for the minimum effective dose of each compound to restore scPCP-induced deficits:

Compound	Test & minimum effective dose				
	NOR: increase in novel exploration time	RL: improve in % correct responding	SI: increase in sniffing behaviour	SI: increase in following behaviour	SI: decrease in avoiding behaviour
AUT6	10 mg/kg, $p<0.001$	30 mg/kg, $p<0.01$	10 mg/kg, $p<0.05$	30 mg/kg, $p<0.01$	10 mg/kg, $p<0.05$
AUT15	3.0 mg/kg, $p<0.001$	10 mg/kg, $p<0.01$	1.0 mg/kg, $p<0.001$	3.0 mg/kg, $p<0.05$	3.0 mg/kg, $p<0.001$
AUT16	10 mg/kg, $p<0.001$				

Conclusion: These in vivo results demonstrate superior potency of AUT15 compared to AUT6 and AUT16 in NOR and AUT15 compared to AUT6 in both RL and SI. In addition, the improvement of the in vivo potency from AUT6 to AUT15 is in agreement with the rank order of the in vitro activity of those compounds at both Kv3.1 and Kv3.2 channels. This result increases the confidence that restoration of scPCP-induced cognitive and social behaviour deficits is via modulation of Kv3.1/Kv3.2 channels.

[4]Exptl. Med., Univ. of Campania "Luigi Vanvitelli", Naples, Italy; [5]Psychology, Sapienza Univ., Rome, Italy

Abstract: The Na^+/Ca^{2+} exchanger 1 (NCX1) is highly expressed in the hippocampus, cortex, and amygdala where it participates in the maintenance of $[Ca^{2+}]_i$ and $[Na^+]_i$ homeostasis. However, the activity of NCX1 was also associated to the regulation of some intracellular pathway such as AKT1 phosphorylation and NMDA-mediated Ca^{2+} influx, two events that participate in the synaptic plasticity and long-term memory. We hypothesized whether NCX1 expression/activity might affect some hippocampal-dependent learning and memory processes. To test this hypothesis, we used a genetically-modified mouse that selectively overexpresses NCX1 in hippocampal, cortical, and amygdala neurons (ncx1.4over) and a newly synthesized compound named CN-PYB2 that selectively stimulates NCX1 activity. Both *ncx1.4over* and CN-PYB2-treated mice showed increased phosphorylated CaMKII levels in the hippocampus and improved long-term spatial learning and memory performance in Barnes maze and context trace fear conditioning. On the other hand, both mouse models bearing an increase of NCX1 activity did not show amelioration in non-spatial memory tests including novel object recognition and cued trace fear conditioning. In addition, both *ncx1.4over* and CN-PYB2-treated mice also displayed an increased level of corticosterone levels 1h after a weak foot-shock and an increased susceptibility to a context-dependent anxiety. Altogether, these results demonstrate that neuronal NCX1 participates in a selective hippocampal-dependent spatial learning and memory processes.

Title: Acute acetaminophen exposure impairs object recognition memory in female mice

Authors: *C. A. STAPF[1], A. A. WISLOTSKY[1], P. T. ORR[2,1];
[1]Neurosci. Program, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: Animal research has often been done with only male animals due to the variable hormonal effects on physiological function experienced by female animals. Previous work has established that a post-training subcutaneous injection of 50mg/kg or 100mg/kg acetaminophen

disrupts memory consolidation in a hippocampal-dependent object recognition memory task in male mice, but it is not currently known if acetaminophen disrupts memory formation in this task in female mice. In this study, we examined the influence of acetaminophen on performance in an object recognition task in female C57Bl/6 mice. Mice were raised in typical housing conditions until around 8 weeks. These mice were then habituated and trained in an object recognition task. Immediately after training, mice were randomly assigned to receive an injection of vehicle (saline) or one of three doses of acetaminophen (10, 50, or 100 mg/kg). Mice were tested 24 hours later. Control mice spent significantly more time with the novel object when compared to time spent with the familiar object showing memory of the previously introduced familiar object ($t(12)=2.114$, $p=0.028$). Mice in the 50 mg/kg group showed evidence of memory in the object recognition task ($t(10)=1.918$, $p=0.042$) while mice in the 10 mg/kg ($t(9)=1.036$, $p=0.163$) and 100 mg/kg ($t(8)=-0.525$, $p=0.307$) dosage groups did not show evidence of memory consolidation. Two weeks after behavioral testing, mice were again injected and culled so hippocampal brain sections can be analyzed via Western blotting for differences in the presence of cell-signaling molecules associated with memory formation. Overall, the data demonstrate that acute acetaminophen injection significantly impairs object recognition memory in female mice, which is consistent with the previously observed effects in males. More research is needed to determine the mechanism through which this impairment occurs.

Title: The effects of AM4113, a neutral cannabinoid antagonist, on object recognition memory in male mice

Authors: *F. A. WALTER, III[1], M. R. JOHNS[1], P. T. ORR[2,1];
[1]Neurosci. Program, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: Cannabinoid receptors are found throughout hippocampus and signaling in these receptors is thought be critical for the impairment of memory by cannabinoids (Elphick & Egertova, 2001; Murray, J.B., 1986). Antagonism of cannabinoid signaling via rimonabant (SR141716) facilitates object recognition memory in rats (O'Brien, et al., 2014) and increases in endogenous cannabinoid signaling demonstrably impair this kind of object recognition and other assessments of hippocampal memory (Basavarajappa, et al., 2014). However, rimonabant is sometimes characterized as an inverse CB1 agonist. It is currently unknown if object recognition memory is sensitive to the CB1 neutral antagonist, AM4113. Thus, this study attempted to

determine if AM4113 could facilitate object recognition memory consolidation in mice. Mice were trained in an object recognition task with a 48 hour delay. They were randomly assigned to receive an immediately post-training intraperitoneal injection of vehicle (1:1:8 ratio of dimethylsulfoxide (DMSO), Tween 20, and .9% saline), 2 mg/kg, 4 mg/kg, or 8 mg/kg of AM4113 in vehicle. This formulation and dose range is based off of previously published work (Sink, et al, 2013), and should be safe. As expected, during testing at a 48 hour delay, vehicle treated mice did not differ significantly from chance performance ($t(12) = -1.685$, $p = .118$). However, we did not observe object recognition memory in the 2 mg/kg ($t(13) = 1.101$, $p = .291$), 4 mg/kg ($t(10) = -.6$, $p = .562$), or 8 mg/kg ($t(9) = 1.132$, $p = .287$) groups, suggesting that this neutral CB1 antagonist did not influence object recognition memory. Future work is needed to refine the effect of AM4113 in this model and to explore the relationship of the cannabinoid system to object recognition memory.

Title: Behavioral state interactions with single neuron and population-wide spatial representations in medial entorhinal cortex

Authors: *I. I. C. LOW, A. H. WILLIAMS, L. M. GIOCOMO;
Stanford Univ., Stanford, CA

Abstract: Behavioral state – such as alertness – profoundly impacts how we think and perform. Yet, in spite of the key role that it plays in both healthy and disordered cognition, how behavioral state influences brain function remains a central mystery in neuroscience.
Medial entorhinal cortex (MEC) is an ideal test-bed to study how behavioral state impacts cognitive processing. MEC is located at the intersection of sensation and behavior, and MEC firing tightly correlates with navigationally relevant variables, such as position. MEC was long

considered to statically represent space; however, intriguing recent work indicates that non-spatial factors such as task context modulate MEC coding. Whether this non-spatial modulation is related to behavioral state remains unknown.
To interrogate the impact of behavioral state on spatial coding by MEC, we have built a high-throughput virtual reality rig that allows for simultaneous neural and behavioral recording. As mice traversed a virtual linear track, we precisely measured arousal correlates (pupil dilation, whisking, running speed, reward consumption). Simultaneously, we used Neuropixels silicon probes to record from hundreds of neurons along the length of MEC. Using a modified linear-nonlinear model, we find that behavioral markers of arousal have diverse impacts on MEC neural activity.
Critically, this work challenges a long-standing belief in the navigation field that MEC statically represents space. Further, it provides a potential explanation for recent findings that non-spatial factors modulate MEC coding. Broadly, our work lays the groundwork to explore an enduring question in neuroscience – how behavior and neural activity dynamically interact with one another – thus enabling new scientific inquiry across a range of neural systems.

Title: Coding of medial entorhinal cortex during navigational decision making

Authors: *A. GONZALEZ, L. GIOCOMO;
Stanford Univ., Stanford, CA

Abstract: A fundamental behavior is the ability to successfully navigate through the environment to reach a goal. An important brain region for navigation and the representation of space is the medial entorhinal cortex (MEC). During open-field foraging, MEC encodes necessary components of navigation: position (grid-cells, border-cells), head-direction, and speed. The stabilty of MEC coding has led to theories about how its invariant representation of space is a critical component of the brain-wide navigation circuit. However, it is not clear what computations or behavioral representations this apparently specialized circuit performs under complex behaviors. Recent results indeed suggest a more flexible role for MEC (e.g. coding for auditory frequency - Aranov et al. 2017, time- Kraus et al. 2015, and reward related changes in the representation of space - Butler et al. 2019). We hypothesize that this region is indeed

flexible in its coding, enabling task-relevant representations and computations. To test this hypothesis, we developed a maze and a task in which the animal performs cue-based goal-directed navigation for a food reward. The maze is a double-Y linear track (two branches, each with two branches to goal locations) with reward wells at a 'home', 'decision', and at the 4 'goal' locations. A visual cue indicates to the animal to go left or right at the decision location (first branching) towards two of the goal locations (final reward location chosen at random). We trained 5 rats to perform this task (reliably ~200 trials, accuracy >80%), each implanted with tetrodes to the MEC. Critically, during the task all environment factors were simultaneously recorded with the electrophysiological data (cue, reward, detections, animals' position). We then trained Poisson Generalized Linear Models on the time by time behavioral and environment states to predict spiking activity of single neurons. As expected, model selection results are mostly dominated by models with positional variables. However, we find models for mixed-selectivity cells that jointly code for cue and position, position-reward, and their combination. Importantly, by also collecting open-fiend foraging data, we demonstrate how single cells adapt their coding properties to task-relevant features.

Title: Large scale recordings reveal algorithms for combining landmark and self-motion cues in entorhinal cortex

Authors: *M. G. CAMPBELL[1], A. ATTINGER[2], S. A. OCKO[3], S. GANGULI[4], L. M. GIOCOMO[2];
[2]Neurobio., [1]Stanford Univ., Stanford, CA; [3]Applied Physics, Stanford Univ., Menlo Park, CA; [4]Sloan-Swartz Ctr. For Theoretical Neurobiology, UCSF, San Francisco, CA

Abstract: The brain builds its spatial maps by combining input from external landmarks with cues arising from the animal's own movement. In previous work, we developed a coupled oscillator attractor network model for how these cues are integrated by entorhinal grid, border, and speed cells that explained a range of neurophysiological and behavioral data (Campbell et al. 2018). Here, we further test the predictions of this model by recording large populations of neurons along the whole dorsal-ventral axis of medial entorhinal cortex using Neuropixels probes while mice ran down a virtual linear track. First, we show that the main prediction of our model holds in large populations of entorhinal neurons: manipulating the gain between the animal's running speed and its progression down the virtual hallway caused maps to shift for small changes in gain, and remap for gain changes larger than a critical threshold. We then experimentally manipulated the strength of the landmark input to entorhinal cortex by reducing the contrast of the visual cues. Lowering the contrast reduced the stability of the spatial maps, and impacted cells' responses to gain changes accordingly. Finally, we leverage our large-scale recordings to test how cell activity correlations, measured in darkness, depend on responses to gain and contrast changes during the task.

Title: Leveraging neuropixels probes and virtual reality in order to identify the mechanisms underlying ketamine's effect on spatial coding

Authors: *F. K. MASUDA[1], L. M. GIOCOMO[2];
[2]Neurobio., [1]Stanford Univ., Stanford, CA

Abstract: Anesthetic drugs have proven to be helpful for elucidating the fundamental mechanisms of spatial memory. Ketamine—a commonly used dissociative anesthetic—has

received significant clinical and scientific attention due to its ability to acutely treat depression. Yet, despite the immense excitement surrounding the clinical use of ketamine, its mechanism of action and its effects on spatial memory remain poorly understood. Ketamine's clinical potential could be expanded if its effects on memory and spatial navigation at sub-anesthetic doses were better understood. To address this gap, we examine how ketamine affects the hippocampal-entorhinal memory circuit from a molecular and circuit perspective. We leveraged the ability of Neuropixels probes to record large populations of spatially-tuned neurons from mice traversing a virtual reality environment in order to examine how ketamine affects the medial entorhinal cortex (MEC). Notably, ketamine disrupts the firing patterns of spatially tuned cells in the MEC. Additionally, hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are known to modulate grid firing patterns in the MEC (Giocomo 2011). While ketamine is traditionally regarded as an NMDA antagonist, recent work has suggested that the ketamine's mechanism of action and receptor affinity is more heterogenous. Thus, we compared the effect of ketamine on hippocampal-entorhinal neural coding in HCN1 knockout animals and neural coding in wild type animals and found differences in the coding of spatial cells and in LFP frequency.

Title: Entorhinal cortex encodes a wide repertoire of self-motion signals

Authors: *C. S. MALLORY[1], K. HARDCASTLE[2], J. L. RAYMOND[3], L. M. GIOCOMO[2]; [1]UC Berkeley, Berkeley, CA; [2]Neurobio., Stanford Univ., Stanford, CA; [3]Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Recent reports have revealed that rodents move their eyes considerably during active navigation, raising questions about whether and how eye movements guide navigation and influence the underlying neural computations. Visual input plays a key role in navigation, and

accurate interpretation of visual signals requires appropriate consideration of eye movements. To estimate the position of visual objects, the direction that the retina is pointing must be considered, which is influenced by the position of the eye within the orbit (eye direction in the head) as well as head direction and body position within the environment. Likewise, to estimate the distance to landmarks or self-motion relative to environmental landmarks from retinal optic flow signals requires consideration of eye velocity, along with angular head velocity and body speed. Two of the self-motion cues needed to integrate visual cues into a global representation of space, head direction and body speed, were previously shown to be encoded by medial entorhinal cortex (MEC), a key hub in the brain's circuitry supporting navigation. We tested whether eye direction, eye velocity and angular head velocity are also encoded, utilizing a recently developed magnetic eye tracking system to monitor eye movements and an LED head tracking system or nine-axis inertial measurement unit to monitor head movements in freely moving mice, while simultaneously performing electrophysiological recordings in the MEC. We report that neurons in MEC encode several previously unrecognized self-motion signals: eye direction, gaze direction, eye speed, and angular head velocity. The representation of these signals is highly mixed with other cues in individual neurons.

Title: Re-organization of long-term spatial representations during methamphetamine place conditioning

Authors: *Y. SUN, L. M. GIOCOMO;
Neurobio., Stanford Univ., Stanford, CA

Abstract: Methamphetamine (MA) is a potent stimulant that exerts a powerful psychological effect. During MA administration, a strong association is formed between the experience of MA and the surrounding spatial context. In humans, this association can manifest in MA cravings and relapse with exposure to spatial contexts previously associated with drug administration. However, the underlying mechanism and circuit basis of MA's impact on spatial cognition remains unknown. As the neural basis for representing space depends on neural circuits in the

hippocampus, we used a miniaturized fluorescence microscope in freely moving mice to examine CA1 place cell representations during the entire process of methamphetamine conditioned place preference (CPP). The CPP protocol included a pre-conditioning baseline, 3 x MA (2mg/kg) or saline conditioning, and 2 post-conditioning tests (4 days apart). Compared to baseline, we found the Ca^{2+} event rate of place cells showed a long-term reduction in the MA-paired side relative to saline-paired side during the post-test sessions. This effect was not observed in control animals, in which saline was paired on both sides. We also observed rate remapping during baseline between place cells with homotopic fields in the two CPP chambers. After MA administration, however, the spatial distance between place fields in the saline versus MA-paired side increased significantly, resulting in a lower spatial correlation between place fields in the two sides of the CPP chamber. Again, these effects were not observed in control animals. Interestingly, the degree to which the spatial correlation between place fields decreased was linearly correlated with the degree of behavioral CPP expression. Longitudinal analysis further revealed, in control animals, place cell ensembles are more stable in the naturally preferred side across sessions compared to the non-preferred side. However, this pattern is reversed in the MA-conditioned animals, in which stable ensembles switch from the naturally preferred side to the MA-paired side (naturally non-preferred side). Together, the data suggest MA administration re-organizes the spatial representations of place cell ensembles by increasing the orthogonality between the MA-paired environment and drug free environment and further strengthen the representation stability in the MA-paired environment for long-term.

Title: Experience drives discrete representations of continuous stimuli in the hippocampus

Authors: *M. H. PLITT[1], L. M. GIOCOMO[2];
[2]Neurobio., [1]Stanford Univ., Stanford, CA

Abstract: The hippocampus is a crucial structure for contextual and spatial learning, and principal cells in this region show striking correlations with behavior. Place cells, for example, fire specifically when an animal occupies one to few restricted locations in space and change their firing properties with context. However, we know very little about how hippocampal populations behave when contextual cues are ambiguous. To answer this question, we trained mice to run in two similar virtual hallways while imaging the calcium activity of large populations of CA1 neurons. Once the animals were experienced in the two hallways, we probed their representations with randomly chosen morphed environments that were a blend of the two hallways. On single trials, the population coherently and rapidly picked one of its previously stored representations for the environments and did not take on intermediate representations. In contrast, if mice were trained by being shown all of the morphed environments from the first session, the population instead represented the ambiguity by blending its representation, or in the case of a small population of cells, specifically forming a separate representation for the morphed environments. A separate cohort of mice were then trained to actively distinguish between the two extreme environments. In this case, the proportion of cells which were classified as place cells increased dramatically; however, the "all-or-none" voting behavior of the population activity was largely similar to the previous task. This fixed point attractor-like representation to ambiguous stimuli appears to be somewhat divorced from the animal's decision of which environment it is in, i.e., population activity near the animal's perceptual threshold is not informative about the animal's decision on that trial. Together, these results suggest that hippocampal activity may approximate something like sampling from a prior distribution over previously experienced states.

Title: Entorhinal velocity signals reflect environmental geometry

Authors: *R. G. K. MUNN[1], C. S. MALLORY[1], K. HARDCASTLE[1], D. M. CHETKOVICH[2], L. M. GIOCOMO[1];

Abstract: The entorhinal cortex contains neural signals for representing self-location, including grid cells that fire in periodic locations and velocity signals that encode an animal's speed and head direction. Recent work revealed that the size and shape of the environment influences grid patterns. Whether entorhinal velocity signals are equally influenced or provide a universal metric for self-motion across environments remains unknown. Here, we report that changes to the size and shape of the environment result in re-scaling in entorhinal speed codes. Moreover, head direction cells re-organize in an experience-dependent manner to align with the axis of environmental change. A knockout mouse model allows a dissociation of the coordination between cell types, with grid and speed, but not head direction, cells responding in concert to environmental change. These results align with predictions of grid cell attractor models and point to inherent flexibility in the coding features of multiple functionally-defined entorhinal cell types.

Planck Inst. of Neurobio., Planegg-Martinsried, Germany; [3]Inst. of Mol. Medicine, Peking Univ., Beijing, China

Abstract: The medial entorhinal cortex (MEC) creates a map of local space, based on the spatial firing patterns of grid, head direction, border, and object-vector cells. How these various cell types are organized anatomically in the MEC is still debated, although reports of clustering among functional properties of grid cells (Heys et al. 2014; Gu et al. 2018) point towards a structured anatomical organization of the MEC network at both micro and macro scales. In-depth analysis of this question has been held back by the absence of suitable recording methods. In vivo single unit electrophysiological methods permit only indirect inference of anatomical organization. Although calcium imaging via miniaturized one-photon microscopes enables large-field-of-view recordings of superficial cortical layers, it falls short of resolving detailed anatomical organization in densely labeled neuronal networks. In contrast, in vivo two-photon microscopy allows for the precise characterization of firing properties of hundreds of simultaneously recorded cells within and across layers. However, the majority of current two-photon imaging experiments require the animal to be head-fixed and to navigate in virtual environments, which can impede the analysis of most spatially tuned cell types (Donato and Moser, 2016). Here we show results from imaging large areas of MEC in more than six mice using a new generation of miniaturized, portable two-photon microscopes (Zong et al., 2017) that have undergone significant development since our previous report (Obenhaus et al., SfN 2018). With its large-field-of-view objective (400x400 μm), decreased weight (2.2g) and axial scanning capability, the microscope enables multiplane, dual channel recordings of hundreds of neurons expressing GCaMP as well as a second red-shifted fluorophore in freely moving animals. We obtained stable long-term recordings through chronic implants consisting of combinations of a gradient refractive index (GRIN) lens and a micro prism positioned between MEC and the cerebellum. The second, non-functional channel was used to label specifically cells with projections from MEC to ipsilateral hippocampus (retrograde AAV carrying tdTomato and injected into the hippocampus; Tervo et al. 2016). The resolution of this improved two-photon system allows us to record from all known spatially modulated cell classes in widespread regions of MEC while mice are moving freely inside an 80x80 cm environment. We are currently investigating how spatial firing properties are topographically organized across layers in superficial MEC, within and between groups of imaged grid cells, object vector cells and head direction cells.

Systems Neurosci, Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) supports the brain's representation of space with distinct cell types whose firing is tuned to features of the environment (grid, border, and object-vector cells) or navigation (head-direction and speed cells), and whose somata are anatomically intermingled in layer 2 of the MEC (MEC-L2). Since no single sensory stimulus can faithfully predict the firing of these cells, and activity patterns are preserved across environments and brain states, attractor network models postulate that spatially-tuned firing emerges from specific connectivity motives among neurons of the MEC. To determine how activity is self-organized in the MEC-L2 network, we tested mice in a spontaneous locomotion task under sensory-deprived conditions, when activity likely is determined primarily by the intrinsic structure of the network. Using 2-photon calcium imaging, we monitored the activity of large populations of MEC-L2 neurons in head-fixed mice running on a wheel in darkness, in the absence of external sensory feedback tuned to navigation. To reveal network dynamics under theses conditions, we applied both linear and non-linear dimensionality reduction techniques to the spike matrix of each individual session. When we applied principal components analysis and sorted cells according to their contribution to the first principal component (PC1), we were able to unveil the presence of stereotyped motifs involving the sequential activation of neurons over epochs of tens of seconds to minutes ("sequences" or "waves"). The same temporal progressions were found with non-linear techniques. To characterize the nature of sequences, we sorted neurons into clusters according to their contribution to PC1, and characterized the transition probabilities between clusters. Transitions between clusters that were close in principal-component space were favored, while transitions between clusters farther apart happened with a lower frequency than chance. The temporal analysis of transitions revealed stereotyped trajectories across multiple clusters ("waves"), lasting up to 2-3 minutes. Similar sequences were not found in spike-time-shuffled or non-sorted data.
Waves swept through the entire network of active cells with slow temporal dynamics, in the order of tens of seconds to minutes, and did not exhibit any anatomical organization. Taken

together, our results suggest that a large fraction of MEC-L2 neurons participates in common global dynamics that often takes the form of stereotyped sequences. These activity patterns might progress through multiple subnetworks and couple the activity of neuron with distinct tuning characteristics in MEC-L2.

Title: Mixed selectivity in outputs from the medial entorhinal cortex to non-hippocampal targets

Authors: *D. C. ROWLAND[1], H. A. OBENHAUS[2], E. I. MOSER[3], M.-B. MOSER[3]; [1]NTNU, Trondheim, Norway; [2]Moser Group, Kavli Inst. For Systems Neurosci., Trondheim, Norway; [3]Kavli Inst. Systems Neurosci, Trondheim, Norway

Abstract: The entorhinal-hippocampal circuit forms a processing loop, whereby outputs from the entorhinal cortex are processed by the hippocampus and returned to the entorhinal cortex. Previous work has focused extensively on how the various functional cell types in the medial entorhinal cortex (grid cells, border cells, head direction cells, speed cells and object vector cells) contribute to the formation and maintenance of hippocampal place fields and vice versa within the context of this processing loop. However, we still do not know what kind of information the medial entorhinal cortex (MEC) broadcasts to other telecephalic targets, such as the nucleus accumbens, amygdala, prefrontal cortex and retrosplenial cortex. Here, we injected retrograde AAVs (Tervo et al., 2016) into the retrosplenial cortex of mice to label projections from the MEC. Consistent with earlier results, we found that the population of retrogradely labelled cells

was nearly exclusively localized to Layer Va of the MEC (Surmeli et al., 2015). We then used the same retrograde AAV system to deliver excitatory or inhibitory opsins for *in vivo* functional characterization of the cells using a phototagging approach. Cells were identified as layer Va cells if they responded immediately and robustly to light delivered from a fiber-coupled laser. In contrast to cells in other layers, the phototagged cells in layer Va were notable for the amount of mixed selectivity they displayed during open field sessions (80x80 cm arena): layer Va cells were frequently tuned to some combination of space, head direction, and speed. The identified population included less than 10% grid cells and grid scores (a measure for six-fold symmetry) for those cells were lower than other layers. Thus, much of the functional specialization that characterizes cells in superficial layers of the medial entorhinal cortex appears to be replaced by a mixed code in the output cells of layer Va. As layer Va is likely to play an important role in sleep-mediated transfer of information from the MEC to other cortical areas, we are currently studying whether Va cells show consistent firing correlations with each other and with other cells between wake and sleep, as seen in other layers of the MEC.

Title: Similar firing properties of neurons in the medial entorhinal cortex in male and female mice

Authors: *M.-B. MOSER[1], D. C. ROWLAND[2], E. I. MOSER[1];
[1]Kavli Inst. Systems Neurosci, Trondheim, Norway; [2]NTNU, Trondheim, Norway

Abstract: Many studies in humans have suggested that males show superior performance in tests of allocentric spatial navigation (Maguire et al., 1999), while females show an advantage in object location memory (Voyer et al., 2007). However, studying sexually dimorphic behaviors in humans is challenging because cultural factors are likely to play an important role (Lawton and Kallai, 2002). This problem can be circumvented by using animal models. Many wild rodents,

including the common house mouse, display sexually dimorphic spatial behaviors, most notably larger home ranges in male compared with female animals (Mikesic and Drickamer, 1992). Perhaps relatedly, in laboratory-reared rodents, males frequently show better performance in the standard version of the water maze task (Perrot-Sinal et al., 1996), while females show better memory for object locations (Saucier et al, 2008). At the subcellular level, CA1 pyramidal cells of laboratory-reared rats undergo a roughly 30 percent fluctuation in spine density over the course of the estrous cycle (Woolley et al., 1990). These results hint at a possible fundamental difference in the neural representation of space in the two sexes. However, recordings from CA1 place cells of female laboratory-reared rats found little difference in the spatial coding properties of the cells over the course of the estrous cycle (Tropp et al., 2005). Here we decided to examine the firing properties of layer II medial entorhinal cells in male and female laboratory-reared mice. The medial entorhinal cortex contains a set of functionally specialized cell types: grid cells, head direction cells, border cells, speed cells and object vector cells. These cell types presumably contribute to different aspects of spatial navigation and are therefore valuable for examining whether the brain's neural representation of space differs between the sexes. We found a striking amount of similarity between the sexes. Male and female mice had similar percentages of cells in each functional category and no significant differences in the key measures of spatial tuning. We found no difference in grid spacing and no difference in grid orientation (i.e. the grid pattern of both males and females was oriented to the walls of the environment with a 5-10 degree offset). The implications of our results are two-fold. First, our analyses suggest that male and female rodents have strikingly similar neural representations of space, in spite of hormonal fluctuations in female mice that drive considerable synaptic plasticity. Second, our results should encourage researchers in the field to use and pool results from both sexes, thereby reducing the total number of animals used.

Title: A novel directional signal expressed during grid-cell theta sequences

Authors: *R. J. GARDNER, A. Z. VOLLAN, M.-B. MOSER, E. I. MOSER;
Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: Theta sequences (TS) are a fundamental feature of position coding in rodents, whereby position-coding cell ensembles encode prospective trajectories originating at the animal's present location. Grid cells are a promising candidate for driving TS, since some influential theoretical models predict that grid modules could generate trajectories from an arbitrary directional input. We were therefore motivated to examine TS in rats implanted with 384-channel Neuropixels silicon probes in medial entorhinal cortex and parasubiculum (MEC/PaS), while the animals ran in an open-field arena.

First, we observed that coding for remote locations during TS substantially distorted grid cells' spatial responses. The maximum spatial offset scaled with grid spacing, suggesting that grid modules encode trajectories across different spatial scales.

Second, by decoding position from MEC/PaS ensemble activity during open-field foraging, we observed TS as forward-directed, linear trajectories which extended as much as 1 m across the environment. Most trajectories were oriented within 60 degrees of the animal's head direction, and their angular offset from the head direction alternated frequently between left and right, resembling 'vicarious trial-and-error' in place cells (Johnson and Redish, 2007).

Finally, we describe a novel 'sweep direction' signal, encoded by theta-rhythmic, directionally selective MEC/PaS cells whose firing sharply coincided with the forward-sweeping phase of the theta cycle. Sweep-direction ensemble activity predicted the direction of TS trajectories substantially better than the animal's true head direction. Conversely, non-theta-rhythmic directional cells did not predict sweep direction, and instead more closely followed the animal's head direction.

Alternation of TS trajectory angles provides a more basic explanation for the phenomenon of theta cycle-skipping in grid and directional cells. Moreover, diffuse tuning to head direction, which is a widespread characteristic of MEC/PaS cells, may be explained as a side effect of selectivity for sweep direction.

In summary, we observed that grid-cell ensemble activity during TS encodes position trajectories whose common alignment across modules is signalled by a novel 'sweep-direction' code. Our results may have important implications for theoretical models of grid cells which use directional input to shift activity across a continuous attractor manifold. Although models typically use this capability to perform path integration, the existence of a sweep-direction code suggests that the same models could alternatively provide a mechanism for grid-cell TS trajectories.

Title: Early postnatal ablation of Cajal-Retzius cells affects hippocampal circuit development

Authors: *G. QUATTROCOLO, E. I. MOSER;
Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway

Abstract: The hippocampal formation plays a major role in the encoding, association, consolidation and retrieval of memories. In particular, it creates spatial maps that animals use to navigate the environment. The microcircuits for these features are refined around birth as well as during the first weeks of postnatal development. In fact, hippocampal-dependent behaviors do not reach maturity until the first couple of months of age in rodents (Wills et al., 2013) and the first years in humans (Lavenex and Banta Lavenex 2013). During this critical time, the hippocampus harbors a transient populations of neurons, the Cajal-Retzius (CR) cells. CR cells are critical orchestrators of cortical development. While cortical CR cells die during the first week of postnatal development, CR cells persist in the hippocampus for several months after birth (Anstötz et al. 2016; 2017). Previous work has showed that CR cells are an active component of the hippocampal circuit (Quattrocolo and Maccaferri 2013; 2014). However, little is known about their role in the hippocampal network. What is the function of hippocampal CR cells during postnatal development? To address this question we decided to ablate CR cells at early time points of postnatal development and determine how their ablation affects maturation of the hippocampal network and hippocampal-dependent behaviors. To achieve the ablation, we inject a Cre-dependent virus expressing diphtheria toxin fragment A (DTA) into the hippocampus of P0 pups of the Pde1c-cre transgenic mouse line. This line is highly selective for CR cells, in the hippocampus, therefore CR cells are the only neurons affected by virally-induced DTA expression. We here show that the toxin successfully ablates hippocampal CR cells, reducing their number, in the dorsal hippocampus, to around 40% by the second postnatal week. Our data show so far that hippocampal levels of BDNF are significantly increased after ablation of CR cells, suggesting an alteration in the maturation of pyramidal cells. In addition, we performed whole-cell patch clamp in CA1 pyramidal cells while electrically stimulating

glutamatergic fibers in Stratum Lacunosum-Moleculare. We find that the AMPA/NMDA ratio is affected after the loss of CR cells, hinting at alterations in the glutamatergic connectivity. These results suggest that the presence of CR cells in the postnatal hippocampus is necessary for the proper maturation of the hippocampal circuit. We are now aiming to perform *in vivo* recordings of hippocampal place cells to understand the role of CR cells in the maturation of the spatial mapping system.

Abstract: Several functionally-specific cell types in the entorhinal-hippocampal network contribute to the brain´s representation of space. Among them we find grid, border, and head-direction cells. While head-direction and border cells are adult-like at the onset of spatial exploration, grid cells undergo refinement within the first month after birth, a process that might depend on the establishment of connectivity motifs between superficial and deep layers of the entorhinal cortex and the hippocampus. The functional maturation of grid cells is accompanied by the structural maturation of the entorhinal-hippocampal network: our work showed that an activity-dependent instructive signal, originating from stellate cells of layer 2 of the medial entorhinal cortex (MEC-L2), propagates through the whole network to drive the stepwise maturation of excitatory and inhibitory neurons, as well as synaptogenesis, during the first month

after birth. Studying the functional ontogenesis of the entorhinal-hippocampal circuit offers a unique opportunity to understand the contribution of individual stages of circuit development to MEC-L2 network dynamics and computations.
Here, we investigated how activity in MEC-L2 self-organizes while juvenile mice perform a spontaneous locomotion task under sensory-deprived conditions. For this we performed daily measurements of activity from large populations of neurons with 2-photon calcium imaging, while animals were head-fixed and ran on a wheel in darkness, i.e. in the absence of external sensory feedback tuned to navigation. While in adult mice, the activity of MEC-L2 neurons progressed through stereotyped motifs involving the temporally sequential activation of clusters of neurons ("sequences" or "waves", Donato et al., SfN 2019), similar sequences were not observed in juvenile mice (P14-P21). Sequences emerged only at later time points, their occurrence increased during the fourth postnatal week, and their temporal dynamics refined with age. The earliest sequences progressed through the network over a time course often of 2-3 minutes, whereas from P30 and onwards, sequences were shorter, usually in the order of tens of seconds. Sequence stabilization coincided with the time when grid cells are known to adopt fully mature firing properties. Taken together, our results indicate that a large fraction of MEC-L2 neurons are coupled by global activity dynamics that emerge progressively during postnatal development. The prolonged maturation of these stereotyped dynamics mirrors the structural maturation of the whole entorhinal-hippocampal network, suggesting that their emergence involves multiple stages of the circuit.

Title: The mammillary bodies convey the ingredients for path integration

Authors: *G. VIEJO, A. PEYRACHE;
Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada

Abstract: Animals can successfully find their way, even in the absence of external signals, by using vestibular and proprioceptive information. This process, referred to as 'path integration', is

believed to be achieved by integrating in time the direction of movement with ongoing speed. Head-direction (HD) and speed cells have been characterized in various structures of the mammalian navigation system, but so far only the medial entorhinal cortex was believed to be modulated by both signals. The mammillary bodies (MBs) are a key relay in the Papez circuit, forming a loop with the anterior thalamus and the hippocampal and parahippocampal systems, yet its dynamics and behavioral correlates remain largely unclear. Here, using silicon probe recordings in freely moving mice, we show that MB neurons are correlated with various aspects of movement, including angular head velocity, head-direction and speed, sometimes conjunctively in the same neurons. Additionally, MB neurons that relay speed or HD signals are sometimes also non trivially modulated by ongoing brain states, preferentially firing either during Rapid Eye Movement (REM) or Non-REM sleep. These results suggest that the MBs are an essential actor for path integration and that they play an active role in the selective transmission of signals to thalamo-cortical networks.

Title: Head direction and place cells interaction during wake and sleep

Authors: *S. ANGELES-DURAN[1,2], G. VIEJO[1], A. J. DUSZKIEWICZ[1,3], A. PEYRACHE[1]; [1]Montreal Neurolog. Inst. and Hosp., [2]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada; [3]Ctr. for Discovery Brain Sci., Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: The hippocampus plays a central role in navigation and memory consolidation. During exploration, hippocampal place cells increase their firing rate when the animal explores a particular location in its environment, forming sequences associated with the animal's trajectories. During sleep, these sequences are replayed, a phenomenon believed to be instrumental in memory consolidation. The formation of place cells depends on the processing of multiple sensory inputs. Perhaps one of the most important is conveyed by the head-direction (HD) cells, which fire for a particular direction of the animal's head. Yet, how HD and place cells interact, during the formation of awake neuronal sequences and subsequent sleep replay, remain unknown. We hypothesised that the activity of hippocampal place cells and the HD

signal in the antero-dorsal nucleus of the thalamus (ADn) may be coupled, and this synchronized activity could modulate the direction of recent replayed trajectories. To this end, we performed high-density dual recordings in hippocampal CA1 and ADn as the mice performed a spatial alteration task on a Y-maze. Preliminary analysis has indicated that HD cell-assemblies in ADn are modulated by hippocampal sharp-wave ripple oscillations during sleep, pointing to a functional relationship between ADn and the hippocampus in the offline state. Further analysis will determine whether there exists any relationship between hippocampal reactivation events and activation of specific cell-assemblies in ADn.

Title: Thalamic reticular nucleus controls the gain of the thalamic head-direction signal

Authors: *A. J. DUSZKIEWICZ[1], E. BROWN[1], E. R. WOOD[2], A. PEYRACHE[1];
[1]Montreal Neurolog. Inst. and Hosp., McGill Univ., Montreal, QC, Canada; [2]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: The representation of animal's current direction originates from the vestibular system and is continuously calibrated based on the visual information. Head-direction (HD) cells serve as the brain's internal 'compass' and each of them is tuned to the specific direction the animal is facing, independently of its location and ongoing behavior. The anterodorsal thalamic nucleus (ADn) is a key relay of the HD signal to downstream cortical targets, yet its exact role in the processing of the HD signal remains unclear. Here, using a combination of high-density single unit recordings and optogenetic interrogation in freely moving mice, we demonstrate that the thalamic stage of the HD circuit is involved in spatial attention.Using viral-genetic tract tracing as well as fluorescent Retrobeads in VGAT-Cre mice, we mapped reciprocal projections between the ADn and the thalamic reticular nucleus (TRN) - an inhibitory thalamic nucleus that controls the routing of sensory information according to attentional demands. In order to assess the functional importance of the inhibitory projection from TRN to ADn, we recorded assemblies of

ADn-HD cells in freely moving VGAT-Cre mice expressing inhibitory opsin ArchT in GABA-ergic TRN neurons. Optogenetic inactivation of TRN neuron terminals in ADn caused widespread increase in ADn-HD neuron firing rates as well as modest broadening of their angular receptive fields, which indicates that TRN is involved in gain modulation of the HD signal in the thalamus. In light of these results, we hypothesized that TRN input to ADn may act to modulate the gain of the thalamic HD signal when there is a mismatch between vestibular and visual directional cues. To this end, we recorded assemblies of up to 20 HD cells in the postsubiculum (PoSub) - the main cortical target of ADn-HD cells and the postulated site where vestibular HD signal is calibrated based on the visual input. Mice then explored a small circular open field with a prominent distal visual cue that was unexpectedly shifted by 90 degrees every few minutes. We found that PoSub-HD cells reliably and coherently realigned their angular receptive fields in sync with the cue. Importantly, preliminary data suggest that increasing the gain of the thalamic HD signal via optogenetic inactivation of the TRN-ADn input slows down the realignment of the PoSub-HD cell receptive fields. Overall, these results indicate that TRN attenuates the thalamic HD signal to facilitate the updating of the current HD representation by the visual system.

Title: Representation of goal location in rat prefrontal cortex

Authors: *R. BASU, S. KOLB, T. HERFURTH, T. TCHUMATCHENKO, H. ITO;
Max Planck Inst. For Brain Res., Frankfurt am Main, Germany

Abstract: The daily activity of rodents includes visiting several distinct bait areas in their territories. Before starting such a journey, they need to decide a pertinent goal location from the others. Previous research has identified neurons in the hippocampus and the medial entorhinal cortex that get activated when an animal visits specific locations, and a population of these neurons together can provide an animal with a rich representation of its current location. However, although place cells in the hippocampus sometimes exhibit brief spike sequences that

are correlated with the animal's immediate future trajectories, it is still largely unclear where and how the brain maintains distinct representations of the goal locations themselves. As the goals may be represented upstream of the hippocampus thereby enabling place cells to generate spike sequences towards the destination, we focused on medial prefrontal (mPFC) and orbitofrontal (OFC) cortices that are anatomically connected to the hippocampus through the thalamus. These brain regions have been implicated in decision making when animals are confronted with multiple alternatives, and a human patient with mPFC lesion has been reported to exhibit difficulty in keeping the goal locations in mind. To investigate the roles of mPFC and OFC in goal representations, we made a linear track with multiple reward sites, and rats were required to visit two given sites alternately to obtain rewards. The reward sites changed after several successful trials in order to renew the animal's goal locations throughout an experimental session. Preliminary electrophysiological recordings from mPFC and OFC of behaving rats revealed two key observations. First, mPFC and OFC neurons showed distinct firing patterns at individual reward sites in the maze. Notably, in contrast to place cells in the hippocampus, we found that the representations of these neurons preserved the topological relationship of positions; the representations are more similar for closer reward locations, and more different for farther sites. Using a decoding approach for mPFC and OFC neurons, we could successfully identify the reward site where the animal is at that moment. Second, before starting the journey towards the next reward site, we observed an abrupt transition of the neural representation from the current to the future reward site that the animal was planning to visit, indicating distinct representations of the next goals in these areas. In summary, our results suggest that prefrontal neurons can create a topologically accurate map of reward locations that can be subsequently used to represent the remote goals that the animal is planning to visit.

Title: Sensory integration of environmental features in rat retrosplenial cortex to compute spatial information of boundaries

Authors: *J. VAN WIJNGAARDEN, S. BABL, H. ITO;
Max Planck Inst. For Brain Res., Frankfurt am Main, Germany

Abstract: Internal representations of space are critically dependent on environmental features. Manipulations of the environment, such as morphing the shape of the arena, directly affect receptive field properties of spatially tuned cells (*e.g.* place, grid or border cells). A recent study further proposed direct contact with environmental boundaries to act as an error-correction mechanism of grid cells (*Hardcastle et al. 2015*). However, it remains unclear how sensory information about such features is processed and integrated for the accurate formation and updating of neural representations of the environment. Human fMRI and patient studies suggest an important role here for the Retrosplenial Cortex (RSC), a cortical brain region involved in landmark processing and known to have orientation-selective cells anchored to salient cues (*Auger et al. 2012; Takahashi et al. 1997; Jacob et al. 2017*). While it is densely connected with (para) hippocampal regions and part of several sensory pathways (including vision and somatosensation), its exact role in spatial and sensory processing remains to be determined. Hence we performed a series of experiments to characterize the influence of environmental variables on the coding principles of neurons in the retrosplenial cortex. We recorded single-unit activity using 28-tetrode drives - implanted along the rostral-caudal axis of the right RSC - in freely foraging rats (n=5) and found consistent firing in a subset of neurons as a function of the animal's position that was anchored to the closest boundary. Cells fired predominantly when the animal was at a specific distance and orientation towards a nearby wall, where new fields formed alongside added walls, yet they remained silent upon introducing objects. The preferred tuning across this population of RSC cells was highly biased for a particular distance and direction, and consistent between days and animals, indicating a strong sensory drive. This is further corroborated by the invariance of their boundary tuning to environmental rotations, in contrast to the remapping of local head-direction cells. Taken together these results suggest that the RSC can play an important role in integrating sensory information, providing both landmark and border information within a self-centred reference frame. This information can then inform downstream regions of the surrounding context, and allow for anchoring and referencing of internal representations to the external world.

Title: A role of nucleus reuniens in goal-directed navigation

Authors: *H.-A. KIM, H. ITO;
Memory and Navigation Circuits Group, Max Planck Inst. For Brain Res., Frankfurt am Main, Germany

Abstract: During navigation, animals require information about their current location as well as the goal destination. While the hippocampus and parahippocampal regions are thought to provide accurate information about the animal's instantaneous position, it is still largely unclear where and how the goal location is represented in the brain. A potential candidate is the medial prefrontal cortex (mPFC), as neurons in this area exhibit enhanced temporal coordination with the hippocampus during trajectory decisions (Jones and Wilson, 2005; Ito et al., 2018), and lesions of mPFC led to impairment in goal-directed navigation (Granon and Poucet, 1995). Since there is no direct projection from the mPFC to the hippocampus, the midline thalamic nucleus reuniens (RE) is considered a key node to link between mPFC and the CA1 region of the hippocampus (Vertes et al., 2007). Our previous study has shown that mPFC-RE input is essential for the next trajectory coding in CA1 place cells (Ito et al., 2015), implying a role of this input in goal-directed navigation. However, animals with lesions in RE did not show significant impairment in the Morris water maze task (Dolleman-van der Weel et al., 2009), putting the RE's role in the navigation into question. To clarify this discrepancy, we used optogenetic and chemogenetic methods to inactivate RE neurons reversibly during goal-directed navigation. Male Long-Evans rats were injected with AAVs expressing either SwiChR or hM4Di in RE, and an optical fiber was implanted together for SwiChR-injected animals. To test goal-directed navigation, we used an open field arena with evenly-distributed 25 wells on the floor to deliver water as rewards. The task is composed of repetitively-alternating two task phases, goal-directed and random-foraging phases (Pfeiffer & Foster, 2013). In the random foraging phase, animals are required to explore the arena to find a randomly-chosen well that delivers water. In the goal-directed phase, the fixed home well is always rewarded, and thus rats usually took a direct path to this remembered well. When RE is inactivated by either laser application or agonist injection, animals took a longer path or spent more time particularly at the initial part of the journey to reach the home well. This is not likely due to the impairment of goal representation or memory, because the error rate of choosing incorrect wells did not increase during RE inactivation, indicating that animals were able to distinguish the home well from others. Our result together points to RE as a key structure for route planning in navigation, probably by interfacing mPFC with an internal spatial map in the hippocampus.

Title: Interaction of place and gaze representations in the hippocampus of food-caching birds

Authors: *H. L. PAYNE, D. ARONOV;
Columbia Univ., New York, NY

Abstract: A key function of the hippocampus is to support navigation to remembered goals. Across animals, hippocampal activity represents a variety of spatial variables, including the animal's physical location (e.g. in foraging rodents) and viewed target (e.g. in head-fixed primates). However, it is unclear how these activity patterns interact and drive goal-directed behavior. Food-caching birds, including chickadees and titmice, are an excellent model for studying this question. They have a greatly enlarged hippocampus necessary for retrieving remembered food caches, and rely on vision for this behavior. Because birds primarily use head saccades to direct vision, both physical location and gaze location can be readily monitored during free motion. We present the first recordings of neural activity in the hippocampus of a food-caching bird, the tufted titmouse. We found robust place cell activity in birds freely foraging for seeds, in contrast to previous studies reporting a lack of place cells in other avian species. Avian place cells shared several similarities with place cells reported in rodents: they occurred with similar frequency and displayed a similar range of spatial specificities, from cells with single sharp firing fields to cells with multiple regions of selectivity. Remarkably, the distribution of sharply tuned place cells varied along the anterior-posterior axis of the hippocampus, analogous to the distribution of such cells along the dorso-ventral axis of the rodent hippocampus. To estimate gaze, we built a marker-based system for tracking 3D head movements. We found that many neurons exhibited firing fields at specific gaze (viewed) locations. In some cells, gaze tuning matched place tuning, but in other cells it did not, indicating that the avian hippocampus encodes both physical location and viewed targets. Neural information about place and gaze varied in time, such that neural activity encoded information about place that was more predictive (related to where the animal will be in the future), while encoding information about gaze that was more reactive (related to where the animal was currently or previously looking). Our results suggest that the avian hippocampus dynamically processes information about the animal's relationship to the world in a way that may support goal-directed navigation.

Title: Imaging activity of large neuronal populations in the hippocampus of freely behaving food-caching birds

Authors: *E. L. MACKEVICIUS, M. C. APPLEGATE, H. L. PAYNE, D. ARONOV; Columbia Univ., New York, NY

Abstract: In humans, the hippocampal formation is critical for forming instantaneous (one-shot) memories. In rodents, hippocampal neurons fire at specific environmental states (e.g., locations) and, as a population, tile the environment. The population replays trajectories through the state space during events called sharp wave ripples. However, the relationship between these firing patterns and the one-shot function of the hippocampus is not well understood. We aim to bridge ideas in the rodent and human fields by recording hippocampal neurons in birds from the food-caching *Paridae* family. These birds, including chickadees and titmice, prolifically cache food in scattered locations, then return later to retrieve their caches using memory. Cache memory requires the hippocampal formation, which is grossly enlarged in these birds.
Previous studies in non-mammals have not found activity patterns akin to place cells or sharp-wave ripples. However, recordings have never been performed during navigation in spatial memory specialists like food-caching birds. Birds offer experimental advantages for functional imaging because the avian hippocampus is on the dorsal surface of the brain, rather than under the neocortex.
We expressed the calcium indicator GCaMP6f in the hippocampus of tufted titmice and recorded large neuronal populations using a head-mounted miniaturized microscope (Inscopix). Birds foraged for food and cached in an arena outfitted with hidden cache sites. Several aspects of our data bear a detailed resemblance to the rodent hippocampal recordings. First, nearly half of the imaged neurons exhibited spatial patterns that closely resembled rodent place cells. These cells were also present in electrophysiological recordings, presented in a companion poster. Second, a prevalent feature of these data were near-synchronous patterns of network activity, reminiscent of sharp wave ripples. Electrophysiological recordings revealed LFP signatures of sharp wave ripples during synchronous events, including low-frequency deflections and ripple-band oscillations. Our findings suggest strong similarities between the hippocampus of food-caching

birds and its mammalian counterpart, paving the way for using this system to investigate one-shot memory in the hippocampus.

Title: Development of a hippocampus-dependent memory task for neural recordings in food-caching birds

Authors: *M. C. APPLEGATE, K. S. GUTNICHENKO, D. F. SCHECK, D. ARONOV; Columbia Univ., New York, NY

Abstract: The hippocampus is necessary for forming episodic memories. However, the exact circuit mechanisms of this process are unknown, partly due to the difficulty of studying episodic memory in lab animals. Food-caching birds like black-capped chickadees offer unique advantages for studying this process. In the wild, chickadees cache up to thousands of food items per day and use memory to recover their caches. This behavior contains discrete instances of caching (memory formation) and retrieval (memory recall), providing well-defined time points for investigating the underlying neural mechanisms. To utilize this natural behavior in the lab, we developed a paradigm which 1) takes advantage of the birds' caching tendencies, 2) permits high-throughput, automated behavioral tracking, and 3) is compatible with modern neuroscience techniques, such as awake-tethered recordings.

We designed an arena with a grid of 64 sites covered by silicone flaps that can be pulled back to cache or retrieve seeds. Site contents were invisible to the bird unless a flap was lifted. The contents and the bird's interactions with each site were tracked automatically through a transparent floor via a camera and custom real-time video processing software. We tested chickadees on sequential trials in which they obtained seeds from motorized feeders, cached 1-3 seeds, and retrieved caches after a 2-min delay (blackout) period.

Most birds learned to cache reliably in this arena and tended to cache into unique sites on each trial. We compared how many attempts it took birds to find their caches relative to trajectories shuffled across trials. Birds required 2-5x fewer attempts than expected by chance, indicating

their use of episode-specific memory. We next asked whether our task required the hippocampus. We designed a method to inactivate a large fraction of the avian hippocampus, taking advantage of its location on the dorsal surface of the brain. Using a drug reservoir, we infused the $GABA_A$ agonist muscimol directly through the brain surface. Hippocampus-inactivated birds continued to cache, but required significantly more attempts to find seeds than on saline control days.
Our results confirm that we have developed a hippocampus-dependent episodic memory paradigm, using an arena compatible with many neuroscience techniques.

Title: Long-term changes to the hippocampal place code as a function of experience and reactivation

Authors: *A. O'LEARY, L. MUESSIG, T. WILLS, F. CACUCCI, C. BARRY;
Univ. Col. London, London, United Kingdom

Abstract: CA1 place codes are thought to evolve with time and experience. New place cell ensembles develop rapidly over the course of the minutes and hours following exposure to a novel environment. Current theory indicates that changes should continue to accumulate over longer time-frames as cells are reactivated during rest and memories are increasingly integrated into cortical networks. However, the potential role of reactivation or 'replay' as a mechanism for stabilizing and subsequently consolidating new place codes over the long term has received little experimental attention. Largely this has been due to a limited ability to robustly record from the same cells across days using typical electrophysiological approaches. Therefore, the aim of the current study was to use chronic two-photon calcium imaging to observe changes to the spatial tuning of hippocampal CA1 cells as a function of experience and replay recruitment. Preliminary data demonstrate 1) detection of replay sequences in two-photon imaging data recorded from head-fixed mice during awake, goal-oriented behaviour and offline rest and 2) changes to the content of offline reactivation as a function of learning.

Title: Investigation of medial septal cholingergic activity using calcium fibre photometry across behavioural states

Authors: *K. A. YOUNG;
Boston Univ., Boston, MA

Abstract: While the presentation of familiar stimuli is thought to allow efficient activation of recurrent hippocampal excitatory activity in CA3, data and modelling also suggest that low cholinergic states may be permissive of recall of previously stored associations. We therefore predicted there may be an observable decrease in Medial Septal cholinergic cell activity during hippocampal reactivation events. We selectively targeted medial septal cholinergic neurons using a Cre-dependent GCAMP6f virus in IRES-ChAT-Cre mice and implanted an optical fibre at the injection site to measure the bulk fluorescence activity from the medial septum, the main source of hippocampally projecting cholinergic afferents. We used a custom-built fibre photometry system to record calcium photometry during animal exploration of an open field environment and initial analyses examine the relationship between animal behavioural state (exploratory vs stationary) and cholinergic calcium signals. Animal exploration is marked by a prominent rise in hippocampal theta activity, whereas sharp wave ripples are often observed during periods of quiet wakefulness, therefore we predict that cholinergic calcium activity will be enhanced during periods of exploration and reduced during quiet stationary behaviour. Implantation of a silicon probe to the hippocampus will enable to align cholinergic calcium activity to the occurrence of sharp wave ripples in upcoming experiments.

Title: The scale of grid cell firing patterns is modulated by spatial uncertainty in rodent virtual reality

Authors: *G. CASALI[1], S. J. SHIPLEY[2], C. BARRY[1];
[1]UCL, London, United Kingdom; [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Medial entorhinal (mEC) grid cells display discrete firing fields organized in a regular hexagonal pattern (Fyhn et al., 2004). Although early studies indicated that the scale of the grid-pattern was constant between environments - supporting the notion that they represent a universal spatial metric (Hafting et al., 2005) - more recent work has demonstrated that grid scale is not static. For example, in response to environmental novelty grid patterns transiently expand (Barry et al., 2012) and on the vertical plane grid scale is permanently increased (Casali et al., 2019). These scenarios are characterised by reduced or unreliable spatial cues and previously we proposed that grid expansion was an adaptive response to elevated spatial uncertainty - computational simulations demonstrated that expansion of grid-patterns mitigated the reduction in accuracy resulting from reduced spatial information (Towse et al., 2014).
We tested this hypothesis by recording grid cells from head-fixed mice running through distinct virtual reality environments characterised by differing levels of spatial uncertainty. Grid firing in these impoverished environments showed clear periodic patterns across trials, consistent with their activity in 2D real world environments. Moreover, in support of our hypothesis, we found that grid scale increased in the environments characterised by the highest levels of spatial uncertainty. Together, these findings suggest that the scale of grid-patterns are modulated to optimise the encoding accuracy of entorhinal networks.

Title: Effect of appetitive and aversive intracranial stimulation on place cell reactivations during sleep

Authors: *D. BRYZGALOV, S. LAVENTURE, T. BALENBOIS, K. BENCHENANE; MOBs team, Lab. Plasticité du Cerveau, ESPCI, PSL Univ., Paris, France

Abstract: In spatial memory processes, hippocampal place cells discharge when the awaken animal is in a particular location of the environment called place fields. Reactivations of these place fields occur mostly during sleep and are thought to represent key moments where the memory is active and labile. Yet, whether sleep reactivations are sensitive to reconsolidation remains unknown. In the current three-part project, we modified the emotional valence associated to a location and investigated the following behavioral and physiological changes. First, building on our previous work (de Lavilleon, 2015), we investigated the role of sleep stages (non-rapid eye movements (NREM) and REM sleep), in the reactivation and reconsolidation of spatial-dependant emotional memories. During the targeted sleep stage, stimulation of the medial forebrain bundle (MFB) was synchronized to the activity of hippocampal place cells associated to a specific location in a U-shaped maze (U-maze). In the second part, using the same behavioral assay we asked how hippocampal place code changes after aversive experience. We are specifically interested in whether the representations of avoided locations are more reactivated during sleep and whether the aversive stimuli induce re-mapping of place code. We used electrical periaqueductal gray matter (PAG) stimulation that induced robust avoidance of the location in the U-maze where the stimulation was triggered. Finally, using a similar protocol we will attempt to reverse a spatial aversive conditioning through MFB stimulation during sleep. This will allow us to explore the possibility to reverse behavioral association and to examine relationships between reward and fear in the brain. Our preliminary results show that both MFB and PAG stimulations induced reliable U-maze location preference and avoidance, respectively. We report that, despite non-altered post-aversive conditioning sleep architecture, hippocampal neurons became more responsive to ripple events, and occurrence of ripples during sleep increased after the aversive experience compared to the baseline sleep. Additional preliminary results from the first and third part of the experiment will also be presented.

Title: Sex differences and effects of estrous stage on the ventral hippocampal-prefrontal anxiety circuit

Authors: *K. J. SCHOEPFER[1], Y. XU[2], W. WU[2], A. A. WILBER[3], M. KABBAJ[1];
[1]Biomed. Sci., [2]Statistics, [3]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Synchronized oscillations in the local field potentials (LFPs) between interconnected brain structures are hypothesized to reflect interactions between these brain regions. In mice and rats, excitatory neurons in the ventral hippocampus (vHPC) monosynaptically project to the medial prefrontal cortex (mPFC) ipsilaterally and bilaterally. As members of the corticolimbic system, the vHPC and mPFC are thought to update and evaluate internal and external cues to assign a behaviorally-relevant emotional valence to the environment. Anxiety is a naturally-occurring adaptive response to potential threat, and inappropriate overrepresentation of the anxiety response can classify an anxiety disorder. Women are ~60% likelier than men to be diagnosed with anxiety disorders, yet possible neural correlates to sex differences in valence processing remain underexplored. In females, natural cycling of the gonadal hormones estradiol (E2) and progesterone (P4) dynamically modifies the expression of anxiety-like behavior in rodents, electrical excitability of HPC and mPFC pyramidal cells, and HPC-mPFC functional connectivity in women. This suggests a role for the hormonal milieu to act on the vHPC-mPFC circuit to regulate anxiety expression. Synchronized theta (4-12 Hz) oscillations between the vHPC and mPFC causally underlie innate anxiety-like behaviors in male rodents. However, in females, the vHPC-mPFC circuit's role in anxiety-like behavior remains unexplored. Here, we directly compare male and female vHPC-mPFC circuit dynamics in relation to anxiety-like behavior and also assess the female estrous stage as a potential additional factor contributing to variance in vHPC-mPFC circuit dynamics and anxiety-like behavior. Rats were chronically implanted with electrodes in vHPC CA1, prelimbic mPFC, infralimbic mPFC, and dorsal HPC (dHPC) CA1 and were acclimatized to a square arena. LFPs were recorded daily in this familiar arena, and theta outputs were analyzed as a function of sex and of estrous stage. Rodents were then recorded on the elevated plus maze (EPM), a validated behavioral test for innate anxiety-like behavior; females were tested either in diestrus (low E2/P4) or proestrus (high E2/P4)

stages. In the familiar arena, we found that vHPC theta phase was preferentially tuned to prelimbic mPFC, but did not observe sex or estrous differences. However, diestrus decreased vHPC-mPFC theta power correlations without affecting single-region theta powers or power correlations in other frequency bands, suggesting that estrous stage may play an indirect role in altering vHPC-mPFC theta signaling in a nonthreatening environment.

Title: Amphetamine-like stimulants promote cortical up state: Role of adrenergic receptors

Authors: *G. SHEN[1], W.-X. SHI[2];
[1]Sch. of Pharm., [2]Sch. of Pharm. and Med., Loma Linda Univ., Loma Linda, CA

Abstract: Evidence suggests that norepinephrine (NE) in the prefrontal cortex (PFC) plays a crucial role in the mechanism of action of amphetamine-like psychostimulants. We have recently reported that the stimulant methylphenidate promotes PFC UP state, leading to a marked decrease in the slow oscillation of PFC activity (SO). To understand the significance and underlying mechanism of this effect of methylphenidate, we made *in vivo* local-field-potential recordings from the PFC in chloral hydrate-anesthetized rats. Like methylphenidate, d-amphetamine dose-dependently promoted PFC UP state and suppressed the SO. Surprisingly, cocaine mimicked those effects only at low, but not high doses. The selective NE reuptake blockers nisoxetine and atomoxetine also promoted PFC UP state and suppressed the SO, whereas the selective 5-HT transporter inhibitor fluoxetine and the dopamine transporter blocker GBR 12909 were much less effective. To further investigate the role of NE receptors in these effects, we pretreated rats with antagonists selective for adrenergic α1 (prazosin), α2 (idazoxan), and β receptors (propranolol). The UP-state promoting effect of d-amphetamine was completely blocked in prazosin-pretreated rats, but it persisted in the presence of either idazoxan or propranolol. To identify the α1 receptor subtype involved in the effect, we pretreated rats with α1A receptors antagonist WB4101, silodosin, and α1B receptors antagonist cyclazosin. WB4101 blocks both central and peripheral α1A receptors, while silodosin blocks only peripheral α1A receptors. The UP-state promoting effect of d-amphetamine was blocked by WB4101 but not by silodosin. Cyclazosin, on the other hand, reduced the effect induced by high, but not low, doses

of d-amphetamine. These results suggest that the effect of d-amphetamine requires activation of central, but not peripheral α1A receptors to express, and that α1B receptors also contribute to the effect induced by high doses of d-amphetamine. Currently, d-amphetamine and methylphenidate are the most effective medications for ADHD. Our findings described above may have important implications in understanding not only the therapeutic effects of the two stimulants but also their addictive and psychotomimetic properties.

Title: Assessing the impact of excessive alcohol consumption on corticostriatal function in mice

Authors: *C. ARDINGER, D. N. LINSENBARDT;
Psychology, Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Addiction to substances such as alcohol is believed to involve functional adaptations in corticostriatal projections regulating its reinforcing properties. However, very little is known about the direct effect of alcohol on corticostriatal function. To address this gap in knowledge, extracellular electrophysiological recordings were collected from ventral striatal (nucleus accumbens; Acb) and cortical (medial prefrontal; mPFC) brain areas of female and male C57BL/6J mice voluntarily consuming alcohol or water using 'drinking-in-the-dark' (DID) procedures. Following a three-day acclimation period wherein mice were only given access to water, animals were given 15 consecutive days of access to alcohol. Each session consisted of a 30 minute baseline period where water was available, and was followed immediately by a 2 hour period where sippers containing water were replaced with new sippers containing either unsweetened 20% (v/v) alcohol (days 4-18) or water (days 1-3). Excessive alcohol consumption was associated with decreases in power at beta frequencies within the mPFC, and decreases in power at delta, beta, and gamma frequencies within the Acb. Furthermore, there was a strong positive correlation between the amount of alcohol consumed and beta power in the mPFC (R = .68) and Acb (R = .64), whereas the amount of water consumed was only weakly correlated with beta power in the mPFC (R = .33) and Acb (R = .26). These observations provide evidence that

excessive alcohol consumption has direct effects on corticostriatal function, and that these effects are dose-dependent.

Title: Neural activity in the medial prefrontal cortex and hippocampus that encodes novel object recognition

Authors: *C. WANG[1], R. MAREK[1], T. M. FURLONG[2], P. STRATTON[1], P. SAH[1];
[1]Queensland Brain Inst., Univ. of Queensland, Brisbane, Australia; [2]Neurosci. Res. Australia, Univ. of New South Wales, Sydney, Australia

Abstract: Novel object recognition (NOR) refers to the ability to distinguish the occurrence of a stimulus that was previously presented in a certain environment from one that was not. Recognition memory is fundamental for animals and human beings to record events and to guide prospective behaviour. Several brain regions have been implicated in this process including the hippocampus (HPC) and the medial prefrontal cortex (mPFC). However, the roles of the mPFC and the HPC and their interaction are not extensively studied.
Subjects (male SD rats, N=10) were trained in an environment with two identical objects on day 1 and tested for object discrimination using a familiar and a novel object on day 2 and 3. We simultaneously recorded local field potentials (LFPs) in the HPC and the mPFC from freely-moving rats that performed this NOR task to assess changes in LFP activity and functional connectivity.
Our results reveal that there is a consistent exploration preference towards the novel object compared to the familiar object. During the training session, theta LFP (2-6Hz) power in the mPFC (n=10), but not the HPC (n=7), was enhanced during object exploration with no difference between the two identical objects. In contrast, during the test session, both the mPFC (n=10) and the HPC (n=7) showed significant enhanced theta power during the exploration of a novel object compared to the familiar one. Coupled theta-oscillations between the mPFC and the HPC showed no difference in training, but was found to be significantly higher during novel object exploration compared to the time animals were exploring the familiar object in test (n=7). The phase difference between these two regions and the Granger Causality analysis suggested that the directionality of the coupling is from the HPC to the mPFC in the NOR phase.

Together, our findings show that the mPFC and its synchronized activity pattern with the HPC play a role in object recognition and novelty discrimination.

Title: Gamma oscillations in basolateral amygdala during escape behaviors: Observations in a group

Authors: *J. KIM[1,2], C. KIM[1,3], W. YOUM[5], S. LEE[5], J. CHOI[1,4];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Korea Univ., Seoul, Korea, Republic of; [3]Univ. of Sci. & Technol., Seoul-City, Korea, Republic of; [4]Univ. of Sci. & Technol., Seoul, Korea, Republic of; [5]Electronics and Telecommunications Res. Inst., Daejeon, Korea, Republic of

Abstract: The basolateral nucleus of the amygdala (BLA) is thought to be essential for rapid escape. These are often thought to be comprised of feedforward action of BLA on the central amygdala. Neither well-understood nor often considered are BLA dynamics during escape behavior, which likely cause neural oscillations particularly in gamma band oscillation (GBO, 30 - 80 Hz). Indeed, GBOs are known to occur in BLA and their occurrence is associated with regulation of emotion, and yet their association with escape behavior remains unknown. To address this, we used a novel technique, cBRAIN (collective brain research aided by instant neurodisplay) to monitor GBO of BLA in a group-housed mice during escape behavior. The headstage of cBRAIN features in (i) wireless recording and transmission of raw data, (ii) blue LED light for tracking the position of the animal, and (iii) red LED light for signaling certain brain activity. We set the threshold for red LED so that it turns on when GBO power exceeds the confidence level of baseline GBO power. In an arena (60 cm x 60 cm), we divided the zone into safe and threat zones with a diagonally cross-sectioning wall. We tested the individual behavior first by applying cBRAIN in one mouse. We observed GBO occurred more frequently when a threat (spider robot) was introduced to the animal. GBO occurred more or less transiently rather than in an ongoing way and the occurrence of GBO was noticeable when the threat was firstly

introduced or attack the animal. On the other hand, GBO occurrence was reduced after the animal successfully escaped from the threat zone to the safe zone. Next, we applied cBRAIN in a group of 8 mice. All 8 mice were placed in the threat zone at the beginning. Likewise, GBO occurred more frequently as the robot was introduced and diminished as the most of the group escaped to the safe zone. But interestingly, the GBO occurrence was significantly less frequent in a group compared to the individual test. Moreover, in many cases, the most dominant mice did not present the GBO when the robot introduced to the threat zone, which was different from its individual test. To sum up, GBO in BLA is associated with escape behavior and the occurrence rate is altered with a company as per its social ranks.

Title: Frequency-specific sinusoidal optogenetic stimulation of hippocampal-prefrontal circuit differentially alters locomotion and avoidance behavior

Authors: *R. M. MIKOFSKY[1], E. ALWAY[1], N. PADILLA-COREANO[3], M. V. MYROSHNYCHENKO[1], J. PASSECKER[1], S. HUPALO[1], D. A. KUPFERSCHMIDT[1], J. A. GORDON[2];
[1]Integrative Neurosci. Section, Natl. Inst. of Neurolog. Disorders and Stroke, [2]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD; [3]The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Anxiety disorders are highly prevalent yet inadequately understood. Neural activity in the ventral hippocampus (vHPC) and medial prefrontal cortex (mPFC) has been implicated in avoidance behavior in the elevated plus maze (EPM), a rodent model for the study of anxiety-related behavior. In mice, oscillatory synchrony in the theta range (~8 Hz) between vHPC and mPFC increases during avoidance behavior in the EPM. Optogenetic inhibition of vHPC inputs to mPFC disrupts both theta synchrony and avoidance behavior, but it remains unclear whether theta synchrony per se is causally related to avoidance. It is similarly unclear whether 8-Hz synchrony in the vHPC-mPFC circuit has a privileged role relative to lower frequencies in promoting avoidance behaviors. To these ends, mice expressing ChR2 (or a control fluorophore) in vHPC projection neurons underwent bouts of sinusoidal light stimulation at 8, 4 and/or 2 Hz while exploring the EPM. While 8-Hz stimulation increased vHPC-mPFC theta synchrony and EPM avoidance behavior, 4-Hz stimulation produced inconsistent avoidance effects and 2-Hz

stimulation had no effect on avoidance. Furthermore, 4- and 2-Hz, but not 8-Hz, stimulation decreased distance traveled, increased compartment bias (the propensity of a mouse to spend more time in the compartment where it was located at stimulation onset) and increased time spent immobile. These results support the hypothesis that 8-Hz oscillatory synchrony in the vHPC-mPFC circuit has a privileged role in driving avoidance, and suggest that lower frequency oscillations in this circuit may affect locomotion.

Title: Maternal microchimeric cells shape the functional development of offspring prefrontal-hippocampal networks

Authors: *S. SCHEPANSKI[1,2], M. CHINI[2], K. THIELE[1], V. STERNEMANN[1,2], C. URBSCHAT[1], D. ZAZARA[1], I. L. HANGANU-OPATZ[2], P. C. ARCK[1];
[1]Lab. for Exptl. Feto-Maternal Med., [2]Developmental Neurophysiol., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Maternal immune cells migrate from the mother to the fetus via the placenta during pregnancy. These maternal microchimeric cells have recently been identified to enter the fetal brain; however, their functional role in the brain is still unknown. Early circuit assembly and cognitive abilities of offspring can be envisioned by identifying how these specific cells modulate neural maturation.
To address this knowledge gap, we developed a mouse model to assess the functional role of maternal microchimeric cells on fetal brains. We mated $Rag2^{-/-}$IL-$2r\gamma^{-/-}$ C57BL/6 (CD45.2, H-$2^{b/b}$) females with congenic WT Balb/c (CD45.1, H-$2^{d/d}$) males and *vice versa*, WT C57BL/6 females with $Rag2^{-/-}$IL-$2r\gamma^{-/-}$ males as controls. These reciprocal mating combinations led to an F1 generation with a significantly lower amount of maternal microchimeric cells in offspring's brains (termed 'MMc^{low}'), compared to the control F1 (termed 'MMc^{+}'), as confirmed by flow cytometry. Phenotyping of the maternal microchimeric cells revealed that the majority of them were microglial cells, whilst fewer T- and B cells could also be detected. Concomitantly, an increased number of host microglia cells was detectable in the brain of MMc^{low} offspring. Via confocal microscopy-based morphometric analysis, an enhanced engulfing of neuronal spines could be detected in the hippocampus and prefrontal cortex of MMc^{low} offspring, along with a

decreased neuronal firing and broad band (4-100 Hz) power of oscillatory activity within prefrontal-hippocampal networks *in vivo*. The MMc^{low} offspring also showed poorer performance in ultrasonic vocalizations. Since adoptive intravenous transfer of immune cells from pregnant wild-type C57BL/6 mice into the $Rag2^{-/-}IL\text{-}2r\gamma^{-/-}$ C57BL/6 dams largely restored the effects observed in MMc^{low} offspring, a causal role of maternal microchimeric cells in modulating circuit wiring and brain function in the offspring can be postulated. These effects may be mediated via suppression of fetal microglia activity or proliferation which are possible candidate functions of maternal microchimeric cells in the fetal brain.

Title: Scopolamine and medial frontal stimulus-processing during interval timing

Authors: *Q. ZHANG[1], D. Y. JUNG[2], T. LARSON[3], Y.-C. KIM[4], N. S. NARAYANAN[5]; [1]Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [2]Univ. of Rochester, Rochester, NY; [3]Univ. of Iowa, Hosp. and Clinics, Iowa City, IA; [4]Neurol., Univ. of Iowa, Iowa City, IA; [5]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: Neurodegenerative diseases such as Parkinson's disease (PD), dementia with Lewy Bodies (DLB), and Alzheimer's disease (AD) involve loss of cholinergic neurons in the basal forebrain. Here, we investigate how cholinergic dysfunction impacts the frontal cortex during interval timing, a process that can be impaired in PD and AD patients. Interval timing requires participants to estimate an interval of several seconds by making a motor response, and depends on the medial frontal cortex (MFC), which is richly innervated by basal forebrain cholinergic projections. Past work has shown that scopolamine, a muscarinic cholinergic receptor antagonist, reliably impairs interval timing. However, the effect of cholinergic inhibition on the MFC network activities during interval timing has not been studied. We tested the hypothesis that scopolamine would attenuate time-related ramping, a key form of temporal processing in the MFC. We trained 8 mice in a 12-s fixed-interval timing task and implanted 16-channel

microelectrode arrays into the MFC. During interval-timing, mice were trained to respond 12 seconds after a discriminative stimulus. Responses prior to 12 seconds were not rewarded. We recorded neuronal ensembles during the interval timing task, 30 min after mice received intraperitoneal injections of normal saline (vehicle) or scopolamine (1mg/kg). Consistent with past work, scopolamine impaired timing. We recorded from 225 neurons during interval timing. To our surprise, we found that time-related ramping was unchanged, but stimulus-related activity was enhanced in the MFC. Principal component analyses revealed no consistent changes in time-related ramping components, but did reveal changes in higher components. Taken together, these data indicate that scopolamine changes stimulus-processing rather than temporal processing in the MFC. These data could help understand how cholinergic dysfunction affects cortical circuits in diseases such as PD, DLB, and AD.

Title: Midfrontal cortical signatures of lower-limb movement in Parkinson's disease

Authors: *A. SINGH, R. C. COLE, A. ESPINOZA, N. NARAYANAN;
Univ. of Iowa, Iowa City, IA

Abstract: Patients with Parkinson's disease (PD) suffer from lower-limb motor abnormalities. Many PD patients fall during walking or lose their balance when they initiate movement, which can cause head injuries or even death. Deep brain stimulation and levodopa therapies typically alleviate only upper-limb motor symptoms. Therefore, there is a critical need for therapies that improve lower-limb symptoms in PD. Evidence suggests an association between lower-limb motor disturbances and cognitive decline in PD patients, but these experiments have not examined the neural mechanisms. Here, we tested the hypothesis that PD patients with freezing of gait (FOG) had abnormalities in mid-frontal theta-band (4-8 Hz) and beta-band (13-25 Hz) activity, which has been linked with PD-related cognitive and motor dysfunctions. We recruited a total of thirty-nine subjects, including PD patients without freezing of gait (PDnoFOG; n=13) and with freezing of gait (PD+FOG; n=13), and demographically-matched healthy subjects (n=13). Scalp electroencephalogram signals were collected from 64 scalp electrodes during a lower-limb pedaling motor task. Pedaling required intentional initiation and stopping of a motor

movement with the lower limbs. FOG scores were significantly correlated with disease severity and cognitive assessment scores. PD+FOG patients pedaled with reduced speed and took more time to reach peak acceleration compared to PDnoFOG and control subjects. PD+FOG patients exhibited attenuated theta-band power and increased beta-band power in the frontal region at mid-frontal Cz electrode during pedaling. Midfrontal theta and beta power values were also correlated with FOG scores. Our data indicate that midfrontal theta and beta oscillations are predictors of lower-limb motor movement in PD and could inform neuromodulation therapy for PD-related lower-limb disorders.

Title: Susceptibility to distraction in Parkinson's disease mediated by midfrontal theta oscillations and basal ganglia spiking activity

Authors: *R. C. COLE[1], A. SINGH[1], A. ESPINOZA[1], J. R. WESSEL[3], J. F. CAVANAGH[4], J. D. GREENLEE[2], N. S. NARAYANAN[1];
[1]Neurol., [2]Neurosurg., Univ. of Iowa Carver Col. of Med., Iowa City, IA; [3]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA; [4]Dept. of Psychology, Univ. of New Mexico, Albuquerque, NM

Abstract: Humans instinctively react to novelty. When a novel event is irrelevant to the task at hand, the resulting distraction can manifest as slow or incorrect responses. We studied this issue in Parkinson's disease (PD), a neurodegenerative disease that can involve attenuated responses to novelty in addition to motor impairments. Previous research has shown that dopamine in the frontal cortex mediates the neural response to novel stimuli and may influence novelty-related distraction. Based on this, we hypothesized that novelty processing and susceptibility to distraction would be affected in PD. We tested this idea using a cross-modal distractor task in which participants (37 PD patients and 39 healthy older adults) responded to a central arrow. The arrow was preceded by two cues, a tone and a colored shape. On each trial, the cues were either both standard or one was standard and the other was an oddball (the visual stimulus was a novel shape and color or the auditory stimulus was a novel birdcall). We found that PD patients were overall slower at responding than healthy adults, and PD patients had attenuated midfrontal theta (4-7 Hz) activity. These findings align with previous reports of attenuated theta in PD during

cognitive control processes, suggesting that midfrontal theta may be a mechanism of cognitive dysfunction in PD. We also collected spiking activity from the basal ganglia and midfrontal electrocorticography during an oddball task from patients undergoing deep brain stimulation electrode implantation. During surgery, patients listened to a series of tones and non-tones (novel birdcall sounds) and responded by pressing left or right buttons, respectively. We found slowed responding to novel stimuli and we will examine basal ganglia novelty-mediated spiking activity. Our results help elucidate the neural mechanisms by which humans respond to novelty.

Title: Temporal processing and probability in nigrostriatal dopamine circuits

Authors: *R. A. BRUCE[1], M. A. WEBER[2], C. INMAN[3], N. S. NARAYANAN[2];
[1]Interdisciplinary Grad. Program in Neurosci., [2]Dept. of Neurol., [3]Carver Col. of Med., Univ. of Iowa, Iowa City, IA

Abstract: Mammals guide their behaviors in time based on temporal probabilities. Previous work has shown time-related ramping activity in both medial frontal cortex and dorsomedial striatum neurons during an interval timing task. Importantly, both this pattern of activity and interval timing performance are disrupted by drugs that manipulate dopamine receptors. Therefore, frontostriatal circuits are critical for the temporal control of action, but it is unknown how they are influenced by probabilistic experience. Here, we trained male and female C57BL/6 mice to perform an interval-timing switch task and then varied the probabilistic structure of the task. Specifically, mice receive a reward following a short-latency interval (6 s) but are required to "switch" to another response port to receive a reward following a long-latency interval (18 s). We then varied the probability of the short interval from 50% to 75% either early or late in training. First, we lesioned the substantia nigra using 6-hydroxydopamine (1.0 µg/0.5 µL 0.03% ascorbic acid) and found that performance on this task is dependent on nigrostriatal dopamine neurons. Specifically, temporal accuracy was attenuated with animals switching later in the task. Second, we studied how responses were sensitive to the probabilistic structure of the task. Third, we used CAV-Cre to isolate striatally-projecting midbrain neurons and recorded from these neurons using fiber photometry. Finally, we further explored these circuits via multielectrode

neuronal ensemble recordings from striatal medium spiny neurons. We interpret these data in the context of temporal processing in the striatum and how neuronal activity might track temporal probabilities. These data are of particular interest for understanding the circuit mechanisms of impaired temporal processing and cognitive dysfunction in Parkinson's disease patients with midbrain dopamine dysfunction.

Title: Prefrontal D1 dopamine-receptor neurons in delayed non-matching task

Authors: *Y.-C. KIM[1], M. A. KENNEDY[2], A. ESPINOZA[2], N. S. NARAYANAN[3]; [1]Neurol., [2]Univ. of Iowa, Iowa City, IA; [3]Neurol., Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: The prefrontal cortex is known to play a key role in active maintenance of task-relevant information short tasks involving working memory. During delayed non-matching task, prefrontal neurons exhibit memory-specific modulation. Prefrontal neurons expressing D1-type dopamine receptors (D1DRs) have been shown to be critical for cognitive processes such as working memory, flexibility, and timing, leading to the hypothesis that prefrontal D1 neurons directly encode cognitive processing. We developed a mouse version of delayed non-matching position task performed in operant chambers. The task was specifically designed to eliminate non-mnemonic strategies. We tested dopamine dependency of the task performance with the D1 dopamine receptor agonist SKF82958; mice specifically were impaired with dopamine receptor agonism. We hypothesized the medial frontal cortex D1DR+ neurons would task specific activity during delayed non-matching task. We tested the idea using a delayed non-matching task, in which we used optogenetics to tag D1DR+ neurons in the mouse medial frontal cortex and recording medial frontal neuronal ensembles. In addition, we stimulated prefrontal D1DR+ neurons optogenetically at 4Hz and 20Hz during delay period. The findings from the study will provide insight into prefrontal networks and have relevance for neuropsychiatric disorders such as ADHD, schizophrenia, bipolar disorder, and major depressive disorder.

Title: Gamma oscillations as a potential cortical signature for Parkinson's disease-related depression

Authors: *A. I. ESPINOZA, A. SINGH, R. C. COLE, N. S. NARAYANAN;
Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Depression is a common non-motor symptom of Parkinson's disease (PD) that impacts quality of life. Furthermore, physicians often overlook depression in PD, complicating their ability to treating PD patients effectively. Depression can also impair already-reduced functional abilities of PD patients, further impacting administration of adequate interventional therapy. Our goal was to identify cortical signatures of PD-related depression objectively via EEG. We recruited a total of thirty-nine subjects, including PD patients without depression (PD; n=19) and with depression (DPD; n=19), and demographically-matched healthy subjects (Control; n=19). Scalp EEG signals were collected from 64 scalp electrodes during resting state activity. We did not find a strong relationship between the Geriatric depression scale (GDS) score and PD severity. However, we observed markedly attenuated gamma power in the right and left motor cortical regions in DPD patients compared to PD and controls. Topographic analysis revealed attenuated gamma oscillations at the global level in DPD compared to PD and controls, with gamma deactivations predominantly to the occipital region. Occipital gamma power values were also correlated with GDS scores in PD patients. These data suggest that attenuated gamma oscillations might be linked with PD-related depression, and this could reflect cortical synaptic dysfunctions that underlie network deficits in PD. Our data indicate that motor cortical and occipital gamma oscillations could be potential signatures of PD-related depression and could inform neuromodulation therapy for depression in PD patients.

Title: Dopamine depletion in the ventral tegmental area impairs interval timing precision

Authors: *M. A. WEBER[1], R. A. BRUCE[2], N. S. NARAYANAN[3];
[1]Dept. of Neurol., The Univ. of Iowa, Iowa City, IA; [2]Interdisciplinary Grad. Program in Neurosci., [3]Dept. of Neurol., Univ. of Iowa, Iowa City, IA

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder in the U.S and is characterized by deficits in motor function and cognition. Motor dysfunction in PD is directly associated with neuronal loss in the substantia nigra. However, the neural mechanisms underlying cognitive dysfunction in PD are poorly understood but may result from neuronal loss in the ventral tegmental area (VTA). Interval timing, i.e. estimation of time over seconds to minutes, is ideally suited to investigate cognitive dysfunction as it is disrupted in PD and requires cognitive processes such as working memory and attention. Previous work has shown that dopamine (DA) receptors in the medial frontal cortex (MFC) are crucial for interval timing, but it is unclear how DA neurons in the VTA that project to the MFC contribute to this cognitive process. Here, we investigated how VTA DA lesions affect interval timing using a switch task in adult male and female C57BL/6 mice. In 50% of trials, subjects receive a reward following a short-latency interval (6 s) but are required to "switch" to receive a reward following a long-latency interval (18 s) in the other 50% of trials. The time to switch is un-cued, so this decision is time-based and guided by interval timing. Following acquisition of the task, all subjects underwent stereotactic surgical procedures in which 6-hydroxydopamine (1.0 µg/0.5 µL) or vehicle (equivalent volume 0.03% ascorbic acid) was bilaterally injected into the VTA (from bregma: AP -3.3 mm, ML ±1.1 mm, and DV -4.6 mm at 10-degree angle). After one week of recovery, all mice were tested on the switch task and measures of timing accuracy and precision were collected. Preliminary results indicate that VTA DA lesions increase the variability of switch timing, suggesting decreased interval timing precision. Together with previous work, these results indicate that VTA DA neurons are necessary for optimal interval timing performance. Future studies will determine if performance on this task is sensitive to drugs that manipulate D1 and D2 receptors. In addition, we will incorporate fiber photometry in MFC-projecting VTA neurons, which will allow us to determine if neural activity in this region encodes temporally-relevant signals.

Abstract: Understanding anesthetic mechanisms with the goal of producing anesthetic states with limited systemic side effects is a significant objective of neuroscience research in anesthesiology. Sevoflurane is an ether anesthetic that is routinely administered in clinical practice. Coherent frontal alpha oscillations, a known electroencephalogram signature of the sevoflurane anesthetized brain, has been postulated as a fundamental mechanism of sevoflurane-induced unconsciousness that remains unproven. In this research, we address and investigate the mechanisms of ether anesthetic action. We recorded high-density 64 channel EEG data by targeting and studying sub-anesthetic, general anesthetic, and deep general anesthetic states using sevoflurane anesthetic concentrations that are consistent with current clinical practice and epidemiologically based characterizations (n = 12). We implemented multitaper spectral analysis, global coherence analysis, non-linear cross-frequency coupling, and phase dependent measures to capture the complex neural dynamics underlying sevoflurane anesthetic states.We found that subanesthetic and general anesthetic brain states emerge from impaired information processing instantiated by a delta-higher frequency phase-amplitude coupling syntax. Our findings also suggest that this syntax may be conserved across drug classes. These results provide fundamental new insights into the neural circuit mechanisms of sevoflurane anesthesia and suggest that anesthetic states may be produced by extracranial perturbations such as direct current stimulations that cause delta-higher frequency phase-amplitude interactions.

Title: Stabilization of cortical population firing rate by paradoxical response to GABA modulation

Authors: *W. L. SHEW[1], V. AGRAWAL[3], P. KELLS[4], J. LI[2], S. GAUTAM[1];
[2]Physics, [1]Univ. of Arkansas, Fayetteville, AR; [3]Univ. of Arkansas-Fayetteville, Fayetteville, AR; [4]NIH, Rockville, MD

Abstract: Among the simplest and most fundamental roles played by inhibition in cerebral cortex is counterbalancing excitation, keeping the ongoing firing rates of the neural population in check. A commonly held view is that if inhibition is disrupted within a cortical circuit, the firing rates of the population will become unstable, decreasing for excessive inhibition or increasing insufficient inhibition. Here we show that, while this view is accurate for extreme disruptions of inhibition, more subtle modulation of inhibition results in a very different and surprising phenomenon. We studied freely behaving rats, and found that moderate levels of GABA agonist (muscimol) or antagonist (bicuculline) in motor cortex caused dramatic shifts in firing rates of individual neurons, while leaving the population firing rate relatively stable. For decreased inhibition (bicuculline), we found that many neurons paradoxically exhibited decreased firing rates, while others fired at greater rates, as expected. Similarly for increased inhibitions

(muscimol) we observed both increases (paradoxical) and decreases (expected) changes in firing. Increases and decreases in firing rates largely canceled, resulting in relatively stable firing at the population level. Using a network level computational model, we show that disinhibitory effects of a small fraction of very strong inhibitory connections in the network may explain this phenomenon. Taken together, our experimental and modeling results point to a new type of homeostasis of population firing rates.

Title: A physiological basis for communication through coherence in the rodent striatum

Authors: *J. E. CARMICHAEL, M. A. A. VAN DER MEER;
Psychological & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The striatum receives multiple converging inputs from brain structures which show prominent rhythmic activity. How these inputs are flexibly combined in support of motivated behavior is an issue of ongoing interest. One influential suggestion is that rhythmic fluctuations in postsynaptic excitability may be exploited for dynamic gain control: those inputs that arrive at peak excitability will be more effective than others ("communication through coherence", Fries, 2015).
Could this idea apply to the striatum and its inputs? Previous work in anesthetized animals has found synchronized membrane potential oscillations, but whether the striatum exhibits rhythmic fluctuations in excitability in awake, behaving states remains unknown. In support of this possibility, striatal local field potentials (LFPs) exhibit a full spectrum of rhythmic oscillations, including cross-frequency coupling, which dynamically synchronize with LFPs in input areas. However, it is unknown whether striatal LFPs in fact indicate the rhythmic excitability fluctuations required by the communication through coherence hypothesis. If they do not, there is no physiological basis for ascribing functional relevance to striatal LFP synchrony and its coherence with other areas. To address this fundamental issue, we applied direct optogenetic stimulation to ChR2-expressing striatal fast-spiking interneurons (FSIs) in head-fixed awake mice who could run freely on a running wheel. We calibrated the stimulus intensity to near-threshold levels, such that a single spike was evoked on some, but not all, trials. We then

determined how well we could predict whether a spike response occurs based on the phase of the LFP in key frequency bands (delta, theta, beta, and different gamma bands).
A total of 23 FSIs (out of a total of 51 recorded, n = 6 mice, of which 5 were female) met our eligibility criteria of eliciting a spike on 20% to 80% of all stimulation trials. Of these eligible neurons, 12/23 (52%) showed significant response modulation by the phase of at least one LFP frequency band, even after correcting for pre-stimulus baseline activity. Delta phase was the strongest modulator overall (35% of eligible neurons), followed by gamma (22% of eligible neurons). Surprisingly, there was substantial diversity across cells in what LFP phase corresponded to maximum excitability.
These results suggest that the striatal LFP, despite is pitfalls, can be interpreted as indicating rhythmic fluctuations in excitability, providing a firmer foundation to work reporting LFP synchrony with the striatum by suggesting a possible physiological basis for communication through coherence.

Title: When random variation among cortical neurons results in functional significance

Authors: *J. BARFIELD[1], P. KELLS[1], J. LI[2], S. GAUTAM[1], W. L. SHEW[3];
[2]Physics, [1]Univ. of Arkansas, Fayetteville, AR; [3]Univ. of Arkansas Fayetteville, Fayetteville, AR

Abstract: As technological innovations push towards recordings of larger and larger populations of neurons, it becomes feasible to assess similarities and differences across neurons with greater statistical rigor. Many functional properties vary dramatically across neurons in cerebral cortex. Two fundamental goals of systems neuroscience are to determine which neurons execute which functions and how the different functional properties of a neuron are related. Often, it is assumed that if two properties are uncorrelated, then there is no interesting relationship to report.
Here we show that this assumption can lead to wrong conclusions; functional segregation can emerge, by chance, due to random variation when that variation is distributed according to skewed, heavy-tailed distributions. We recorded single neuron spiking activity in motor cortex and body movement of freely moving rats. For each neuron, we assessed two functional properties: population coupling and body coupling. Population coupling quantifies how a

neuron's firing rate covaries with the rest of the cortical population. Body coupling quantifies how a neurons firing rate covaries with body movement. Both population coupling and body coupling varied greatly across neurons according to highly skewed distributions. Body coupling and population coupling were nearly uncorrelated across neurons. Nonetheless, there was a clear functional segregation; one group of neurons was strongly coupled to the body, while a different group of neurons was strongly coupled to the population. We contend that these results are a prime example of the more general phenomenon of functional segregation due to random variation.

Title: Testing the mechanisms of cortical fragmentation with propofol induced loss of consciousness and large scale cortical recordings in the non human primate

Authors: *A. M. BASTOS, J. DONOGHUE, C. SHVARTSMAN, J. YANAR, M. LUNDQVIST, J. TAUBER, M. MAHNKE, A. WAITE, E. N. BROWN, E. K. MILLER; MIT, Cambridge, MA

Abstract: The neuronal mechanisms of anesthetic action point strongly towards the drugs producing oscillations that impair communication among brain regions. One prominent model, cortical fragmentation, suggests that a loss of cortico-cortical coordination in the slow-delta frequency range is one such mechanism for producing unconsciousness. To test this, we anesthetized 4 macaques with propofol and recorded LFP and single-unit neuronal activity from a network of frontal, parietal, and mid-level sensory (Superioral Temporal Gyrus and V4) cortical areas both during and before/after loss of consciousness. The awake state was characterized by within-area and between-area coherence in the theta (4-6 Hz), and alpha/beta (10-30 Hz) frequency bands. The anesthetized state was characterized by a marked reduction in theta-beta coherence and the emergence of delta (0.5-2 Hz) coherence. To investigate sensory processing, we used two paradigms. In the visual paradigm, the screen was flashed from black to white. In the auditory paradigm, we used a sequence of deviant/oddball tones. We used multi-contact laminar probes placed perpendicular to the cortex in V4 to investigate the patterns of

sinks and sources evoked in visual cortex to the screen flash. Sink/source pairs were frequently observed to reverse in awake vs. anesthesia, suggesting a re-organization of intra-laminar processing. In the auditory cortex, oddball (unexpected) sounds resulted in more spiking compared to expected sounds. This effect was significantly attenuated during anesthesia. These results suggest that a form of cortical fragmentation is the result of a shift in coherence from theta/beta during wakefulness to slower frequencies during anesthesia-induced unconsciousness rather than a loss of coherence in the slow-delta band. These slower frequencies may impede neuronal coordination by imposing long periods of relative hyperpolarization lasting hundreds of milliseconds. In addition, the loss of inter-regional coherence in the theta-beta bands under anesthesia could explain the reductions in the oddball effect. Those frequencies have been hypothesized to underlie information transmission as well as the regulation and updating of expectation. Finally, in normal cortical communication different layers support feedforward vs feedback flow. Thus, changes in the intralaminar signal flow under anesthesia could interfere with communication between areas. Together, our results shed light on how cortical coordination is compromised during anesthesia-induced unconsciousness.

Abstract: General anesthesia (GA) reversibly induces unconsciousness. It is arguably the most powerful brain state manipulation that clinicians and researchers can reliably perform. However, the systems-level mechanisms underlying GA are not understood. In order to explore the neural correlates of GA, we recorded spiking activity and local field potentials (LFPs) from multiple cortical and thalamic regions while rendering monkeys unconscious through the use of two distinct anesthetics. In our first set of experiments, we administered the GABAergic anesthetic propofol. Propofol decreased brain-wide spiking activity and high-frequency LFPs (gamma, 30-80 Hz) while producing prominent slow oscillations (0 - 4 Hz). Slow rhythms were incoherent within the prefrontal cortices (PFC), yet synchronized across frontoparietal cortex and with the intralaminar nuclei of the thalamus. Spiking activity became tightly phase-locked to local slow oscillations, alternating between hyper-active UP states and silent DOWN states. These states could be predicted from the thalamic LFP, suggesting a role for the thalamus in entraining cortex during propofol anesthesia. We sought to test the causal role of the thalamus in maintaining unconsciousness by activating the intralaminar nuclei with high-frequency electrical stimulation. Remarkably, thalamic DBS immediately and continuously reversed GA, characterized by eye opening, air-puff responses and restored limb movement, despite continued anesthetic infusion. DBS produced an awake-like cortical state, eliminating slow oscillations and inducing a shift to higher-frequency rhythms and awake-like spiking dynamics. In our second set of experiments, we explored an alternative unconscious state mediated by the anti-glutamatergic anesthetic ketamine. Ketamine substantially increased spiking and gamma power throughout cortex, while eliminating beta (13 - 25 Hz). During GA, slow waves periodically interrupted gamma activity and PFC entrained central thalamic LFPs. DBS of the central thalamus did not produce anesthesia reversal effects, despite eliciting a massive arousal response as measured by increased sympathetic activity. Seemingly, ketamine harnesses an excitatory mechanism to disrupt conscious processing, overwhelming cortex with disordered spiking activity and entraining the thalamus. Both anesthetic regimes caused slow oscillations, disrupted cortical beta rhythms, and affected thalamocortical connectivity. Together, this collection of work demonstrates the distinct network mechanisms that can each drive GA and a systems-level approach to enhanced control of conscious states.

Title: Coherent alpha dynamics during recovery from traumatic coma detected using global coherence analysis

Authors: *D. W. ZHOU[1], C. CHATELLE[2], E. N. BROWN[1], B. L. EDLOW[3];
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Neurol., Univ. Hosp. of Liège, Liège, Belgium; [3]Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: The disruption of brain networks following severe traumatic brain injury (TBI) has been shown to alter brain synchrony, motivating the development of coherence-based electroencephalographic (EEG) biomarkers [1]. One of the canonical oscillations of the uninjured brain is the alpha rhythm, emerging from healthy thalamocortical activity. One method to study synchrony is global coherence analysis, an eigendecomposition technique that characterizes the dominant modes of coherence in multivariate time series. The objective of this study was to develop a coherence-based signature of severe TBI. Here, we apply global coherence analysis to EEG recordings collected at early and late recovery stages in 12 severe TBI patients, as well as in 16 control subjects during waking rest. Three patients were administered propofol for sedation before or during EEG acquisition. All subjects were given physical and auditory stimulation preceding rest blocks (median epoch size = 298 seconds, IQR = 2s) in which global coherence was computed. We analyzed the within-cohort and between-cohort separation between coherence patterns, obtained by computing the principal angle between two eigenvectors. In the alpha frequency, within-cohort angular separation values were higher in patients in early recovery (median 1.09, IQR=0.20) than in control subjects (median 0.914, IQR = 0.398), suggesting patient-specific perturbations of coherence patterns from normal occipital alpha patterns of resting wakefulness. Control/early and early/late between-cohort angular separations (medians 1.21 and 1.20, IQRs = 0.19 and 0.15, respectively) were greater than within-cohort separations as well as control/late separations (median 0.99, IQR = 0.41), suggesting late recovery from acute injury to coherence patterns closer to control subjects. Together, these results suggest a robust EEG signature of alpha coherence in patients with acute severe TBI that could enable the systems-level investigation of thalamocortical circuit function in this population. The alpha coherence signature identified in this study is distinct from that of propofol, reflecting thalamocortical dysfunction that may be specific to severe TBI.

Abstract: The nucleus accumbens (NAc) receives convergent inputs from corticolimbic structures that possess rhythmic activity, such as the prefrontal cortex, amygdala, and hippocampus. A prominent theory of NAc function is that it acts as a "switchboard", dynamically gating information flow from different input regions. A prominent proposal of how such dynamic gain control is implemented is through synchronization of rhythmic activity across regions ("communication through coherence"). Could this idea apply to the NAc?
In support of this idea, the NAc itself displays a full spectrum of rhythmic activity that modulates local spiking activity, is related to various behavioral and task components, and is coherent with local field potentials (LFPs) in input regions. This raises the possibility that the NAc contains multiple processing channels defined by rhythmic properties and shaped by interactions with different input and output structures, a property that would support the switchboard hypothesis of NAc function. If this were true, we would expect a relationship between what rhythm(s) a given neuron phase-locks to, and what properties of the task/behavior it encodes. For instance, are neurons that show delta phase-locking more likely to encode reward receipt than to encode lever presentation? Second, this relationship should be dynamic, such that individual neurons flexibly phase-lock to distinct LFP bands during different behavioral or task states.
To address these questions, we recorded single units and LFPs from the NAc of 4 male Long-Evans rats during sequential performance of an autoshaping and a place conditioning task, and evaluated spike-field relationships with the pairwise phase consistency (PPC) measure. (1) We first looked at the distribution of units with significant PPC values across these behavioral and task states. Different task components were associated with different proportions of phase-locked units. For instance, low gamma phase-locking was prominant during the reward receipt epoch (23% of units). (2) Next, we compared PPC values across the various behavioral and task components, and found that ~80% of units showed modulation by the phase of separate frequency bands at mutually exclusive task/behavioral states.
Together, our results of dynamic spike-field relationships helps to develop an "oscillatory taxonomy" account of NAc function, suggesting that the NAc may indeed possess multiple processing channels that are mediated by distinct rhythms. This opens up a new framework for

conceptualizing NAc function, facilitating the development of future work that uses spike-field relationships as a marker for different processing channels.

Title: A comprehensive characterization of rhythmic spiking activity in the rat ventral striatum

Authors: *M. A. VAN DER MEER, J. GMAZ, J. E. CARMICHAEL;
Dartmouth Col., Hanover, NH

Abstract: Oscillations in neural activity are ubiquitous in the brain, readily accessible in the clinic and the lab, and shared by humans and animals to facilitate translational work. The ventral striatum (vStr) is a promising target structure for such a rhythmic activity perspective, not in the least because its local field potential (LFP) shows prominent task-related oscillations across a range of frequencies. However, recent work has shown that major components of the vStr LFP are in fact generated elsewhere in the brain, raising the question of how the LFP relates to local spiking activity. Previous studies of spike-field relationships in the vStr have been limited to specific cell types and/or frequency bands, and to our knowledge there have been no studies of rhythmic spiking activity in the vStr without reference to the LFP.
Thus, we sought to characterize rhythmic activity in vStr spiking by analyzing extracellular recording data (approx. 2500 cells total) collected from 11 male Long-Evans rats performing modified T-maze tasks. Spike train rhythmicity was generally limited to low frequencies such as delta and theta, whereas spike-field relationships were seen across a broad spectrum of frequencies, with about 90% of neurons showing spike-field locking to at least one rhythm. Overall, putative medium spiny neurons (MSNs) tended to favor theta-band phase preferences, while FSIs favored delta and gamma overall. Spike train rhythmicity without reference to the LFP showed more modest frequency content, and was generally independent of phase-locking except for theta and beta bands - that is, a theta phase-locked neuron is likely to spike at theta frequency, but a gamma phase-locked neuron is no more or less likely to spike at gamma frequency.
Next, using a novel time-resolved generalized linear model (GLM) approach, we further show that the contribution of LFP phase to spike timing is dynamic over time, and was enhanced by the inclusion of the LFP from the hippocampus - a new measure of inter-area coupling. Taken together, hese results provide a foundation for providing more accurate interpretation of the vStr LFP, suggest the possibility of an oscillatory taxonomy of ventral striatal neurons, and provide a

starting point for investigating the role of rhythmic activity in linking cell-, circuit-, and systems-level dynamic coordination in the vStr.

Title: Central lateral thalamus causally influences states of consciousness by regulating neural interactions within and between areas in fronto-parietal cortex

Authors: *M. J. REDINBAUGH[1], J. M. PHILLIPS[1], N. A. KAMBI[1], S. MOHANTA[1], S. ANDRYK[1], G. DOOLEY[1], A. RAZ[3,2], Y. B. SAALMANN[1];

Abstract: Thalamo-cortical and frontal-parietal circuits are implicated in the neural correlates of consciousness, yet their precise influence on conscious states remains unclear. Frontal and parietal cortices have direct feedforward (FF) and feedback (FB) connections stemming from different cortical layers, and indirect connections via the central lateral nucleus (CL) of the intralaminar thalamus, which, when damaged, leads to disorders of consciousness. We hypothesized that CL influences consciousness by regulating fronto-parietal information transmission.
We used laminar probes to simultaneously record spikes and local field potentials (LFPs) from the frontal eye field (FEF), lateral intraparietal cortex (LIP), and CL in 2 macaques during general anesthesia (propofol or isoflurane) and wakefulness (resting state). Structural MRI of probes *in situ* verified positioning, and we used current source density to designate cortical layers. To manipulate thalamo-cortical dynamics, we electrically stimulated thalamic sites across 16 probe contacts with 100-300 μA at 10, 50 and 200Hz. Data from stable eye epochs, with and without stimulation, were analyzed. To monitor level of consciousness, we recorded EEG, EMG, eye position, and vital signs. Recordings took place in a dark room with the animal's head stabilized.
Our results show propofol and isoflurane anesthesia affected neural interactions within cortical areas, e.g., decreasing spike-field coherence between superficial and deep layers, and between

areas, altering FF and FB communication. Anesthesia had the largest suppressive effect on the spike rate of cells in deep cortical layers.
CL stimulation at 50Hz, mimicking the wakeful spike rate of a subset of CL neurons, was sufficient to counteract the effects of propofol and isoflurane anesthesia and render animals conscious: stimulation reduced EEG power at delta frequencies and reinstated behavioral signs of arousal, such as eye openings and purposeful movements. These effects were time-locked and specific to stimulation within CL more so than other neighboring thalamic nuclei.
Thalamic stimulation under anesthesia promoted wake-like neural processing, enhancing FF and FB alpha coherence while decreasing delta coherence, and reinstated within-area coherence between superficial and deep cortical layers. Thalamic stimulation also increased cortical spike rate during anesthesia and shifted spiking activity from periodic to tonic patterns.
Our data suggest that anesthesia perturbs multiple circuit mechanisms. CL influences levels of consciousness by modulating neural interactions within and between fronto-parietal cortical areas.

Title: Electrophysiological differences between unconscious states induced by gabaergic agonists and glutamatergic antagonists

Authors: *F. J. FLORES[1,3], S. B. GONCALVES[4], I. C. RICE[5], J. AN[6], O. AKEJU[2], J. SCHOLVIN[7], E. S. BOYDEN[7], E. N. BROWN[7,2];

Sci. and Technol., Harvard Univ. and MIT, Cambridge, MA; [7]MIT, Cambridge, MA

Abstract: The treatment or prevention of certain conditions requires to keep patients in deeply anesthetized states, clinically referred to as *induced coma*. Traditionally, this has been achieved using gabaergic agonists, such as the volatile ethers (sevoflurane, isoflurane, desflurane) or the intravenous propofol. However, the infusion of ketamine, an NMDA receptor antagonists, to

induce a state known as *ketamine coma*, has been gaining clinical attention. Ketamine coma has been used to treat refractory headaches and to alleviate acute pain syndromes that are refractory to standard opioid treatments. The use of EEG recordings during these procedures has revealed that gabaergic agonists produce a comatose state associated with a pattern called *burst-suppression*, where bursts of delta (1-4 Hz) and alpha (8-12 Hz) activity are interspersed with relatively isoelectric periods. Similarly, ketamine-induced unconsciousness produces and EEG pattern called *gamma burst*, as periods of gamma activity (> 30 Hz) are preceded by a slow/delta oscillation (0.1-4 Hz). In order to gain better understanding of the neurophysiology underlying these two phenomena, we recorded spiking activity and local field potentials in the prefrontal cortex of deeply anesthetized mice, either with isoflurane or ketamine, using close-packed probes. We used statistically rigorous models to identify periods of burst suppression and gamma bursts. Both treatments produced conspicuous periods of either burst suppression or gamma bursts, with frequency slightly lower than those observed in human EEG recordings. However, ketamine-induced gamma bursts were always preceded by a positive-going deflection in the LFP, and vigorous spiking that subsided soon. Isoflurane-induced burst suppression was preceded by a short (<1 sec) period of high frequency activity followed by activity in the delta and alpha ranges, and spiking was mostly continuous throughout the bursts. No spiking activity outside the bursts was observed in any case. Spiking was also coherent with the LFP at the initial high-frequency period and at subsequent delta frequencies during burst suppression, but was coherent at delta, theta, and alpha bands during the gamma burst. Our results are consistent with the two different mechanisms proposed for each comatose state, where the gabaergic-induced burst suppression might be the result of cyclic metabolic changes, while the ketamine-induced gamma burst might be related to transient removal of excitatory inputs which results in hyperpolarization followed by rebound spiking.

Title: Aging increases time to recovery from anesthesia but does not affect power and coherence of cortical rhythms in rats

Authors: *E. D. MELONAKOS[1,2,5], K. NIKOLAEVA[3], M. SIEGMANN[3], E. N. BROWN[4,1,2], K. SOLT[1,5], C. NEHS[1,2,5];

Abstract: General anesthesia is characterized by unconsciousness, analgesia, amnesia, akinesia, and physiological stability. It is a critical component of modern surgical medicine, with over 60,000 patients undergoing general anesthesia each day in the United States. As a result, anesthetics often also cause unwanted side-effects, including cognitive deficits in the elderly. In humans, EEG power and coherence during anesthesia decrease with age, especially in the alpha band (8 - 12 Hz). In rats, the time needed to recover from anesthesia increases with age, and the broadband EEG power during the awake state decreases with age. However, age-related differences in the cortical electrical rhythms of rats during anesthesia have not been fully described. In order to describe these differences, we performed multi-site EEG (left prefrontal and parietal cortices) and LFP (bilateral prelimbic and right parietal cortices) recordings during administration of four anesthetics with different primary molecular targets or routes—propofol ($GABA_A$ receptors, intravenous), sevoflurane ($GABA_A$ receptors, inhalational), ketamine (NMDA receptors, intravenous), and dexmedetomidine (α_2-adrenergic receptors, intravenous)—in young adult (7 months) and aged (25 months) rats. Like previous studies, we used time to righting following cessation of anesthetic delivery as a measure of recovery time. We found that the time to righting increased with age for all anesthetic drugs. However, we found minimal differences in the EEG and LFP power and bilateral prelimbic cortices' coherence across ages, including in the alpha band; only the duration of the anesthetic-induced cortical dynamics differed across ages. This study offers a detailed view of the spectral content of multi-site recordings of the rat cortex during a variety of anesthetics and indicates that differences in time to righting may not be correlated with changes in spectral content between ages.

Sci., Tokyo, Japan; [6]Fukushima Med. Univ., Fukushima, Japan; [7]Tamagawa Univ. Brain Sci. Inst., Tokyo, Japan

Abstract: The interaction between the prefrontal cortex and the basal ganglia underlies our value-based decision making. Among subareas of the prefrontal cortex, the lateral part (LPFC) strongly project especially to the caudate nucleus (Cd) in the striatum. Several human fMRI studies assigned different functions to this LPFC-Cd pathway. So far, however, mainly due to technological constraint, no study directly elucidates what role this pathway plays on the value-based decision making. In this study, we used a chemogenetic technique that can reversibly modulate the activity of specific projection neurons by expressing the Designer Receptors Exclusively Activated by the Designer Drugs (DREADDs) through the double virus vector infection and by administering its extrinsic ligand, Clozapine-N-Oxide (CNO). This technique was applied to the bilateral LPFC-Cd pathway in the macaque brain. The monkey was trained one-direction reward (1DR) saccade task, which is a version of the memory-guided saccade task with asymmetric reward schedule. After administering CNO to a doubly-infected monkey, task performance gradually deteriorated. This effect was stronger for small reward trials than large reward trials. Moreover, saccade latency became shorter and peak saccade velocity became faster during choice period. These results are consistent with the inhibitory control hypothesis on the function of the LPFC-Cd pathway. Spike activities and local-field potentials (LFP) were recorded simultaneously from the LPFC and the Cd. Firing rates of LPFC neurons were decreased after CNO administration. We calculated coherence between the LPFC and the Cd based on LFP signals and found that cue-induced elevation of coherence around beta-band was

decreased after CNO administration. The effect was observed only in small reward trials, which may explain increased error especially in small reward trials after CNO administration.

Title: Viral strategies to target frontostriatal circuits for the investigation of action control

Authors: *Z. JÄCKEL, S. HARDUNG, B. DE LA CROMPE, I. DIESTER;
Albert Ludwig Univ. of Freiburg, Freiburg, Germany

Abstract: Selecting appropriate actions while inhibiting inappropriate ones is crucial to successful interaction with one's environment. The inhibition or stopping of an action can be classified into proactive (i.e. based on a subject's internal processes) and reactive (i.e. based on an external cue) components. Previously, we identified the prefrontal cortex (PFC) as a critical structure in action control, with individual subsections exerting different effects on proactive and reactive motor control (Hardung *et al*., 2017). Here, rats performed in a response preparation task where they were required to press a lever and then release it after a short or long delay period. Asides from interconnectivity within PFC subregions, the PFC is also densely connected with subcortical structures such as the striatum, which is also hypothesized to play a role in motor inhibition. We use optogenetics to target cells in a projection specific manner and test the efficacy of the combination of a cre/double-floxed inverse open reading frame (DIO) system with a recombinant adeno associated retrograde virus expressing cre recombinase (rAAV2-retro-cre) vs. a canine adenovirus expressing cre recombinase (CAV2-cre). While both viral constructs showed similar expression patterns for corticostriatal pathways, we found differing expression patterns in other circuits; in the corticothalamic circuit, CAV2-cre infected mostly layer VI cells, while rAAV2-retro-cre mainly targeted layer V cells in the PFC, confirming prior findings (Collins *et al*., 2018). Also, only CAV2-cre sufficiently targeted the thalamocortical circuit. In the response preparation task, we observed similar effects on performance with both viral constructs: an increase in early releases in long delay trials while inhibiting PL-striatal projecting cells, and an increase in late releases in short delay trials while inhibiting IL-striatal projecting

cells. However, the percent change in the performance was greater and more significant for inhibition of PL-striatal projecting cells while using rAAV2-retro-cre. Thus, rAAV2-retro-cre seems better suited for targeting the corticostriatal pathway, while CAV2-cre more effectively targets the thalamocortical path.
When applying this projection specific targeting to a cohort of rats (n=3) in the behavioral task, we found similar effects of inhibition of PL- and IL-striatal projecting cells on performance as for the inhibition of PL and IL populations. This suggests that previously identified roles of PL and IL in proactive inhibition depend on these striatal projections, underlining the relevance of the frontostriatal circuit for motor inhibition.

Title: Neural correlates of dorsolateral striatum under HDAC5 overexpression during a decision-making task

Authors: *H. J. PRIBUT[1,2], D. VAZQUEZ[1,2], A. D. WEI[2], S. TENNYSON[2], I. R. DAVIS[2], M. R. ROESCH[1,2], X. LI[1,2];
[1]Neurosci. and Cognitive Sci., [2]Psychology, Univ. of Maryland, College Park, MD

Abstract: Relapse is a key issue in the treatment of drug addiction, influenced by both drug-associated cues and poor decision-making. Previous studies in rats have identified that histone deacetylase 5 (HDAC5), an epigenetic enzyme crucial for gene suppression, plays a novel role in the time-dependent increase of methamphetamine seeking after forced abstinence (incubation of methamphetamine craving). Knocking down or overexpressing HDAC5 in the whole dorsal striatum (DS) attenuates or potentiates the incubation of methamphetamine craving, respectively (Li et al., 2018). Additionally, dorsolateral striatum (DLS), a sub-region of DS, plays important roles in impulsive decision-making after exposure to drugs of abuse. For example, after cocaine self-administration, single-unit activity of DLS during a value-based decision making task is enhanced for higher-valued rewards, biasing rats' choice (Burton et al., 2018). These two lines of research converge on the importance of HDAC5 in DLS in regards to addiction and related decision-making impairments, and yet no work thus far has examined these topics in concert with each other. We attempted to address this gap in knowledge by overexpressing HDAC5 in

DS and recording DLS activity in drug naïve rats as they performed a value-based decision-making task. Thus far, we have observed that HDAC5 overexpression in DS reduced reaction time in the task but it also reduced sensitivity to delay-manipulations of reward. Continued recording from DLS will indicate how HDAC5 overexpression may influence DLS encoding of size-manipulations under drug naïve conditions, and will inform future experiments examining the role of HDAC5 in DLS encoding in decision-making during incubation of methamphetamine craving.

CAS, Praha, Czech Republic; [5]Bioengineering, UCSD, La Jolla, CA; [6]Dept. de Neurociencias, Univ. de Chile, Santiago, Chile; [7]Dept. Neurosci., Albert Einstein Coll Med., Bronx, NY

Abstract: The nucleus accumbens (NAc) is proposed to link motivation with action. Motivation is reflected in the speed with which an animal approaches a place where it has previously been rewarded. To test how NAc neurons encode speed during approach to reward, we recorded the unit firing activity of 66 NAc shell neurons in adult male Wistar rats that had been overtrained

on a radial 8 arm maze task in which the same 3 arms were baited with chocolate milk reward. For one group of 2 rats, the same amount of reward was always delivered in each of the 3 arms. For the other group of 3 rats, the 3 arms were baited as follows: 1 drop of chocolate milk was delivered with 100% probability in the low reward arm, 4 drops were delivered with 66% probability in the medium reward arm, and 4 drops were delivered with 100% probability high reward arm. Rats were given 12 trials per day to explore the maze and obtain all the rewards; reward was delivered only on the first arm entry per trial. Pearson's correlations between neuronal activity and speed were calculated in the periods the rats moved from one arm to the reward area of the next visited arm. Significant ($p < 0.001$) positive or negative correlations between firing rate and speed were found in nearly 40% of neurons. To examine these correlations further, we subdivided the data into 6 temporal windows according to the target arm reached during the run and the phase of locomotion (increasing velocity from just prior to locomotion start to the speed peak, or during decreasing velocity from the speed peak or to just after locomotion stop). In the rats that were trained with the same reward in the 3 arms, 20% of neurons exhibited significant correlations (in the same direction) between firing rate and speed in all 6 windows. In contrast, in the rats trained with different reward values in the 3 arms, the correlations between firing and speed were more variable, with no neuron exhibiting significant correlations in all 6 phases. These results suggest that the way NAc neurons encode running speed is influenced by motivational factors such as the amount of reward expected.

Title: Deletion of beta2* nicotinic acetylcholine receptors expressed by striatal interneurons leads to behavioral alterations

Authors: *H. JANICKOVA[1], A. ABBONDANZA[1], J. HÖFFLIN[2], J. ELIAS[3,4], P. KASPAREK[3,4], R. SEDLACEK[3,4];
[1]Inst. of Physiol. CAS, Prague, Czech Republic; [2]Rheinische Friedrich-Wilhelms-Universität Bonn, Bonn, Germany; [3]Lab. of Transgenic Models of Dis., [4]Czech Ctr. for Phenogenomics, Inst. of Mol. Genet. of the ASCR, Vestec, Czech Republic

Abstract: While functional role of nicotinic acetylcholine receptors (nAChRs) expressed by striatal glutamatergic and dopaminergic terminals has been extensively studied, much less is known about function of nAChRs expressed by striatal neurons. The striatal projecting neurons (SPNs) express low levels of nAChRs, hence the vast majority of nAChRs is expressed by striatal interneurons, either cholinergic or GABAergic (CINs and GABAINs, respectively). We hypothesize that acetylcholine released by CINs activates nAChRs expressed by GABAINs and that this activation is important for striatal signaling and function. The main objective of our study is to determine role of nAChRs expressed by striatal interneurons in the control of striatal-based behavior. To do that, we decided to use less specific Cre/loxP approach followed by more precise CRISPR/Cas9 method allowing us to delete nAChRs in specific types of GABAINs. First, we used mice carrying floxed gene *CHRNB2* coding for β2 subunit of the nAChR and we injected them with AAV5-Cre vector into the dorsal striatum. After three weeks allowing for viral expression, we tested mice with the deletion in a battery of behavioral tests mainly focusing on striatal-based behavior. We also measured markers of neuronal activation, Fos and phosphorylated ribosomal protein S6, to see if activity of SPNs was increased after deletion. In the mice with deletion, we detected changes in several behavioral domains: they were impaired in the cued Morris water maze, they had decreased motivation and they showed anti-depressive and anti-social behavior comparing to mice injected with AAV5-GFP control virus. In contrast, mice with deletion did not show any changes in baseline locomotion or in locomotor response to amphetamine and there was no change in Fos expression after acute administration of amphetamine. In addition to non-specific β2 deletion in all striatal neurons , we also decided to target specifically 5HT3a and NPY-expressing GABAINs. For that we used previously published (Peng et al., Eur J Neurosci, 2018) sequences of gRNA targeting *CHRNB2* gene. We confirmed efficiency of these gRNAs in 3T3 cells so they can be virally transduced in striatal cells and used for specific deletion of β2 in 5HT3a and NPY-expressing GABAINs using mouse lines expressing Cas9 under the control of respective promoters. Based on the current data, we conclude that the deletion of β2* nAChRs expressed by interneurons in the dorsal striatum leads to alterations in specific behavioral domains. Acknowledgement: The β2-flox/flox mice for this study were provided by Prof. Michael Crair from Yale University School of Medicine.

Title: Modulation of value and error signals using caudate electrical stimulation

Authors: *S. R. SANTACRUZ[1,2], E. L. ZIPPI[3], J. M. CARMENA[3,4];
[1]Biomed. Engin., Univ. of Texas At Austin, Austin, TX; [2]Inst. for Neurosci., Univ. of Texas at Austin, Austin, TX; [3]Helen Wills Neurosci. Inst., [4]Electrical Engin. and Computer Sci., Univ. of California, Berkeley, Berkeley, CA

Abstract: Valuation of alternative actions is a process in decision-making that is indispensable for adaptive and healthy behavior. In many psychiatric patients, dysfunctional decision-making and reward processing are known to contribute to the disease state. Determining the neural circuitry that drives flexible decision-making is thus extremely relevant to understanding healthy and pathological behaviors. In this work, we examine how value information is integrated within the corticostriatal circuitry and used to guide decision-making behavior. The dorsomedial striatum (caudate; Cd) has been shown to encode values of alternative choices prior to choice selection. Many other brain regions, such as the prefrontal cortex, also have value representations and the anterior cingulate cortex (ACC) is known for its role in flexible decision-making. In two rhesus macaque subjects, high-frequency stimulation is administered in the Cd during a two-armed bandit task, resulting both in a change in the functional decision-making behavior and the underlying encoding of value and error signals. High-frequency stimulation paired with a particular stimulus during an instructed trial biased the subjects to select that stimulus with a higher rate in free-choice trials irrespective of the reward likelihood. We hypothesized that caudate microstimulation differentially inflates value independent of action and reward, and that, even though the brain has bilateral value representations, unilateral manipulations of value are sufficient to mediate choice behavior. This is supported by neural data which indicates that value-coding neurons in Cd and ACC are preferentially modulated by stimulation. Stimulation was found to have selective effects on different categories of value-coding neurons in these nuclei. Additionally, changes in firing rate activity of Cd and ACC neurons encoding reward prediction error (RPE) were found, reflecting a change in the distribution of RPEs experienced by the subjects.

Title: Roles for ventral pallidum GABA neurons in appetitive and aversive motivation during risky decision making

Authors: *M. R. FARRELL[1], J. ESTEBAN[2], S. V. MAHLER[3];
[1]Univ. of California Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [3]Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: The brain is tuned to balance appetitive and aversive drives when making decisions, and this process goes awry in disorders like drug addiction. However, the neural circuits involved in this balance remain poorly understood. The ventral pallidum (VP) lies at an anatomical nexus of appetitive and aversive neural circuits, and contains segregated neuronal populations that seem to regulate both appetitive and aversive motivational states. We previously showed that inhibiting VP neurons decreases translationally-relevant relapse-like behaviors, and inhibiting VP GABA neurons in particular facilitates a shift in decision making towards a small but safe reward option (1 food pellet) and away from a large but risky one (2 food pellets + chance of footshock). We also showed that VP GABA neuron inhibition reduced effortful seeking of palatable food on a progressive ratio task, supporting a role for these neurons in driving appetitive motivation. However, it is unclear how these neurons regulate aversive motivation. Therefore, we tested whether chemogenetic inhibition of VP GABA neurons disrupted active operant avoidance of shock, or affective reactivity to shock. GAD1-Cre rats expressing inhibitory hM4Di designer receptors (hM4Di DREADDs) in VP GABA neurons were trained on an operant active avoidance task (Oleson et al., 2012, *J Neuroscience*). Levers were extended every 20s signaling impending repeated footshock after a 2s delay. A press on the active lever during this delay period prevented footshock (avoidance response), whereas a press after shock initiation terminated ongoing footshock (escape response). A 20s white noise safety signal was presented upon an avoidance or escape response. If VP GABA neurons are required only for appetitive motivation, then DREADD-mediated inhibition of these neurons will not alter avoidance or escape responding. Subsequently, we recorded and quantified ultrasonic vocalizations and motoric responses (Orsini et al., 2017, *J Neuroscience*) to non-contingent, unavoidable footshock (ascending in intensity from 0.15mA-0.50mA) to test whether VP GABA inhibition altered affective responses to shock. These results will tell us a great deal about how VP GABA neurons operate during aversive motivational states, and ultimately during the pathological decisions commonly made by addicted people.

Title: Glutamatergic regulation of reward-related timing in the dorsolateral striatum

Authors: *S. A. YOUSEFZADEH, S. WEN, S. PRAKASH, W. H. MECK;
Duke Univ., Durham, NC

Abstract: The ability to time durations in the seconds-to-minutes range is an essential component of reward prediction and reinforcement learning. Reward-related timing is mediated through the dopamine-glutamate pathways in the cortico-striatal-thalamic loops. It has been shown that medium spiny neurons (MSNs) in the dorsal striatum receive glutamatergic and dopaminergic input from various regions of the brain including the prefrontal cortex and substantia nigra pars compacta, respectively, and are critical for processing temporal information. In this study, we investigated the role of glutamatergic neurotransmission in the dorsal striatum and its contribution to reward-related timing mechanisms. Using a bi-peak timing procedure, rats were trained to reproduce two target durations (12 and 36 s). The training phase was followed by bilateral infusions of NMDA or AMPA receptor agonists or antagonists into the dorsolateral striatum 30 minutes prior to the beginning of the test sessions. Our results demonstrated that glutamatergic antagonists produced proportional leftward shifts for both target durations, consistent with an overestimation of time resulting from a faster internal clock. In contrast, glutamatergic agonists produced proportional rightward shifts for both peak functions, consistent with the underestimation of duration as a result of a slower internal clock. These findings indicate that the glutamatergic input received by MSNs has a regulatory effect on their spike patterns, thereby leading to alterations in timing and time perception as reflected in the speed of the underlying timing mechanisms.

Title: Chemogenetic inhibition of ventral tegmental area projections to the medial prefrontal cortex affects decision-making

Authors: *M. D. SINGSTOCK, D. TAPP, B. KLEIN, M. S. MCMURRAY;
Psychology, Miami Univ., Oxford, OH

Abstract: Impulsive decisions are a natural component of healthy behavior; however, instances of chronic impulsivity can have a profound impact on the individual and society. Foremost, drug

addiction has been reliably shown as a correlate and cause of increased impulsivity. In addiction, there are abnormalities in the medial prefrontal cortex (mPFC), a region of the brain primarily involved in regulating behavior and goal-directed decision-making, causing an increase in premature and risky decisions. Much is known about the mPFC alone; however, considerably less is known about the neural circuitry that connects the mPFC to other brain regions, especially the circuit connecting it with the ventral tegmental area (VTA), a structure in the midbrain that is crucial to reward assessment. The purpose of this study was to determine if inhibition of the VTA-mPFC neural circuit affects basic decision-making. To test this hypothesis, we selectively silenced this connection using Designer Receptors Exclusively Activated by Designer Drugs and measured impulsivity and risky decision-making in delayed and probabilistic decision-making tasks, respectively. We found that inhibition of this connection does have a significant impact on preference for risky rewards, causing rats that were affected by DREADD activation to undervalue the larger, riskier rewards; however, there was no impact on impulsivity in the delay discounting task. Silencing this connection also impaired behavioral flexibility, measured in a probabilistic reversal learning task. Thus, our results indicate that projections from the VTA to mPFC play a critical role in some forms of decision-making, namely probability estimation, but not delayed reinforcement. These results have important implications on our understanding of the psychiatric diseases that are characterized by excessive risk-taking, and on the role of the prefrontal cortex in these diseases.

Title: The neurobiology of interval timing is epigenetically regulated

Authors: *M. FALAPPA, V. TUCCI;
Italian Inst. of Technol., Genova, Italy

Abstract: Introduction:
The understanding of how timing in the brain is epigenetically regulated is important for a better description of cognitive processes.
For this reason, we investigate the neural basis of interval timing in mice according to their epigenetic landscape. We have previously reported that timing in mice is guided by parent-of-origin effects and that genomic imprinting is one of the epigenetic mechanisms that exerts a control on this neurobiological process. Now, we focused on neuronal populations of the dorsal striatum, that play functionally roles in timing processes, and we checked whether the activity of

these neurons is influenced by a parent-of-origin epigenetic component.

Methods:

We studied the peak procedure timing task in the AKR/J and DBA/2J inbred strains during in vivo calcium recording in the dorsal striatum. Then we compared the activity profiles and the behavior between parental strains and their reciprocal hybrids. The behavioral test was performed in home-cage equipped with the Choora feeder by AM Microsystems, an operant wall with two hoppers with infrared beam and a pellet dispenser. The calcium signals were acquired by using nVista HD (Inscopix). After behavioral training mice were injected with AAV1Camk2aGCaMP6m, then implanted with lens probe and a baseplate above the lens for mounting a miniature fluorescence microscope. The synchronization between the two systems during the recording was ensured by TTL from Choora feeder managed by Phenopy.

Results:

Our results show no differences in the error rate while the timing strategy adopted from the two experimental group was different in different cohorts. Indeed, DBA/2J show less accuracy to choose the right time window to get the reward. They delay their responses. This phenotype was inherited in a prent-of-origin manner. Then, we found an activation on the dorsal striatum related to the judgment of time during the task, as we expected. Preliminary analyses reveal a combination of neuronal and behavioral profiles that are parent-of-origin inherited and that account for the epigenetic differences between the different cohorts.

Conclusions:

While we are performing further studies to confirm these preliminary data, our early results suggest that timing is an interesting endophenotype that is regulated by epigenetic mechanisms. Individual neurons in the brain show different epigenetic changes that account for their variable activity. This phenomenon influences time perception and potentially many different behaviors. Therefore, future studies into the epigenetics of single neuronal profile will be mandatory in Neuroscience.

Title: The posterior tail of striatum plays an important role in tonal associative learning

Authors: *M. LIU[1], H. WANG[2], T. LI[4], Y. WANG[5], D. CAI[3], K. YUAN[2];
[1]Inst. of Neural Engin., Beijing, China; [2]Tsinghua Univ., Beijing City, China; [3]Dept. of Biomed. Engineering,School of Medicine, B219A, Tsinghua Univ., Beijing, China; [4]Inst. of Neural Egineering, Beijing, China; [5]USC, Tucson, AZ

Abstract: The striatum is traditionally divided into three subdivisions based on connection and function, including dorsomedial striatum, dorsolateral striatum, and ventral striatum. These subdivisions are critically involved in various brain functions, including associative learning. Very recently, the posterior tail of the striatum (TS) started to be considered as the fourth subdivision because of its independent dopamine source, and the understanding of its function is still very limited. Although a few studies have shown the essential role of TS neurons in learned discrimination task, whether and how these neurons might play a specific role during associative learning remains unknown. To address this question, we adopted a Go-Nogo behavioral task, in which mice learn to associate one tone with reward (sucrose water) and the other tone with punishment (air puff). We firstly expressed GCaMP6 in the TS of Vgat-ires-Cre mice, then we made fiberphotometry recordings from TS neurons expressing GCaMP6 during the training. We found that the medial and lateral part of the TS showed differential responses to tonal cues. The medial part demonstrated significantly stronger adaptation to tones in the first day of training than the lateral part did.. To find out whether difference in connection might account for the difference in neural responses, we used retrograde mono-transynaptic rabies virus to identify the inputs of medial and lateral TS. We found that the lateral part received more inputs from the auditory cortices, while the medial part received substantially more inputs from somatosensory cortices. Our immunohistological results showed that medial TS is rich of D1R neurons and almost absent of D2R neurons, while lateral TS has more D2R neurons than D1R neurons, suggesting that D2R neurons, which are located laterally, might be more important for associative learning using tonal cues. To test this hypothesis, we optogenetically activated either D1R or D2R neurons during training. We found that both the activation of D1R and D2R neurons significantly accelerated learning process by improving the performance of correct rejection. However, the improved performance was preserved after days of light stimulation only in mice received D2R activation. The performance of mice received D1R activation dropped to control level in the first day of light-off. These data suggest that TS neurons are indeed involved in tonal associative learning, and that D2R neurons might play a more important role.

Title: *In vivo* striatal neural activity during motor skill learning in Huntington's disease mice

Authors: *E. T. KOCH, M. D. SEPERS, L. A. RAYMOND;
Dept. of Psychiatry and Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington's disease (HD) is a genetic neurodegenerative disorder characterized by motor, cognitive and psychiatric deficits. The dorsal striatum is the major site of neurodegeneration in HD, particularly the spiny projection neurons, along with atrophy of other areas including the cortex. HD patients and animal models display deficits in striatum-dependent learning, such as motor skill learning, that worsen with disease progression. The YAC128 mouse model of HD shows progressive deficits in the accelerating rotarod motor learning task as well as anxiety-like behaviours and changes to locomotor activity. These mice also display aberrant cortico-striatal signalling, including changes to glutamate release and deficits in cortico-striatal plasticity. The contribution of these changes in cortico-striatal signalling to motor skill learning deficits *in vivo* has never been tested. Here, we have combined the accelerating rotarod task with GCaMP7f imaging using fiber photometry to correlate activity in striatal neurons with task performance and motor learning. We have found that population activity in the dorsal striatum increases and remains elevated during rotarod performance, and returns to a relatively low level afterwards. Over days of training, the amplitude of population activity during rotarod performance reduces as mice become more proficient at the task. We also measured GCaMP7f activity of mice freely moving in an open field to assess anxiety-like behaviour and locomotor activity and the corresponding neural activity in striatum. We examined GCaMP7f dynamics during these behavioural tasks in YAC128 mice compared to their wild-type littermates at early stages (2-3 months) and at fully symptomatic stages (6-7 months). This research contributes to our understanding of the changes to striatal signalling that may contribute to motor, cognitive and psychiatric symptoms in HD.

Title: A computational model of cortico-basal ganglia circuits for deciding between reaching actions

Authors: *D. THURA[1], P. E. CISEK[2];
[1]Lyon Neurosci. Res. Ctr., Inserm, Bron, France; [2]Univ. of Montreal, Montreal, QC, Canada

Abstract: When decisions are made between actions, they appear to involve the same cortical and subcortical regions that are implicated in the control of those actions, but the causal role of each region is difficult to establish. In recent studies, we recorded neural activity in the dorsal premotor (PMd), dorsolateral prefrontal (dlPFC), and primary motor cortex (M1), as well as in the external and internal globus pallidus (GP), while monkeys performed a dynamic decision-making task in which sensory evidence about the choice changed continuously in each trial and decisions could be made at any time. During deliberation, PMd, M1, and dlPFC activity continuously reflected the evidence until a moment of commitment was reached, marked by a peak of activity in PMd. In contrast, GP activity did not reflect evidence at all and instead appeared to provide a ramping "urgency" signal that pushed the monkeys to decide as time elapsed. GP activity only became directionally tuned after the moment of commitment was reached in PMd (Thura & Cisek, 2014; 2017). Here, we model these phenomena with a recurrent attractor model in which dlPFC, PMd, M1, and GP are each represented by a pair of mutually inhibitory cells. The model dlPFC projects to PMd, PMd and M1 are reciprocally connected, and the GP forms a double-inhibitory loop with PMd. Evidence enters as input to PFC while a ramping urgency signal is the (inhibitory) input to GP. The activity in the network evolves over time as a competition between left vs. right-selective cells in each region, until one of each pair fully suppresses the other in a "winner-take-all" fashion. Key to the operation of the model are the sigmoidal functions that govern interactions between regions and mutual inhibition within each. In the cortical regions, these are relatively linear, allowing the sensory evidence to continuously shift neural activity. In contrast, the GP interaction function is flat for much of its range, and therefore only a strong signal from PMd will differentially engage tuning in GP. Once

such tuning begins to emerge, however, it produces a positive feedback with PMd that exaggerates the currently winning population and produces a point-of-no-return. The model reproduces many of the phenomena we observed in our recordings, including the presence of deliberation-related activity in cortex and its absence in the GP, the commitment-related peak in PMd and its absence in dlPFC, variations of activity with shifts of the speed-accuracy trade-off, and the delaying of commitment with cortical microstimulation. It also makes additional predictions for future experiments, including simultaneous stimulation and recording in cortical and subcortical regions.

Title: Striatal glutamatergic signaling elicited by turn cues, but not stop cues

Authors: *M. SARTER[1], C. AVILA[2];
[1]Dept. of Psychology, [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Moving across dynamic surfaces and obstacles requires the integration of extero- and interoceptive cues into movement selection and sequencing. Cortico-striatal projections are thought to transfer information about behaviorally significant, attended cues to the striatum to guide the striatal sequencing of movements. Here we recorded, at real time, dorsomedial (or "associative") striatal glutamatergic signaling in rats trained to walk a treadmill, to utilize one cue (tone or light) to turn prior to the treadmill restarting in reversed direction, and the other cue (light or tone) to stop prior to the treadmill restarting in the same direction. Glutamate-sensitive biosensors were implanted into the dorsomedial caudate nucleus for amperometric recordings of glutamate currents (5 Hz sampling rate). Animals were retrained to reach criterion, defined as 70% correct responses to both cues. Recordings were time-locked to task events (cue on- and offset, treadmill stops and starts). Trials were video-recorded for off-line analysis of the timing and type of turns and stops. Turn cues which elicited turns evoked glutamatergic signals with peak amplitudes (17.31±0.83 µM) robustly greater than turn cues which failed to elicit a turn (4.52±0.31 µM) and stop cues, successful or failed (1.72±0.82 µM). Indeed, peak amplitudes during failed turns and successful and failed stops were within 1 SD of currents seen while rats were walking in the absence of events. Glutamatergic transients during successful turn trials began to rise within 0.31±0.04 s and peaked within 1.27±0.20 s of cue onset. Treadmill stops

produced variable increases in glutamatergic activity. Turn cues - if successful - evoke a complex task shift, including reorienting of the body while maintaining balance, and the selection and sequencing of the steps needed to turn around - often before the treadmill stops. In contrast, stop cues do not need to elicit such a complex task shift; as rats await the treadmill stop. As we previously demonstrated that attentional cues involving task shifts elicit cortical cholinergic signaling (Howe et al., 2013), turn cue-evoked striatal glutamatergic activity may be secondary to this detection. Loss of cortical cholinergic afferents, observed in Parkinsonian fallers, therefore disrupts the transfer of behaviorally significant cues into the striatum, thereby revealing striatal impairments in the orchestration of complex movements. The forthcoming demonstration of attenuated striatal glutamatergic signaling in rats with cholinergic lesions will also support the hypothesis that turn cue-evoked glutamatergic signaling originates from cortico-striatal projections.

Title: M_1 muscarinic receptor agonist treatment differentially modulates dorsolateral and dorsomedial striatal glutamate during repetitive behaviors in the BTBR mouse

Authors: *M. E. RAGOZZINO[1], K. E. NISBETT[2], P. TENEQEXHI[3], R. OCAMPO[3], O. ATHNAIEL[3], W. S. MESSER, JR[4];
[2]Neurosci., [3]Psychology, [1]Univ. of Illinois at Chicago, Chicago, IL; [4]Pharmacol. and Exptl. Therapeut., Univ. of Toledo, Toledo, OH

Abstract: Recent findings from the laboratory indicate that acute treatment with the partial M_1 muscarinic receptor agonist, CDD-0102A attenuates elevated stereotyped motor behaviors (digging and self-grooming behavior) in the BTBR T+Itpr3^{tf}/J (BTBR) mouse. Past studies indicate that striatal circuitry is involved in the expression of stereotyped motor behavior and glutamate signaling in striatal circuitry contributes to the expression of stereotyped motor behaviors. Further, there is evidence that central muscarinic receptors can modulate glutamate transmission that has been proposed as a key neurotransmitter disrupted in ASD. The BTBR T+Itpr3^{tf}/J (BTBR) mouse serves as a polygenic model of autism displaying elevated repetitive motor behaviors. The present study determined whether systemic treatment with CDD-0102A, concomitantly attenuates repetitive motor behaviors and modifies striatal glutamate signaling in

BTBR and B6 mice. Prior to testing, an enzyme-based, glutamate biosensor was inserted into the dorsolateral or dorsomedial striatum of each mouse. After a 3-hour equilibration period, mice received an intraperitoneal injection of either saline or CDD-0102A 0.12 mg/kg. Twenty-minutes post-injection, nesting material was removed from a mouse's home cage. The time spent digging in bedding and self-grooming was measured for 20 minutes while changes in glutamate efflux were measured with a 1 second time resolution. Treatment with CDD-0102A significantly reduced self-grooming behavior in BTBR mice as observed previously. Change in glutamate efflux from both striatal subregions increased ~1500nM in BTBR compared to ~1000nM in B6 mice during digging and grooming behavior. CDD-0102A treatment reduced this magnitude glutamate change in the dorsomedial striatum to ~700nM, whereas it increased glutamate change in the dorsolateral striatum to ~1800nM during digging and grooming. The current findings suggest that glutamate transmission is dysregulated in BTBR mice, contributing to the elevated stereotyped motor behaviors. Moreover, activation of M_1 muscarinic receptors modulates glutamate signaling in the dorsal striatum in distinct ways based on subregion. Overall, the results suggest that treatment with a partial M_1 muscarinic receptor agonist may alleviate repetitive behaviors and restricted interests in part by modifying glutamate signaling.

Title: Functional characterization of cortical D2 dopamine receptor in adult mice

Authors: *C. QUINTANA, M. BEAULIEU;
Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada

Abstract: The dopamine D2 receptor (DRD2) remains the principal target of antipsychotic drugs used for the management of schizophrenia and other psychotic disorders. DRD2 is highly expressed within the basal ganglia, more specifically the striatal caudate nucleus and the nucleus

accumbens and its general functions in this region are well understood. Early studies have been shown also the presence of DRD2 in several cortical areas. Cortical DRD2 has been at the centre of interest because of its involvement in regulation of cognitive, emotional and social behavioural processes and its regulation by antipsychotic drugs. However, further investigations of cortical DRD2 functions have been hindered by relatively low receptor expression, antibodies and ligand selectivity or limits of gene reporter systems. We used high sensitivity approaches to map cortical DRD2 expressing neurons and its projections. Results from these investigations revealed highly heterogeneous expression of DRD2 in principal neurons and various populations of interneurons which are not exclusively expressed on parvalbumin positive interneurons. Moreover, DRD2 expressing neurons do not always follow the characteristic pattern of projection of the region where they reside (Khlghatyan et al. 2018). We then explored the functional role of DRD2 in prefrontal cortex (PFC) by using somatic CRISPR/Cas9 mediated knockout of DRD2 to investigate the behavioral responses of DRD2 regulation in differential populations of PFC DRD2 expressing. Also, the involvement of DRD2 in different subtype of interneurons expressing these receptors was examined. Chemogenetic manipulation of DRD2 expressing neurons discriminates the role on its involvement of neuronal activity. Then, dopaminergic and glutamatergic modulation was investigated by microdialysis to highlight the implication of the regulation of PFC DRD2 in a network context. Cell type specific DRD2 knockout by using somatic CRISPR/Cas9 is a powerful tool to study the function of DRD2 in selective manner. This comprehensive analysis of PFC DRD2 expressing neurons provides indications for its functional implications in healthy and disease conditions and paves the way for a re-examination of cortical DRD2 functions, which could provide information about neuronal circuits involved in psychotic and mood disorders.

Title: Prefrontal adrenergic and cholinergic fluctuations define global arousal after stress

Authors: J. CRESSY[1], A. P. KAYE[1], M. G. RAO[1], J. FENG[2], J.-H. KIM[4], S.-H. LEE[5], Y. LI[3], *A. C. KWAN[1];

Abstract: Across the cerebral cortex, neurons increase their firing when the pupil dilates, reflecting a combination of adrenergic and cholinergic control of arousal. By recording only the pupil, the global arousal state of neurons throughout the cortex can be inferred. Precisely defining the neurochemical basis of dynamic changes in arousal may offer insight into the mechanisms of arousal dynamics and how they are altered by emotional states. Previous work performing calcium imaging of the axons of acetylcholine (ACh) and norepinephrine (NE) neurons in sensory cortex has suggested distinct timescales of modulation by these neurotransmitters. Direct measurement of ACh and NE concentration fluctuations in relation to the pupil have not been reported, and the existence of spontaneous fluctuations in NE concentrations is disputed. In order to better understand the role of neuromodulators in pupillary arousal, we employed recently developed fast, specific fluorescent G-protein coupled receptor sensors for norepinephrine and acetylcholine (Grab-NE2h and ACh4.3). Here we used a miniature, head-mounted microscope to image NE/ACh fluctuations in medial prefrontal cortex (mPFC). We observed distinct temporal relationships between the pupil and prefrontal NE/ACh concentrations. The relationship between pupillary arousal and neuromodulator fluctuations was differentially altered following exposure to an acute stressor (stress-enhanced fear learning). We performed microendoscope calcium imaging in mPFC and in order to understand neural ensemble coupling to arousal after stress. We propose a computational model for defining arousal states based on pupillary fluctuations, which may facilitate the understanding of their role in stress-related hyperarousal and arousal states at large.

Title: Prefrontal tDCS of the primate brain has diverse effects on LFP power spectra across cortical and subcortical areas

Authors: *S. E. SEIDL[1], C. RANGANATH[2], W. M. USREY[1], E. G. ANTZOULATOS[1];

Abstract: Transcranial direct current stimulation (tDCS) is a promising brain-stimulation technique that is used to modulate cortical excitability. However, there is considerable controversy as to whether or how tDCS affects neural activity, and understanding the potential effects is complicated by variability in the location, polarity, and intensity of stimulation. The current study set out to test how tDCS affects neural activity at the population level, and to determine the effects of varying stimulation polarity and intensity. We performed simultaneous multi-electrode intracranial recordings of local field potentials (LFP) in awake non-human primates during prefrontal tDCS. We compared the effects of stimulation on LFP power spectra among frontal areas, including the lateral and caudal prefrontal cortex, anterior cingulate, and dorsal premotor cortex. We also compared frontal cortical regions to dorsal striatum. We find that the neurophysiological effects of tDCS are partly dependent on polarity (anodal/cathodal), intensity of stimulation (0.5-1.5mA), and electrode montage, but also vary in amplitude and direction of change across areas. These results suggest a non-homogeneous effect of tDCS across frontal brain regions and may help us understand the factors that shape the local effects of diffuse stimulation.

Title: Chemogenetic inhibition reveals regional specificity of direct pathway control of action sequencing

Authors: *E. GARR[1], A. R. DELAMATER[2,1];
[1]The Grad. Center, CUNY, New York, NY; [2]Brooklyn College, CUNY, Brooklyn, NY

Abstract: Humans and non-human animals engage in intricately woven and choreographed action sequences that are constructed from instrumental learning. There is broad consensus that the basal ganglia play a crucial role in the formation and fluid performance of action sequences. To investigate the role of the basal ganglia direct pathway in action sequencing, we virally expressed Gi-DREADDs in either the dorsomedial (DMS) or dorsolateral (DLS) striatum during and/or after action sequence learning in D1 Cre rats. There were four training groups: DREADD+CNO, DREADD+vehicle, mCherry+CNO, and mCherry+vehicle. When DREADDs were expressed in the DMS, CNO injections slowed sequence performance early in training but had no effect on sequence acquisition. When DREADDs were expressed in the DLS, CNO injections facilitated sequence performance and acquisition. A subsequent analysis revealed that quicker task acquisition was likely due to a greater number of sequences performed early in training, and hence more experience with the task. Outcome devaluation tests conducted after training revealed that target sequence rates were goal-directed across all training and testing conditions, as were sequence initiation latencies. Specifically, rats suppressed the rate of sequence performance when rewards were devalued, while also increasing the latency to initiate sequences. Sequence completion latencies were generally not sensitive to outcome devaluation, except in the case where DREADDs were expressed in the DMS and CNO was administered during training and test. This result suggests that the direct pathway via the DMS thwarts the development of goal-directed sequence completion. Gi-DREADD function was verified by comparing c-Fos counts between hemispheres in rats that expressed DREADDs unilaterally and received injections of CNO followed by a high dose of caffeine. Data from D2 Cre rats will also be presented.

Title: Inactivation of the prelimbic cortex attenuates operant responding in both physical and behavioral contexts

Authors: *C. M. P. THOMAS, E. A. THRAILKILL, M. E. BOUTON, J. T. GREEN; Psychological Sci., Univ. of Vermont, Burlington, VT

Abstract: The recognition of the role of context in the control of both voluntary (instrumental) and involuntary (Pavlovian) behavior has led to major changes in the ways that we approach altering behavior, such as addiction therapies and dieting. Generally, research has focused on the importance of the physical context; however, we now know that context can include things such as cues, internal states, time, etc. Recently, evidence has suggested that when a sequence of two instrumental behaviors is required to earn a reinforcing outcome, the first response can be the "behavioral" context for the second response. That is, the second response is performed as a result of having just completed the first response, and the physical context, composed of the surrounding visual, tactile, auditory and olfactory stimuli, is important for the first response and not the second (Thrailkill, Trott, Zerr, & Bouton, 2016). The present experiments aimed to determine if the prelimbic cortex (PL), which we have previously shown to be important for the effect of the physical, training context on instrumental responses (Trask, Shipman, Green, & Bouton, 2017), is also important for behavioral contexts. Rats first learned a heterogenous behavior chain in which the first response (i.e. pressing a lever or pulling a chain) was cued by a discriminative stimulus and led to a second stimulus which cued a second response (i.e. pulling a chain or pressing a lever); the second response led to a sucrose reward. When the first and second responses were tested in isolation in the training context, pharmacological inactivation (baclofen/muscimol) of the PL resulted in a reduction of the first response only. But when the second response was performed in the "context" of the first response (i.e., as part of a behavior chain), PL inactivation reduced the second response. Overall, these results support the idea that the PL is important for mediating the effects of a training context on instrumental responding, whether that training context is physical or behavioral.

Title: Separating goal-directed action from habit: Role of the context in which taste aversion learning occurs in creating the reinforcer devaluation effect

Authors: *M. E. BOUTON[1], S. ALLAN[1], A. TAVAKKOLI[2], M. STEINFELD[1], E. THRAILKILL[1];
[1]Psychological Sci., Univ. Vermont, Burlington, VT; [2]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Goal-directed actions and habits are two types of instrumental behavior that can be distinguished with reinforcer devaluation methods. For example, after instrumental learning, the reinforcer can be devalued by conditioning a taste aversion to it before the instrumental behavior is tested in extinction. If responding is suppressed by devaluation, it is considered a goal-directed action; if responding is not suppressed, it is considered a habit. Here we show that the *context* in which aversion conditioning occurs influences the reinforcer devaluation effect. In all experiments, female Wistar rats (n = 8) first received brief lever-press training (120 response-outcome pairings on a VI 30-s reinforcement schedule) that earlier research indicated would produce action. In Experiment 1, Paired rats then received pairings of the pellet reinforcer and ip injections of LiCl in either the operant chamber (pellets presented to the food cup on a VT 30-s schedule) or in in the home cage (pellets presented in a dish). Unpaired controls received the LiCl and pellet exposures in either context, but on separate days. When lever pressing was tested in extinction in the operant chamber, it was suppressed if aversion conditioning had occurred there, but not in the home cage. In the latter condition, the Paired and Unpaired groups responded equivalently. Experiment 2 replicated the result and found that an opportunity to consume the home-cage-averted pellets in the operant chamber before testing did not cause the devaluation effect to emerge. Experiment 3 found the same results as Experiment 1 using counterbalanced contexts provided by operant chambers with different odors, visual cues, floors, and locations in the lab. Aversion conditioning in either context involved presenting pellets to the food cup on the VT 30-s schedule. Physical environment, and not mode of pellet delivery, is thus a factor. The results suggest that a goal-directed action can be mistaken for habit if taste aversion conditioning occurs in a different context. The animal evidently encodes the context in which the reinforcer occurs in its representation of the goal. The fact that taste aversion always transferred across contexts, whereas the devaluation effect did not, was especially interesting.

Title: A signal for the bayesian update of a learned preference in the macaque prefrontal cortex

Authors: *R. BARTOLO, R. C. SAUNDERS, A. R. MITZ, B. B. AVERBECK;
Lab. Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: In a noisy environment, learning requires organisms to keep track of choices and their associated outcomes across successive decisions to form beliefs about value in the world. This allows them to predict future outcomes and to update their belief after each outcome. Knowledge about environmental statistics allows for increased updating flexibility. The primate prefrontal cortex (PFC) integrates information carried by reward circuits and has also been proposed as an integrator of new information and previous knowledge. Thus, the present study explores the PFC computations related to updating current beliefs in multifaceted environments. We conducted high-channel count single-unit simultaneous recordings in two male macaques (N=3225 neurons), while they executed a two-armed bandit reversal learning task, responding with a saccade towards the chosen target. By trial and error, animals associated either screen locations or images with a reward. In each block of 80 trials, one of two images (WHAT blocks) or one of two locations (WHERE blocks) at which the images randomly appeared had a higher reward probability with respect to the other. The block type was randomized and not cued, so the animals had to form a belief about whether WHAT or WHERE determined the reward during each block. Within each block, reward contingencies were reversed at a randomly defined trial within a fixed interval (trials 30-50), requiring the animals to reverse their choice preference. Monkeys were familiar with the existence of two possible block types and that a reversal would occur within each block. Bayesian modeling of the monkeys' choices allowed us to estimate posterior probability distributions for choice reversal across trials, revealing that they used the prior knowledge to detect reversals and quickly update their choice preferences. We found that populations of PFC neurons deliver a signal that peaks sharply during the trial at which the monkey reversed its behavior with a magnitude that is inversely related to the dispersion of the reversal probability distribution. Furthermore, this signal starts to develop after the outcome of the trial before the monkey's reversal. This finding is consistent with model-based/meta-learning processes that have been previously attributed to the PFC. In addition, at the beginning of each block we found a signal that gradually decreased across trials, consistent with the gradual build-up of new information that characterizes model-free learning processes.

Title: Dopamine signals in ventral striatum code reward prediction errors but not cue values in reinforcement learning

Authors: *H. TANG, V. COSTA, R. BARTOLO, A. MITZA, M. ELDRIDGE, B. AVERBECK;
NIH, NIMH, Bethesda, MD

Abstract: Reinforcement learning (RL) refers to the behavioral process of learning from experience to make better choices in the future. Dopamine appears to play a well-known role in RL, coding temporal difference reward prediction errors. However, most of the work on dopamine has focused on tasks that use Pavlovian paradigms and many of the experiments have not examined learning in choice tasks. To examine the role of dopamine in learning in the context of choice, we trained a monkey on a two-armed bandit reversal learning task and measured dopamine signals in the ventral striatum using the genetically encoded dopamine indicator dLight and photometry. In the task, animals repeatedly learned to associate either actions or objects with rewards. At the beginning of each block, we introduced two new visual stimuli that the animal had never seen before. Each block was either a What block, where rewards were associated with images, or a Where block, where rewards were associated with locations. The block type was not cued. The animal had to learn by trial-and-error whether it was a What block or a Where block. There was also a choice-outcome reversal in the middle of the block, which allowed us to examine changes in values for actions or objects. We found that dopamine coded robust RPEs at the time of reward. The dopamine signal was linearly correlated with the positive RPEs but not negative RPEs. All negative RPEs were encoded with a single amplitude change. Furthermore, we found no responses to the cues, except on the first trial of each block, when a new pair of cues was introduced. These results reveal that dopamine signals in ventral striatum code RPEs at the time of reward during learning, consistent with previous studies. However, we do not find cue related value coding at the time of choice. It is possible that cue related dopamine signals develop on a much slower time-scale than learning, which we will examine in future studies.

Title: Quantification of heterogeneous afferent connections across the ventrolateral prefrontal cortex: Functional implications

Authors: *L. R. TRAMBAIOLLI[1], W. TANG[1], S. N. HABER[2];
[1]McLean Hosp. - Harvard Med. Sch., Belmont, MA; [2]Univ. of Rochester, Rochester, NY

Abstract: Human neuroimaging studies report the existence of a rostro-caudal organization of cognitive control processes across the lateral prefrontal cortex (LPFV). The ventral portion of the LPFC (VLPFC) is large (containing BA 44, 45 and 47) and is involved in several functions relevant to cognitive control, such as sensory integration, memory retrieval, stimulus-outcome estimation, and motor inhibition. The aim of this study was to evaluate this rostro-caudal organization using the precision of quantitative neuroanatomy.
We quantified the number of labeled cells in each frontal cortical area following retrograde tracer injections into different VLPFC areas. These values were then converted in percentage scores, to represent the connectivity strength. Then, we performed a correlation clustering analysis, where the inputs strengths from pairs of injections were compared using Pearson's correlation.
All VLPFC sub-regions are highly interconnected. However, there were two main clusters of injection sites based on their inputs from other frontal cortical areas: 1. a rostral cluster composed by injections in areas 45 and 47L; and 2. a caudal cluster including areas 44 and 47L. The rostral vlPFC has strong connections from the orbitofrontal cortex (OFC) and dorsal portion of the LPFC (DLPFC), areas related to goal-directed memory retrieval. The caudal cluster receives strong inputs from the premotor cortex and the frontal eye field (FEF). This suggests that the caudal vlPFC is involved in monitoring both motor behavior and attentional focus. Interestingly, area 47L had the greatest input from the ACC. Thus, we postulate that the information from both clusters is combined in 47L with inputs from the ACC to monitor conflicting information and, consequently, to start motor inhibition or reflexive reorienting behaviors.
Although preliminary, this study adds to the existing imaging literature by using the precision of anatomical methods to describe the rostro-caudal organization of vlPFC connections. The understanding of the VLPFC organization is crucial to identify future targets for invasive or non-invasive psychiatric therapies.

Title: A connectional hub in the rostral anterior cingulate cortex links areas of emotion and cognitive control

Authors: *W. TANG[1], S. JBABDI[2], Z. ZHU[3], M. COTTAAR[2], G. GRISOT[4], J. F. LEHMAN[3], A. YENDIKI[4], S. N. HABER[3];
[1]Basic Neurosci. Div., McLean Hosp., Belmont, MA; [2]Ctr. for Functional MRI of the Brain, Univ. of Oxford, Oxford, United Kingdom; [3]Dept. of Pharmacol. and Physiol., Univ. of Rochester, Rochester, NY; [4]Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: The rostral anterior cingulate cortex (rACC) sits at the crossroads of the brain networks that are associated with emotion, cognition and executive control. An important question is how the composition of inputs to the rACC supports its multiple functional roles. One possibility is that information processing changes sequentially across subregions within the rACC, from emotion/motivation in subregions close to the subgenual ACC, to cognition at the center of the rACC, and then to executive control in subregions close to the dorsal ACC. Alternatively, different functional processing may be integrated in a central location, or hub. Hubs are nodes of a network that have unusually high connectivity to other nodes (degree-centrality) and high connectivity to other hubs (eigenvalue-centrality). Networks in this study are based on anatomical connections, which allows for measurement of degree-centrality only. We thus define the hub according to its high degree of inputs and its position in the network for cross-domain integration.
We investigated afferent inputs from all areas in the frontal cortex (FC) to different subregions in the rACC. Using retrograde tracing in macaque monkeys, we found that the projection from different FC regions varied across injection sites in strength, following different spatial patterns. Importantly, a site at the rostral end of the cingulate sulcus showed strong inputs from many

areas in diverse FC regions. Moreover, it was at the integrative conjunction of three projection trends across sites. This site marks a connectional hub inside the rACC. Tractography with monkey diffusion magnetic resonance imaging (dMRI) located a similar hub region comparable to the tracing result. Applying the same tractography method to human dMRI data, we demonstrated that a similar hub can be located in the human rACC.
Based on the FC areas sending convergent inputs to the hub, dysconnectivity with the hub may be involved in the imbalance between goal directed control, emotion and higher cognition in various disorders. Major depression disorder (MDD) and obsessive-compulsive disorder (OCD) both show treatment response in the rACC activity. The distinction in their pathophysiology lies in the type of networks involved: MDD engages the networks for self-reference and cognitive control, while OCD engages those for reward-driven and goal-directed behaviors. The hub connects a majority of FC areas involved in the above networks, which makes it a site prone to damage in both disorders. The precise pattern of its anatomical connections provides important information for testing the disorder-specific disconnections.

Title: Effects of cortisol reactivity and REM theta activity on emotional memory consolidation

Authors: *S. Y. KIM[1], S. M. KARK[2], R. T. DALEY[2], S. E. ALGER[1], E. A. KENSINGER[2], J. D. PAYNE[1];
[1]Univ. of Notre Dame, Notre Dame, IN; [2]Boston Col., Chestnut Hill, MA

Abstract: Sleep and stress independently have been shown to benefit emotional memory consolidation. In particular, theta oscillations (4-7 Hz) during rapid eye movement (REM) sleep have been linked to coherence in an emotional memory network and enhanced emotional memory. Here, we tested the hypothesis that pre-encoding stress exposure and theta power during REM sleep would interact to predict memory for emotional information. Participants underwent a psychosocial stressor (the Trier Social Stress Task; n = 32) or a comparable control task (n = 32) prior to encoding. Task-evoked cortisol reactivity was assessed by salivary cortisol rise from pre- to post-stressor. Participants in the stress condition were categorized as high or low cortisol responders via median split. During encoding, participants studied 150 negative,

neutral, and positive images. All participants slept overnight in the lab with polysomnographic recording. The next day, they were given a surprise recognition memory task. As predicted, high responders exhibited greater cortisol reactivity relative to both low responders ($t(15.80) = 6.14$, $p < 0.001$) and controls ($t(17.36) = 5.67$, $p < 0.001$). For high responders, REM theta significantly predicted memory for emotional information, specifically for positive items ($b = 0.15$, $R2 = 0.34$, $p < 0.05$). Notably, for low responders and controls, there was no relationship between theta and memory of any valence. These findings provide initial evidence that events occurring at encoding, and accompanying changes in neuromodulators such as cortisol, and theta activity during REM sleep may interact to promote selective consolidation of emotional information during sleep.

Title: Medial prefrontal cortex plays a causal role in selectively enhancing consolidation of emotional memories: A TMS-EEG study

Authors: *N. YEH[1], N. S. ROSE[1], J. D. KOEN[1], S. Y. KIM[1], E. A. KENSINGER[2], J. PAYNE[1]; [1]Univ. of Notre Dame, Notre Dame, IN; [2]Dept Psychol, Boston Col., Chestnut Hill, MA

Abstract: Emotional aspects of episodic memory are preferentially benefited at the expense of co-occurring neutral aspects. This is known as the emotional memory trade-off effect, which is enhanced over consolidation delays that include a period of sleep. Previous research implicates an association between retrieval-related activity in medial prefrontal cortex (mPFC) and memory for emotional (versus neutral) stimuli following a night of sleep. Moreover, sleep often exerts its strongest effects on gist-based memory, rather than recollection of specific details. However, it is not clear how mPFC activity during encoding interacts with consolidation processes to enhance emotional aspects of memories after a night of sleep. This study aimed to provide a causal link between mPFC activity during encoding and the enhancement of emotionally salient aspects of episodic memory. Healthy young adult participants incidentally encoded 128 scenes comprised of negative (e.g. snake) or neutral (e.g. chipmunk) objects placed on plausible neutral backgrounds (e.g. forest scene) while undergoing simultaneous TMS and EEG recording during a memory encoding phase. One group of participants ($N = 23$) received 2s trains of intermittent theta burst stimulation (iTBS) to the mPFC (i.e., experimental condition) whereas the other group ($N = 21$) underwent an identical iTBS protocol with a left motor cortex target (i.e., active

control condition). iTBS was conducted at 80% of active motor threshold. Recognition memory for the objects and backgrounds was assessed at two delays (i.e., 30 minutes, 24 hours). The test items included identical studied objects and backgrounds (same), similar but not identical to old items (similar), or entirely new items (foil). Consistent with our hypothesis, iTBS to the mPFC led to enhanced gist memory for negative objects following a 24 hour delay that included sleep compared to active control stimulation, despite equivalent false alarms rates and self-reported emotional ratings (i.e., arousal, valence). Because these findings did not emerge following a short 30 minute delay, they suggest that iTBS to the mPFC during encoding may interact with subsequent consolidation processes to selectively preserve the gist of negatively salient information.

Title: Neural representations underlying acquisition of category knowledge

Authors: *C. R. BOWMAN, D. ZEITHAMOVA;
Univ. of Oregon, Eugene, OR

Abstract: Healthy memory function involves both the ability to remember details of specific past events and the ability to link across related events to create knowledge that generalizes to new situations. Both of these functions have been linked to the hippocampus, with substantial debate about how they relate to one another. Some have posited that generalization judgments involve joint retrieval of multiple individual episodes, and that better memory for specific instances leads to better generalization. Others have posited a trade-off between memory for individual events and formation of generalized representations, which may lead to poorer generalization when related events are coded more distinctly. In the present study, we aimed to test the relationship between encoding of individual items and subsequent generalization performance in a category-learning task. While undergoing fMRI, 31 subjects completed observational training where they learned to classify cartoon animals into two species. Following training, participants were tested on their ability to generalize category labels to new examples. Behavioral results showed generalization performance that was well above chance, but not as good as classification of old (training) items. Using representational similarity analyses, we

measured the strength of item representations during training as the neural pattern similarity for repetitions of the same item compared to pattern similarity for items in the same category. In the hippocampus, we did not find reliable item representations when averaging across the group. However, we found that individuals who showed item representations in the posterior hippocampus showed poorer subsequent generalization. Cortical regions showing significant item representations across the group included fusiform, lateral occipital and lateral parietal cortices. Lateral occipital and superior parietal cortices showed a similar pattern to the posterior hippocampus, with a numerically negative relationship between the strength of item representations and subsequent generalization. Other regions with item-specific representations (fusiform, inferior parietal) showed no evidence of a relationship between the strength of item representations and generalization. No region tested showed a positive relationship between the two measures. Together, results show that some regions can form highly specific representations without affecting later generalization. Elsewhere, including in the posterior hippocampus, there may be a trade-off between distinctive encoding of individual items and the subsequent ability to generalize.

Title: Generalized memory representations emerge across paired-associate training

Authors: *S. R. ASHBY, C. R. BOWMAN, D. ZEITHAMOVA;
Psychology, Univ. of Oregon, Eugene, OR

Abstract: Memory studies typically focus either on memory for individual experiences (specificity) or the ability to link information across events (generalization). However, experiences in daily life are rarely separated into specificity vs. generalization tasks. Instead, we have to make different judgments based on the same experiences. Do we spontaneously extract generalized knowledge even when the task at hand demands specificity? We assessed behavioral and neural measures of memory specificity and generalization during a task where participants learned face-name associations. To create an incidental category structure, face stimuli were constructed as 50/50 blends of never-seen “parent” faces. Three parent faces were selected to determine category membership (family names Miller, Wilson, Davis) and blended with other parent faces to create multiple family members. Each blended face was assigned a unique first

name and participants were instructed to memorize the full name for each face while undergoing fMRI. Behavioral results showed that participants successfully remembered specific faces but were also able to generalize last names to new faces. Neural pattern similarity analyses were used to examine evidence for representations of individual faces (i.e. similarity for repetitions of the same face vs. faces within the same family) and representations of family categories (i.e. similarity for repetitions of faces within the same family vs. faces that share a parent but are from different families). Results showed evidence for representations of individual faces in occipital and parietal cortices early in training. These same regions, as well as frontal cortex, showed representations of family categories, but only later during training. Within the hippocampus, representations for individual faces predicted performance on measures of memory specificity but not generalization. These results demonstrate that multiple types of memory representations may form and coexist for the same experiences to support a range of decisions.

Title: Eye fixation frequency affects visual episodic memory

Authors: *B. FEHLMANN, D. COYNEL, N. SCHICKTANZ, A. MILNIK, P. HOFMANN, L. GSCHWIND, A. PAPASSOTIROPOULOS, D. J. DE QUERVAIN;
Univ. of Basel, Basel, Switzerland

Abstract: Visual memories fundamentally depend on visual input. It is unclear, however, if eye fixation frequency during encoding affects memory strength. First, we identified individual memory-related scanning characteristics by collecting eye tracking data in a picture encoding task performed by 967 healthy subjects. We found a positive correlation between fixation frequency in semantically informative regions and subsequent free recall and recognition performance. fMRI results indicate a positive correlation of the number of such fixations with functional brain activation in regions related to vision and memory, including the medial temporal lobe. In a further experiment, we manipulated the visual scanning pattern in 64 subjects within a given exploration time. We thereby disentangled two distinct causal mechanisms underlying the exploration-memory relationship: While both increasing fixation frequency and the sampling of semantic regions positively affected free recall, only the latter affected passive recognition. Since successful recognition can be achieved by familiarity, the findings suggest

that eye fixation frequency during encoding visual information primarily affects episodic aspects of memory. Our results have important implications. First, they indicate the importance of measuring eye movements in visual memory studies. Second, altered scanning characteristics that are often observed in neuropsychiatric conditions may contribute to the memory deficits that are also frequently observed in these conditions.

Title: Spared perception of the structure of scenes after hippocampal damage

Authors: *Z. J. URGOLITES[1,2], R. O. HOPKINS[5,6], L. R. SQUIRE[1,2,3,4];
[1]Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [2]Dept. of Psychiatry, [3]Dept. of Neurosciences, [4]Dept. of Psychology, UCSD, La Jolla, CA; [5]Dept. of Psychology & Neurosci. Ctr., Brigham Young Univ., Provo, UT; [6]Dept. of Med., Pulmonary and Critical Care Division, Intermountain Med. Ctr., Murray, UT

Abstract: To explore whether the hippocampus might be important for certain spatial operations in addition to its well-known role in memory, we administered two tasks in which participants judged whether objects embedded in scenes or whether scenes themselves could exist in 3D space. Patients with damage limited to the hippocampus performed as well as controls in both tasks. A patient with large medial temporal lobe lesions had a bias to judge objects in scenes and scenes themselves as possible, performing well with possible stimuli but poorly with impossible stimuli in both tasks. All patients were markedly impaired at remembering the tasks. Thus, the hippocampus appears not to be essential for judging the structural coherence of objects in scenes or the coherence of scenes. The results are in accord with earlier findings that the hippocampus is not needed for a variety of spatial tasks and emphasize the importance of the hippocampus for memory. Interestingly, other patients have sometimes been reported to be disadvantaged by spatial tasks such as the ones studied here, despite less hippocampal damage and milder memory impairment. It seems unlikely that these impairments are due to hippocampal damage itself.

Title: Neural pattern similarity is moderated by age and subsequent memory in scene-selective but not face-selective cortical regions

Authors: *S. SROKOVA[1], P. F. HILL[1], J. D. KOEN[2], D. R. KING[1], M. D. RUGG[1];

Abstract: The aging brain is characterized by decreased selectivity and reduced functional specialization in category-selective cortical regions. These age differences in cortical selectivity have been proposed to play a causal role in cognitive aging. In this experiment, young and older adults underwent fMRI as they studied words paired with images of faces or scenes prior to a subsequent memory test. We employed multivoxel pattern similarity analysis to identify age differences in category-selective neural pattern similarity under the assumption that reduced cortical selectivity would be reflected in lower category-selective similarity. Using univariate analyses, we identified three scene-selective (Parahippocampal gyrus, Middle Occipital gyrus, Retrosplenial cortex) and four face-selective (Fusiform gyrus, Medial Prefrontal cortex, Precuneus, Medial temporal lobe) regions-of-interest (ROIs). The similarity index for a given ROI was operationalized as the difference between average trial-wise within-category and between-category correlations. We identified lower similarity indices in older adults for scene stimuli in all three scene-selective regions, but minimal evidence for age differences in similarity indices for faces in face-selective ROIs. The indices from the scene-selective ROIs were further analyzed as a function of age group and subsequent memory performance, where study items were binned according to whether or not the words went on to receive a source correct memory judgment for their associated image category (face vs. scene). A 2 (Age group) x 3 (Scene-selective ROIs) x 2 (Subsequent memory) ANOVA identified a significant 3-way interaction. This was driven by greater similarity indices for source correct trials relative to incorrect trials in younger adults, especially in retrosplenial cortex and middle occipital gyrus, while no such effects were evident in older adults. An analogous analysis with face-selective ROIs did not reveal moderating effects of age or subsequent memory on neural pattern similarity. These results suggest that older adults show less precise neural representations for scenes and that the moderating effects of age and subsequent memory are category- and regionally-specific.

Title: Differential effects of age and task load on the neural correlates of retrieval monitoring revealed by modulation of univariate fMRI BOLD amplitude and functional connectivity

Authors: *E. D. HORNE, M. DE CHASTELAINE, M. D. RUGG;
The Ctr. for Vital Longevity and Behavioral and Brain Sci., Univ. of Texas At Dallas, Dallas, TX

Abstract: We investigated the impact of a dual task manipulation during associative retrieval on the neural and behavioral correlates of post-retrieval monitoring in a sample of 28 older (65-75 years) and 28 younger (18-30 years) adults. Participants completed an associative recognition task (intact/rearranged/new decision to word pairs) in the MRI scanner. Low (400 Hz) and high (900 Hz) pitch tones played continuously during retrieval, and participants alternated between ignoring tones during single task blocks and responding to occasional target tones during dual task blocks. Consistent with our pre-experimental predictions, older adults' associative memory performance was significantly lower under dual relative to single task conditions due to an elevated false alarm rate. Post-retrieval monitoring effects (difference in BOLD signal for test pairs judged rearranged vs intact) in bilateral dorsolateral prefrontal cortex (DLPFC) and anterior cingulate cortex (ACC) were attenuated for younger adults under dual relative to single task conditions. By contrast, older adults' monitoring effects were smaller than younger adults' during single task blocks, but were not significantly modulated by the dual task manipulation. We interpret these results as consistent with the CRUNCH model introduced by Reuter-Lorenz and Cappell (2008). Whereas dual task demands were required to deplete frontal resources supporting monitoring in younger adults, in older adults the mere requirement to ignore tones in single task blocks was seemingly sufficient to deplete resources otherwise available to support monitoring. Despite this age-related difference in the modulation of monitoring effects by the dual-task manipulation, psychophysiological interactions (PPI) analyses revealed age- and task-invariant increases in connectivity between left and right DPLFC and ACC and bilateral occipital cortex, and between the DLPFC and left intra-parietal sulcus. We interpret these latter findings as evidence that post-retrieval monitoring entails interactions both between prefrontal cortex and

posterior cortical regions participating in the representation of retrieved content, as well as between the different members of the 'fronto-parietal control network'. These inter-regional interactions appear to be relatively impervious to the effects of task-demands or age.

Title: Age-invariant, overlapping pre- and post-stimulus subsequent memory effects in dorsal medial prefrontal cortex

Authors: *E. S. LIU[1], J. D. KOEN[2], M. D. RUGG[3];
[1]Univ. of Texas At Dallas, Dallas, TX; [2]Univ. or Notre Dame, Notre Dame, IN; [3]Ctr. for Vital Longevity, Univ. of Texas at Dallas Ctr. for Vital Longevity, Dallas, TX

Abstract: Decline in episodic memory performance with increasing age has been attributed in large part to ineffective encoding. Here, we asked whether age differences in the neural correlates of episodic encoding are evident in *pre-stimulus subsequent memory effects* (preSMEs) - differences in neural activity preceding the onset of a study item that are predictive of later memory performance. It has been proposed that preSMEs reflect differential engagement of preparatory processing in anticipation of the upcoming study item. In light of evidence that older adults are, in general, less likely to engage proactive processing, we predicted that preSMEs would be attenuated in older adults relative to young participants. Healthy young and older adults (Ns=28) underwent fMRI while performing a study task requiring one of two judgments (size or location) on images of objects. A pre-stimulus cue signaling the nature of the study judgment was presented prior to the study item. The cue-stimulus interval was jittered to allow deconvolution of pre- and post- stimulus activity. In a subsequent test phase outside the scanner participants performed a recognition memory test for the objects and, for any object judged old, a source memory test for the study task. A 2 (Age group) x 3 (correct subsequent source judgment, correct item judgment only, item missed) ANOVA and follow-up analyses identified a region of dorsal medial prefrontal cortex (dmPFC) where the pre-stimulus BOLD signal varied inversely with memory strength: lowest for items subsequently attracting a correct source judgment, intermediate for item correct only, and greatest for subsequently missed. This 'negative' preSME did not differ in magnitude between the age groups. Post-stimulus SMEs were evident in numerous regions; importantly, these included the same dmPFC region that

manifest the aforementioned preSME. This post-stimulus effect was negative, consistent with prior reports of negative SMEs in this region. These findings suggest that negative SMEs in the dmPFC onset prior to the presentation of a study item, and hence that the region might play a role in preparatory processes that facilitate encoding. Contrary to our prediction, the findings provide no evidence that these processes differ according to age.

Title: A phenomenological model of power-law forgetting

Authors: *A. GEORGIOU, M. KATKOV, M. TSODYKS;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Persistence of information with time in the brain, or in other words memory, is a necessary condition for higher cognitive abilities. Due to the state of the world being in constant flux, with its inherent uncertainty, the ability to discard no longer relevant information is equally important. The process of forgetting, i.e the transient nature of memory, is hypothesized to be essential for adaptive behavior. A number of experiments under the realm of psychology and neuroscience over the past hundred years have showcased that forgetting occurs in a power-law manner, reflecting the fact that the probability that a piece of information is retained, is a decaying function of its age. Most theoretical models of memory however, utilizing forgetful learning rules, like memory palimpsests, treat forgetting as a linear process in time, with older memories being more likely to be forgotten than newer ones, which is not compatible with power-law retention. We have devised a phenomenological model that encapsulates the statistics of forgetting observed experimentally which we solved analytically. It is an implementation of retroactive interference, where newly acquired memories disrupt already stored ones, based on the salience of incoming items, formalized as a numerical value. When an element is commited, it acts on older memories, discarding those that have a lower value. We can expand this notion into n-dimensions considering multiple axes of importance for each element, requiring the above rule to be true in every axis for an item to be forgotten. An analytic solution exhibits power-law forgetting with the prefactor depending on the number of dimensions. Furthermore, we conducted two-alternative forced choice recognition experiments utilizing Amazon's mTurk platform, thus ascertaining the compatibility of our model to experimental data. Participants were presented with a stream of words sequentially, and at random points during the trial they were asked to select between a lure word and one of the first twenty five words presented, in order to

establish the relationship between memory recognition and its age. The results show a retention curve that is closely approximated by the model, posing it as a valid candidate of a forgetting mechanism.

Title: Free recall of common facts

Authors: ***M. KATKOV**, M. NAIM, M. V. TSODYKS;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: A classical way of studying human episodic memory is free recall of randomly assembled words, where participants are presented with a list of words and are requested to report as many words as they could. Many experimental studies highlighted the main characteristics of this phenomenon: recency, higher probability to recall recently presented words; primacy, better recall of words in the beginning of list; contiguity, tendency to recall in temporal proximity words that were presented in temporal proximity. It was also observed that the number of words recalled depends sub-linear with the list length. In order to understand the generality of these phenomena to different types of information rather than single words, we performed recall experiments with lists of short sentences expressing unrelated common facts. We took advantage of the Amazon Mechanical Turk (R) platform, to perform experiments over the internet, with the pool of about 300 facts assembled specifically for this project. Interestingly, the number of facts recalled was similar to those of random words, for same list length. We also observed similar contiguity curve for facts and words. However, we observed that there was practically no recency effect in the recall of facts. Our results suggest that facts operate as units in free recall similar to words.

Title: Epilepsy patients with verbal memory deficits demonstrate differential transcript expression in the temporal lobe compared to those with intact memory

Authors: *R. M. BUSCH[1], L. YEHIA[1], M. SEYFI[1], I. BLUMCKE[2], B. HERMANN[3], I. NAJM[1], C. ENG[1];
[1]Cleveland Clin., Cleveland, OH; [2]Inst. of Neuropathology, Univ. Hosp. Erlangen, Erlangen, Germany; [3]Univ. of Wisconsin, Madison, WI

Abstract: Temporal lobe epilepsy (TLE) is the leading cause of seizure disorders in adults and is associated with a high risk for memory deficits. While a host of demographic and disease-related variables have been associated with episodic memory dysfunction in TLE, a substantial proportion of the variance in memory performance remains unexplained. The objective of this pilot study was to compare the brain transcriptome between patients with and without verbal memory impairments to identify genes and signaling networks important for episodic memory. We performed RNA-seq of total RNA extracted from brain tissues originating from 23 adults who underwent dominant temporal lobectomy for treatment of pharmacoresistant epilepsy. Patients were classified as having “reduced” or “intact” memory based on preoperative performance on measures of list learning and story recall. To control for potential effects of *APOE ε4* or *APOE ε2* on memory, only those homozygous for the *APOE ε3* allele were included. The two memory groups were well-matched on demographic and disease-related variables. Following standard quality control, we performed differential expression analysis using NOISeq-sim algorithm. We identified differentially expressed genes (DEGs) between the memory groups followed by pathway enrichment analyses using the clusterProfiler R package. Overall, we identified 135 unique DEGs between patients with and without memory impairments. The majority of DEGs (96 of 135; 71%) were underexpressed in the memory impaired group compared to the intact memory group. Gene ontology (GO) enrichment analyses identified multiple biological processes relevant to neuronal function, including cell growth, neuronal apoptosis, microtubule polymerization or depolymerization, and axonal transport of mitochondria. Similarly, GO cellular components were enriched for neurological and immune-related terms, including dendritic spine, neuron spine, neuron projection cytoplasm, axon cytoplasm, glial cell projection, and MHC protein complex. Our observations indicate that TLE-

associated memory function/dysfunction may be influenced by differences in gene expression profiles within the temporal lobe, particularly in genes implicated in neuronal-related pathways.

Title: Effects of HD-tDCS on item and associative encoding are modulated by individual differences in self-reported side effects of stimulation

Authors: *A. M. GAYNOR[1], E. F. CHUA[2,3];
[1]Mem. Sloan Kettering Cancer Ctr., New York, NY; [2]Dept. of Psychology, Brooklyn Col., Brooklyn, NY; [3]The Grad. Center, CUNY, New York, NY

Abstract: Previous research has shown that the dorsolateral prefrontal cortex (DLPFC) plays a role in associative encoding, whereas the anterior prefrontal cortex (aPFC) is involved in the subjective confidence in one's own encoding success. It remains unknown whether these regions differ in their causal contributions to subjective and objective encoding for items as compared to associations. We applied 2mA of high-definition transcranial direct current stimulation (HD-tDCS) over the aPFC, DLPFC, and sham stimulation while subjects studied 100 word pairs. For each pair, subjects also made a Judgment of Learning (JOL), a memory monitoring judgment in which subjects judge their ability to accurately recognize each word pair at later test. Twenty-four hours later, subjects were tested on 150 pairs of words that were identified as "intact", "rearranged", or "new". Repeated measures ANOVAs on preliminary data (n=14) showed no effect of stimulation on the magnitude or accuracy of JOLs, and no significant effects on corrected associative or item recognition. Separate analyses of the side effects of stimulation (e.g. scalp tingling, burning sensations, and trouble concentrating) showed greater intensity of scalp sensations, but less trouble concentrating during aPFC stimulation compared to other stimulation conditions. To control for this, multilevel models with individual differences in head size, gender, age, and side effects of stimulation showed effects of stimulation on memory. Specifically, for associative memory, aPFC stimulation impaired associative encoding relative to sham ($p<0.01$) and DLPFC stimulation ($p<0.05$), whereas for item memory, both aPFC and DLPFC stimulation impaired encoding of individual items compared to sham ($p<0.001$). Scalp tingling, burning sensations, headache, and trouble concentrating during encoding also predicted

both associative and item recognition; greater intensity of these side effects was associated with poorer associative recognition performance under sham and DLPFC stimulation, but greater burning, tingling, and scalp pain were associated with better associative recognition following aPFC stimulation. For item recognition, greater intensity of side effects was associated with better memory for items across all stimulation conditions, but the correlation between side effects and recognition was strongest under aPFC stimulation. These results suggest HD-tDCS over the aPFC impaired encoding, but stimulation-related side effects may have induced a cognitive placebo effect whereby subjects' overall encoding under aPFC was similar to the DLPFC and sham sessions, perhaps due to increased arousal and attention.

Title: The subsequent memory effects of associative memory before and during memory encoding period of scalp EEG

Authors: *D. KIM[1], W. JEONG[3,4], J. KIM[2], C. CHUNG[1,3,4];
[1]Dept. of Brain and Cognitive Sci., [2]The Res. Inst. of Basic Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Dept. of Neurosurg., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [4]Neurosci. Res. Inst., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: *Introduction:* The previous studies have shown that the success or failure of the memory can be predicted by the brain state either before or during memory encoding period. These brain states which called subsequent memory effects (SMEs) have been widely studied using fMRI modality. Those previous studies reported that neocortical brain areas (e.g., posterior parietal cortex, PPC) in addition to medial temporal areas contribute to successful episodic memory encoding. However, due to the low time resolution of fMRI, SMEs change over time can not be investigated. Here, we investigated the SMEs of the word and scene association task before or during the of the encoding period using scalp-EEG.
Methods: Eleven right-handed healthy subjects (4 females, 23 to 31 years old) were recruited. During the encoding period, the subjects were instructed to associate word-picture pairs by generating mental images. During the retrieval period, subjects were asked to recall the word cued by the scene presented. We investigated the differences in EEG activity during pre-stimulus period and encoding period between subsequently remembered and forgotten events through the

time-frequency analysis (alpha, beta and theta band).
Results: In the pre-stimulus period (-200~0 ms), there was stronger beta (14-30 Hz) power over electrodes in right PPC to subsequently remembered stimuli than to those forgotten. In the memory encoding period (200~400 ms), more increased theta (3-7 Hz) power over frontal midline and electrodes in right PPC was observed in remembered stimuli than forgotten stimuli.
Conclusions: In the present study, we found cortical contribution of successful episodic memory period using scalp-EEG. Interestingly, similar to the fMRI results, we also found the contribution of PPC on successful memory encoding process. Specifically, we found that beta power was increased before encoding period, which could reflect inhibition of task irrelevant information, and theta power was increased during encoding period, which is common feature of SMEs. In the future, our results could be used to prediction of memory success by utilizing SMEs according to the memory period, especially activities in PPC or midfrontal areas.

Title: Contributions of semantic relatedness, distinctiveness, and emotion to enhanced emotional memory: An event-related potential study

Authors: V. C. ZARUBIN[1], T. K. PHILLIPS[2], E. G. ROBERTSON[2], *K. R. MICKLEY STEINMETZ[2];
[1]Univ. of California, Davis, Sacramento, CA; [2]Wofford Col., Spartanburg, SC

Abstract: Traditionally the enhanced emotional memory (EEM) effect has been explained by emotionality leading to enhanced processing for emotional stimuli. Some literature, however, suggests that the relative difference in memory between emotional and neutral stimuli may actually be due to an interruption in processing neutral stimuli when presented with emotional stimuli (Watts, Burrato, Brotherhood, Barnacle, & Schaeffer, 2014). Further, instead of emotion itself, confounding factors such as semantic relatedness or distinctiveness of emotional items may have a significant role in leading to these memory enhancements (Talmi, Luk, McGarry, & Moscovitch, 2007). The present study sought to examine whether the reduction in event related potential (ERP) differential memory (Dm) activity was best accounted for by emotion or by the inherent semantic category of emotional stimuli. To do so, ERPs were recorded while participants were presented with three types of images: negative images, semantically related neutral images, and unrelated neutral images. These images were presented in either mixed lists, composed of all three image types mixed together, or pure lists, composed of one type of image

per list. Immediate recall performance was used to bin images into remembered and forgotten categories for Dm analysis of ERPs. Behavioral results indicated that negative images were best recalled overall. Further, semantically related neutral images were better remembered than unrelated neutral images. ERP results help to explain this behavioral effect: negative and unrelated neutral in mixed lists had a stronger Dm effect than in pure lists, suggesting that an item's distinctiveness in mixed lists provides an advantage at encoding. In contrast, related neutral images, though recalled better than unrelated neutral images, showed a diminished Dm effect. Thus, while distinctiveness influences encoding, relatedness may be more likely to exert its influence at retrieval.

Title: Novelty influences coupling across multiple learning systems during post-task rest

Authors: *M. R. FAIN[1], I. O'SHEA[2], I. C. BALLARD[3], L. ELLMAN[1], V. P. MURTY[4]; [1]Temple Univ., Philadelphia, PA; [2]Northeastern Univ., Boston, PA; [3]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [4]Psychology, Dr., Philadelphia, PA

Abstract: Fundamental to adaptive behavior is the ability to detect, learn about, and respond to change in the environment. Hippocampal novelty responses signal environmental change and predict neural and behavioral adjustments to it. Rodent work has shown that novelty can induce dopamine release (Lisman and Grace, 2005), a neuromodulatory system known to facilitate plasticity across multiple learning systems. Dopamine has been shown to enhance plasticity in both the procedural learning system centered on the dorsal striatum and the episodic learning system centered on the hippocampus (Shohamy and Adcock, 2010). However, the extent to which novelty facilitates interactions across these learning systems remains relatively unknown. Prior work suggests that the dorsal striatum and hippocampus are competitive during learning, thus proposing that novelty may facilitate an inverse relationship across these systems. Alternatively, novelty can simultaneously engage both the dorsal striatum and hippocampus, suggesting that novelty facilitates a positive relationship across these regions. To arbitrate between these hypotheses, we collected fMRI data during which participants completed a

resting-state scan, and then performed a target-detection task wherein participants were exposed to novel and previously familiarized trial-unique stimuli. Following this task, participants completed a post-novelty resting-state scan (N=12). We compared changes in functional coupling between the hippocampus and dorsal striatum during rest periods before and after exposure to novelty. We found a trend towards greater functional coupling between the hippocampus and dorsal striatum during post-novelty rest compared to pre-novelty rest ($p<0.06$). These preliminary findings suggest that there is a facilitation of information processing across the dorsal striatum and the hippocampus following exposure to novelty.

Title: Differential effects of visuospatial interference on consolidation of emotional and neutral episodic-like memory in virtual reality

Authors: *S. FLASH, S. BARHOUM, J. DENGLER, K. SHAH, V. CASTILLO, G. HANSON GOTTHARD;
Muhlenberg Col., Allentown, PA

Abstract: The working memory capacity theory of memory consolidation proposes that visuospatial interference tasks (VSI; e.g., Tetris) can disrupt memory consolidation by overloading working memory stores. Virtual reality (VR) was used to examine working memory capacity theory in the context of emotional and neutral information. VR is a valuable tool because it provides users with a highly immersive experience that produces more realistic episodic-like memories (Sauzeon et al., 2012). Experiment 1: Participants (n=68) consisted of undergraduate students from Muhlenberg College. Groups played either Job Simulator (n=40; emotionally-stimulating auto mechanic role playing game - PlayStation 4 VR system) or Venice (n=28; emotionally-neutral gondola tour in Venice during which a tour guide describes scenes along a canal - Oculus Rift VR system). Following the game, participants spent 10 minutes completing a visuospatial interference task (n=34; i.e., the computer game Tetris) or a control task (n=34; i.e., basic multiplication problems). Participants then completed a free recall test, a cued recall test, and a recognition test. Significant differences were observed for free recall [$F(3,64)=6.7$, $p=.001$, partial $\eta^2=.24$]. The Tetris/Job Simulator group had significantly lower free recall scores than Tetris/Venice ($p=.002$], Control/Job Simulator ($p=.006$), and Control/Venice ($p<.001$). No significant differences were observed between groups on cued

recall [F(3,64)=1.1, p>.05] or recognition [F(3,64)=0.1, p>.05].
Experiment 2: Participants (n=17) consisted of undergraduate students from Muhlenberg College. Groups played Ritchie's Plank Experience (n=17; highly emotionally-stimulating game in which participants ride an elevator to the top of a tall building and walk out onto a plank - Oculus Rift VR system). Following the game, participants spent 10 minutes completing a VSI task (n=8; i.e., the computer game Tetris) or a control task (n=9; i.e., basic multiplication problems). Participants then completed a free recall test, a cued recall test, and a recognition test. Tetris produced marginally significant reductions in free recall [t(15)=-2.02, p=.06, d=.97] and statistically significant declines in recognition [t(15)=-2.8, p=.014, d=1.34]. No differences were observed for cued recall [t(15)=-.3, p>.05]. The present studies demonstrated that a VSI task (i.e., Tetris) was able to decrease free recall of emotional episodic-like memory but not neutral episodic-like memory. Less impairments were seen in tasks that provided cues (e.g., cued recall), which may support a retrieval failure interpretation (Gisquet-Verrier et al., 2015).

Title: Oscillatory activity supports contextual binding in young and old adults

Authors: *A. E. KARLSSON, M. C. SANDER;
Ctr. for Lifespan Psychology, Max-Planck Inst. For Human Develop., Berlin, Germany

Abstract: Reinstatement of the learning context during retrieval boosts memory performance. Although old adults benefit from context reinstatement, they have more difficulties retrieving the specific item-context association as compared to young adults. To better understand these age differences, we investigated the neural mechanisms of memory formation for item and context information in young (n=49, 20-30 years) and old (n=43, 65-75 years) adults. Participants were familiarized with pictures of objects and outdoor scenes in a pre-learning fMRI session. Then, while EEG data was recorded, participants performed an item-context binding task during which they imagined using the presented object in the context depicted by an outdoor scene shown as background. Subsequently, all objects were presented again in a post-learning fMRI session. Finally, in a surprise memory test, participants discriminated between old and new objects. Old objects were either presented on the same background as during the learning phase or on a different background. New items were presented either on an old or a new background. Participants had to judge whether the item was old or new followed by a judgment on whether

the item-context pairing was old or new. We computed corrected recognition scores to assess the effect of context reinstatement on item retrieval. Item memory performance did not differ between age groups, and both groups benefited from context reinstatement. However, as predicted, pair memory was reduced in old compared to young adults. Time-frequency analysis of the EEG data was performed to investigate the neural underpinnings of contextual memory formation. A positive subsequent memory effect (SME) was found in the theta band between 0-600 ms and a negative SME in the alpha band between 0-3000 ms. Whereas the theta SME may reflect the associative strength between an item and its context, alpha band SME may indicate the depth of elaboration contributing to successful memory formation. Accordingly, only the theta SME varied by later context reinstatement. These effects were larger in older than in younger adults. We are currently relating the behavioral context effects with the neural SME and learning-related changes in neural patterns of item representations in the hippocampus, as measured with fMRI. Thus, we will provide novel insights into the neural substrates of contextual binding in young and old adults.

Title: Reward motivation during encoding influences free recall accuracy and dynamics

Authors: *E. A. EBERTS[1], B. KATERMAN[1], S. DUBROW[2], V. P. MURTY[1];
[1]Psychology, Temple Univ., Philadelphia, PA; [2]Psychology, Univ. of Oregon, Eugene, OR

Abstract: Reward motivation reliably influences memory encoding to benefit the storage of high value information in long-term memory (Murty & Adcock, 2017). Previous investigations of reward memory have mostly focused on accuracy, but the influence of reward on memory organization remains unclear. There are two contexts by which information is typically organized: temporal (associations formed during a learning episode for items studied nearby in time) and semantic (long-standing associations between word meanings). This investigation aimed to characterize how reward motivation influences free recall accuracy as well as the use of temporal and semantic contexts for memory organization. In the current study, 59 participants learned pure word lists that were associated with either high or low reward for successful memory. Memory was tested using a free recall paradigm immediately and after 24 hours. Here, we report the 24-hour data. Results show better long-term recall for high value versus low value words ($p < .01$), suggesting that individuals have greater access to valuable information during retrieval. There was also a trend towards greater temporal clustering among high value words (p

= .095), suggesting that individuals re-instate the original encoding experience to structure the retrieval of valuable information. Interestingly, there was no effect of reward on semantic clustering (p = .69). These findings extend prior models of reward memory to include how reward changes the structure of memory organization. In future studies, we will use a mixed list design in order to determine whether individuals may also use reward value to organize memories (i.e., cluster information based on high and low reward, rather than temporal context).

Title: Heart (EKG) and brain (ERP) activity as predictors of subsequent memory for emotional images

Authors: *T. J. BUNGE[1], P. G. BOLTON SWAFFORD[1], D. P. AGUILLARD[1], V. C. ZARUBIN[2], C. M. MARTSBERGER[1], K. R. MICKLEY STEINMETZ[1];
[1]Wofford Col., Spartanburg, SC; [2]Univ. of California, Davis, Sacramento, CA

Abstract: Negative information is often remembered better than neutral information. However, it is difficult to determine if this is solely due to the emotional nature of negative stimuli, as results are often confounded by negative stimuli being more interrelated and more distinctive than neutral comparison images. To investigate differences in emotional response systems in the brain and the sympathetic nervous system, heart rate and event related potentials (ERPs) were recorded while participants viewed three types of images: negative images, semantically related neutral images, and unrelated neutral images. These images were presented in either mixed lists, composed of all three image types mixed together, or pure lists, composed of one image type per list. Participants completed immediate recall tests following the presentation of each list. Participants remembered negative images more often than both related and unrelated neutral images. Related neutral images were better remembered than unrelated neutral images. For mixed lists, heart rate increased significantly more in response to negative images than for either type of neutral image. Notably there was no heart rate increase at all for related neutral images. For pure lists there were relatively few differences in heart rate between emotion categories. When investigating the ERP data, subsequent memory effects (Dm) were not found for related neutral images. This suggests that both emotion and distinctiveness (mixed lists) can boost sympathetic response and encoding activity. However, the memory boost found for related neutral stimuli relative to unrelated neutral stimuli can likely be attributed to processes at retrieval.

Title: Neural implementation of behavioral models of working memory tasks

Authors: *Z. TIGANJ, N. A. CRUZADO, M. W. HOWARD;
Dept. of Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: Constrained by results from classic behavioral experiments we provide a neural-level cognitive architecture for modeling behavior in working memory tasks. We propose a canonical microcircuit that can be used as a building block for working memory, decision making and cognitive control. We show that this type of cognitive architecture can account for results in behavioral experiments such as judgment of recency, probe recognition and delayed-match-to-sample. In addition, the neural dynamics generated by the cognitive architecture provides a good match with neurophysiological data from rodents and monkeys. For instance, it generates cells tuned to a particular amount of elapsed time (time cells), to a particular position in space (place cells) and to a particular amount of accumulated evidence.

Title: Pseudo-reward processing during human reinforcement learning

Authors: *S. D. MCDOUGLE, A. G. E. COLLINS;
Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Human reinforcement learning (RL) theory is built around two primary psychological variables - a value function and the reward prediction error that updates it. In human RL experiments, rewards themselves are often defined a priori, via explicit cash incentives, “points” exchanged for money, or subject-rated appetitive stimuli (e.g., food preferences). Because of this, a key variable of RL, the reward function, is usually pre-specified, and the value function is then estimated. However, in the real world, humans often need to specify their own reward functions. For instance, when learning how to make a cappuccino, one should be incentivized to achieve the correct coarseness when grinding the beans, even though this particular step is abstracted from the primary rewards of the task (e.g., caffeine). Here, we ask how abstract “pseudo-rewards” and concrete primary rewards are leveraged during RL, and if they are similarly processed in the brain. Human subjects performed a probabilistic learning task while undergoing fMRI. In this task, subjects had to learn which of two arbitrary choice stimuli was more likely to yield reward. Two conditions were intermixed during learning: pseudo-reward and primary-reward. In the pseudo-reward condition, correct trials were cued by arbitrary fractal stimuli that were specified every trial. In the primary-reward conditions, money-like points were given after correct trials, unambiguously signaling rewards. Subjects performed well in the task in both conditions, though expressed a slower learning rate in the pseudo-reward condition. Moreover, their performance on an independent working memory task correlated positively with their performance in the pseudo-reward task. We discuss preliminary cortical and subcortical imaging results related to these findings, and propose that working memory is critical for flexibly setting a reward function during learning, allowing RL to operate over arbitrary, novel stimuli in the environment.

Title: The neural link between subjective value and decision entropy

Authors: *S. BOBADILLA SUAREZ[1], O. GUEST[1], B. C. LOVE[1,2];
[1]Univ. Col. London, London, United Kingdom; [2]The Alan Turing Inst., London, United Kingdom

Abstract: A number of brain regions, such as ventromedial prefrontal cortex (vmPFC), are associated with value-based choice. Recently, signals related to decision confidence have been found to accompany value signals in vmPFC. Here, we find that these seemingly ancillary confidence signals are in fact the primary drivers of activity in a number of so-called value areas. We analyzed fMRI data from a mixed (containing gains and losses) gambling task in which participants either accepted or rejected a gamble on each trial. We fit a cognitive model to each individual's behavioral data, which allowed us to assess the subjective value (a weighted combination of possible gains and losses) and decision entropy (akin to inverse confidence) on each trial. Entropy peaks when the fitted model predicts there is a 50% chance that a participant would accept a gamble and is minimal when there is a 0% or 100% chance of acceptance. Using the trial-by-trial value and entropy estimates of the cognitive model, we were able to characterize fMRI activity related to choice. We found entropy signals to be stronger and more widespread throughout the brain than value signals. Value and entropy signals were not independent of one another, but correlated such that voxels that showed a positive effect for value also tended to show a positive effect for entropy. Likewise, voxels that showed a negative effect for one signal also tended to show a negative effect for the other signal. The intricate link between subjective value and decision entropy suggests that both quantities are required for full characterization of brain activity when making choices under risk.

Title: Theta phase synchronization underlays intuitive calculation in an arithmetic task

Authors: *A. OKUWA[1], A. FUNASE[1], H. NAKATANI[2], I. TAKUMI[1];
[1]Nagoya Inst. of Technol., Nagoya, Japan; [2]The Univ. of Tokyo, Grad. Sch. of Arts a, Tokyo, Japan

Abstract: [Purpose]In cognitive science research, we have been devoted to study on experts who have an expertise and high performance. Calculation experts can solve the arithmetic problem quickly with "intuitive calculation". "Intuitive calculation" enables calculation experts to understand the pattern of the problem quickly underlaying cognitive expertise. Therefore they

make an answer in short response time without actual calculating process. Neuroimaging study find the calculation expert's superior cognition is sustained by right prefrontal and medial temporal activity, however their functional connectivity remains unrevealed. Here, We analyze EEG phase synchronization to investigate the functional connectivity in understanding the pattern of the problem. In this research, We aim to reveal the functional connectivity underlaying calculation expert's quick solving the problem.[Experiments]We carry out Factorization task as mental arithmetic task. In each trial, subjects factor an arithmetic equation. Each trials consists of 3 phases as following. 1) participants fixate a cross shown in the center of the display. 2) participants factor a quadratic equation presented after fixation as quickly as possible and push the button when they come up with an answer. 3) participants answer that solution orally and take 5 [sec] rest. Participants totally repeat the trial 180 times and take a short break per 90 trials in the experiment. We measure the response time to solve the problem between the stimulation and button-push in each trial. We focus on the expert's brain activity within 1[sec] of perception. We record the EEG signals and focus on Fz, T8 and Pz electrodes to identify global brain connectivity in front and temporal-parietal. We conduct the time-frequency analysis and phase synchronization analysis to evaluate the functional connectivity. [Results and Discussion]From results, we obtain distinctive brain activity and functional connectivity related to quick solving the problem. Transient periods of time-frequency amplitude in the theta band is shown in Fz and T8 electrodes in short latency of 300[ms]. Subsequent to front-temporal activity, Time-frequency amplitude in Pz electrode is shown in long latency of 700[ms]. Theta band amplitude featured above is larger in short response time within 1[sec] than in long response. Furthermore, theta phase synchronization appears in front-temporal and front-parietal concurrently with task relevant brain activity. Functional connectivity between frontal and temporal-parietal in theta band is related to calculation expert's quick solving the arithmetic problem.

Title: Temporal expectation drives proactive preparation in simple response tasks

Authors: ***M. WANG**[1], H. ZHANG[1,2,3];
[1]Sch. of Psychological and Cognitive Sci. and Beijing Key Lab. of Behavior and Mental Hea,

[2]PKU-IDG/McGovern Inst. for Brain Res., [3]Peking-Tsinghua Ctr. for Life Sci., Peking Univ., Beijing, China

Abstract: In a simple response task, subjects are required to respond as fast as possible to the onset of an unambiguous target. Previous studies suggest that simple response tasks are not simple at all but reflect the temporal predictions of the brain. In particular, it is widely believed that the response time (RT) at a specific SOA (time from trial start to target onset) is determined by the hazard rate of the target at the moment. Though hazard rate has proved to be an effective predictor of RT, the instantaneousness of hazard rate is inconsistent with the cumulative motor preparation observed in neural data. Here we proposed a new computational model to account for the RT patterns in simple response tasks, which assumes that sensorimotor preparation is proactive and cumulative, taking into account the probabilistic expectation for all future moments. We designed a behavioral experiment where our model and the hazard rate theory would lead to distinct predictions. Each trial started with a centered gray disk. Subjects (N=14) were asked to press mouse button as soon as the disk briefly turned green. There were three possible SOAs: 500, 1170, and 2720 ms. We varied the probabilities of different SOAs across seven blocks of 147 trials, which were 1:1:1 for the first block, and were 1:2:4, 1:4:2, 2:1:4, 2:4:1, 4:1:2, and 4:2:1 in the following six blocks, with block order randomized for each subject. Different blocks would lead to different temporal expectations and we found that subjects' RTs varied with SOA ($F(2, 273) = 19.40$, $p < 0.0001$) , block ($F(6, 273) = 9.42$, $p < 0.0001$) and their interaction ($F(12, 273) = 1.80$, $p = 0.049$). We further compared RTs between conditions of the same SOA and hazard rate. Had RT been determined merely by hazard rate, these RTs would be equal. However, at SOA=1.17, RTs were significantly longer for 1:2:4 than for 4:1:2 (363 vs. 324 ms, $t(13) = 5.28$, $p < 0.001$), and significantly longer for 1:4:2 than for 4:2:1 (339 vs. 315 ms, $t(13) = 4.93$, $p < 0.001$). In two follow-up experiments, we replaced the stimulus with a concentric sinusoidal grating that contracted towards its center, where subjects were asked to press button as soon as the contracting speed turned faster. The first follow-up experiment (N=7) had the same design as the original experiment except for not including 1:1:1 block and the second experiment (N=6) only included 1:2:4 and 4:1:2 blocks. The significant RT difference between 1:2:4 and 4:1:2 at SOA=1.17 was replicated in both experiments ($t(6) = 2.93$, $p = 0.013$ and $t(5) = 3.71$, $p = 0.010$). These RT patterns violate the predictions of the hazard rate theory but are well predicted by our model. Model comparison analysis provided converging support for our model.

Title: Behavioral modeling and temporal dynamics of intertemporal choice

Authors: *W. YI, Q. LIU, B. M. TURNER;
Psychology, The Ohio State Univ., Columbus, OH

Abstract: Intertemporal choice is decision making about preference related to two dimensions of information: time delay and reward. This decision can be changed as time goes by. We investigated the temporal dynamics of intertemporal choice with an electroencephalogram (EEG) in this study. To identify the interaction of delay and reward information, we developed the Multialternative Decision Field Theory (MDFT) model of intertemporal choice under the Bayesian modeling framework. Specifically, intertemporal choice can be assumed to have the accumulation processes of reward and delay information, and this accumulation can include information loss (leakage) and competition (lateral inhibition) among the intertemporal choice options. We compared several candidate models and selected the best model based on the information criteria. In addition to the MDFT model, an EEG can be used for its temporal dynamics of intertemporal choice. The brain activity of the EEG data can reflect the traces of intertemporal choice related to different brain areas. Based on these activity patterns, the functional connectivity of the EEG data can also reveal the inter-relationship among the different brain areas of intertemporal choice decision.

Title: Cognitive basis of reasoning: A flexible analogical access (FAA) model

Authors: *N. C. CATANZARITE, K. N. DUNBAR;
Univ. of Maryland, College Park, MD

Abstract: Identifying relations between our current knowledge and new situations is an essential component of learning, but the cognitive processes that underlie relational reasoning are unclear. We conducted three experiments with a total of 189 undergraduate students to investigate the reasoning strategies used to identify categorical and analogical relations. Participants completed an information encoding task, then an information retrieval task. In Experiment 1, we found that reasoning strategies remain consistent across time. A week-long lag between the encoding and retrieval tasks decreased the number of relations participants were able to identify, but did not

change the types of relations they identified. In Experiment 2, we found that the framing of the questions asked during the retrieval task influence the type of reasoning strategy participants will use. Questions that target memory facilitate access to categorical relations, while questions about relationships facilitate access to analogical relations. In Experiment 3, participants were asked multiple types of questions in counterbalanced orders. Surprisingly, regardless of question order, participants identified mostly categorical relations in response to surface-level questions, and analogical relations in response to causal questions. This was intriguing because even after demonstrating cognitive access to analogical relations, participants proceeded to access only categorical relations in response to subsequent questions. Overall, these experiments indicate that reasoning strategy does not change over time (one week), and that the type of relations accessed by a particular question does not necessarily reflect the type of relations available. Rather, participants retrieve information about a subset of relations that are consistent with the framing of the retrieval questions. We propose the Flexible Analogical Access (FAA) model to interpret these findings and argue that this model can account for a wide variety of findings in the Analogical Reasoning literature. Currently, we are using fNIRS to investigate the neural mechanisms underlying these reasoning strategies and aim to determine their time course of activation.

Title: Predicting trial-wise choices from multi-modal data in a new environment

Authors: *H. PARK, J. YANG, W.-Y. AHN;
Dept. of Psychology, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: A hallmark of a good model is to make accurate predictions to new conditions. To maximize prediction accuracy, it is critical to understand neurocognitive mechanisms underlying choice behavior and incorporate them into a quantitative model. While computational modeling of behavior data has greatly advanced our understanding of cognitive processes underlying our decision making, it is still challenging to make accurate predictions of choice behavior in a new environment using computational modeling and behavioral data alone. Here, we tested the hypothesis that incorporating multi-modal data such as eye movements and facial expressions into quantitative models will increase prediction accuracy in a new environment. In the current

study, participants performed description-based decision-making tasks for two consecutive days. Eye movements and facial expressions were recorded in real time while participants performed the tasks. We used the data of the first day to build a model that make use of all multi-modal data, and assessed the prediction accuracy of the model on the choice data of the second day. Our preliminary results demonstrated that incorporating fixation time, pupil dilation, and facial expressions into a computational model significantly improved the prediction accuracy compared to a model that uses choice data alone. These results highlight that facial expressions and eye movements provide useful information regarding our decision making and may help us make better predictions of others' behaviors.

Title: Dynamics of evidence accumulation in a visual motion direction discrimination task containing change-points

Authors: *A. E. RADILLO, J. I. GOLD;
Dept Neurosci, Univ. Pennsylvania, Philadelphia, PA

Abstract: Judgments about noisy time-varying stimuli require the temporal integration of sensory information. It is known that the rate at which a stimulus undergoes abrupt, unsignaled state changes (or change-points) should and does influence the timescale of this integration. In particular, there is typically a negative correlation between the frequency of change-points in a stimulus and the timescale of sensory evidence integration. However, the exact temporal dynamics of evidence integration around the time of a real or expected change-point is not known, leaving open the more general question of how our brains implement information integration in our ever-changing world. To better understand this process, we set up a human psychophysical experiment in which we asked each subject to report the final direction of motion of a random-dot kinematogram. The dots stimulus contained a single change-point in the direction of coherent motion on some randomly chosen trials. To assess the time dynamics of evidence integration, we varied the viewing duration between 100-400 msec in steps of 100 msec, while fixing the single change-point time at 200 msec. The probability of a change-point

occurring on any given trial longer than 200 msec was manipulated across blocks, between 0.1-0.9. We hypothesize that the probability of a change-point modulates the dynamics of the accrued evidence according to the normative model. More precisely, we expect subjects to behave as perfect integrators before and after the change-point. However, around the expected time of a possible change-point and on trials in which the sensory evidence is weak, we expect the dynamics change in a manner that is governed primarily by the instructed probability of a change-point, as opposed to whether or not it actually occurred. To assess the time course of the accrued evidence around this time, we use a reverse-kernel analysis on the motion energy of the dots kinematograms. The results will allow us to better constrain future theoretical and neuronal models of human adaptive decision-making in realistic, dynamic environments.

Title: Individual decision-making underlying the tragedy of the commons

Authors: ***M. CHAWLA**[1], M. R. PIVA[2], S. AHAMMAD[1], R. JIA[2], I. LEVY[3], S. W. CHANG[4]; [1]Dept. of Psychology, [2]Interdepartmental Neurosci. Program, [3]Departments of Comparative Medicine, Neurosci. and Psychology, [4]Departments of Psychology and Neuroscience, Kavli Inst. for Neurosci., Yale Univ., New Haven, CT

Abstract: Introduction: The tragedy of the commons is an economic theory (Hardin, 1968) that predicts the overuse and eventual depletion of shared resources. Development of a computerized paradigm amenable to behavioral modeling and simulation analyses could allow for exploration of whether resources will be overused in a given group of individuals and allow for the rapid testing of behavioral interventions designed to reduce instances of resource overuse. **Methods:** Using a newly developed group decision-making task, we studied how participants made decisions to utilize shared resources for the potential to receive a larger amount of money or conserve shared resources for a smaller amount of money. Eighty participants (53F, mean age=26.5, sd=7.6, range=18-55) completed the task along with questionnaires relating to social attitudes online. Participant choices in the task were modeled to conceptualize subjective value as a function of monetary reward and resource availability to extrapolate sensitivity to resource availability for each participant (parameter *k*). Simulation analyses via bootstrapping were

performed to examine the effect of individual differences in decision-making on task outcomes. **Results:** Behavioral modeling indicated that a parabolic function best fit participants' responses (BIC: linear=3000, exponential=3241, hyperbolic=3373, parabolic=2572). Simulation analyses revealed that higher reward levels increased resource overuse more than diminished amounts of resources available. Simulation analyses further revealed that participants who utilized resources more often earned more than those who chose to conserve resources, although this effect was reversed when participants who chose to use more resources were placed in a group together. Furthermore, as additional people who chose to use more resources were placed in a single group, average group earnings catastrophically decreased following the point at which 30% of a given group was comprised of such individuals. Finally, self-reported antisocial attitudes correlated with sensitivity to resource availability (k) across participants (r=-0.348, P=0.004). **Conclusion:** Subjective value was substantially affected by shared resource availability only when the amount of resources available was exceptionally low, suggesting that participants may have been more likely to overuse middling amounts of resources. Participants with higher measures of antisocial attitudes were less sensitive in their subjective valuation to diminished resources, in turn resulting in resource overuse particularly in groups in which at least 30% of group members displayed these characteristics.

Title: A combination of perceptual and reward information predicts choice and individual differences in optimality

Authors: *M. GHANE[1,2], S. A. JAPEE[1], J. A. RICHEY[2], L. G. UNGERLEIDER[1];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Dept. of Psychology, Virginia Tech., Blacksburg, VA

Abstract: Background: Several psychiatric conditions are affected by co-occurring difficulties in perceptual and reward-based decision-making (PDM; RDM). PDM and RDM are often studied separately, either by manipulating uncertainty about what a stimulus is, or what it is worth. However, in the real-world, uncertainty in these two domains often co-occurs. The current study tested the hypothesis that decisions are best modeled using combined sensory and reward

information rather than either alone. It also aimed to determine whether a two-parameter model of decision-making could help identify individual differences in behavior. **Methods:** Nine adults completed two versions of a combined noisy target search and probabilistic reward task. In task 1 we manipulated perceptual uncertainty (PU) across trials (dynamic), and reward uncertainty (RU) between runs (stable); vice versa in task 2. On each trial, participants viewed two targets (face/house) and two distractors (cars) and were instructed to select one of the four images to maximize reward. Probabilistic contingencies and relative target visibility were known. We performed a 2 (Task) x 5 (RU Levels) x 5 (PU Levels) repeated measures ANOVA predicting target selection percentages to first test whether PU and RU interacted in the context of choice. We then used logistic regression to test the degree to which PU, RU, or a combination best classified individual subject choice. Single parameter models were compared with the two-parameter model using a difference in log-likelihood ratios. **Results:** ANOVA results revealed a significant interaction between PU and RU ($F(16,128) = 11.701$, $p < .001$, $\eta_p^2 = .594$). Participants selected high RU targets more often if they were easier to detect (greater in task 2) and high PU targets more when reward was more likely (greater in task 1). The two-parameter model fit data better in all subjects compared to either single parameter model ($MDiff_{Per}$=-58.23; $MDiff_{Rew}$ = -166.34). There was evidence for individual differences in sensory or reward-based choice biases and degree of optimal integration ($SD_{MDiffPer}$=57.50; $SD_{MDiffRew}$=73.44). **Conclusions:** Overall, decision relevant uncertainty, independent of PU or RU domain, modulated choice behavior. Participants were more biased by perceptual or reward information when uncertainty in the other domain was high, and task structure moderated these effects. Our unique approach also allowed us to identify individual differences in optimal integration of PU and RU. Ongoing fMRI studies will examine whether shared or distinct neural substrates underlie estimation of choice relevant PU and RU in perceptual and reward biases during decision making.

Title: Model comparison with multimodal data: Bayesian inference on integrated models of behavioural and imaging data

Authors: *D. CUSTOVIC[1], B. NIKOLIC[3], C. CLOPATH[2], A. HAMPSHIRE[1];
[1]Dept. of Med., [2]Dept. of Bioengineering, Imperial Col. London, London, United Kingdom;
[3]Astrophysics Group, Cavendish Lab., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Introduction
Theoretical models in cognitive neuroscience make predictions across multiple data modalities, e.g. behavioural and imaging data. Testing these models thus requires a unified approach to inference from multimodal data: a successful inference approach must be able to concurrently fit models to multiple data sets and to discriminate between models on their explanatory power across data sets while taking model complexity into account.
These requirements can be met by modern Bayesian inference algorithms. Bayesian inference (BI) provides a rigorous mathematical basis for the notion of model comparison; the basic insight of BI is that the extent to which the data favours one model over another can be stated as the ratio of their *Bayesian evidences*, a principled metric of goodness-of-fit robust to overfitting. Our chosen BI algorithm, MultiNest, provides an efficient means to simultaneously fit model parameters and calculate model evidence. For many models, the shape of the likelihood function is unknown, motivating the use of a more computationally expensive approach over faster approximation methods.
We present two studies showing how BI can be successfully applied to problems in cognitive neuroscience.
Methods
Study 1: Behavioural data was gathered on 18 subjects performing the simple reaction time task. We considered four variants of the drift diffusion model to explain SRT performance, including one with collapsing bounds (CB). Log-likelihood functions were built for each model and used within MultiNest to find, for each subject and model, the best-fit parameters and Bayesian evidence. The models were compared for their performance against the data at the best-fit parameters, and the quantitative conclusion reached through Bayesian analysis compared with the models' performances at their best-fit parameters.
Study 2: We extend the methodology to fit two models of a learning curves task to imaging and behavioural data simultaneously, to uncover the roles of different ROIs, especially the LFC, in the task learning process.
Results
Study 1 finds the data decisively favours (by Bayes factor 80) a CB DDM. Comparison of model predictions at best-fit parameters with the empirical data finds the CB model is capable of explaining numerous effects in the data which the others cannot.
Study 2 gives proof-of-principle that models can be fit to multimodal data and compared within a unified framework. We show that including a hyperparameter to adjust the weighting of each data set allows us to account for the relative information content in each data set. We show that this unified approach provides tighter constraints than considering the two data sets separately.

Title: Modafinil effects on inhibitory control in methamphetamine-dependent individuals: A Bayesian model-based fMRI study

Authors: *H. WANG[1], D. GHAHREMANI[1], D. GUO[4], A. J. YU[4], *E. D. LONDON[1,2,3]; [1]Psychiatry and Biobehavioral Sci., [2]Mol. and Med. Pharmacol., [3]Brain Res. Inst., UCLA, Los Angeles, CA; [4]Cognitive Sci., Univ. of California San Diego, La Jolla, CA

Abstract: Methamphetamine (MA) is one of the most widely used illicit drugs worldwide, partially due to its low cost and long-lasting psychoactive effects (Panenka et al., 2013). Chronic use of MA is associated with prefrontal cortical dysfunction and cognitive impairment, especially with respect to features of inhibitory control that could influence the maintenance of addiction. Modafinil, a medication that is used to treat narcolepsy, has been shown to improve cognitive performance in a number of clinical populations (Minzenberg & Carter, 2008), including MA-dependent individuals (Ghahremani et al., 2011). We conducted a randomized, double-blind, placebo-controlled study on the acute effects of modafinil (200 mg, 2 hours before testing) on motor response inhibition and related neural activity in 18 MA-dependent individuals. Previous work indicated lower prediction error-related neural activation in MA-dependent individuals than in healthy control subjects performing the Stop Signal Task (SST; Harlé et al., 2016). We used the SST and fMRI to evaluate whether modafinil enhances prediction error-related neural activation in this clinical population. We estimated prediction error parameters by characterizing the effects of sequential task performance using a Bayesian Dynamic Belief Model (DBM), which describes the expectation of a stop trial (i.e., P(stop)) incorporating prior belief and trial history. We included trial-wise signed prediction error (SPE) and unsigned prediction error (UPE), derived from DBM, as parametric modulators in fMRI analyses. Consistent with the assumptions of the model, P(stop) was linearly positively correlated with RT in non-stop trials (Go RT) in both drug conditions; and modafinil reduced Go RT (478 ms vs. 494 ms after placebo; $p < 0.001$). Modafinil modulated SPE-related activation more than placebo in left precentral gyrus and inferior frontal gyrus, as measured with fMRI (whole-brain, cluster

corrected at $P < 0.05$, height threshold of $Z > 3.1$). The results present an initial model-based account of the effect of modafinil on response inhibition by MA-dependent individuals. Such a model-based approach may unveil subtle effects of modafinil, with implications for treatment of MA Use Disorder and potentially other psychiatric diseases.

Title: Bounded rationality and temporally extended actions shape optimal perceptual decisions

Authors: *J. R. CASTIÑEIRAS, A. RENART;
Champalimaud Res., Champalimaud Fndn., Lisbon, Portugal

Abstract: Adaptive behavior in a perceptual decision making (PDM) task involves a trade-off between the performance deficit of responding too soon and the cost of time associated to gathering evidence. The optimal solution to this problem has been understood using the Partially Observable Markov Decision Process framework (POMDP). However, these kinds of policies assume perfectly rational agents and therefore ignore constraints that real agents have to confront. Here, we generalize ideas from optimal control theory to derive optimal policies that solve a categorical PDM task in the presence of two generic kinds of such constraints.
One is a “cost of control”, which penalizes policies that deviate from the agent’s default actions. In particular, we consider the effect of impulsivity, a spontaneous tendency to respond (consistent with the concept of exploration). The other cost is derived from the fact that the actions which communicate the agent’s choices and trigger the offset of the stimulus are extended in time (e.g. a nose poke, or an arm movement). This implies that since the initiation of an action until the moment that the stimulus stops, there is a certain period that we term "execution delay" in which the agent’s beliefs are subject to change. We show that the optimal policy in this setting involves a separation between a first commitment to act, and a final revision of that action, in which it could be maintained or switched to the alternative option.

We provide semi-analytical solutions for the probability that the agent will choose an option at a given time with a given belief, deriving predictions on measurable observables: choice, reaction time (RT) and decision confidence. We show that when the cost of control or the execution delay are significant, the behavior of decision confidence departs from the POMDP solution and resembles predictions of signal detection theory. Moreover, these different regimes also lead to distinct profiles on the distributions of anticipatory responses and "lapses".
Overall, our results clarify the link between the observed phenomenology of decision confidence and different notions of optimality, and also provide a more general notion of normative behavior that includes both task contingencies as well as unavoidable costs faced by real organisms.

Title: Uncertainty-based arbitration between incremental and episodic control over decisions

Authors: *J. NICHOLAS[1], N. D. DAW[2], D. SHOHAMY[1];
[1]Columbia Univ., New York, NY; [2]Princeton Univ., Princeton, NJ

Abstract: Decisions between two familiar options can be made by consulting an average value built over many experiences or by retrieving value from a single past episode. However, it remains unknown how these two strategies trade-off. Here we tested the hypothesis that uncertainty modulates the relative contribution of incremental vs. episodic influences on choice. In Experiment 1, participants (n=100) made a series of choices for possible reward. Feedback was provided after each choice in order to promote learning about the value of two cues: incremental (card decks with average value) and episodic (unique objects on each card in a deck). Incremental cue outcomes came from either a certain or an uncertain distribution centered around the same average value. We found that participants were more likely to use episodic cues to guide choices when the incremental cue's value was less certain. Moreover, we found that the interaction between uncertainty and episodic choice was more pronounced early in learning. This result suggests that ambiguity about value plays an important role in adjudicating between incremental and episodic control. Experiment 2 tested this hypothesis directly by manipulating the volatility of the choice environment. Participants (n=160) in two groups completed a similar

task where each deck's average value switched between high and low. One group completed the task in an environment with fewer switches (stable) than the other (volatile). We measured the effects of a switch on choices. Because ambiguity about the decks is greatest following a switch, we predicted that volatility would increase the use of episodic cues both within (as a function of distance from switch) and between participants (predicting that the volatile group should be more sensitive to the value of episodic cues). We found that the high volatility group showed poorer learning overall for both cues. In the stable condition we also found that the effect of episodic choice was greater as distance from the switch increased, suggesting that resolving incremental ambiguity takes precedence over using episodes. Together, these results suggest a trade-off between incremental and episodic control that is governed by uncertainty, shedding light on when episodes are used for decisions.

Title: Dopamine and serotonin in reward and addiction

Authors: C. SCHMIDT[1], V. VOON[2], ***A. MOLLER**[3];
[1]Dept. of Nuclear Med. and PET Ctr., Aarhus, Denmark; [2]Univ. of Cambridge, Cambridge, United Kingdom; [3]Aarhus Univ. Hosp., Aarhus, Denmark

Abstract: Addiction as a phenomenon has existed for centuries in the forms of substance use and behaviour, and is demarcated by impulsivity and compulsivity, leading to clinical symptoms of tolerance and withdrawal. In numerous western countries such as the U.S., addiction is one of the costliest public health problems, and present technological advances have paved the way for new addictive phenomena, which rely on behaviour rather than drugs of abuse. These addictive processes are primarily guided by the neurotransmitters of dopamine (DA) and serotonin (5-HT), which play crucial roles in aspects of reward processing in the human brain, where overconsumption can lead to addiction. It is therefore of the highest relevance to assess more precisely the underlying mechanistic neurobiological aspects of reward processing, and assess addictive disorders in order to improve their options for treatment. In the present PhD project the roles of DA and 5-HT in reward processing, and the neural properties of gambling disorder (GD) and compulsive sexual behaviour disorder (CSBD) have been examined. The experiments were carried out in a between-subjects double blinded design and contained testing of more than 200 subjects, including healthy volunteers (HV) and GD subjects, and CSBD subjects; both psychiatric patient groups with profound deficits in impulsivity and compulsivity. This was done

in order to isolate the neural and behavioural correlates of both increasing DA and depleting 5-HT to investigate: 1) how this affected neural activity in a task-based fMRI experiment on different forms of rewards 2) cognitive components of impulsivity and compulsivity through behavioural testing 3) how these two points relate to GD and CSBD patient groups 4) a connectome-based diffusion tensor imaging (DTI) sequence assessing structural neural networks.

Title: How do monetary gains and losses affect the arbitration between reinforcement-learning strategies in adolescents and adults?

Authors: *F. BOLENZ[1], B. EPPINGER[2];
[1]Technische Univ. Dresden, Dresden, Germany; [2]Concordia Univ., Montreal, QC, Canada

Abstract: Motivated behavior undergoes substantial changes during adolescence. Recent findings suggest that adolescents show a strong asymmetry in the neural processing of monetary gains and losses, but it is unclear whether these developmental asymmetries in value processing also affect higher-order decision mechanisms, such as the arbitration between different reinforcement-learning strategies. We investigated developmental asymmetries in the arbitration between model-free and model-based reinforcement learning. Adolescents (12-17 y) and adults (18-25 y) performed a sequential decision-making task and across trials, the magnitude of outcomes was manipulated which lead to different pay-offs of the model-based strategy. Furthermore, during some blocks of the task, outcomes were framed as gains while during others, outcomes were framed as losses. Replicating previous findings, we found that in blocks with gains, reliance on model-based reinforcement learning was increased in trials with amplified rewards. In blocks with losses, we observed a reduced adaptation of reinforcement-learning strategies. However, we did not find developmental differences in the effect of gains and losses on the arbitration of reinforcement-learning strategies. Interestingly, this is in contrast with the effects of outcome valence in a risk-preference task in the same sample. Our findings show that monetary gains and losses differ in how they affect the arbitration of reinforcement-learning strategies with gains leading to a stronger adaptation to different reward magnitudes. However, we do not find support for the idea of a developmental asymmetry in the value-based engagement in different reinforcement-learning strategies.

Title: Evidence accumulation and optimal stopping in stochastic choice

Authors: ***S. F. BUCHER**[1], P. W. GLIMCHER[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: Drift-diffusion models (DDM) have had empirical success in fitting both behavior and electrophysiological recordings during binary choice tasks. They model response times along with choice probabilities and permit insights into the processes from which (perceptual or value-based) decisions originate. In the recent theoretical literature, the DDM has been shown to arise as the solution to a subset of narrowly defined optimal stopping problems. This literature assumes that evidence accumulates according to an (unobserved) underlying stochastic process with a drift that depends on the stimulus, but usually neither on the state of the accumulator nor on time. We present a behavioral experiment designed to visualize the "drifting particle" of the DDM by measuring directly how choice accuracy evolves with time. This permits more direct inference on the form of the underlying stochastic process than do traditional approaches, allowing us to better differentiate between competing models of evidence accumulation. In each of 360 trials, subjects are briefly shown 100 small circles, some red and some blue, and are asked whether the majority of these are red or blue. What is systematically varied is the duration for which the circles are visible prior to onset of a visual mask. Three treatments are examined: unpredictable-time-of-offset, unpredictable-time-of-onset, and free-response. The free-response trials, in which subjects may take as long as they like, correspond to the standard reaction time version of a DDM-style experiment. Finally, separate blocks of trials also systematically manipulate the prior probability that the correct response is red, allowing us to visualize the time-varying effect of prior probability on the decision variable. On each trial, after subjects choose "red" or "blue", we elicit their probabilistic beliefs (or confidence) that their preceding choice was correct. As expected and previously demonstrated, the accuracy of choices increases as a function of the time during which the dots are displayed. Shifting prior probabilities have large early influences on the decision variable, which rapidly decay. Reported confidence is linearly correlated with the accuracy of the decisions, and provides further empirical restrictions on how the underlying stochastic process modeled by the DDM evolves with time. This experimental

methodology thus promises empirical insights that permit us to refine bounded accumulation models in a way that is not possible when relying on decisions and response times alone.

Title: Relating human substantia nigra neural activity to eye movement

Authors: A. G. RAMAYYA[1], *B. J. MCSHANE[1], L. Y. BUCH[1], M. DONELEY-FLETCHER[1], L. DING[2], J. I. GOLD[3], G. H. BALTUCH[1];
[1]Pennsylvania Hosp., Philadelphia, PA; [2]Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [3]Dept Neurosci, Univ. Pennsylvania, Philadelphia, PA

Abstract: Introduction: The ability to direct one's gaze appropriately based on incoming sensory information is essential to survive and thrive in our dynamic and uncertain world. Impairments in the ability to select eye movements is disrupted in diverse conditions such as schizophrenia, traumatic brain injury and Autism. Animal studies have shown that the Substantia Nigra, Pars Reticulata (SNr), an output nucleus of the basal ganglia (BG), acts as a gating mechanism that suppresses unwanted eye movements but allows wanted ones. However, the function of this nucleus during human eye movements has not been studied in detail.
Methods: We performed intra-operative studies in patients undergoing deep brain stimulation (DBS) for Parkinson's disease. These studies combined single-unit recording from SNr and extra-occulography (EOG) to measure horizontal and vertical eye movements on both visual- and memory-guided saccade tasks.
Results: We recruited 22 patients. Intra-operative studies were completed for 14 of these patients. The average patient age was 65 +/- 12.2 years. We identified 11 neurons from SNr in 7 patients. We observed a mean firing rate of 18 Hz (range: 5.1-37.3 spikes/second) and a mean waveform duration of 2.06 ms (range: 1.64 - 2.52), which likely includes both dopamine and GABA neurons (Ramayya et al, 2014). Preliminary analyses identified firing rate modulation the 500 ms interval prior to saccade onset in several units.
Conclusions: We report preliminary results relating human SNr neurons to eye movements. Identifying pauses in SNr activity in the moments leading up to human eye movements would support the hypothesis that human SNr neurons act as a gating mechanism to select appropriate eye movements during decision-making.

Title: Differences between learners and non-learners during visual category learning

Authors: ***B. REUVENI**, B. FEINSTEIN, P. J. REBER;
Psychology, Northwestern Univ., Evanston, IL

Abstract: The development of expertise in complex decision-making tasks relies on multiple strategies including implicit statistical learning, and effortful explicit rule discovery as well as successfully incorporating feedback. To study this development, we use fMRI and a visual category learning paradigm that first teaches participants to sort 2D sinewave gratings that vary on spatial frequency (line thickness) and orientation (tilt) according to a simple rule based on line thickness. We then gradually expose the true category structure, that requires both line thickness and tilt. This is done via online model-driven adaptive stimulus selection aimed at facilitating a transition from one strategy to the other by actively disconfirming unidimensional rules and confirming a more complex two-dimensional one. The model, PINNACLE 2.0 (Nomura & Reber, 2012; Reuveni & Reber, *in prep*), is based on memory systems theory and provides a framework for understanding the roles of implicit / explicit memory and their interplay during learning. Prior work has demonstrated the success of this relatively simple model in accounting for participant behavior using 3 relevant strategies based on stimulus features (i.e. line thickness, tilt, or a combination of both). In the current study, a large subset of participants (19/32) fail to adapt to the changing task demands and remain at chance performance after an initial period of successful learning. In contrast, participants who do adapt show an initial dip in performance as task demands change followed by a gradual improvement throughout 400 trials. Neuroimaging analysis contrasting learners vs. non-learners showed greater activity in medial cingulate as well as in the precuneous for learners suggesting that even though learners perform less errors, they are more responsive to error signals and evidence accumulation.

Title: The role of perceptual uncertainty in value learning and naturalistic stimulus categorization

Authors: *A. GEANA[1], W. MAHAPHANIT[1], M. J. FRANK[2];
[1]Brown Univ., Providence, RI; [2]Brown Univ., Carney Inst. for Brain Sci., Providence, RI

Abstract: To successfully navigate our daily environment, humans (as well as non-human organisms) rely on the crucial skill of selecting perceptual information into relevant categories (e.g. 'things that are edible', 'things that are dangerous' etc.). This categorization process entails extracting relevant information from an often noisy environment, and using that information to make decisions about category boundaries (e.g. 'is this four-legged furry animal the type that wil try to eat me?')—decisions which later play into higher-level behavioral decisions (e.g. 'should I run or can I pet the four-legged furry animal?'). There has been a growing emphasis in the field of computer vision on integrating categorization algorithms into learning and decision-making studies, and recent advances have included creating complex perceptual models to classify image stimuli in a way that correponds to observed findings from human psychophysics and neural data (Sofer, Crouzet, & Serre, 2015), thus tying neural evidence for perceptual categorization to decision-making behavior. In the current study, we used a logistic regression classifier with L2 regularization to categorize naturalistic stimuli (man-made or natural scenes) and obtain their respective distances from a perceptual decision boundary line (Sofer al., 2015), and used the resulting stimulus set to test the extent to which humans integrate perceptual uncertainty into their value learning process. We tested Amazon Mechanical Turk participants on a complex two-phase task that combines facets of reinforcement learning and memory encoding (Jang et al. 2018). We captured the contribution of perceptual uncertainty with a mixed reinforcement learning model that uses a POMDP to infer underlying perceptual belief states, and found preliminary evidence for a role of perceptual uncertainty in value computations at the learning level, with more uncertain stimuli contributing less to overall value learning.

Title: Reward structure regulates belief update strategy during hierarchical reasoning

Authors: *M. SARAFYAZD, Jr[1], M. JAZAYERI[2];
[1]MIT, Cambridge, MA; [2]Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: A hallmark of intelligence is the ability to represent uncertain and dynamic environments in terms of a hierarchy of states, and update beliefs about those states using decision outcomes. This belief update process, however, depends critically on the nature of reward contingencies. For example, when reward is contingent upon committing to a specific path along the hierarchy, the belief update process has to take into account the specific path taken. In contrast, when reward depends only on the endpoint of the hierarchy, the update process has to consider all the paths that are consistent with that endpoint.
To investigate the computational principles of such high-level reasoning, we trained monkeys to perform two variants of a hierarchical decision-making task with distinct reward contingencies. In task one, monkeys made two sequential decisions corresponding to two levels of hierarchy in a decision tree, and received reward if both decisions were correct. Task 2 was governed by the same hierarchical structure but monkeys only reported their final decision, and received feedback based on that decision. We used these tasks to address two interrelated questions: (1) is the belief update process consistent with an optimal probabilistic model that takes reward contingencies into account? (2) can the sensitivity of the belief update process to reward contingencies be implemented by a vector-space evidence integration model?
According to an ideal observer model, monkeys should adopt two different reasoning strategies for the two tasks. For task 1, the expected reward has to be evaluated through conditionalization; i.e., “what is the probability of reward for my second decision given my first decision?” For task 2, in contrast, it has to be evaluated through marginalization; i.e., “what is the probability of

reward for my second decision considering the two possible choices I could have made for the first decision?"
The behavior was consistent with the predictions of the ideal observer: monkeys' responses conformed to the conditionalization strategy in task 1 and the marginalization strategy in task 2. Currently, we are developing vector-space models that can capture the belief update process in terms of outcome-dependent evidence accumulation. Preliminary work suggests that these two belief update strategies can be implemented by representing the integrated evidence in two different forms: graded evidence for marginalization and binary evidence for conditionalization.

Title: Inhibitory selectivity and choice performance in a circuit model of perceptual decision making

Authors: *J. P. ROACH, A. K. CHURCHLAND, T. A. ENGEL;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Cortical circuits perform computations to generate appropriate behaviors based upon diverse sensory inputs an example of which are perceptual decision-making tasks. The classical circuit model of decision-making focuses solely on the effects of recurrent excitation, treating inhibitory neurons as agnostic facilitators of competition between excitatory subpopulations. Inspired by recent experimental results reporting highly selective inputs to and firing by inhibitory neurons within cortical circuits, we've developed a mean-field firing rate model of a cortical decision-making circuit which parameterizes selectivity in connection strengths between subgroups within the excitatory and inhibitory populations. Analyzing this model, we've found that in order to produce network selectivity for a single choice outcome excitatory-excitatory selectivity (recurrent excitation) must always be high while excitatory-inhibitory selectivity can be varied over a wider range, as long as inhibitory selectivity is changed as well. Specifically, for every decrease in excitatory-inhibitory selectivity, there must be a corresponding increase in inhibitory selectivity. Additionally, this model reproduces the attractor-based decision-making dynamics previously demonstrated by non-selective inhibition models. The updated model

shows that selective inhibition does not disrupt overall network choice selectivity and predicts that perturbations to excitatory selectivity will disrupt decision-making behaviors more than perturbations to inhibitory selectivity. To extend our present findings, we implemented inhibitory selectivity into a full spiking network model which can validate the results of the mean-filed model and allow for more direct comparison with experimental results. From this work we can make an inference as to the circuit structures which support reliable perceptual decision making with equal excitatory and inhibitory selectivity, providing greater insight into the role of inhibition in cortical computation.

Title: A neurocognitive architecture for audio-visual signal detection

Authors: *J. M. EGAN[1], S. KELLY[1], R. G. O'CONNELL[2];
[1]Univ. Col. Dublin, Dublin, Ireland; [2]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland

Abstract: We currently know very little about how we respond to multiple signals that occur at the same time. For example, a rock tumbling down a steep slope could be detected by either our sight or hearing, and we often respond faster to the presence of two such co-occurring signals than we would to those signals in isolation. However, despite extensive research, we still do not know whether the signals are processed entirely by separate parallel channels, or whether processing converges to a common channel. Many alternative models of the evidence accumulation process that produces our responses to such sensory signals can fit behavioural data. Here we used a human EEG signature of the process ("CPP") along with behavioural data to distinguish between potential architectures, where using behavioural data alone could not. We asked participants to report periods of coherency in otherwise incoherent auditory and visual stimuli while we recorded EEG. In half of the blocks participants were asked to report either visual or auditory events, or their co-occurrence [redundant detection]. In the other half the participants were asked to only report the co-occurrence of auditory and visual events [conjunctive detection].We found that a model consisting of separate unimodal evidence accumulators that converge to a common later stage could be used to explain the data from the redundant detection task, while data from a model consisting of separate unimodal evidence

accumulators that have gated access to a common later stage explained the data from the conjunctive detection task. In both cases the models were fit to behavioural data and then used to simulate CPPs. However, some commonly proposed alternative models failed to explain our data. We then extended our search for viable models by jointly fitting models to both behavioral and EEG data, allowing us to search through larger parameter sets. Overall, our research demonstrates the usefulness of the CPP in combination with behaviour in determining the neurocognitive architectures that underlie simple perceptual tasks.

Title: Neural activity in the human subthalamic nucleus during stochastic decision making depends on presented evidence

Authors: Z. E. PATAI[1,2], T. FOLTYNIE[2], P. LIMOUSIN[2], M. I. HARIZ[2], L. ZRINZO[2], R. BOGACZ[1], *V. LITVAK[2];
[1]MRC Brain Network Dynamics Unit, Univ. of Oxford, Oxford, United Kingdom; [2]UCL Queen Square Inst. of Neurol., London, United Kingdom

Abstract: During decision-making, humans often accumulate noisy information and only commit to making a choice after sufficient evidence has been integrated. How and where the brain determines if the evidence is sufficient is still largely unknown. One candidate region implicated in this process is the subthalamic nucleus (STN), where the activity has been shown to modulate how high this evidence criterion, or the decision threshold, is set. To date, however, no study has investigated how the responses in the STN depend on the continual unfolding of evidence over time. To understand how the neural activity in STN changes during the evidence accumulation, we used an expanded judgement task, in which evidence is presented at discrete moments in time. Here we report on recordings of the STN in 15 Parkinson's patients (14 male, mean age: 59, range 47-71) while they performed an expanded judgment task. During each trial, patients were presented with a series of images of a mouse facing either left or right ('cue'). The cues were continuously presented until the patient responded with a prediction as to the probable direction in which the mouse would run (left or right). The two directions were equally likely across trials and within a trial the mouse faced in the correct direction with a probability of 0.7.

All but two patients were able to perform this task above chance (mean accuracy= 0.69±0.2 s.d.), and varied on the number of stimuli they observed before making a response (5.44±1.9 s.d.). Based on the hypothesized role of beta oscillations in inhibiting impulsivity during conflict, we analyzed induced responses in bilateral STN, locked to the cue images. We found that the power of beta oscillations in the STN was modulated by the visual cues. Specifically, these changes were dependent on the sequence of stimuli presented: we found increased beta power when two sequential cues were the same (e.g. L cue followed by L cue). Moreover, this increase for 'same cues' was only present on trials in which patients correctly guessed the running direction of the mouse, underscoring the notion that these beta power differences were task-relevant. Finally, we also examined button press-locked beta, but found no effect of choice correctness, despite patients receiving immediate feedback, highlighting that the effects seen during the cue periods are distinct from movement- and feedback- related beta changes. Although the STN is traditionally considered to be primarily a motor structure, these results suggest that beta power in the STN is responsive to sequential changes in evidence, which is consistent with the role of STN in modulating decision processes according to regularities in the presented evidence.

Title: Choice history biases subsequent evidence accumulation

Authors: A. E. URAI[1], J. W. DE GEE[2], K. TSETSOS[4], *T. H. DONNER[3];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Neurophysiol. und Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Neurophysiol. & Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, University Medical-Center Hamburg-Eppendorf, Germany; [4]Neurophysiol. & Pathophysiology, Univ. Med. Ctr. Hamburg Eppendorf, Hamburg, Germany

Abstract: Perceptual choices depend not only on the current sensory input, but also on the behavioral context. An important contextual factor is the history of one's own choices. Choice history often strongly biases perceptual decisions, and leaves traces in the activity of brain regions involved in decision processing. Yet, it remains unknown how such history signals shape the dynamics of later decision formation. Models of perceptual choice construe decision formation as the accumulation of sensory evidence towards decision bounds. In this framework, it is commonly assumed that choice history signals shift the starting point of accumulation towards the bound reflecting the previous choice. We here present results that challenge this idea.

We fit bounded-accumulation decision models to behavioral data from multiple perceptual choice tasks (different task protocols and sensory modalities), and estimated bias parameters that depended on observers' previous choices. Individual history biases in overt behavior were consistently explained by a history-dependent change in the evidence accumulation, rather than in its starting point. This was true irrespective of the outcome (correct or incorrect) of the previous choice. The effect of choice history on drift bias was long-lasting, decaying over approximately 3 past trials. Lastly, we fit a leaky accumulator (Ornstein-Uhlenbeck) model, revealing that choice history biases the input to the evidence accumulation process.

Choice history signals thus seem to bias the interpretation of current sensory input, akin to shifting endogenous attention towards (or away from) the previously selected interpretation.

Title: Probing sensory evidence accumulation and decision-related signals using human intracranial EEG

Authors: *S. BICKEL[1,3], N. MARKOWITZ[2], J. L. HERRERO[2], E. ESPINAL[1], S. GHERMAN[1], R. G. O'CONNELL[4], A. D. MEHTA[2], S. KELLY[5];

Abstract: The brain continuously receives noisy sensory signals which need to be evaluated prior to leading to specific actions. However, the neuronal cascade in the human brain from

perceived sensory evidence to specific actions remain poorly understood. Recordings in non-human primates identified specific brain regions, such as the lateral intraparietal area (LIP), which participate in such decision-making processes, reflecting the accumulation of sensory evidence towards a decision bound. Similarly, scalp EEG recordings in humans identified signals building up over widespread central-posterior regions during sensory evidence accumulation. However, to our knowledge, the exact anatomical location of the generators of these complex signals have not yet been identified in the human brain. Intracranial EEG (iEEG) recordings in presurgical epilepsy patients may provide the opportunity to fill this gap as this approach allows to record directly from potential target sources with high spatial and temporal resolution. In this study, we recorded two sensory evidence-based decision-making experiments in patients implanted with depth electrodes to identify the local sources of these evidence accumulation processes and investigate its temporal dynamics across brain regions. In task one, subjects viewed two patches of randomly moving dots with embedded coherent motion and were asked to respond with different key presses depending on the direction of the coherent motion. In an auditory adaptation of this task, a mixture of tones was presented with the emerging dominance of tones of either high or low pitch, which again have to be discriminated by the subject. Indeed, we found specific brain regions that showed a ramping up of activity mirroring accumulating sensory evidence, reminiscent of signals found with scalp EEG. This study provides preliminary evidence of the feasibility and complementary value of iEEG to scalp EEG and invasive animal studies to investigate the neural underpinnings of perceptual decision making.

Title: Evidence accumulation in abstract decisions cued by varying perceptual information

Authors: *M. L. NEWTON[1,2], A. S. KAYSER[3];
[1]Univ. of California Berkeley, Berkeley, CA; [3]Neurol., [2]Univ. of California San Francisco, San Francisco, CA

Abstract: Perceptual decision making is thought to depend on the accumulation of sensory evidence in the intraparietal sulcus (IPS), independent of the specific motor effector. However, whether similarly general mechanisms apply to evidence supporting abstract decisions is

unknown. Under a general accumulator framework, evidence used to drive both concrete (1st order) and abstract (2nd order) stimulus-response (S-R) relationships should accumulate in the same area of IPS. In contrast, progressively higher-order policy requires progressively more anterior regions of the lateral frontal cortex, each of which is most strongly connected to different parietal regions. Under a network-based hypothesis, evidence used to drive concrete (1st order) and abstract (2nd order) S-R relationships should thus accumulate within different areas of IPS. To evaluate these competing hypotheses, we designed a task in which the coherence of a perceptually graded stimulus (motion, color, or shape) and the level of policy abstraction (1st or 2nd order) were independently varied. Following training to ensure stable performance, subjects each completed 5 fMRI sessions, for 660 total trials. Within a trial, subjects viewed 3 separate, sequentially presented stimuli - dot motion (up/down), dot color (blue/gray), and shape (circle/triangle) - in pseudorandomized order before making a button press. Prior to each run, subjects were informed that one stimulus (e.g. color) would represent the 2nd order cue. Based on the 2nd order percept for each trial (e.g. blue/gray color), subjects then made a button press response based upon one of the other features (the relevant feature - e.g. motion) while ignoring the third (the irrelevant feature - e.g. shape). Behavioral results indicate that subjects benefit from higher coherence, utilize abstract information, and attend less to irrelevant stimuli, as predicted. Preliminary imaging results show greater activity in anterior frontal cortex including pre-PMd, a region implicated in 2nd order abstract decisions, when subjects view a 2nd order versus 1st order stimulus. Select bilateral IPS regions show greater activation in this comparison as well. In a univariate contrast of 1st order relevant versus irrelevant cues, greater activity in motor planning regions such as supplementary and premotor cortex, as well as higher order visual areas in lateral occipital gyrus, is seen. Further work with greater subject numbers will seek to confirm or refute these initial imaging findings.

Title: Neural representations of number across semantic, phonological, visual, and manual formats

Authors: *G. E. KOCH, R. LIU, M. E. LIBERTUS, J. A. FIEZ, M. N. COUTANCHE; Psychology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Five fingers held up in the air can convey the same information as the symbol “5” drawn on a chalkboard, but how does our brain represent these different visual forms so that we understand the meaning of the number *five* in both cases? Four constituents have been implicated as being involved in adult numerical processing: semantic, visual, manual, and phonological, however, all four constituents have rarely been studied simultaneously using a single paradigm. We have developed a novel paradigm to identify and investigate the four constituents of the number processing network. We collected functional magnetic resonance imaging (fMRI) data from 18 adult participants while they completed our novel paradigm, as well as a traditional paradigm that has been used previously to study numerical processing in adults and children (Cantlon & Li, 2013; Emerson & Cantlon, 2015). Our novel paradigm uses a 2-by-2 factorial design, in which participants view one of two stimulus types indicating a quantity from 1 to 9: Arabic numerals or hands. Orthogonally, participants complete one of two tasks: deciding if the shown quantity is greater than another number (e.g., “greater than 3?”) or if the quantity contains a long vowel sound (i.e. long *e* in “three”). In the traditional paradigm, participants decide whether pairs of numbers, faces, shapes, and words are the same or different (e.g., same number of dots as a shown numeral). Collecting data from the same participants with both paradigms afforded us the opportunity to identify neural regions sensitive to numbers resulting from each paradigm separately, and to also directly compare paradigms and evaluate overlapping regions. Univariate analyses targeting numerical processing reveal highly overlapping activation patterns for both paradigms in the intraparietal sulcus, with additional activation in the medial frontal gyrus and insular cortex for our novel paradigm. Orthogonal multivariate analyses utilizing machine learning classifiers for the novel paradigm suggest that neural representations reflecting differences between semantic (numerical) and phonological processing can be successfully detected within the regions identified through the univariate approach. Additionally, underlying differences in numerical and phonological processing are robust enough to generalize across stimulus types (i.e. training on numerals and testing on hands). Our findings indicate that within brain regions sensitive to numbers, the underlying neural representations pertaining to numerical processing are invariant to visually-presented form.

Title: Influence of repetitive transcranial magnetic stimulation of the posterior medial frontal cortex on the behavioral and electrophysiological measures of cognitive dissonance

Authors: *E. RYBINA[1], A. SHESTAKOVA[1], V. KLUCHAREV[2];
[2]Dept. of Psychology, [1]Natl. Res. Univ. Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Choosing between two similarly valued alternatives is a complex behavior. Multiple studies have shown that making such kind of difficult choice leads to the devaluation of the rejected alternative (Brehm, 1956). This choice-induced preference change (CIPC) is one of the main observable effects of cognitive dissonance (CD) that occurs as a reaction to inconsistency (Festinger, 1957). Temporal dynamics and neuronal mechanisms of the CD and subsequent CIPC are still not fully understood. Neuroimaging studies revealed probable crucial brain regions, including posterior medial frontal cortex (pMFC). An activity of this region is associated with performance monitoring and detection of cognitive conflicts (Debener et al., 2005) and expressed in the generation of electrophysiological error-related negativity component (ERN). Modern CD theories assume the role of the pMFC is linked with the detection of dissonance in difficult choices.
Latest studies of our research group were dedicated to the possibility of CIPC modulation using transcranial direct current stimulation (tDCS) of the pMFC. One of the previous studies (Colosio et al., 2018) showed that cathodal (inhibitory) tDCS has a small decreasing effect on CIPC comparatively to the spurious stimulation (sham) ($t(16) = -3.29$, $p = .002$, Cohen's $d = .29$). However, the application of the anodal (excitatory) tDCS did not show a significant result ($t(17) = -1.08$, $p = .15$). The ongoing study is aimed to check the effect of the stimulation of the pMFC in more robust conditions and using a more focused stimulation protocol.
We suppose to modulate both behavioral (CIPC) and electrophysiological (ERN amplitude) measures of the CD using transcranial magnetic stimulation (TMS). Here we use 20-40 s of the theta burst stimulation (TBS) before performing the difficult choices between two alternatives. For the checking duration and depth of the stimulation effect, we carry out additional control study using the same TBS protocol of the inferior part of the primary motor cortex with the registration of the motor evoked potential (MEP). Obtaining the deflection in CIPC and ERN under the TBS will allow to link the activity of the pMFC and CD processes more reliably. More importantly, through the observation of MEP amplitude damping and adjusting duration of stimulation, we may be able to clarify does CIPC occur already on the decisional stage of choice or after it as mostly considered before. It also can give us an opportunity to go further in the specification of the temporal neurodynamics of the CD using online TMS.

Title: Reinforcer devaluation in humans using task delays as reinforcers

Authors: *H. LIN, S. ZIMMERMAN, C. LONG, C. L. PICKENS;
Kansas State Univ., Manhattan, KS

Abstract: Reinforcer devaluation refers to tasks in which a cue predicts an outcome in a first phase, the value of the outcome is decreased subsequently, and there is then a test of whether participants spontaneously decrease their responding associated with that outcome. This task is common in non-human animals, but less common in humans. One possible reason why devaluation tasks are rare in humans is that the standard devaluation task tends to use tangible reinforcers (ex: foods) or physically aversive stimuli (ex: shocks) as the outcomes, and it is more difficult to use these outcomes with human participants. Our present experiment was meant to determine whether shorter task delays (that made task end sooner) would be reinforcing, and whether this reinforcing value would be sensitive to devaluation. Undergraduate students were given cue exposure phases alternating with response phases. In the cue exposure phases, the participants were exposed to black shapes (spade, club, heart, diamond) associated with delays that were longer (18-second) or shorter (0.5-second) than the intermediate delay of 8 seconds (associated with a circle shape). In the response phases, the participants were presented with different colored squares (yellow, green, blue, red). Responses during presentations of the different colored squares earned a shape (ex: responses during the yellow square earned the spade and a 0.5-second delay, responses during the red square earned the diamond shape and an 18-second delay). Withholding responses during the shapes always earned the circle shape and an 8-second delay. In the final cue exposure phase, the value of one of the card suit shapes that previously predicted a short delay was decreased/devalued by now having it predict a longer delay (ex: the spade shape went from being associated with a 0.5-second delay to being associated with an 18-second delay). In the subsequent response phase (which functioned as an extinction test, as responses always led to the circle shape and 8-second delay), responses to the colored square that predicted the devalued shape were decreased compared to responses to another colored square that continued to predict a shape associated with a 0.5-second delay. This suggests that task delays changes can act as reinforcers to support responding, and these reinforcers are sensitive to devaluation.

Title: Neuro - computational process for deciding with predicting others' decision

Authors: *N. MA[1], N. HARASAWA[1], K. UENO[2], N. ICHINOHE[4], M. HARUNO[5], K. CHENG[3,2], H. NAKAHARA[1];
[1]Lab. for Integrated Theoretical Neurosci., [2]Support Unit for Functional Magnetic Resonance Imaging, [3]Lab. for Cognitive Brain Mapping, RIKEN Ctr. for Brain Sci., Wako, Japan; [4]Dept. of Ultrastructural Res., Natl. Inst. of Neuroscience, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [5]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communication Technol., Osaka, Japan

Abstract: In social life, humans are often required to consider others' decisions to make better decisions. A question of the neuro-computational process is poorly understood: how does the prediction about others' decisions contributes to one's own better decision-making? We addressed this issue by tracking the corresponding brain signals in human fMRI in relation to behavior which helped us dissociate them. We devised a novel behavioral task in human fMRI, combined with computational modeling. In our task, there is a main trial together with two types of control trial, self and other trials. In the main trial, the subject was required to make a choice from two options while predicting others' choice of two options, because the subject received outcomes differently, dependent upon the choice of others. In self and other trials, we separately examined each of two elementary processes in the main trial, making self value-based decisions and predicting others' decisions, respectively. In behavior, we found that the subject made choices in the main trial, combining two possible decision values (DVs), each of which would be generated by having two different prediction of others' choice, and weighting them with the predictions. Using model-based analyses, we examined the BOLD signals, in contrast with those by the DVs in the self trial and predicted-others' DVs in the other trial. First, we found that the self DV had significant activations in the medial prefrontal cortex (mPFC) for both main and self trials, while the others' DV had significant activations in the right temporoparietal junction (rTPJ) for both main and other trials. Second, to probe integration process of predicting others' decision to decisions, we introduced an intermediate variable called effectivity, which quantified how much the prediction contributed to the decisions in the main trials. We found the effectivity correlated with significant activations of the right anterior insula (rAI) and left dorsolateral prefrontal cortex (ldlPFC). Finally, using connectivity (psychophysiological interaction) analysis, we found that the rTPJ responses had significant impacts on the mPFC responses, but only mediated through rAI in the main trials, whereas there was direct impact of the rTPJ on the mPFC responses in the other trials. Taken together, these findings suggest that the additional neuro-computational processes are recruited to integrate the prediction about others' decisions for making one's own better decisions.

Title: Phasic arousal suppresses suboptimal decision biases in mice and humans

Authors: *J. W. DE GEE[1], K. TSETSOS[2], L. SCHWABE[3], A. E. URAI[4], A. BERGT[3], D. A. MCCORMICK[5], M. J. MCGINLEY[1], T. H. DONNER[6];

Hamburg-Eppendorf, Hamburg, Germany

Abstract: Decisions under uncertainty entail an accumulation of ambiguous evidence supporting different choice alternatives. The brain's arousal systems are rapidly recruited during such decisions. But how do the rapid ("phasic") arousal boosts affect decision-making? We here established a principle of the function of phasic arousal in decision-making, which generalizes across species (humans and mice) and behavioral tasks (from perceptual to memory-based and numerical decisions): suppressing maladaptive biases in the accumulation of evidence leading up to choice. We exploited that pupil dilation indexes cortical arousal state as well as response of the noradrenergic locus coeruleus in humans, monkeys and mice.
We recorded the pupil diameter of 20 humans and 5 mice during a difficult auditory go/no-go detection task. Humans responded with a button press, mice by licking for sugar water reward. In addition, 15 human subjects performed a forced-choice decision task based on identical stimuli under systematic manipulations of target probabilities, 54 human subjects performed a memory-based decision task, and 37 human subjects performed a basic laboratory task model of value-based stock market decisions.
In mice and humans, task-evoked pupil responses occurred early during decision formation, even on trials without any motor response, and predicted a suppression of a suboptimal conservative choice bias. Drift diffusion modeling revealed that the bias reduction was due to a selective interaction with the evidence accumulation process, rather than a shift in starting point. We showed that, within the same subjects, phasic arousal flexibly reduces both conservative and

liberal accumulation biases in a context-dependent manner. The same pupil-linked suppression of evidence accumulation bias also when evidence is accumulated from memory. Finally, by comparing a leaky selective integration model to other accumulation-to-bound models, we found a similar reduction in evidence accumulation bias towards risk-seeking, a higher-level form of human bias widely known in behavioral economics.
Our findings point to a precise, yet broadly generalized, role for global arousal state of the brain in decision making in the face of uncertainty. Our results indicate that pupil-linked phasic arousal suppresses choice biases in evidence accumulation across species and across domains of decision-making, ranging from decisions based on low-level perceptual evidence, to evidence sampled from memory, to high-level numerical evidence. In conclusion, phasic arousal calibrates a key computation during decision-making.

Title: Helping or punishing: The influence of testosterone and acute stress

Authors: *H. WANG[1,2], C. LIU[1,2], R. ZHU[2,1], S. ZHANG[2,1];
[1]Beijing Normal Univ., Beijing, China; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China

Abstract: Humans display an intriguing propensity to help the victims of social norm violations or punish the violators. The acute stress have been implicated in modulating various social behaviors including trust, risk-taking. However, it is still elusive how stress influence the third-party altruistic decision, especially when people face the conflict of self-interest and others' interests. To address this question, the participants were exposed to either a physical stressor (CPT, Cold Pressor Test) or a (TSST, Trier Social Stress Test) or a accordant control condition , and then completed an economic decision making task in which they could use MUs from their own endowment to either punish a norm violator or help a victim. After the decision making task, the participants was also asked to finish an analogous scenario task. Across both studies, the participants in stress group had a significant increase in cortisol, but the influence of different stressors on third-party decision making are inconsistent. After a psychosocial stress, participants showed more prosocial behaviors. Specifically, stressed participants transferred more MUs to the

victims in the economic decision task when the transgression is more severe, and were more likely to help the victims in scenario task than the control group. On the contrary, after a physical stress, participants prefer to punish the violators and decrease the tendency to help the victims, moreover, for the scenario task, most participants are prone to help the victims, physical stress has no significant impact.
As the previous studies found that testosterone can promote punish perpetrators. To explore the increased punishing behavior after physical stress, we focus on the dual-hormone effect in the CPT study. As a result, for individuals who showed higher basal testosterone was prior to punish violators, for those who has a lower basal testosterone trends to help victims, but this only occurs when the individuals are not under stress conditions. In the stress condition, the helping behavior of lower basal testosterone individual was suppressed, but the punishing behavior of higher basal testosterone was enhanced. This is consistent with previous findings about dual-hormone effect.

Title: The neural correlate of legal judgment: Do legal expertise and a trust in the law make a difference ?

Authors: T. ASAMIZUYA[1], H. SAITO[1], S. OTA[2], *J. KATO[1];
[1]The Univ. of Tokyo, Tokyo, Japan; [2]Meiji Univ., Tokyo, Japan

Abstract: The neural correlate of the legal judgment of ordinary people has been underexplored, although the lay-judge system is an important part of the court system in many countries, including Japan, Korea, the United States, and the United Kingdom. On campus, we recruited two groups of participants: students on campus who are not specialized in law and law students who had just passed the national bar exams. We also recruited lawyers who have had experience in legal practice. The novelty of our approach is examining the difference in brain activation between legal professionals and lay people. In addition, we examined the difference in rsfMRI between legal professionals and lay people. Inside an MRI machine, participants were asked to read vignettes about criminal procedure cases and make legal judgments. With close cooperation from legal specialists, five murder cases were used to examine the effect of the repentance of the

defendant on the judgment of an appropriate punishment. We focused on the brain activity that is associated with legal judgment when a defendant does or does not show repentance. We examined whether and to what extent legal expertise and one's attitude toward the legal system make a difference in a participant's neural correlates when he/she makes legal judgments. Differential activation was found between those with and without legal expertise in the default mode network, i.e., the dorsal anterior cingulate cortex, the caudate nucleus, and the insula. The results also indicate that the strength of support for the legal system dissociates brain activation when non-law students made a legal judgment, but did not when law students and lawyers made a judgment. Overall, the neural correlates suggest that both legal expertise and a trust in the law make a difference in the brain activity.

Title: Trait level influences on political preference shifts differ between Democratic- and Republican-supported laws

Authors: *B. B. LU[1], J. ZIMMERMANN[3], J. J. VAN BAVEL[2], P. W. GLIMCHER[1];
[1]Ctr. for Neural Sci., [2]Psychology, New York Univ., New York, NY; [3]Dept. of Neurosci., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Unlike value-based decisions, it is unclear if political decisions are made using a principled evaluation of alternatives. Scholars long considered political preferences to be a privileged class of decision-making, much like religious beliefs, that defy logical thought processes. Since the mid-20th century, political science has tried to make sense of this behavior, first using normative economic and later decision theoretic models. Competing schools of thought disagree on the influence of trait political awareness—one's tendency to keep up with politics—as compared to partisanship or in-group identification on voters' preference malleability . Using a novel psychophysical task that orthogonalizes partisanship and political information, we employed a neuroeconomic approach to examine how political information alters preferences. Two behavioral studies, one online and another in the lab, made preference ratings on real proposed laws that have appeared before US Congress. Subjects first reported their preferences based solely on a synopsis of the law, and later reevaluated those preferences after learning about the percent of members of Congress in each party who voted in favor of the

law. Laws' true congressional support were unrelated to their perceived partisanship (i.e., the true levels of support for each bill were completely uncorrelated with participants' estimates of that support). Partisanship predicted preference alignment with the in-group for members of both parties. However, desire for social esteem only predicted alignment with Democrat-favored laws and degree of self-regarding preference only did so for Republican-favored laws. A third study employs a version of this task adapted for functional neuroimaging to pinpoint the neural locus of political preference representation in the brain. While previous studies reported a common neural representation for differing goods types and personal preferences, it is still unclear whether political preferences lie on this same axis.

Title: Inhibition of fast glycine re-uptake restores deficits in mismatch negativity caused by depletion of GluA1 from parvalbumin interneurons

Authors: *R. SPRENGEL[1], M. ZONOUZI[2], V. MACK[2], H. ROSENBROCK[2], **N. SCHUELERT**[2];
[1]Max Planck Inst. for Med. Res., Heidelberg, Germany; [2]CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach an der Riss, Germany

Abstract: Mismatch negativity (MMN) is an auditory event-related potential that provides an index of automatic context-dependent information processing that can be measured in humans and in animal models. Cognitive impairment in schizophrenia is linked to robust abnormalities in the generation of MMN. It has been suggested that cognitive dysfunction might arise from an aberrant interplay of inhibitory parvalbumin (PV) and somatostatin (SOM) positive interneurons with pyramidal cells, leading to an excitation-to-inhibition imbalance and abnormal sensory processing revealed by reduced MMN. In this exploratory study we investigated the impact of Cre-mediated selective depletion of the AMPA-type glutamate receptor subunit 1 (GluA1) from PV positive interneurons in mice on cortical network oscillations and auditory event-related potentials. Previous studies have shown that the lack of GluA1 expression in PV interneurons reduces the excitatory input onto PV positive interneurons leading to neurophysiological abnormalities and cognitive impairment. We have performed wireless EEG recordings from implanted epidural electrodes above the primary auditory cortex and the medial prefrontal cortex of adult of $GluA1^{PVCre-/-}$ and control mice. Our results indicate that GluA1 in PV-positive

interneurons is dispensable for the generation of basal and auditory evoked high frequency oscillations in cortical areas. In contrast, the PV specific depletion of the AMPA receptor subunit GluA1 led to impaired MMN, reminiscent of a cortical processing deficit observed in Schizophrenia. The effect on MMN might indicate a lack of separation between sensory information caused by a lower excitatory input to PV neurons. This effect could be rescued by the GlyT Inhibitor Bitopertin highlighting the impact of NMDA receptor signalling on sensory processing and intact MMN. Thorough histological studies are currently performed to gain more insight to potential changes in cortical network assembly caused by depletion of GluA1 from PV interneurons. Thus $GluA1^{PVCre-/-}$ mouse might represent a suitable model to investigate pathological mechanisms related to insufficient recruitment of PV interneurons and pathological sensory processing.

Title: Neuroprotective effect of ethyl acetate fraction of terminalia macroptera leaf against ketamine-induced schizophrenia related behaviour in mice

Authors: *O. O. SUNDAY[1], L. IOR[2];
[2]Dept. of Pharmacol., [1]Univ. of Jos, Jos, Nigeria

Abstract: It has been hypothesized that oxidative imbalance and alterations in nitrergic signaling play a role in the neurobiology of schizophrenia. The leaf of *Terminalia macroptera* has been reported to possess a number of psychopharmacological activities by traditional herbalists in Northern Nigeria. The present study was carried out to investigate the protective effects of ethyl acetate fraction of *T. macroptera* in an experimental model of ketamine-induced schizophrenia related behaviour in mice. Schizophrenia related behavior was induced by administering sub anaesthetic dose of Ketamine (30 mg/kg) daily for seven days. The effect of the Ethyl Acetate fraction of methanolic extract of *T. macroptera* (100, 200 or 400mg/kg) were compared with the effect of a standard atypical antipsychotic, risperidone (0.5 mg/kg). Behavioral effects monitored include: locomotor activity, stereotype behaviour, immobility duration and memory retention. The effect of test agents on catalepsy in mice was also accessed in wood block test, using haloperidol 1 mg/kg and risperidone 0.5 mg/kg as reference drugs. *T. macroptera* at the dose of 100 - 400 mg/kg significantly ($P \leq 0.05$) reduced ketamine-induced hyperactivity, immobility and memory deficit. The efficacy of Ethyl Acetate fraction of the extract (at the doses used) was

comparable to that of risperidone. The extract did not produce extrapyramidal side effects, as evidenced by decreased descent latency in the wood block catalepsy test in mice. The study revealed that ethyl acetate fraction of *T. macroptera* ameliorate schizophrenia related symptoms in mice, underscoring its antischizophrenic profile. Our findings support the folkloric use of extract of *T. macroptera*.

Title: *In-vivo* optogenetic stimulation of prefrontal PV+ interneurons has a recovering role in a rat model of schizophrenia-like cognitive inflexibility

Authors: *E. PATRONO[1], K. HRUZOVA[1], J. CHVOJKA[2], H. BROZKA[1], D. RADOSTOVA[1], J. SVOBODA[1], P. JIRUSKA[2], A. STUCHLIK[1];
[1]Dept. of Neurophysiol. of Memory, [2]Dept. of Developmental Epileptology, Inst. Of Physiol. CAS, Prague, Czech Republic

Abstract: Cognitive flexibility is an ability to adjust a response based on changed conditions and is disrupted in schizophrenia-like psychosis. Parvalbumin-positive (PV+) interneurons into the medial prefrontal cortex (mPFC) have a critical role in flexibility, and poor function of mPFC-PV+ interneuron is linked to schizophrenia. The aims of the study were 1) to create a new model of acute cognitive inflexibility using systemic injections of MK-801, an NMDA receptor antagonist, and measure it by an Attentional Set-Shifting Task (ASST); 2) to investigate the therapeutical role of mPFC-PV+ interneurons in the acute model of cognitive inflexibility, using in-vivo optogenetics PV+ stimulation in channelrhodopsin-2 (ChR2) transfected rats; 3) to validate the in-vivo optogenetics behavioral outcomes, to check the viral transfection, and the optical stimulation proficiency onto mPFC-PV+ cells. In the ASST, rats learned to dig/retrieve food reward from a cup, after a two dimension-operant-association - relevant (odor) and irrelevant (digging medium). Reversal learning (RL-odor switch) and extra-dimensional shift (EDS-relevancy switch) sessions measured the cognitive flexibility in the rat. AAV-containing-

ChR2 transfections and optic fiber implant were stereotaxically applied into the rat mPFC, unilaterally, 2 weeks before assessing ASST. Immunohistochemistry was performed on transfected/implanted rats previously performing ASST. An in-vitro Opto-Electrophysiology method was used on transfected/implanted rats of the same group. Results showed that acute MK-801 during RL and EDS induced cognitive inflexibility compared to the saline. Moreover, mPFC-PV+ optogenetic stimulation recovers the ability to switch odor and/or medium relevancy. Finally, by immunohistochemistry, AAV-ChR2 transfection occurred in Pre- and Infra-Limbic Cortex; by in-vitro Opto-Electrophysiology, a blue LED light was able to induce a firing activity on transfected brain slices, in Pre- and Infra-Limbic Cortex. We observed that enhancing the inhibitory activity of PV+ interneurons in mPFC is a new experimental therapeutic opportunity to rescue cognitive flexibility in schizophrenia-like psychosis. Moreover, we elaborated a new complex method to validate the behavioral outcomes from in-vivo optogenetics experiments. This work was supported by GACR grant 17-04047S and AZV grant 17-30833A. Institutional support for IPHYS provided by RVO: 67985823. Additional support from MEYS (LM2015062) Czech-BioImaging and H2020 INFRADEV-01-2017 project ID-EPTRI (European Paediatric Translational Research Infrastructure - EPTRI Grant Agreement 777554).

Title: The NMDA receptor antagonist ketamine exerts biphasic effects on mismatch negativity in the rat

Authors: *S. KANTOR[1], B. LAURSEN[2], N. UPTON[1], J. F. BASTLUND[3];
[1]Transpharmation LTD., London, United Kingdom; [2]Translational Biol., Lundbeck, Valby, Denmark; [3]H. Lundbeck A/S, Valby, Denmark

Abstract: Background: Mismatch negativity (MMN) is a component of event-related potentials recorded in the scalp EEG. MMN is diminished in many neuropsychiatric disorders including schizophrenia. Antagonists of the N-Methyl-D-aspartate (NMDA) receptor, such as ketamine, mimic symptoms of schizophrenia and disrupt MMN in healthy volunteers. MMN can be measured in rodents as well. To examine the back-translational potential of the MMN assay, we tested whether ketamine could impair MMN in the rat similar to humans.
Methods: 24 adult (200-250 g) male CD rats (Charles River, UK) were surgically implanted with telemetry transmitters (HD-S02; DSI, USA) for fronto-parietal EEG and EMG recordings.

MMN was elicited in awake, freely-behaving rats by an auditory oddball paradigm in which a deviant ('oddball'; DEV) tone occurred randomly within a sequence of identical tones ('standards', STD). Components of the auditory evoked potential (AEP) were measured in difference (DIF) waves that were generated by subtracting STD waves from DEV waves. After establishing the baseline MMN, the rats were treated with ketamine (3, 10 and 30 mg/kg, s.c.) or its vehicle (saline, 5 ml/kg) in a cross-over design with 3-4 days washout between the treatments. The MMN protocol was started immediately after the treatment and the data recorded between 20-80 min post-treatment was used for analysis. In addition to analysing MMN, we also performed a spectral analysis of the EEG.
Results: We found that high dose of ketamine (30 mg/kg) significantly reduced the amplitude of AEP in DIF waves compared to vehicle treatment, thereby demonstrating impaired MMN in the rats. Specifically, we found that ketamine (30 mg/kg) reduced the absolute distance between N1-P2 peaks (10.5 ± 1.1 μV vs. 7.3 ± 0.5 μV) as well as the area under N1 peak (30-60 ms; -70.3 ± 11.2 μV^2 vs. -31.0 ± 5.3 μV^2) in DIF waves. In contrast, the low dose of ketamine (3 mg/kg) improved some components of the AEP including the sum of all values in the 20-50 ms region of N1 in DIF waves (-7.7 ± 8.411.2 μV^2 vs. -31.4 ± 7.3 μV^2). Besides altering MMN, ketamine also increased EEG gamma (30-100 Hz) oscillations in the rats in a dose-dependent manner.
Conclusion: We have shown that rats have a clear electrophysiological correlate of the clinical MMN and that can be impaired by high dose ketamine treatment. Our data also suggest that low doses of ketamine may have beneficial effects on MMN that is in contrast with the detrimental effect caused by high doses of the drug. Overall these data demonstrate that MMN may be a valuable translational tool for testing therapeutics targeting neuropsychiatric disorders including schizophrenia.

Title: GPR52 agonists represent a novel approach to treat unmet medical need in schizophrenia

Authors: A. J. GROTTICK[1], B. GRAYSON[2], G. PODDA[2], N. IDRIS[2], J. C. NEILL[2], ***S. HOBSON**[3];
[1]Beacon Discovery Inc., San Diego, CA; [2]Div. of Pharm. and Optometry, Univ. of Manchester, Manchester, United Kingdom; [3]CNS Dis. Res., BI Pharma Gmbh & Co. KG, Biberach a.d. Riss, Germany

Abstract: GPR52 is an orphan G-protein coupled receptor that is selectively expressed in brain. In the cortex, it co-localizes with dopamine D1 receptors (D1R) on glutamatergic neurons. Deficiencies in D1R activation are associated with both cognitive impairments associated with schizophrenia (CIAS) and negative symptoms. In contrast, in the striatum, GPR52 co-localizes almost exclusively with dopamine D2 receptors, where inhibition mediates antipsychotic efficacy. Based on GPR52's expression pattern and Gs functional coupling, agonists would be predicted to functionally resemble D1 agonists in cortical areas and to resemble D2 receptor antagonists in the striatum, thus holding the potential to provide a novel treatment for the three core symptom domains associated with schizophrenia. To assess for antipsychotic potential, a GPR52 agonist was tested in an amphetamine-induced hyperlocomotion model. The efficacy of a GPR52 agonist for CIAS and sociability, an aspect of negative symptoms, was assessed in the sub-chronic phencyclidine (scPCP) model for schizophrenia, known to induce long-lasting cognitive and social behaviour deficits, in addition to a reduction in parvalbumin-positive GABAergic interneurons in hippocampus and pre-frontal cortex. In the scPCP model, rats were tested in the attentional set shifting task (ASST) for executive function and the social interaction (SI) test for sociability, respectively, following treatment with a GPR52 agonist. GPR52 agonists were efficacious in these animal models assessing the three main symptom domains associated with schizophrenia. Efficacy in ASST and SI demonstrate both pro-cognitive efficacy and restoration of an aspect of negative symptoms, in a well-established model inducing behavioral and neuropathological deficits associated with schizophrenia. Furthermore, GPR52 agonists reduced psychostimulant-induced hyperlocomotion, an effect associated with antipsychotic efficacy. Taken together, these data demonstrate the potential of this innovative mechanism to simultaneously treat the three core symptoms domains associated with schizophrenia.

Title: Rapid augmentation of antipsychotic drugs by sodium nitroprusside. Behavioral assessment and effect on brain dopaminergic transmission in rats

Authors: *J. TITULAER[1,2], A. MALMERFELT[1], M. MARCUS[1], A. PERRONE[3], G. ALKEN[3], J. P. LOWRY[4], T. H. SVENSSON[1];
[1]Karolinska Institutet, Stockholm, Sweden; [2]Dept. of Pharmaceut. Biosci., Uppsala Univ., Uppsala, Sweden; [3]BDD Berolina Drug Devolopment, Berlin, Germany; [4]Maynooth Univ., Maynooth, Ireland

Abstract: Background
Recently, a single injection of the nitric oxide donor sodium nitroprusside (SNP) was found to induce a rapid (within 4 hours) and sustained (several weeks) antipsychotic effect in treatment-resistant schizophrenic patients [1]. Moreover, SNP was shown to generate both rapid and persisting changes in brain synaptic plasticity, including enhanced excitatory postsynaptic current responses and spine morphology in layer V pyramidal cells in rat medial prefrontal cortex (mPFC) brain slices [2]. Here, we have studied the antipsychotic-like effect of SNP in combination with risperidone (RISP) in rats.
Methods
We used the conditioned avoidance response (CAR) test to investigate the antipsychotic-like efficacy, as well as in vivo microdialysis and NO selective amperometry in freely moving animals to measure neurotransmitter efflux in the mPFC and the nucleus accumbens (NAc). All experiments were approved by the local animal ethics committee, Stockholm North, and the Karolinska Institutet, Sweden.
Results
Addition of SNP to RISP dramatically enhanced the antipsychotic-like effect of RISP in the CAR test. In the mPFC, addition of SNP significantly enhanced the risperidone-induced dopamine output, whereas there was no difference in the NAc in risperidone-induced dopamine output after SNP was added. Furthermore, we found that SNP resulted in a strong and immediate but short-lasting increase of NO levels in the mPFC and the NAc.
Conclusions
The present preclinical results support the clinical observation that a single injection of SNP can rapidly and dramatically augment the clinical efficacy of antipsychotic drugs in schizophrenia. SNP selectively increased risperidone-induced prefrontal dopamine release, while not increasing risperidone-induced dopamine release in the NAc. Therefore, the antipsychotic effect of SNP seems to be achieved by enhanced prefrontal dopamine output. Based on these findings it could be expected that SNP improves cognition as D1 receptors in the prefrontal cortex play a crucial role in cognition. Our results were obtained using a low dose of SNP and a low dose of RISP, indicating that both drugs could be administered in a lower dose in patients, reducing the risk of side effects.

Title: Discovery of TAK-041: A potent and selective GPR139 agonist for the treatment of negative symptoms associated with schizophrenia

Authors: *R. HODGSON[1], J. ATIENZA[2], H. REICHARD[2], V. MULLIGAN[3], J. CILIA[3], H. MONENSCHEIN[2], D. COLLIA[3], J. RAY[4], N. L. BRICE[5], G. KILPATRICK[3], M. CARLTON[3], S. HITCHCOCK[2], G. CORBETT[3], H. H. SCHIFFER[6];

Abstract: Individuals with schizophrenia frequently have residual motivational and social deficits, in addition to cognitive impairment, which are thought to relate to abnormalities in midbrain dopamine activity. The habenula is a well conserved paired structure, which is part of the reward pathway and functions with dopamine neurons in the ventral tegmental area to mediate reward related signals, specifically aversive and negative stimuli (Hikosaka, 2010); pathology in the habenula contributes to schizophrenia (Sandyk, 1992; Caputo *et al*., 1998; Shepard et al., 2006). Despite many studies on the habenula, its precise function remains unclear. Here we describe functional consequences of regulation of GPR139, an orphan *G protein-coupled receptor* (GPCR) that is specifically expressed in the CNS and enriched in the habenula (Matsuo *et al*., 2005) in mouse models of schizophrenia. Specific expression of mouse GPR139 in the habenula was evaluated using BacTrap and confirmed by immunohistochemistry.

GPR139-/- mice were generated by removal of a 736bp region encoding the seven-transmembrane domain. We expressed full length GPR139 in CHO cells and screened a 600K compound library using a calcium assay to identify small molecule agonist. Hits were identified and physical properties optimized to produce the GPR139 agonist molecule TAK-041 suitable for *in vivo* evaluation. Using BacTRAP we observed enriched expression of GPR139 in substance P positive cells of the medial habenula. This expression was confirmed with immunohistochemistry. To determine if GPR139 regulates the hypothesized role of the habenula in learning, motivation, and social behavior, GPR139 -/- animals inbred on a 129/SvEv background were generated and phenotyped. These animals appeared normal and performed comparably to wild-type animals in a range of standard tasks. However, they were significantly impaired in models that reflect aspects of negative symptoms such as progressive ratio, a measure of motivation, and nest-building, a model of self-neglect. Furthermore, these animals showed deficits in the novel object recognition model of working memory. The small molecule GPR139 agonist TAK-041 was observed to reverse deficits in models of schizophrenia, including cognition in a subchronic PCP-impaired attentional set-shifting paradigm (Birrell and Brown, 2000) and impaired social interaction in the Poly(I:C) maternal immune activation model (Bitanihirwe *et al*., 2010). These data further support the hypothesis that the habenula plays an important role in schizophrenia, and that selective GPR139 agonists may be a beneficial treatment for the disease.

Title: Acute restraint stress differently alters prepulse inhibition of the acoustic startle reflex and social interaction in male wistar rats. The role of the inferior colliculus in the modulation of these responses

Authors: *R. SILVA, P. SILVA, A. WERDER, R. DE OLIVEIRA, J. SIMOES, D. ORTOLANI, I. CESPEDES, R. SPADARI, M. B. VIANA;
Biociencias, Univ. Federal de São Paulo, Santos, Brazil

Abstract: Stress plays a role in many psychiatric disorders that are characterized by deficits in prepulse inhibition,PPI. PPI impairment is observed in schizophrenic patients and serves as an index of attention deficit. These deficits may be linked to impairments in sensorimotor gating a mechanism that enables normal individuals to suppress irrelevant information which allows the hierarchical organization of the most relevant information. The inferior colliculus, IC, is a critical structure of the auditory pathway mediating acoustic PPI. One of the main negative symptoms of schizophrenia is social withdrawal. Social behavior can be measured in rodents by the interaction between animal pairs, being a component of the pair considered a reference for the test. The aim of this study was to investigate the effect of exposure of male wistar rats, 250-280 g, to restraint stress, RS, in PPI, social interaction, SI, and corticosterone levels, CL. Analysis of fos protein immunoreactivity, fos-ir, was used to map areas activated by exposure of rats to RS for 15 min, in an acrylic restraining cylinder, previously to the tests. For the PPI test, 18 rats were divided in 2 groups N=9 per group: nonstressed, and stressed. The stressed rats showed a significant increase in PPI response observed in all three prepulse intensities levels compared to nonstressed controls. A possible explanation would be that RS exposure alters processing of external stimuli enhancing attention and thereby influences the effectiveness of a prepulse to inhibit startle responding. For SI test, 40 rats were divided in 4 groups N=10 per group: vehicle-nonstressed; vehicle-stressed; clozapine-nonstressed, and clozapine-stressed. Prior to RS the animals received intraperitoneal injection of vehicle or clozapine, 5 mg/kg.The vehicle/stressed group showed a significant decrease in SI duration in comparison to the other groups probably due to an increase in anxiety levels. Pretreatment with clozapine, prior to RS, was effective in blocking anxiety, facilitating SI behavior in the clozapine/stressed group showing an anxiolytic effect. Measurement of CL showed a significant increase in vehicle/stressed animals. Analysis of fos-ir showed that, among all the analyzed areas, the IC presented the highest mean of activation in the stressed animals. In conclusion, our results confirm that exposure to stressful events is considered an important risk factor in the pathophysiology of schizophrenia triggering physiological, behavioral and emotional changes. Moreover, although the IC is classically related to auditory pathways it seems to be also involved in the elaboration of emotional responses.

Title: SUVN-1702012 a multimodal molecule demonstrating separation between antipsychotic and motor side effects

Authors: *A. K. SHINDE, **J. TADIPARTHI**, J. FERNANDES, R. MEDAPATI, A. VYURU, S. PETLU, V. MEKALA, R. SUBRAMANIAN, S. EDULA, M. SRIRANGAVARAM, R. ABRAHAM, P. ACHANTA, J. THENTU, N. MUDDANA, R. NIROGI;
Discovery, Suven Life Sci., Hyderabad, India

Abstract: There is an unmet medical need in the treatment of psychotic patients due to treatment resistance or debilitating side effects. SUVN-1702012 is a multimodal lead molecule having affinity for 5-HT/dopamine receptors and proposed for the treatment of psychosis. *In-vitro* pharmacological properties of SUVN-1702012 were evaluated in radioligand binding assay. The pharmacokinetic profile and brain penetration of SUVN-1702012 was evaluated in rodents. SUVN-1702012 reversed head twitches induced by 1-(2, 5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI) and hyperlocomotion induced by amphetamine. The doses, at which significant effect was observed in the above assays did not cause motor in-coordination, assessed using the rotarod test. SUVN-1702012 did not induce catalepsy and the time taken to correct the posture was similar to that of vehicle. SUVN-1702012 did not have propensity to induced tardive dyskinesia at the tested doses. Non-radiolabeled assay was used to assess the occupancy of test compound at 5-HT2a, 5-HT1a and D2 receptors in rats. From the current research we conclude that SUVN-1702012 has therapeutic potential to reverse psychosis without inducing debilitating side effects associated with antipsychotics

Title: Nasal respiration drives high frequency oscillations after ketamine in the rat olfactory bulb

Authors: *J. J. WROBEL[1], W. SREDNIAWA[1,2], D. K. WOJCIK[1], M. J. HUNT[1];
[1]Lab. of Neuroinformatics, Nencki Inst. of Exptl. Biol. PAS, Warsaw, Poland; [2]Univ. of Warsaw, Warsaw, Poland

Abstract: Subanesthetic doses of ketamine are used to model schizophrenia in humans and experimental animals. Abberant high frequency oscillations (HFO) 130-180 Hz have been reported in various rodent brain regions following ketamine administration, however the mechanisms underlying the generation of this activity remain unclear. We have shown recently that the rat olfactory bulb (OB) is an important generator of HFO, post ketamine, indicating that sensory input may drive this activity. In this study we recorded local field potentials in the OB and nasal respiration using thermocouples, in freely moving rats. We found that ketamine 20 mg/kg, at a dose that increased locomotion (measured by beam breaks), increased the amount of fast exploratory sniffing behaviour. Post ketamine, HFO in the OB were modulated by a slower 2-12 Hz oscillation that was coupled to nasal respiration on a cycle-by-cycle basis. Unilateral naris blockade attenuated ketamine-induced increases in HFO power on the ipsilateral, but not contralateral side. Bilateral naris blockade produced more complex effects on ketamine-induced HFO, with both reductions in HFO frequency and power observed. Notably, following bilateral naris blockade we also observed a significant reduction in ketamine-induced locomotion, not present after unilateral blockade. Together, these findings show that nasal respiration drives and underlies the coupling of HFO, post ketamine, to lower frequencies. We speculate that the presence of HFO, after ketamine, leads to abnormal processing of olfactory information which contributes to behavioural hyperactivity in rodents.

Title: Obsessive-compulsive disorder-like behaviors in clozapine-treated mice

Authors: *S. KANG, H. NOH, C. KIM;
Dept. of Pharmacology, Brain Korea 21 PLUS project for Med. Sci., Yonsei Univ. Col. of Medecine, Seoul, Korea, Republic of

Abstract: Clozapine is an atypical antipsychotic drug, which has been used as an effective treatment for schizophrenia. However, their wide range of pharmacological actions to multiple receptors can give rise to various adverse effects. Several clinical studies have reported obsessive-compulsive disorder (OCD) symptoms in schizophrenic patients with chronic pharmacotherapy of clozapine. So far, the relationship between OCD and schizophrenia remains complex, and possible explanations as to why OCD is frequently associated with schizophrenia have been proposed including that OCD is a subgroup of schizophrenia or unmasked by treatment in schizophrenia or induced *de-novo* as one of the aversive effects of treatment. To find out the effects of clozapine on the emergence of OCD symptoms, using mice model of clozapine administration was required. Therefore, we used C57BL6/J wild-type (WT) adult mice to investigate whether clozapine induces *de-novo* onset of OCD-like behaviors. The mice were administered with either clozapine or placebo for 28 weeks, starting from 12-week-old. They were regularly implanted every 60 days with subcutaneous pellets, which release clozapine 0.06 mg/day for 60 days. Behavioral analysis of grooming time and grooming bouts was conducted using video recording at the age of 15, 20, 30 and 40 weeks. Here, we showed that clozapine-treated mice significantly increase repetitive self-grooming behavior after 18 weeks of clozapine treatment. Previous studies reported that genetic deletion of SAP90/PSD95-associated protein 3 (SAPAP3 also known as DLGAP3) induced OCD-like behavior in mice; furthermore, there are significant associations between clozapine-induced OCD symptoms and genetic variants of DLGAP3 in schizophrenic patients. Hence, we wanted to further analyze clozapine-induced OCD-like behavior using DLGAP3 heterozygous knock-out (HET) mice. We observed that clozapine-treated DLGAP3 HET mice also significantly increased self-grooming behaviors, and moreover, it was triggered at an earlier time point compared to the WT mice. Together, these findings highlight that chronic clozapine treatment induces *de-novo* OCD-like symptoms in mice model, suggesting that clozapine might induce OCD-like symptoms in schizophrenic patients irrespective of the brain pathology and the course of schizophrenia.

Abstract: Compelling animal and clinical studies support the N-methyl-d-aspartate receptor (NMDAR) hypofunction hypothesis of schizophrenia and suggest promising pharmacological agents to ameliorate negative and cognitive symptoms of schizophrenia. Sarcosine, a glycine transporter-1 inhibitor, was found to improve schizophrenic symptoms in add-on and monotherapy clinical studies. It is imperative to evaluate the therapeutic effect of sarcosine in animal models, which provide indispensable tools for testing drug effects in detail and elucidating the underlying mechanisms. In this study, a series of 7 experiments was conducted to investigate the therapeutic effect of sarcosine in the amelioration of schizophrenia-related behavioral deficits and the underlying mechanism in pharmacological (i.e., MK-801-induced) and genetic (i.e., serine racemase-null mutant ($SR^{-/-}$) mice) NMDAR hypofunction models of schizophrenia. In Experiments 1, our results indicated that the acute administration of 500/1000 mg/kg sarcosine (i.p.) had no adverse effects on motor function and serum biochemical responses. In Experiments 2-4, sarcosine significantly alleviated MK-801-induced (0.2 mg/kg) brain abnormalities and behavioral deficits in MK-801-induced and $SR^{-/-}$ mouse models of NMDAR hypofunction. In Experiment 5, the injection of sarcosine enhanced CSF levels of glycine and serine in rat brain. In Experiments 6-7, we show for the first time that sarcosine facilitated NMDAR-mediated hippocampal field excitatory postsynaptic potentials (fEPSPs) and

influenced the movement of surface NMDARs at extrasynaptic sites. Collectively, sarcosine effectively regulated surface trafficking of NMDARs, NMDAR-evoked electrophysiological activity, brain glycine levels, and MK-801-induced abnormalities in the brain, which contributed to the amelioration of schizophrenia-related behavioral and cognitive deficits in NMDAR hypofunction models of schizophrenia.

Title: Disruption of CA1 sharp-wave ripples by the nonbenzodiazepine hypnotic eszopiclone

Authors: L. A. BECKER[1], H. PENAGOS[2], D. S. MANOACH[3], M. A. WILSON[2], *C. VARELA[4];
[1]Stony Brook Univ., Stony Brook, NY; [2]MIT, Cambridge, MA; [3]Psychiatry, Massachusetts Gen. Hospital, Harvard Med. Sch., Charlestown, MA; [4]Florida Atlantic Univ., Boca Raton, FL

Abstract: Sleep-dependent memory consolidation relies on the coordination of hippocampal, thalamic and neocortical activity. Hippocampal sharp wave ripples (SWRs), which correspond to the reactivation of memory representations, are correlated with neocortical slow oscillations and thalamocortical spindles, and this coordination is thought to facilitate the transfer of memory traces from the hippocampus to neocortex during sleep. Neuropsychiatric disorders such as schizophrenia show disrupted sleep oscillations, which correlate with cognitive impairment. Compounds that enhance these oscillations could therefore have value for the treatment of cognitive deficits in schizophrenia. One candidate is *eszopiclone* (ESZ), a nonbenzodiazepine sedative hypnotic that is used to treat insomnia. We sought to characterize the single-cell and circuit-level effects of ESZ on coordinated sleep oscillations.
We used multi-tetrode implants in male Long-Evans rats (n = 3) to record local field potentials (LFPs) and single units from CA1 in the hippocampus, the retrosplenial cortex and the thalamus. The rats were also implanted with an intraperitoneal infusion cannula for drug delivery.
We recorded from these three brain regions for > 3 hours/recording session in 3 rats. We used

two controls: we compared two ESZ (10 mg/kg) and two vehicle infusions per rat; we also recorded one hour before infusion to obtain a within-session baseline. We find that cell firing in the retrosplenial cortex and in CA1 decreases after ESZ compared to vehicle, and the effect is strongest in CA1 (up to 40 % decrease in firing). To study sleep population dynamics, we detected sleep events from the filtered LFPs: K-complexes in retrosplenial cortex (KCs, which mark the down-states of the slow oscillation), and SWRs in CA1. We observed a reduction in the number of SWRs after ESZ, and no substantial change in the rate of KCs. Lastly, spectral analyses show a decrease in power in the CA1 100-275 Hz band, confirming a disruption of CA1 SWRs.
The results suggest that ESZ may have an adverse effect on hippocampus-dependent memory due to an impairment of CA1 SWRs. These results may explain its failure to improve sleep-dependent memory consolidation in humans; they also validate a rodent preparation that can be used to evaluate the effect of drugs on the oscillations that are key for memory consolidation, prior to clinical trials to improve memory in schizophrenia and other disorders.

Title: Cerebrolisyn treatment improves behavioral deficits and neuronal changes in a prenatal immune challenge

Authors: *G. TELLEZ[1], F. DE LA CRUZ[1], G. FLORES[2];
[1]Inst. Politécnico Nacional, Mexico, Mexico; [2]Inst. de Fisiología Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: Cerebrolysin (CBL) is a neuropeptide mixture that is known to stimulate the activation of neurotrophic factors (Ubhi et al., 2015), increase neuronal survival in a transgenic mouse model of Alzheimer disease (Rockenstein et al., 2015) and ameliorate neuronal changes in limbic regions and behavioral deficits (Vazquez-Roque et al 2012, 2014) in an animal model of schizophrenia.
Also, it was observed that CBL treatment improves cognitive deficits in schizophrenic patients (Xiao et al., 2012). The prenatal immune challenge using lipopolysaccharide (LPS), a potent immune activator. It is based on the fact that maternal infections during pregnancy can result in

behavioral and neuronal dysfunctions in the adult offspring, which are associated with schizophrenia-related behavior in rodents. Currently, the main objective of schizophrenia treatment is based on counteracting the positive symptoms. However, other aspects of the pathology also need to be addressed. In the present report, we evaluate the effect of chronic CBL treatment at post-pubertal age on behavior and neuronal morphology changes induced by LPS prenatal exposure in rats. Open field and social interaction tests were performed. Golgi-Cox staining method was used to analyze neuronal morphology in the prefrontal cortex and basolateral amygdala. In a previous study, we found a significant increase in motor activity and a decrease in social interaction in LPS offspring. Also, we reported hypertrophy in the prefrontal cortex and basolateral amygdala. We observed that the CBL treatment ameliorate motor activity and social interaction. The morphological analysis of the prefrontal cortex and basolateral amygdala showed atrophy in the animal exposed to LPS that was restored by the CBL treatment. Our result suggests that CBL ameliorate the behavioral dysfunction and morphological alterations caused by the prenatal immune challenge. (Supported by: CONACyT grants (No. 385511) to GTM).

Title: Nicotine pre-exposure alters PCP-induced hyperlocomotion in adolescent C57BL/6 mice: The impact of the dopaminergic system

Authors: *A. C. DUTRA-TAVARES[1], V. H. DUARTE-PINHEIRO[2], J. O. SILVA[2], A. BANDEIRA-MARTINS[2], C. C. FILGUEIRAS[2], A. C. MANHAES[2], Y. ABREU-VILLAÇA[2]; [1]Physiological Sci., Univ. Do Estado Do Rio De Janeiro, Rio de Janeiro, Brazil; [2]Physiological Sci., State Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: The prevalence of tobacco use is much higher in schizophrenic patients than in individuals that do not develop this disorder. Recently, epidemiological data has shown that

tobacco use often precedes the first psychotic event. Notwithstanding, there is a lack of experimental studies that investigate the impact of previous exposure to nicotine in schizophrenia models. Considering that hyperactivity is a positive symptom of schizophrenia that can be induced in the rodent phencyclidine (PCP) model of this disease, this work aimed to evaluate the effects of nicotine (NIC) pre- and concomitant exposure on PCP-induced hyperlocomotion. Given the established role the dopaminergic system in locomotor activity, we further investigated whether raclopride (RAC), a D2 antagonist, mediates PCP and nicotine effects. To do this C57BL6 mice were exposed to nicotine (24mg/kg/day) or deionized water through osmotic minipumps (1002 model, Alzet) from postnatal day (PN) 37 to PN50. From PN41 to PN43, mice were habituated to an open field arena (60min/day) and to subcutaneous injections. Subsequently, for 7 consecutive days (acquisition period, PN44-PN50), both nicotine-exposed and control mice were submitted to daily open field sessions divided into 3 blocks: 1) 10 min of testing to assess baseline ambulation, 2) raclopride (0.25mg/kg, s.c.) or saline injection followed by 10 min of testing and 3) PCP (2.5mg/kg, s.c.) followed by a 40-min ambulation assessment in the open field. All mice received PCP injections, accordingly, there were four groups: CTRL, n=6; RAC, n=7; NIC, n=8; NIC-RAC, n =7). Ambulation reduced throughout the sessions blocks of the habituation phase. Comparisons between open field blocks 1 and 3 indicated that PCP induced hyperlocomotion throughout acquisition phase. Although in the first acquisition day nicotine reduced PCP-induced hyperlocomotion, with repeated PCP administration a potentialization of PCP-induced hyperlocomotion effect by chronic nicotine was observed. Concerning raclopride effects, this drug decreased PCP effects during acquisition phase. Newsworthy, nicotine increased raclopride inhibitory effect on PCP-induced hyperlocomotion. These results suggest that previous exposure to nicotine can magnify PCP effects, an established pharmacological animal model of schizophrenia, corroborating the shared vulnerability theory of schizophrenia-nicotine dependence comorbid association. Finally, the reduced locomotor activity in mice exposed to raclopride indicate that both PCP and nicotine hyperlocomotor effects are mediated, at least in part, by the activity of the dopaminergic system.

Title: Serpentine and AJC-61 effects on cognitive deficit, locomotor activity and social interaction in phencyclidine (PCP)-treated mice and other behaviors are blocked by the 5-HT_{2C} receptor antagonist, SB242084

Authors: *H. Y. MELTZER[1], K. SCHEIDT[2], A. J. CSAKAI[2], J. MCCORVY[3], L. RAJAGOPAL[4], M. HUANG[5];

Abstract: 5-HT_{2C} agonists have considerable therapeutic potential. The 5-HT_{2C} agonist, vabicaserin, WAY 163909, was effective in preclinical models of antipsychotic activity and in treating acutely psychotic schizophrenia patients. Another 5-HT_{2C} agonist, lorcaserin, is approved but only for weight loss. Weight gain due to antipsychotic drugs (APDs) is due, in part, to 5-HT_{2C}R antagonism. An APD with minimal weight gain and facilitation of weight loss would be highly desirable. We have found that the alkaloids, alstonine, a natural product, and its isomer, serpentine, have 5-HT_{2C}R agonist-like effects. These include inhibition of LMA due to phencyclidine (PCP), an NMDAR uncompetitive antagonist, an indication of antipsychotic activity. This effect is blocked by the neutral 5-HT_{2C} antagonist, SB242084. Based on the structure of these natural products, we have synthesized a series of 9*H*-pyrido[3,4-*b*]indol-6-ols and extensively characterized one of them, AJC-61, in a variety of behavioral assays and microdialysis. Like other 5-HT_{2C} agonists, serpentine and AJC-61 inhibit the release of DA in PFC and dSTR of awake freely moving mice, in an SB242084 dependent manner. Serpentine and AJC-61 restored novel object recognition and reversal learning in mice treated with PCP for 7 days, followed by withdrawal. Both AJC-61 and serpentine restored social interaction in scPCP mice. Thus, AJC-61 has promise as a treatment for cognitive impairment, positive and negative symptoms. AJC-61 restored NOR in 20 month old mice and was also active in the forced swim, marble burying and nestlet shredding tests, indications of efficacy as an antidepressant and OCD. AJC-61 inhibited the increases in cortical glutamate, and other neurotransmitters, following PCP. AJC-61 has only weak affinity for the 5-HT_{2C} and had even lower affinity for D_2, 5-HT_{2A} or other GPCRs, and had little activity in cell-based assays for 5-HT_{2C} activity. AJC-61 or other compounds in this series are being investigated for several clinical indications, including schizophrenia. Supported by donations from the Weisman and Price families and a grant from the Center for Life Processes, Northwestern University.

Title: Schizophrenia-like cognitive control failure after NMDAR blockade reflects disrupted interactions between prefrontal cortex and MD thalamus

Authors: *A. L. DENICOLA[1,2], M.-Y. PARK[1,2], D. A. CROWE[3,2], M. V. CHAFEE[1,2]; [1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Brain Sci. Ctr., Veterans Affairs Hosp., Minneapolis, MN; [3]Biol., Augsburg Univ., Minneapolis, MN

Abstract: Cognitive control deficits are a hallmark of schizophrenia. Our lab studies cognitive deficits in a model of schizophrenia using the Dot-Pattern Expectancy Task (DPX). This task consists of a cue stimulus, a delay period, a probe stimulus and then a response. The response is determined by the combination of the cue and probe: A-cue followed by an X- probe requires a target response and all other cue-probe combinations (AY, BX, and BY) require a nontarget response. Trials are presented in two different set types, balanced (25% of each trial type) and prepotent (69% AX, 12.5% AY and BX, and 6% BY). Patients with schizophrenia perform worse on BX trials due to potential deficits in working memory, context processing, and habitual response inhibition. Brain regions associated with cognitive control and have been found to be hypoactive in patients with schizophrenia include the dorsolateral prefrontal cortex (PFC) and the mediodorsal nucleus of the thalamus (MDT). We have developed a monkey model of schizophrenia by injecting of Ketamine or Phencyclidine (PC), resulting in a BX error during acute drug exposure. Using this model we explored the role of the PFC and MDT during performance of the DPX task. We recorded in both brain regions simultaneously using 32-channel linear silicone electrode arrays, allowing for tetrode-like recording of spike data.
We found that MD contained the full complement of neural signals present in PFC during the task, including 'switch' neurons maximally activated by B-cues during the cue period and the AY cue-probe sequence during the probe period. These neurons appear to encode the likelihood of having to override the prepotent 'target' response in the task based on the stimuli shown and therefore reflect cognitive control. Interestingly, we found that response related activity (both numbers of neuron and signal strength) was strongly enriched in the MD thalamus in comparison to PFC. In addition, we found that the habitual 'target' motor response was much more strongly encoded in MD than PFC, which appeared principally engaged to override this response. Finally, blocking NMDAR using PCP significantly reduced cognitive control signals in both PFC and

MD, but PFC signals were particularly weakened by NMDAR blockade under conditions of increased cognitive control load. These data suggest that, when the network is not working properly, as in the schizophrenia-like state caused by NMDAR synaptic failure, BX errors emerge due to the inability of the PFC to inform the MDT to inhibit the prepotent response.

Title: Disrupting NMDAR synaptic transmission changes causal relationships between cell and network level physiological signals in the prefrontal-parietal network

Authors: E. KUMMERFELD[1], S. MA[2], ***D. A. CROWE**[3], R. K. BLACKMAN[4], M. V. CHAFEE[5];
[1]Inst. for Hlth. Informatics, [2]Div. of Gen. Intrnl. Med., Univ. of Minnesota, Minneapolis, MN; [3]Augsburg Univ., Minneapolis, MN; [4]Psychiatry Residency Program, Brown Univ., Providence, RI; [5]Dept Neurosci / Brain Sci., Univ. Minnesota, Minneapolis, MN

Abstract: A crucial challenge in the biology of neuropsychiatric disease is understanding the relationship between changes in brain function at the cell level, (such as are caused by synaptic failure or genetic mutation,) and changes in brain function at the network level, (such as are detectabledetectible with human neuroimaging techniques and are related to information processing for behavior). To understand these relationships, we applied dynamic causal discoverymodeling to time series of neural data at the cell level (spike trains of individual neurons) and the network level (oscillatory power in local field potential recordings) obtained from monkey prefrontal and parietal cortex during the performance of a task measuring cognitive control failure in schizophrenia. We contrasted causal relationships between these variables (a) , under control conditions, and (b) following systemic blockade of NMDAR synaptic transmission in monkeys we have shown mimics the cognitive control error pattern of patients.
We found that dynamic causal discoverymodeling detected causal relationships between neural signals at the cell level (cell-to-cell based on spike timing), the network level (LFP-to-LFP at different brain sites based on modulation of oscillatory power), and across levels (LFP-to-cell and vice versa). Fitting causal models to neural data recorded under controlbaseline conditions and following NMDAR blockade revealed the contribution of NMDAR synaptic transmission to network dynamics. Blocking NMDAR produced opposite changes in prefrontal and parietal

neural dynamics. Both cell-to-cell and LFP-to-LFP causal interactions were weaker in prefrontal cortex and stronger in parietal cortex following NMDAR blockade. Finally, we found interactions between LFP and cell spiking were strongest in different frequency bands in parietal cortex (primarily theta band) and prefrontal cortex (delta band), and differentially aeffected by NMDAR blockade. These results provide evidence that prefrontal and parietal network dynamics are differentially dependent on NMDAR synaptic mechanisms and that dynamic causal discoverymodeling can capture interactions between brain signals at different levels of physical scale (cell and network). Thisthat could make it possible to infer the state of cell-to-cell interactions in the human brain based on network signals that can be measured in humans.

Title: Administration of rapastinel on multiple dose schedule enhances its antidepressant and cognitive enhancing properties: Evidence for a 5-HT_{1A} dependent mechanism of action

Authors: *M. HUANG[1], L. RAJAGOPAL[1], A. M. ELZOKAKY[1], C. A. RYAN[1], P. BANERJEE[2], H. Y. MELTZER[1];
[1]Psychiatry and Behavior Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL;
[2]Allergan Plc., New Jersey, NJ

Abstract: Rapastinel, an NMDAR positive modulator, has shown antidepressant and cognitive enhancing actions in rodent models, with inconclusive results as adjunctive treatment in depressed patients. We reported that rapastinel 1.0 mg/kg, but not 0.3 mg/kg, significantly reversed the deficit in novel object recognition (NOR) in mice administered the NMDA receptor antagonist, phencyclidine (PCP), for one week (sub-chronic PCP, sc-PCP), suggesting possible efficacy in treating cognitive impairment in schizophrenia and other psychotic spectrum disorders. We have now examined the ability of rapastinel administered subcu at various schedules to restore NOR and mobility in the forced swimming test (FST), a test of antidepressant action, in sc-PCP-treated mice, as well as the role of 5-HT_{1A} agonism in its mechanism of action. We now report that administration of rapastinel at 8 hr intervals on a bid schedule for 3 or 5 days at doses up to 30 mg/kg in sc-PCP mice restored NOR and improved

mobility in the FST, not evident with lower single doses or bid doses for 1 or 2 days. For example, rapastinel (1 mg/kg, subcu bid for 3 days) restored NOR for 9 weeks, while 5 days bid treatment restored NOR for 17 weeks. Rapastinel (10 mg/kg, subcu bid for 3 days) increased mobility in FST for 7 weeks in scPCP mice. This suggests rapastinel has the ability to stimulate neuroplasticity and a link between cognitive impairment and depression based upon shared mechanisms of synaptic dysfunction. Using microdialysis in freely moving mice, we found that rapastinel (3 and 10 mg/kg, subcu) increased efflux of cortical 5-HT, along with dopamine, norepinephrine, acetylcholine, but not glutamate, which might contribute to its cognitive enhancing and antidepressant actions. Pretreatment with the 5-HT_{1A} antagonist, WAY100635, blocked the effect of rapastinel in NOR in wildtype mice and FST in mice which had received both sc-PCP and chronic unpredictable stress, a model of treatment resistant depression. These data suggest that bid schedule with rapastinel may trigger synaptic plasticity. Whether this type of repeated administration will enhance clinical efficacy of rapastinel requires clinical testing.

Title: Bumetanide rescue of phencyclidine-induced deficits in cognition, positive and negative symptoms in mice implicates NKCC1/KCC2-mediated changes in GABAA function in the pathophysiology and treatment of schizophrenia

Authors: *L. RAJAGOPAL[1], H. R. KIM[2], M. MARTINA[3], H. Y. MELTZER[4]; [1]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Dept. of Physiol., Northwestern Univ., Chicago, IL; [3]Northwestern Univ. Med. Sch., Chicago, IL; [4]Northwestern Univ. Sch. of Med., Chicago, IL

Abstract: GABA is the major inhibitory neurotransmitter in the developing and adult brain but in the earliest weeks of life, and in various pathological conditions, it is excitatory, and helps to shape neurocircuitry and neuroplasticity. Whether GABA neurons are excitatory or inhibitory is a function of their chloride content, with high intracellular chloride leading to excitatory

GABAergic activity. The ratio of the activity of two membrane transport proteins which transport sodium, potassium, and chloride ions across the cell membrane, NKCC1 and KCC2, enabling chloride to enter the cell or be extruded, respectively, determines whether stimulation of $GABA_A$ receptors will be depolarizing or hyperpolarizing. Bumetanide is an inhibitor of NKCC1 and can convert $GABA_A$ currents from excitatory to inhibitory. We have found that after one week administration of the NMDAR inhibitor, phencyclidine (PCP), to rodents, a widely studied model of schizophrenia, bumetanide acutely rescued the deficit in novel object recognition, executive function, and working memory produced by PCP treatment. Five days treatment with bumetanide to PCP mice followed by withdrawal restored NOR for up to four weeks with a lesser effect each week. Bumetanide also acutely improved the scPCP-induced deficit in negative symptoms and inhibited amphetamine- and PCP- induced locomotor activity, two distinct models of positive symptoms. Sub-effective doses of bumetanide and the selective GABAA agonist, Gaboxadol, acutely restored NOR in PCP mice. Bumetanide was also effective to alter PCP-induced changes in locomotor activity and social interaction indicating that all major dimensions of schizophrenia may be sensitive to this mechanism. We subsequently found that scPCP in 20 week old mice increases NKCC1, without altering the level of KCC2, in the PLC sub-region of the PFC (Kim et al. this meeting). Formal clinical trials of bumetanide are required to test its efficacy as a treatment for schizophrenia.

Title: Increased NKCC1 expression in mPFC pyramidal cells of the subchronic phencyclidine (scPCP) mouse model of schizophrenia causes a depolarizing shift of $GABA_A$ current reversal potential and mediates cognitive impairment

Authors: H. KIM, L. RAJAGOPAL, H. Y. MELTZER, *M. MARTINA;
Northwestern Univ. Med. Sch., Chicago, IL

Abstract: Cognitive deficits are the major determinants of functional outcome in schizophrenia. Current atypical antipsychotic drugs (APDs) only partially address these deficits and only in some patients. Previous studies suggested that alteration of GABAergic inhibition in the medial prefrontal cortex (mPFC) is critical for cognitive deficits in schizophrenic patients. However,

there is a longstanding debate on the role of altered GABA, and how the mPFC networks of dorsal/ventral (prelimbic cortex; PLC, infralimbic cortex; ILC) subdivisions are affected in schizophrenia remains unclear. We utilized mice withdrawn from subchronic treatment (7 days 10mg/kg bid) with the NMDAR uncompetitive antagonist, phencyclidine (PCP), an established model for cognitive deficits in schizophrenia, to investigate the role of GABAergic signaling in the mPFC. Ex-vivo whole-cell patch clamp recordings in acute slices showed that scPCP treatment caused increased excitability of pyramidal neurons in the ILC, but not PLC, without apparent differences in the frequency of $GABA_A$-mediated synaptic currents. We then performed gramicidin perforated patch clamp recordings in acute PFC slices to record electrical signals while keeping intact the intracellular chloride concentration. We found that the reversal potential of the $GABA_A$ current in ILC pyramidal neurons from scPCP mice was depolarized compared to the control (vehicle-treated) group. Next, we used quantitative *in situ* hybridization to examine the expression level of the ion cotransporters controlling intracellular chloride concentration and found that the expression of the sodium-potassium-chloride cotransporter NKCC1 was selectively increased in the ILC of the scPCP mice, suggesting a possible molecular basis for the impaired neuroplasticity and the vulnerability to excitotoxic damage to the ILC. We, therefore, tested the effect of bumetanide, a relatively selective NKCC1 inhibitor, in acute slices and found that it normalized the reversal potential of the $GABA_A$ current in scPCP mice. Additionally, behavioral analysis showed that bumetanide treatment *in vivo* rescued the cognitive impairment of these mice (Rajagopal et al. this meeting).

Title: Epistatic interaction between dopamine D3 receptor and dysbindin modulates cortical functions and behavior related to schizophrenia in human and mice

Authors: *S. SALOMONE[1], G. LEGGIO[1], S. A. TORRISI[1], F. DRAGO[1], F. PAPALEO[2]; [1]Univ. of Catania, Catania, Italy; [2]Fondazione Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Dopamine D2-like receptors, including D2R, D3R and D4R subtypes, have been implicated in schizophrenia neuropathology and its therapeutic treatments. However, it is still unknown whether intracellular trafficking of the D2R-like family might play a role in the pathology onset and therapy efficacy. Here we focused on dysbindin-1, a protein implicated in

D2R-like intracellular trafficking, and D3R expression and activity. We first analyzed the genotype of schizophrenic patients (CATIE). Those patients exhibiting concomitant reduced function of both D3R and dysbindin-1 showed better executive and working memory functions (Wisconsin Card Sorting Test and Working Memory performances). Based on these data we hypothesized an interaction between these genes in humans and tested this interaction in mice, by generating a mouse line with concomitant hypofunction of both Dys and D3R genes ($D3^{+/-}$ *$Dys^{+/-}$). These double mutants showed an improvement in PFC-dependent working memory abilities, compared to single D3R+/- and Dys+/- and their wild-type +/+ littermates, as assessed in experimental behavioral paradigms, such as the Temporal Order Recognition (TOR), the working memory discrete paired-trial variable-delay T-maze task, the startle/prepulse inhibition (PPI), the social interaction, locomotors activity. Furthermore, the double mutant showed a rescue in PFC neuronal excitability and extracellular dopamine levels, that were changed in the Dys+/-. No epistatic effects were detected on positive and negative symptoms in humans (PANSS) and in their mouse equivalent (sensorimotor gating, locomotor functions and social behavior). These behavioral differences are consistent with a genetic-driven D2/D3 receptor unbalance in the PFC, but not in the striatum, which may serve as target for pro-cognitive treatments in schizophrenia, in the context of genetic-based precision medicine.

Abstract: In recent years, it has been suggested that inflammation is involved in the pathophysiology of various psychiatric disorders such as major depressive disorder, bipolar disorder, and schizophrenia. It has been demonstrated that schizophrenia patients show high blood levels of inflammatory cytokines. Previously, we had revealed that stress causes inflammation in the brain, and that NLRP3 is a critical molecule that causes inflammation. In preclinical studies, we showed that stress activated NLRP3 and increased pro-inflammatory cytokine levels in brain. Moreover, pro-inflammatory cytokines did not increase under stressful conditions if NLRP3 was inhibited. Also, in clinical trials by another group, NLRP3 was increased in major depressive disorder patients, and antidepressant treatment reduced NLRP3. We can conclude NLRP3 seems to play an important role in the pathophysiology of psychiatric disorders in terms of inflammation. Here, we investigated whether NLRP3 is involved in the pathophysiology of schizophrenia on a small number of patients as a preliminary study. The study consisted of a schizophrenia group of 7 patients with initial or relapsed phase, compared with 7 healthy subjects. There was no difference between the mean age and gender ratio of the schizophrenia group and the healthy group. Some patients in the schizophrenia group were taking antipsychotic drugs. Blood samples were collected, and the concentration of NLRP3 in monocytes and plasma was examined by western blotting. The results showed that there was no significant difference in NLRP3 concentration between schizophrenic and healthy group. In addition, when comparing before and 2 months after the treatment, there was no correlation between the PANSS score and the concentration of NLRP3. To our knowledge, two reports have examined NLRP3 in schizophrenia so far, and it has been reported that there is no difference between schizophrenic and healthy individuals. Although the sample size was small, our data showed similar results. In addition, it was found that the PANSS score and the levels of NLRP3 did not correlate in the same patient in spite of the treatment. These findings suggest that there may be no relationship between schizophrenia and NLRP3. Activation of IL-1β is known to be regulated by NLRP3, but elevated levels of pro-inflammatory cytokines such as IL-1β in schizophrenia may be controlled by other factors. Since this study was conducted in a small group, further large-scale investigation is needed. The study was approved by the Ethics Committee of the Faculty of Medicine of Tottori University, Tottori, Japan.

Title: Vesicle trafficking mechanisms in BLOC-1 deficiencies

Authors: R. DZVURUMI, S. HATCHER, A. LOMBARDO, R. THOMPSON, A. WAGNER, S. CORDERO ROMERO, ***J. L. LARIMORE**;
Agnes Scott Col., Atlanta, GA

Abstract: Dysbindin is a subunit of the octomeric biogensis of lysosme related organelles complex 1 (BLOC-1) which regulates vesicle trafficking from the early endosome to the lysosome, and, in neurons, to the axon terminal. Dysbindin has been implicated in several neurodevelopmental disorders including Rett syndrome (RTT) and schizophrenia (SZ). Endosomal proteins have been identified in genomic studies in both disorders, suggesting a common molecular mechanism between these neurodevelopmental disorders. This study explores the levels of key endosomal and secretory pathway proteins in coronal brain sections from Mecp2 null mice and BLOC-1 deficient mice to determine if trafficking proteins are altered in the dentate gyrus. Further characterization of vesicle trafficking protein levels in the dentate gyrus is necessary to better understand how the endosomal pathway regulates proper neuronal development in the hippocampus.

Title: Ndel1 neuropeptidase activity as a potential biomarker of early and late stages of schizophrenia

Authors: *M. F. H. HAYASHI;
Unifesp, São Paulo, Brazil

Abstract: Aim: We have showed reduced Ndel1 enzyme activity in patients with chronic schizophrenia (SCZ), and only a subtle *NDEL1* mRNA increases in antipsychotic-naïve first-episode psychosis (FEP) individuals compared to matched healthy controls (HC). Aiming to refine the evaluation of Ndel1 enzyme activity in early stages of psychosis, we compared 4 groups composed by (1) subjects at ultra-high-risk (UHR) for psychosis, (2) antipsychotic-naïve

FEP individuals (assessed in three moments, at baseline (FEP-0), and after 2 months (FEP-2M) and one year (FEP-1Y) of treatment with risperidone), (3) chronic SCZ patients, and (4) HC volunteers.
Methods: Blood samples were collected from all subjects into heparin vacuum tubes for plasma preparation. Ndel1 enzyme activity was measured essentially by measuring the hydrolysis of a FRET substrate at 37ºC.
Results: There was no significant difference in Ndel1 enzyme activity between UHR and HC, but this activity was significantly lower in FEP compared to HC. Conversely, Ndel1 activity in HC groups was higher than in FEP even before (FEP-0) or after the treatment with risperidone (FEP-2M and FEP-1Y). Progressive decrease of Ndel1 activity and significant symptomatic improvement were observed with this treatment. In addition, a positive correlation was observed for Ndel1 activity with clinical symptoms amelioration, as assessed by PANSS or GAF scores, although this correlation was not observed for chronic SCZ.
Conclusion: We show here that even under maintenance of the treatment with antipsychotics, the Ndel1 activity does not return to the levels determined at pre-morbid stage UHR or to those found in HC.

Title: mTOR complex specific abnormalities in schizophrenia brain

Authors: *R. CHADHA[1,2], J. H. MEADOR-WOODRUFF[1];
[1]Dept. of Psychiatry, [2]GBS, Neurosci. theme, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Cognitive deficits are observed in a majority of schizophrenia (SZ) patients. The AKT-mTOR pathway is an important signaling cascade associated with cognitive dysfunction. This pathway is tightly regulated by differential phosphorylation of key proteins. AKT is a serine-threonine kinase which regulates cell survival, proliferation and growth and requires phosphorylation at S473 and T308 for complete activation. Prior literature suggests reduced expression of AKT in SZ. mTOR is a kinase that forms 2 distinct complexes- mTORC1 and mTORC2. mTORC1 consists of mTOR, Raptor, GβL, PRAS40 and Deptor proteins. It facilitates

ribosome biogenesis and protein translation and acts downstream of AKT. mTORC2 consists of mTOR, Rictor, GβL, Protor, mSin1 and Deptor proteins. It plays an important role in actin dynamics and acts upstream of AKT. mTOR is phosphorylated at S2448 and S2481 sites for activation in both complexes. Abnormalities in the mTOR complexes can contribute to dysregulated protein synthesis and actin dynamics, both of which which have been implicated in SZ. Previously, we found decreased levels of AKT and GβL protein expression in SZ brain. Phosphorylated forms of AKT (S473), mTOR (S2448) and S6RP (S235/236 and 240/244) were also found to be reduced. Therefore, in this study, we investigated if there are mTOR complex specific deficits in SZ. We used postmortem dorsolateral prefrontal cortex (DLPFC) from 22 matched pairs of SZ and comparison subjects. The DLPFC plays an important role in cognitive functioning and has widespread evidence in support of its role in SZ. We co-immunoprecipitated mTORC1 using Raptor and mTORC2 using Rictor proteins, to determine the structural and functional integrity of each complex. Using western blot analysis, we measured protein expression of raptor, rictor and mTOR, as well as phosphorylation of mTOR in both complexes. To assess the relative abundance of mTOR complexes, we co-immunoprecipitated mTOR and measured the ratio of raptor to rictor. Our findings suggest that the AKT-mTOR signaling pathway is downregulated in SZ DLPFC. Given the importance of this pathway in synaptic plasticity via its regulation of protein synthesis and cytoskeletal organization, these abnormalities may represent a mechanism underlying cognitive dysfunction in SZ.

Title: Treatment of pregnant rats with N-acetylcysteine does not alter kynurenic acid levels in the fetal brain

Authors: *K. V. SATHYASAIKUMAR, M. A. R. THOMAS, R. SCHWARCZ;
MPRC, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Elevated brain kynurenic acid (KYNA) levels are implicated in the pathophysiology of schizophrenia. In rats, prenatal treatment with KYNA's immediate bioprecursor kynurenine leads to elevated brain KYNA levels and to cognitive deficits reminiscent of schizophrenia in adulthood (Pocivavsek et al., 2014). KYNA synthesis from kynurenine occurs mainly through irreversible enzymatic transamination by kynurenine aminotransferases (KATs). In the brain of

adult rats, KAT II is the principal enzyme responsible for the neosynthesis of rapidly mobilizable KYNA and therefore constitutes an attractive target for pro-cognitive interventions (Schwarcz et al., 2012). We recently demonstrated that N-acetylcysteine (NAC) inhibits KAT II activity in liver and brain tissue homogenates in rats and humans (Sathyasaikumar et al., SfN 2018), and therefore suggested that this effect may play a critical role in the pro-cognitive effects of the compound seen in humans (Steullet et al., 2016). In further support of this hypothesis, we also showed that NAC reduces *de novo* production of KYNA in the medial prefrontal cortex of unanesthetized adult rats treated with kynurenine *in vivo*. As NAC crosses the placenta in humans (Horowitz et al., 1997), and in view of the developmental etiology of schizophrenia, we now designed a follow-up study to examine the effects of *prenatal* treatment with NAC on KYNA levels and neosynthesis in *fetal* brain and liver as well as in the dam. To this end, we fed pregnant rats with kynurenine alone (100 mg/day in chow; N=4), NAC alone (350 mg/day in chow; N=2), or kynurenine + NAC (100 mg/day + 350 mg/day in chow; N=4) from embryonic day (ED)15 until ED20. Control rats (N=3) received normal chow. Tissues were collected from dams and fetuses (3-4 fetuses per dam) 4 h after the last feeding on ED20. Compared to controls, dams exposed to kynurenine showed a ~3-4-fold elevation in KYNA levels in the brain, and quantitatively similar increases were seen in fetal brains and livers. NAC treatment did not attenuate the kynurenine-induced KYNA formation in fetal brain and liver. This could be due to the very low KAT II activity in the fetus (Ceresoli-Borroni and Schwarcz, 2000, and unpublished data). Unexpectedly, NAC also failed to inhibit the kynurenine-induced ~3-fold increase in the brain of dams, and NAC treatment alone did not influence the endogenous levels of KYNA in tissues assessed in either embryos or dams. Our results demonstrate that treatment of pregnant rats with NAC during the last week of gestation is not an effective strategy to reduce KYNA levels in the fetal brain.

Title: Mitigating role of antioxidant supplementation in N-methyl-D-aspartate receptor hypofunction in a Wistar rat model of schizophrenia

Authors: *O. O. AFOLAYAN[1], A. OLAIBI[1], I. O. ISHOLA[2], A. O. OKANLAWON[1]; [1]Anat., [2]Pharmacol., Univ. of Lagos, Lagos, Nigeria

Abstract: Introduction: The *N*-methyl-D-aspartate (NMDA) receptor hypofunction is one of the postulated hypothesis of schizophrenia that describes its cognitive, positive and negative

symptoms. Many antipsychotics are used in the treatment of schizophrenia but most have been observed to have significant side effects. Bioflavonoids and certain vitamins have been postulated to have individual/synergistic neuroprotective and antioxidant properties. Thus, this study sought to investigate ameliorative effects of rutin, ascorbic acid and α-tocopherol in ketamine-induced NMDA receptor hypofunction in Wistar rats. **Methodology**: Forty male Wistar rats (12 weeks old) were randomly divided into eight groups: control (10 ml/kg distilled water p.o), ketamine (25 mg/kg, i.p), ketamine (25 mg/kg, i.p) + haloperidol (0.25mg/kg, i.p), ascorbic acid (10 mg/kg, p.o.) + ketamine (25 mg/kg, i.p.), ketamine + haloperidol + α-tocopherol (100 mg/kg, p.o), ketamine + haloperidol + rutin (25mg/kg, p.o), ketamine + haloperidol + combination of rutin, ascorbic acid and α-tocopherol, ketamine + combination of rutin, ascorbic acid and α-tocopherol. Administration lasted 14 days, within which the following behavioural tests were performed: Y-Maze test, Beam balance test and Light-dark box test on days 0, 1, 7 and 14. Thereafter, oxidative stress markers were analysed in the prefrontal cortices on day 14. **Results:** Haloperidol induced increased rearing and grooming behaviour, which was ameliorated by rutin, ascorbic acid and α-tocopherol treatments. Ketamine-induced deficits in spatial working memory and exploratory activity were prevented by the treatment of rats with rutin, ascorbic acid and α-tocopherol combination. In addition, ketamine reduced the levels of superoxide dismutase, catalase, and glutathione, while increasing malonaldehyde levels. However, these effects were reversed by the treatment of rats with ascorbic acid, α-tocopherol and rutin. **Conclusion**: Findings from this study showed that the combined use of rutin, ascorbic acid and α-tocopherol as adjuvants alleviate ketamine-induced schizophrenic-like behaviour and extrapyramidal side-effects caused by treatment with haloperidol by enhancing the antioxidant defence system. **ETHICAL APPROVAL DETAILS**: This research was approved by the Health Research Ethics Committee of the College of Medicine, University of Lagos with protocol number CMUL/HREC/10/18/448.

Title: MAP2 pathology in schizophrenia: Postmortem patterns and functional consequences

Authors: *R. A. DEGIOSIO[1], R. KELLY[2], M. GRUBISHA[1], A. M. DEDIONISIO[1], J. T. NEWMAN[1], K. N. FISH[1], A. R. SAMPSON[2], D. A. LEWIS[1], R. A. SWEET[1,4,3];
[1]Psychiatry, [2]Statistics, [3]Neurol., Univ. of Pittsburgh, Pittsburgh, PA; [4]Mental Illness Research, Educ. and Clin. Ctr., VA Pittsburgh Healthcare Syst., Pittsburgh, PA

Abstract: As a predominant regulator of dendritic cytoskeletal organization, microtubule-associated protein 2 (MAP2) is known to influence dendritic arbor and spine morphology, which are altered in schizophrenia (SZ). Several groups have demonstrated that the immunoreactivity (IR) of MAP2 is significantly lower in several cortical regions of individuals with SZ relative to non-psychiatric comparison subjects (NPCs), despite no observed change in expression levels of the protein. Further, we have previously demonstrated that MAP2-IR is correlated with dendritic spine density in one cortical region in SZ, indicating that IR changes may reflect a structural change in MAP2 which bears functional consequence. We set out to determine whether: 1) MAP2-IR deficit occurs throughout cortex within an individual subject with SZ; 2) whether MAP2 phosphorylation state- a common post-translational modification which can alter protein structure- may be altered in SZ; and, if so, 3) whether SZ-associated MAP2 (de)phosphorylation events are capable of altering MAP2 function and/or dendritic morphology. We characterized patterns of MAP2-IR across three cortical regions at different levels of the rostral-caudal axis in subjects with SZ and NPCs. MAP2-IR levels were measured by quantitative fluorescence microscopy in deep layer 3 of dorsolateral prefrontal cortex (DLPFC), lateral intraparietal cortex (LIP) and primary visual cortex (V1). We observed significantly lower levels of MAP2-IR in SZ subjects relative to NPCs, without a significant region by diagnosis interaction. Logs of within-pair ratios (SZ:NPC) of MAP2-IR were significantly correlated across the regions. These findings demonstrate that MAP2-IR deficits in SZ are consistent across three neocortical regions within individual subjects. We also present evidence that the phosphorylation state of MAP2- which is known to regulate its biological functions- is altered in SZ, and that mimicry of a SZ-associated MAP2 phosphorylation event (S1782E) can alter protein function *in vitro* as well as dendritic morphology *in vivo*. Together, these data prompt further investigation of MAP2 dysregulation via phosphorylation as a potential mediator of dendritic pathology in SZ in multiple cortical regions.

Abstract: Nowadays atypical antipsychotics are widely used in the treatment of Schizophrenia (SCHZ), Olanzapine (OLZ) is a drug used to reduce positive and negative symptoms, however its mechanism of action has not been fully described yet. Besides the neonatal ventral hippocampal lesion (nVHL) has emerged as a model of schizophrenia-related behavior in the rat. These rats exhibit behavioral changes that manifest mainly after puberty. This animal model induces behavioral alterations like social interaction and deficits in memory and learning. We recently demonstrated that nVHL animals exhibit dendritic atrophy and spine loss in the Prefrontal Cortex (PFC) and Basolateral Amygdala (BLA). This study aimed to determine whether OLZ treatment (0.25 mg/kg/day for 21 days) was capable of reducing PFC layer V and BLA neuronal alterations in morphology and density spines observed in nVHL rats. We evaluated social interaction in these animals. The morphological evaluation included examination of dendrites and spines density using the Golgi-Cox procedure.
Golgi-Cox staining revealed that nVHL induced dendritic retraction and spine loss in PFC pyramidal neurons of layer V and glutamatergic neurons in BLA. Interestingly, repeated OLZ treatment ameliorated dendritic pathology and neuronal loss in the PFC layer V and BLA of the nVHL rats. Our data show that OLZ may foster recovery of PFC layer V and BLA damage in post-pubertal nVHL rats and suggests that the use of neuroleptic agents for the management of some schizophrenia-related symptoms may help to understand the PFC and Nacc alterations pathways in these disorders (Supported by: CONACyT grants to Vazquez-Roque (No. 55569) (No. 926349) to Apam-Castillejos (No. 575264) to Tendilla-Beltrán and (No. 252808) to G Flores.

Abstract: Identifying individual cells and their genetic makeup are critical for understanding their roles in how the central nervous system (CNS) physiologically functions, develops, and organizes; as well as how these modalities are altered in diseased states. Traditional analytical methods lack either the cellular resolution and/or throughput necessary to fully compare the different cell types that exists within the mammalian CNS. Single cell RNA sequencing (scRNA-seq) has become a viable strategy for generating vast cellular expression datasets, while simultaneously highlighting previously obscured or unknown subpopulations of cell types within the mammalian brain. However, dissociation of neurons and glial cells from native tissues results in the loss of the spatial localization of the cells. In recent years, spatial transcriptomics technology addressed these limitations by integrating both histological and sequencing data. This was achieved by capturing polyadenylated RNA transcripts from brain tissue sections placed onto a spotted oligo array containing unique spatially encoded barcodes. The generated sequencing libraries were then combined with the histological images from the same brain tissue section to provide a detailed spatial reference. Here we demonstrated a significantly improved version of the spotted oligo array technology that increases tissue coverage and spatial resolution by reducing the spot size, and increasing spot number and packing density. Through advancements in the biochemistry, we exhibited substantially increased sensitivity while simultaneously reducing experiment duration. To better illustrate the capabilities of our approach, we applied our technology on the APPSWE [Tg2576] mouse model of familial Alzheimer's Disease, outlining the added benefits from standard scRNA-seq data alone. Together, this confluence of imaging and sequencing will serve as a valuable tool for understanding the relationships between CNS cell types and functions by providing researchers with an unbiased anatomical and gene expression-driven method of analysis.

Title: Pairing gene expression and spatial location to learn whole brain patterns of transcription

Authors: *S. LU, D. FÜRTH, A. ZADOR, J. GILLIS;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: To fully appreciate the brain as a complex system, its component parts should be studied across multiple modalities of data. One such source of information from the brain is spatial gene expression. We generated a whole-brain, adult mouse spatial gene expression dataset using Spatial Transcriptomics (ST), an array-based transcriptome-wide mRNA assay that maintains the spatial origin of transcripts. After benchmarking a variety of analytical approaches, we found that most well-represented brain areas, as annotated by mapping the ST spots to the Allen Reference Atlas, are learnable using LASSO regression with respect to all other brain areas using only gene expression. We further extend these analyses through meta-analysis of the Allen Institute's transcriptome-wide adult mouse in situ hybridization data (ABA ISH). Specific brain areas that were learnable in the ST data are similarly learnable in the ABA ISH data. Encouragingly, preliminarily LASSO models trained in the ST dataset have performed similarly in learning brain areas on held out ST data and on the ABA ISH data, and vice versa. Through this meta-analysis, I will determine the replicability of learning canonical anatomically-derived brain area assignments using gene expression from various types of spatial transcriptomic data and ultimately propose new transcriptionally-defined groupings.

Title: Spatial cell type analysis in tissue sections by next generation *in situ* sequencing

Authors: *M. KÜHNEMUND[1], X. QIAN[2,1];
[1]CARTANA, Stockholm, Sweden; [2]Sci. for Life Laboratory, Stockholm Univ., Solna, Sweden

Abstract: Single cell RNA sequencing (scRNAseq) has enabled the classification of cell types from nearly all tissue types based on their unique gene expression patterns. scRNAseq methods, however, require the isolation of cells from its natural morphological context inside the tissue losing the information of the spatial organization of cell types. A range of spatial transcriptomics techniques have been devised over the past few years, all with their unique advantages and drawbacks. *In Situ* Sequencing (ISS) takes place in intact morphologically preserved tissue sections and can be used to sequence short stretches of cDNA or barcodes inside ligated probes. A key advantage of ISS over other multiplexed *in situ* hybridization or sequencing methods is its high specificity, enabling mutation and splice variant analysis, and high throughput (10cm^2 of tissue/week). At CARTANA, we have developed an improved protocol for targeted *in situ* sequencing using barcode padlock probes and a new sequencing chemistry that requires less manual steps, generates higher signal/noise ratios and better preserves the tissue, making it possible to combine the ISS assay with protein staining in the same tissue section. We now apply our new ISS technology to map scRNAseq-defined cell types- and states by targeted probe panels for cell type marker genes in rodent and human brain and spinal cord samples generating cell type tissue maps.

Title: Using *in situ* sequencing to map spatial distribution of brain cell types

Authors: *X. QIAN, D. GYLLBORG, M. NILSSON;
Stockholm Univ., Stockholm, Sweden

Abstract: Single-cell RNA-sequencing (scRNA-seq) has revealed hundreds of transcriptomically defined cell types in the brain. Categorizing all cell types is an important step towards understanding the building blocks of the brain, but this is far from answering the functional and structural interactions between cells that underlie the complex functions of an organ. Studying cells *in situ* and spatially mapping scRNA-seq defined cell types is an indispensable step towards this goal (1).
Multiple methods are currently available for spatially resolved transcriptomics. SpaceTx project, part of Human Cell Atlas initiative (2), is an effort towards standardization and controlled comparison of different methods for their suitability in spatial cell type mapping. Our group previously developed *in situ* sequencing (ISS) technology (3). The technology, combined with a probabilistic cell calling algorithm and termed pciSeq, has been used to create a spatial atlas of fine interneuron cell types in mouse hippocampus CA1 (4).
ISS is based on padlock probes and rolling circle amplification. The amplification generates bright signals and thus does not require high-power imaging, which makes ISS a high-throughput method. In the current study, we developed ISS v2.0 to resolve more signals and generates even brighter and cleaner signals, which is advantageous when working with human samples, where lipofuscin poses a serious challenge for many imaging-based methods.
We generated ISS benchmarking dataset for human and mouse brain samples, targeting 120 and 119 genes respectively, which were a result of automatic gene selection and manual curation of SpaceTx consortium. The generated dataset is a great resource for the whole neuroscience community to develop computational methods. And the preliminary results of pciSeq on the data also validates the known biology of laminar structure of cortex.

Abstract: The spatial organization of the genome plays an important role in cell fate and function through control of nuclear processes such as gene regulation. In principle, the nucleus is amenable to study in its native context via high resolution imaging, which can capture many spatial and structural features simultaneously. However, in practice, no tools exist for genome-wide imaging.

We have developed an *in situ* sequencing method to directly resolve the 3D structure of the genome in its native context within single cells. Here we describe the methodological developments underpinning this new imaging/sequencing approach. In brief, we construct a whole-genome sequencing library *in situ* in fixed cells via enzymatic fragmentation, adaptor ligation, and amplification of genomic DNA. We then sequence the amplicons *in situ*, with each cycle read out using fluorescence microscopy. This sequencing process is automated using a fluorescence microscope with integrated computer-controlled fluidics.

As a proof of principle, we use this approach to spatially resolve hundreds of genome-wide reads per cell from ~200 individual cells. We expect this platform technology will expand the scope of possible measurements of genome organization, including high-throughput genome-wide architectural mapping of higher order chromatin folding and chromosome domains. We anticipate these novel imaging-based genomic measurements will yield new insights about the processes that underlie genome structure and regulation.

Abstract: Mapping the precise sequences and locations of RNAs within cells in intact tissues is important for understanding diverse biological processes. In the brain, the transcriptome defines cell types and states, and prescribes the available mechanisms for high speed neural computations, long-term synaptic changes, and disease progression. To date, methods for multiplexed single-molecule RNA imaging in tissue have been limited to thin sections and lack high resolution subcellular landmarks, limiting the ability to assign transcripts to cells, and to probe the subcellular organization of transcripts into nanoscale compartments.
We here report the ability to perform both untargeted and targeted *in situ* sequencing in intact thick tissue sections, alongside antibody-based morphological analysis. Our strategy, expansion sequencing (ExSeq), builds upon expansion microscopy (ExM) [1, 2], which physically expands biological specimens to enable super-resolution imaging. RNA molecules are anchored to a swellable hydrogel synthesized throughout the specimen, and isotropically separated from one another, creating space for subsequent chemical and enzymatic steps to be performed to prepare the DNA library for readout by *in situ* sequencing [3, 4].

Using untargeted *in situ* sequencing, we were able to observe tens of thousands of reads from hundreds of neurons in mouse brain, with an average read length of 76 bases, allowing for subcellular mapping of the locations of expressed genes, analysis of splice variation, detection of novel expressed sequences, and other details previously difficult to study. We utilized targeted *in situ* sequencing, in which oligonucleotide barcodes target specific transcripts, to perform highly multiplexed gene expression mapping, revealing cell types, and nanoscale organization of transcripts, within dendritic processes in mouse brain hippocampus.

Sch., Brookline, MA

Abstract: Spatial positions of cells in tissues strongly influence function, yet a high-throughput, genome-wide readout of gene expression with cellular resolution is lacking. We developed Slide-seq, a method for transferring RNA from tissue sections onto a surface covered in DNA-

barcoded beads with known positions, allowing the locations of the RNA to be inferred by sequencing. Using Slide-seq, we localized cell types identified by scRNA-seq datasets within the cerebellum and hippocampus, characterized spatial gene expression patterns in the Purkinje layer of mouse cerebellum, and defined the temporal evolution of cell-type-specific responses in a mouse model of traumatic brain injury. These studies highlight how Slide-seq provides a scalable method for obtaining spatially resolved gene expression data at resolutions comparable to the sizes of individual cells.

Title: Mixed long-range projections of transcriptomic subtypes of intratelencephalic neurons revealed by *in situ* barcode sequencing

Authors: ***X. CHEN**[1], Y.-C. SUN[1], A. M. ZADOR[2];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Zador Lab., Cold Spring Harbor Lab., Cold Spg Hbr, NY

Abstract: The vertebrate brain consists of myriad neurons with diverse characteristics, such as anatomy, gene expression, and activity. How neurons are organized by these different characteristics into functional circuits is largely unknown. Previously, we have reported highly diverse but organized long-range projections in the cortex using BARseq, a high-throughput single-cell projection mapping technique based on *in situ* barcode sequencing. However, it remains unclear how projection patterns are organized by neuronal subtypes defined by gene expression. Here we combine BARseq with multiplexed *in situ* hybridization to interrogate the transcriptomic subtypes and long-range projections of thousands of intratelencephalic (IT) neurons in the auditory cortex at cellular resolution. We identify distinct distribution of projections across transcriptomic IT subtypes and further identify projection correlates of gene expression within a subtype. These differences across subtypes, however, do not explain the majority of variance in projection patterns: projection patterns remain largely overlapping across transcriptomic subtypes and highly diverse within a subtype. Our results indicate that adult

neuronal subtype defined by transcriptomics is not a major determinant of long-range projections across neuronal types.

Title: Correlation between combinatorial cadherin expressions and neuronal projections revealed by targeted *in situ* sequencing

Authors: *Y.-C. SUN[1], X. CHEN[1], A. M. ZADOR[2];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Zador Lab., Cold Spring Harbor Lab., Cold Spg Hbr, NY

Abstract: In vertebrate brains, the combinatorial expression of genes, such as cell adhesion molecules, are required to establish the highly diverse neuronal projections in the vertebrate brain. Understanding the organization of neuronal circuits thus requires characterizing, among various neuronal properties, how combinatorial gene expressions directs neuronal connectivity. This requires high-throughput gene detection and projection mapping in the same neurons while retaining spatial information at cellular resolution. Here, we combine targeted *in situ* sequencing and BARseq, a high-throughput technique for mapping long-range axonal projections based on *in situ* sequencing of RNA barcodes, to correlate gene expression and projections at cellular resolution. We use this approach to test the hypothesis that combinatorial cadherin expressions specify neuronal connectivity in the mouse auditory cortex. Our method uncovers the degree to which combinatorial cadherin expressions can predict neuronal projection patterns and thus potentially illuminate the gene expression logic underlying neuronal connectivity.

Title: A spatial-temporal map of the protocadherin expression code in the CNS

Authors: *W. X. WANG, J. L. LEFEBVRE;
Neurosciences and Mental Hlth., Hosp. for Sick Children Res. Inst., Toronto, ON, Canada

Abstract: The assembly of neuronal circuits is dependent on complex and selective cell-cell interactions, mediated by cell-surface receptors. Studies to date have focused on receptor interactions at the level of cell-types, despite evidence that individual neurons within the same cell-type are also shaped by distinct cues. A promising candidate for generating single neuron identities is the clustered Protocadherins (Pcdhs), a family of 58 cell-surface recognition molecules. Profiling studies suggest that stochastic and combinatorial expression of Pcdh isoforms in single neurons further amplifies Pcdh expression diversity to an astounding 10 billion combinations. However, it remains unknown if combinatorial Pcdh expression is a general feature in the nervous system, and whether Pcdh signatures change during development. To tackle these questions, we devised a novel strategy using multiplexed, single-molecule fluorescence *in situ* hybridization (multiplex smFISH) techniques to map the spatial-temporal expression profiles of all 58 highly-related Pcdh isoforms across neuron types in the cerebellum, cortex, and retina. To increase the number of targets that can be imaged simultaneously, we are employing sequential barcoding techniques to combinatorially label each isoform with a colored (fluorophore) barcode, which is decoded through sequential rounds of single molecule RNA imaging. This work aims to gain insight into the logic behind molecular diversity and complexity, and their roles during neuronal wiring.

Abstract: Single cell transcriptomics datasets provide unprecedented detail regarding the variety of molecularly defined cell types in the cortex. Recent work in mouse and human cortex has identified hundreds of discrete, transcriptomically defined cell types which may have unique spatial distributions, connectivity, intrinsic membrane properties and function. However, due to the nature of single cell transcriptomics, the number, proportion and spatial location of these cell types are not precisely understood. To provide an accurate census of these cell types and describe their spatial relationship to one another, we generated combinatorial gene panels designed to identify molecularly defined cell types with a minimum number of genes. Using these gene panels as a starting point, we identified and mapped these cell types in brain tissue to create a spatial census of brain cell types. These data describe the spatial distribution of each discrete type investigated, its proportion in a given area of tissue relative to other types, and provide insight into the probable function of transcriptomically defined types within brain tissue.

Abstract: Defining a complete set of cell types within the cortex requires reconciling disparate results achieved through diverging methodologies. To address this correspondence problem, multiple methodologies must be applied to the same cells across multiple single-cell experiments. We present an approach applying spatial transcriptomics using multiplexed fluorescence *in situ* hybridization, (mFISH) to brain tissue previously interrogated through two photon optogenetic mapping of synaptic connectivity or whole-brain serial two photon tomography. This approach can resolve the anatomical, transcriptomic, connectomic, electrophysiological, and morphological characteristics of single cells within the mouse cortex. A systematic interrogation of the correspondence between single-modality-defined types and the diversity within these types requires a large-scale effort to capture these details at sufficient resolution. To this end we describe a data generation pipeline capable of completing dozens of experiments per week. Key components include cross-team specimen hand-off, data, reagent, and probe tracking infrastructure, and workflow optimizations. We will describe several of these advances and how they support the goal of a robust, auditable, and reliable pipeline for multimodal correspondence data generation. With this pipeline infrastructure, we can disambiguate cell types within cells expressing a sub-class-level transgenic reporter. We focus on putative somatostatin-expressing interneurons. Within this sub-class the mFISH pipeline can distinguish unique cell types by probing a modest set of 15 or fewer transcript targets. Aligning results from the mFISH analysis with those from an upstream synaptic connectivity experiment provides cell-type resolution of connectivity rates and strength while maintaining the high-throughput capabilities of both light sheet imaging and two-photon optogenetic probing.

Title: Confirmation and spatial mapping of diverse striatal cells identified by single cell RNA sequencing in the mouse brain at single-cell resolution with a multiplex *in situ* hybridization technology

Authors: J. PHATAK, H. LU, *L. WANG, H. ZONG, M. ROUAULT, C. MAY, C. ANDERSON, B. ZHANG, X.-J. MA;
Advanced Cell Diagnostics, Newark, CA

Abstract: Complex, highly heterogeneous tissues such as the brain are comprised of multiple cell types and states with exquisite spatial organization. Single cell RNA sequencing (scRNA-seq) has become a universal tool for classifying and characterizing known and novel cell populations of complex heterogenous tissues, leading to a new age of single cell biology. However, scRNA-seq is limited to dissociated cells and results in the loss of spatial organization of these cell populations, thus requiring a multiplexed spatial approach that can interrogate gene expression with single cell resolution in the tissue context. In this study, we used the RNAscope Multiplex Fluorescent and HiPlex RNA *in situ* hybridization (ISH) assays to confirm and spatially resolve the diverse striatal neurons identified by scRNA-seq in the mouse brain (Gokce *et al*, *Cell Rep*, 16(4):1126-1137, 2016). We confirmed the gene-signatures of two discrete D1 and D2 subtypes of medium spiny neurons (MSN): *Drd1a/Foxp1, Drd1a/Pcdh8, Drd2/Htr7*, and *Drd2/Synpr*. Further cellular heterogeneity within the MSN sub-populations was marked by a transcriptional gradient, which we could spatially resolve with RNA ISH. scRNA-seq also revealed that the mouse striatum was comprised of numerous non-neuronal cell populations, including vascular cells, immune cells, and oligodendrocytes, which the presence and co-expression of these cell markers was confirmed with the multiplex ISH assay. Lastly, to simultaneously visualize the spatial organization of the D1 and D2 MSN subtypes identified by Gokce et al. we utilized the RNAscope HiPlex assay, which allows for visualization of up to 12 targets simultaneously in intact tissues. In conclusion, we have demonstrated the capabilities of two multiplexed RNAscope assays for the confirmation and spatial mapping of scRNA-seq results in the highly complex and heterogenous mouse striatum at the single cell level. Single-cell transcriptomics combined with spatial mapping by the RNAscope technology is well suited for resolving heterogeneous tissues at cellular resolution and providing insights into cellular organization and function of diverse cell types in healthy and disease states.

Title: Cellular compartment analysis of temporal activity by fluorescent *in situ* hybridization (catFISH) in the rat transcardially perfused brain

Authors: *A. GHEIDI[1], V. KUMAR[1], C. J. FITZPATRICK[2], R. ATKINSON[1], J. D. MORROW[2];
[2]Psychiatry, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: *Background:* Cellular compartment analysis of temporal activity by fluorescent in *situ* hybridization catFISH allows high spatiotemporal resolution mapping of immediate early genes in the brain in response to internal/external stimuli. One caveat of this technique and indeed other methods of *in situ* hybridization is the necessity of flash-freezing the brain prior to staining. Often however, the mammalian brain is transcardially perfused to use the brain tissue for immunohistochemistry, the most widely-used technique to study gene expression. *New Method:* We have developed a technique, modified from that of Guzowsky and Worley, 2001, that allows the catFISH method to be used in adult rats that have been transcardially perfused with 4% paraformaldehyde. *Results* c-Fos activity induced by either an auditory tone or status epilepticus was visualized using the catFISH procedure. We see clear distinction of the compartmental distribution of c-Fos mRNA in the nuclei and cytoplasmic regions of the rat prefrontal cortex, hippocampus and amygdala. Furthermore, the qualitative proportion of c-Fos compartmentalization is similar to previous reports of c-Fos expression pattern in rodents navigating novel environments. *Conclusion:* c-Fos catFISH on perfused rodent brains is an attractive addition to the traditional histological methods using fluorescently labeled riboprobes, and opens several avenues for future investigations.

Title: Selective behavioral and circuit deficits in adulthood following widespread postnatal excitation of neocortical pyramidal cells

Authors: *A. BJOREFELDT[1], W. E. MEDENDORP[3], A. PAL[4], M. L. WADDELL[4], C. I. MOORE[2], U. HOCHGESCHWENDER[5];
[1]Dept. of Neurosci., [2]Neurosci., Brown Univ., Providence, RI; [3]Neurosci., Central Michigan Univ., Mount Pleasant, MI; [5]Neurosci., [4]Central Michigan Univ., Mt Pleasant, MI

Abstract: The amount and pattern of neuronal activity present during the early developmental period is believed to guide structural and functional properties of neural circuit assembly that persist into adulthood. Thus, alterations in neuronal activity during this time period may lead to aberrant circuit formation, a mechanism that has been implicated in certain psychiatric disorders such as autism. Here we took advantage of a bimodal experimental approach, bioluminescence-driven optogenetics, to assess the impact of cortical pyramidal cell hyperexcitation during this critical time period. To enable manipulation of cortical pyramidal cell activity during development, mice expressing the excitatory luciferase-opsin fusion LMO3 (sbGluc fused to VChR1) under a Lox-Stop-Lox sequence were crossed with Emx1-Cre mice. In presence of the luciferase substrate coelenterazine (CTZ), light emission from sbGluc drives activation of VChR1 to depolarize the cell and evoke action potential firing. CTZ was delivered intraperitoneally once a day during post-natal days 4-14 in developing mouse pups. Starting at postnatal day 50 (P50), mice that received either CTZ or vehicle treatment during development were tested in a number of behavioral paradigms and effects on morphological and electrophysiological properties were examined. Behavioral testing revealed that CTZ-treated Emx1-Cre/LSL-LMO3 mice display adult behavioral phenotypes similar to those observed in existing animal models of autism. Taking advantage of the option to interrogate the same LMO3-expressing neurons using optogenetics in *in vivo* and *ex vivo* electrophysiological recordings from cortex, these animals showed evidence of neurophysiological alterations in the form of altered neuronal network oscillations, excitation-inhibition balance and intrinsic excitability. In

conclusion, we leveraged the advantage of a dual chemo- and optogenetic approach to study the impact of neuronal activity during early development on adult neurophysiology and behavior that could aid investigation of pathophysiological mechanisms underlying psychiatric disorders such as autism.

Title: A new approach to anatomical and functional imaging: Recording and labelling of insect auditory neurons through the intact neurolem

Authors: *B. HEDWIG[1], M. D. ISAACSON[2], K. KOSTARAKOS[3];
[1]Zoology, Univ. of Cambridge, Cambridge, United Kingdom; [2]Janelia Farm Res. Campus, Howard Hughes Med. Institute,, Ashburn, VA, VA; [3]Zoology, Univ. of Graz, Graz, Austria

Abstract: The delivery of tracers into populations of neurons is essential to visualize their anatomy and to analyze their function. Some model systems allow a genetically-targeted expression of fluorescent proteins; however, these genetic tools are not available for most organisms and alternative labeling methods are very limited. We developed a new method for neuronal labeling by electrophoretic dye delivery from a suction electrode, filled with a polar tracer, directly through the neurolem of nerves and ganglia in insects. Application of current delivered the dye into the neuronal tissue and labeled the neurons at the opening of the electrode. In the peripheral nervous system polar tracer molecules were injected into the locust auditory nerve without destroying its function, simultaneously staining peripheral sensory structures in the hearing organ and central axonal projections. Upon the delivery of calcium indicators, we recorded sound evoked fluorescent signals in the central metathoracic auditory neuropils. In cricket brains, single auditory neurons and local populations could be labelled directly through the neurolem. The specificity and selectivity of the electrophysiological recordings were determined by the electrode location. The same electrodes were used to deliver fluorescent tracers into the brain by means of electrophoresis. This allowed us to retrograde label recorded ascending auditory neurons, and to reveal their cell body and dendritic structure in the first

thoracic ganglion. By adjusting the amount of dye injected, we specifically stained the ring-like auditory neuropil in the brain, demonstrating the clusters of cell bodies contributing to it. Furthermore in-vivo optical imaging of sound-evoked activity in brain neurons was achieved through the delivery of calcium indicators. Our method provides a new tool for studying how sensory stimuli are processed in peripheral and central sensory pathways and is a significant advance for the study of nervous systems in "non-model" invertebrates.

Title: Bioluminescence driven control of photosensory proteins

Authors: *E. L. CRESPO[1], G. LAMBERT[3], N. C. SHANER[3], U. HOCHGESCHWENDER[2]; [1]Central Michigan Univ., Mount Pleasant, MI; [2]Neurosci., Central Michigan Univ., Mt Pleasant, MI; [3]UCSD, San Diego, CA

Abstract: Bioluminescence is light emitted by a luciferase oxidizing its substrate. We previously demonstrated that such "biological" light can activate optogenetic elements, such as channelrhodopsins and pumps, effecting membrane potential changes and resulting in activation or silencing of neurons in vitro and in vivo. We explored whether bioluminescent light production can be utilized beyond activating ion-moving photoreceptors to the larger array of photosensory proteins employed as optical switches in cellular processes such as protein translocation and transcription. In initial proof-of-concept experiments we co-transfected HEK293 cells with a blue light emitting luciferase and a blue light sensing photoreceptor. Light emitters were sbGLuc, a copepod luciferase variant, NanoLuc, a luciferase derived from shrimp, as well as two novel engineered synthetic luciferases. Photoreceptors were CRY/CIB, a light-gated dimerization system, and LOV, based on light dependent protein unhinging. Bioluminescence driven activation of these photoreceptors was measured as increased transcription of luminescent and fluorescent reporter proteins in direct comparison to LED driven activation. Quantification of bioluminescence driven photoreceptor activation revealed that both light-gated switches, cryptochrome protein dimerization and light-oxygen-voltage J-alpha helix unfolding can be efficiently activated by biological light sources. Furthermore, the higher light

emission of our synthetic luciferases resulted in better activation of transcription. There are many ways to improve further on these basic results. Collectively, bioluminescence driven activation of the larger families of photoreceptors will expand their use for in vivo applications that benefit from non-invasive light sources and engagement of spatially distributed cells.

Title: Modular family of readily interchangeable head-post attachments for drug delivery, imaging, electrophysiology and brain maintenance in awake, behaving mice

Authors: *J. W. MURPHY[1], N. G. FRIEDMAN[1], D. CELINSKIS[2], D. LIPSCOMBE[1], N. C. SHANER[3], U. HOCHGESCHWENDER[4], M. GOMEZ-RAMIREZ[1], C. I. MOORE[1]; [1]Neurosci., [2]Sch. of Engin., Brown Univ., Providence, RI; [3]Neurosciences, Univ. of California at San Diego, San Diego, CA; [4]Neurosci., Central Michigan Univ., Mt Pleasant, MI

Abstract: Cranial windows for optical imaging in rodents are widespread and useful. They allow for long-term imaging of neural activity as well as optical access for the stimulation of optogenetic elements. As genetically targeted imaging and manipulation of neural activity *in vivo* becomes increasingly widespread, certain experimental questions necessitate direct access to the brain otherwise typically sealed beneath glass. Specifically, the delivery of drugs directly to the restricted brain area beneath the optical window in an even and controlled manner while maintaining suitable optical access for imaging is a central challenge to many experimental preparations. A second challenge is the frequent need for simultaneous acquisition of imaging and electrophysiological data, which requires access of the recording probe to the tissue of interest. Previous approaches to these challenges have either allowed for access to only a small sub-region of the entire cranial window via a re-sealable hole in a glass or silicone window, or are sealed microfluidic devices that do not allow for direct access to the tissue. We sought to design an inexpensive, modifiable and scalable device for simultaneous optical imaging, drug delivery and electrophysiological recording. The device we present is 3D printed and affixes to our pre-existing titanium headposts through the use of thin (<1mm) neodymium disc magnets. The device was designed using open source software (OpenSCAD) and printed on a low cost 3D printer (Creality Ender 3). Central to the design of the device is that the swappable magnetic

approach allows for interchangeable attachments geared toward the specific task. For instance, a microfluidic chamber enclosed by a glass window allows for drug infusion with simultaneous optical access for imaging while an optically opaque cover with a silicone disk allows for compression and protection of the craniotomy while the animal is in its home cage. We present data showing the successful activation of a bioluminescent enzyme expressed in cortical neurons by infusion of the corresponding bioluminescent substrate through our magnetic perfusion chamber. Additionally, we show that optical access remains clear over multiple experimental sessions.

Title: Transsynaptic neuronal activation via bioluminescent optogenetics

Authors: *R. SCHUMAKER, M. PRAKASH, A. PAL, E. CRESPO, U. HOCHGESCHWENDER;
Central Michigan Univ., Mount Pleasant, MI

Abstract: Biological light activation of optogenetic sensors across synaptic partners offers the potential to optogenetically dissect synaptic communication non-invasively. The genetically encoded light source, a luciferase, is expressed pre-synaptically, and the light-sensing opsin is expressed post-synaptically. In the presence of the luciferase substrate, coelenterazine (CTZ), the pre- and post-synaptic partners will be in close proximity to allow activation of the opsin by luciferase-produced light. In order to improve the specificity of trans-synaptic signaling, we are exploring several designs of trans-synaptic reconstitution of split molecules. First, Gaussia luciferase (GLuc) is split into inactive N- and C-terminal portions, each of which are then tethered to the pre-synaptic membrane or post-synaptic opsin, respectively. Second, in a

luciferase - fluorescent protein fusion construct the fluorescent protein is split such that resonance energy transfer from the luciferase and subsequent light emission for opsin activation only occurs in the presence of CTZ in synapses allowing reconstitution of the fluorescent protein. Experiments are carried out in HEK cells and cultured primary neurons.

Title: Behavioral outcomes after cerebral ischemic stroke of young adult and aged mice receiving transplantation of iPSC-derived neural progenitor cells and optochemogenetics treatment

Authors: Z. Z. WEI, M. J. H. LEE, W. W. ZHONG, A. WU, S. P. YU, *L. WEI;
Anesthesiol./Neurol., Emory Univ. Sch. Med., Atlanta, GA

Abstract: Stroke is a major cause of death and paralysis; stroke survivors often develop long-term sensorimotor and cognitive deficits, as well as emotional disturbances. Aging and aged populations are the most vulnerable groups to strokes. Our previous investigations developed a focal cerebral ischemic stroke rodent model with low mortality rates. This cortical stroke model is suitable for long-term studies of the target specific neuronal repair and functional/behavioral alterations in aging and aged mice. In the present investigation, we tested the effects of transplantation of iPSC-derived neural progenitor cells (iPSC-NPC) in aged (18-month-old) male and female mice and compared with that in young (2-month-old) adults. Mouse iPSC-NPC were transduced with a novel optochemogenetics fusion protein, enhanced luminopsin 3 (eLMO3), which consists of a bioluminescent luciferase, *Gaussia* luciferase (GLuc), and an opsin, *Volvox* Channelrhodopsin 1 (VChR1). These eLMO3-iPSC-NPC can be activated by either photostimulation using light or by the luciferase substrate coelenterazine (CTZ). Stroke mice received vehicle or cell transplantation 7 days after stroke and daily intranasal delivery of CTZ (2 mg/kg). At 21 days after stroke, mice received eLMO3-iPSC-NPC and CTZ treatment showed significantly higher levels of SDF-1, synapsin-1, and PSD-95 in the peri-infarct region. The home-cage monitoring system was used to assess animal behaviors at different time points (7-21

days after stroke) in a native environment without human intervention. Compared to non-eLMO3-cell-transplanted animals, significant improvements in general home-cage activities were observed in mice receiving eLMO3-iPSC-NPC and CTZ treatment. All eLMO3-iPSC-NPC-treated animals were able to show less depressive like behavior in the sucrose splash test and the sucrose preference test 28 days following the ischemic insult in all transplantation groups. Pain and other abnormal behaviors were also monitored and measured. Our data provide information and evidence to explain the distinctive neurological consequences of our recently developed iPSC-NPC and optochemogenetics therapy after ischemic stroke at young and old ages. The sensitive and significant functional improvement with lower mortality rates of this ischemic stroke suggests that it is an appropriate stroke model for aged rodents and suitable for evaluation of potential cell therapies for ischemic stroke under clinically relevant conditions.

Title: Use of bioluminescent optogenetics (BL-OG) to enhance motor axon regeneration after peripheral nerve transection and repair

Authors: O. C. MISTRETTA[1], A. J. LOPEZ[2], C. WYNANS[1], K. BERGLUND[3], ***A. W. ENGLISH**[1];
[1]Cell BIology, Emory Univ. Sch. of Med., Atlanta, GA; [2]Rehabil. Med., [3]Neurosurg., Emory Univ., Atlanta, GA

Abstract: Activity-dependent experimental therapies, including optogenetic stimulation, have been most effective in enhancing the regeneration of motor axons following peripheral nerve injury in laboratory rodents. Bioluminescent optogenetics (BL-OG) uses luminopsins, light-sensing ion channels fused with light-emitting luciferase. When exposed to a cognate substrate (i.e. coelenterazine, CTZ), bioluminescence is generated by the luciferase moiety and the attached opsin is activated. We propose that BL-OG using an excitatory opsin, such as channelrhodopsin, could be used as a pharmacologic version of an activity-dependent therapy to treat nerve injuries. Mice expressing cre recombinase under control of the promoter for choline acetyl transferase (ChAt-cre) were induced to express an excitatory luminopsin (eLMO3) either by breeding with mice expressing a cre-dependent eLMO3 or by sciatic nerve injection of an adeno-associated viral (AAV) vector expressing cre-dependent eLMO3. Application of CTZ in these mice produced intense bioluminescence in the sciatic nerve that was detectable *in vivo* for

at least 45 min. Functioning eLMO3 expression in both model systems was confirmed by increases in motoneuron excitability following CTZ application (10 mg/Kg, i.p.). No increase in resting EMG activity was found after CTZ injections but stimulus thresholds for producing fast spinal evoked motor potentials decreased by 15% within 5 minutes of CTZ application and returned to baseline after four hours. In both groups of eLMO3-expressing mice treated once with CTZ at the time of sciatic nerve transection and repair, amplitudes of direct muscle EMG responses (M waves) were four-fold larger than found in untreated eLMO3-expressing mice or CTZ-treated wild type mice four weeks later. More spinal motoneurons could be retrogradely labeled in treated eLMO3-expressing mice than controls and more muscle fibers had been reinnervated in mice exposed to the BL-OG-based treatment. Treatment of injured peripheral nerves using BL-OG is an effective means of applying an activity-dependent therapy to promote regeneration of motor axons after peripheral nerve injury.

Title: Chemogenetic activation of GABAergic neurons in dorsal and ventral hippocampus reduces epileptiform discharges in a mouse pentylenetetrazole seizure model

Authors: *A. M. FERNANDEZ[1], S.-E. PARK[3], K. BERGLUND[4], C.-A. N. GUTEKUNST[2], R. E. GROSS[5];
[2]Neurosurg., [1]Emory Univ. Sch. of Med., Atlanta, GA; [3]Georgia Inst. of Technol., Atlanta, GA; [4]Neurosurg., Emory Univ., Atlanta, GA; [5]Dept Neurosurg., Emory Univ. Sch. Med., Atlanta, GA

Abstract: One third of patients with epilepsy are resistant to drug therapy. Thus, there is a need for alternative modes of treatments for seizures. Optogenetics has proven to be a useful tool to understand network dynamics, but it has translational challenges. We have developed a chemogenetic tool, called luminopsins (LMOs), that consists of a light-sensitive channel fused with a luciferase enzyme that bioluminesces in the presence of its substrate coelenterazine (CTZ), eliminating the need for external hardware. Previous studies in our laboratory have shown that simultaneous inhibition of glutamatergic neurons in the dentate gyrus and anterior nucleus of thalamus with an inhibitory luminopsin reduces seizure severity and duration in a pentylenetetrazole (PTZ) seizure model (Tung et al., 2018). The present study aimed at exploring

the effect of specifically activating GABAergic neurons in dorsal and ventral hippocampus with the goal of achieving greater seizure control. We hypothesized that activation of GABAergic neurons suppresses electrographic spike-and-wave discharges (SWDs) at a low dose (40 mg/kg) of PTZ, as well as behavioral events (i.e. jerks and tonic-clonic seizures) at a higher dose (50 mg/kg) of PTZ. To test this, adult VGAT-Cre mice received intracranial bilateral injections of a recombinant adeno-associated viral vector carrying the floxed excitatory luminopsin gene into dorsal and ventral hippocampi. Mice were implanted with EEG screws over frontal and parietal cortex and subjected to a PTZ test two weeks after virus injection. Mice were pre-treated with either vehicle or CTZ (intraperitoneally or intranasally) 20 minutes before PTZ injection and monitored for 45 minutes. One week later, this procedure was repeated in the same mice, with the opposite treatment. For the following two weeks, the dose of PTZ was increased. The rate of SWDs and behavioral events were quantified. Mice pretreated with CTZ showed a reduction in the rate of SWDs and behavioral events. Postmortem histology confirmed adequate targeting of the dorsal and ventral hippocampus with luminopsin. These results support our hypothesis of seizure suppression in the PTZ model due to inhibition of the entire hippocampal formation, underscoring the importance of inhibitory circuits in a seizure-prone state.

Title: Improved membrane trafficking of luminopsins for more efficient optogenetic and chemogenetic control of neuronal activity

Authors: *K. BERGLUND, J. Y. ZHANG, J. K. TUNG, Z. WANG, S. YU, R. E. GROSS, L. WEI;
Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Luminopsins (LMOs) are fusion proteins consisting of a luciferase and an opsin. They provide control for neuronal activity via chemogenetic and optogenetic activation. We have shown that both an external light source and the luciferase substrate, coelenterazine (CTZ), could modulate neuronal activity *in vitro* and *in vivo*, although luminopsin's efficacy can be further improved. In this study, we aimed at improving membrane expression of the third version of LMO (LMO3) by inserting a Golgi trafficking signal (TS) sequence. In cortical neurons in culture, expression of enhanced LMO3 (eLMO3) resulted in significant reductions in the formation of protein aggregates, as well as in a significant increase in total photocurrents. Furthermore, we corroborated the findings *in vivo* by injecting adeno-associated viral vectors into the barrel cortex of male mice. We observed significantly reduced fluorescent puncta in eLMO3-expressing cortical neurons compared to the original LMO3. Finally, we quantified CTZ-driven behavior, namely whisker touching behavior. After CTZ administration, mice with eLMO3 displayed significantly longer whisker responses than mice with LMO3. We did not observe any noticeable behavioral change when vehicle was injected instead of CTZ as control. In conclusion, we have engineered the superior LMO by improving membrane trafficking and demonstrated improved efficacy of LMOs through multiple readouts.

Title: AAV engineering by multiplexed-create selection and rational peptide insertion yields variants with enriched targeting of CNS astrocytes upon systemic delivery

Authors: *X. CHEN, S. RAVINDRA KUMAR, X. DING, V. GRADINARU;
Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Astrocytes are key CNS contributors at around 30% of the total cells (Liddelow, et al, Immunity, 2017) and are involved in synapse development, neuronal activity, and maintenance of immune homeostasis. Astrocytes could therefore be an important gene therapy target for a variety of neurological and psychiatric diseases. However, the commonly-used intra-cranial injection required to bypass the blood-brain barrier (BBB) and access CNS cells can cause local inflammation and drive astrocyte reactivity (Liddelow, et al, Immunity, 2017) therefore confounding research results and causing side effects. Systemic AAV delivery provides a noninvasive alternative for broad gene delivery to the CNS. We previously identified a few highly efficient CNS transducing variants including AAV-PHP.A (Deverman BE, et al, Nat. Biotech., 2016) and AAV-PHP.eB (Chan K, et al, Nat. Neuro., 2017) using the Cre recombination-based AAV targeted evolution (CREATE) method. PHP.eB can transduce astrocytes but is also very efficient at transducing neurons brain-wide, creating concerns with off-target effects when targeting astrocytes under strong ubiquitous promoters. PHP.A, on the other hand, target astrocytes with better specificity but is a subpar virus producer, limiting its application. To identify AAV variants that can more specifically target astrocytes, we utilized the newly-developed Multiplexed-CREATE method (Kumar, et al, under review, 2019): M-CREATE is a high-confidence positive and negative AAV selection platform that uses next generation sequencing (NGS) to obtain a comprehensive recovery of viral capsid libraries. For the lead variants, we then performed site-targeted rational peptide insertion to fine-tune their specific tropism. This combined approach of directed evolution of AAV capsids and rational peptide insertion allowed us to identify several novel variants showing more specific transduction of astrocytes in mice upon systemic delivery. This systemic AAV toolbox tailored for gene delivery across the BBB for astrocytes could be enabling for research focused on neuron-immune interactions and gene therapy for disease models.

Title: Approaches towards engineering the neuronal Arc capsid for efficient and targeted RNA delivery

Authors: *T. DOBREVA[1], A. TAIBI[2], M. FLYNN[1], X. DING[1], M. ELOWITZ[1], J. SHEPHERD[2], V. GRADINARU[1];
[1]Caltech, Caltech, CA; [2]Univ. of Utah, Salt Lake City, UT

Abstract: Efficient and targeted RNA delivery could have numerous applications, from trafficking undesired RNA to degradation sites and studying intracellular trafficking, to perturbation studies of intercellular communication. The neuronal immediate early gene, Arc, has been found to contribute to virus-like particles and transfer RNA intercellularly [1]. Inspired by this finding, we are engineering Arc to target specific RNA for delivery to sites of interest. Deactivated Cas13 (dCas13) enzymes, such as dPspCas13b and dLwaCas13a, have been shown to bind RNA without cleaving the target [2]. Cox, et. al have also demonstrated that dCas13 enzymes fused to ADAR2, an RNA-binding and editing protein, edit RNAs specifically. As such, in order to target Arc to a specific RNA, we have generated and tested fusions of Arc and deactivated Cas13 enzymes. We observed dCas13-Arc monomer fusions between 75 kDa and 100 kDa using fluorescent western blot against Arc antibody, an increase from the native 50 kDa size of Arc. Using transmission electron microscopy (TEM), we have also observed capsid formation of these dCas13-Arc fusions from capsids and extracellular vesicles purified by ultracentrifugation from HEK cells. Performing the donor-recipient assay [1], we observed transfer, albeit at low efficiency, of RNA with dCas13-Arc fusions into untransfected naïve HEK cells. Due to modest release of Arc capsids from HEK cells, it was necessary to increase Arc capsid release for downstream detection assays. In HIV and EIAV, p6 and p9 gag motifs, respectively, bind ESCRT proteins and assist with viral budding [3]. Given Arc's primary sequence structural similarity to HIV capsid domain, we hypothesized that integrating these domains into Arc could potentially enhance capsid release [4]. To this end, we have investigated two approaches: (1) fusion, insertion, and substitution of p9 and p6 gag motifs with Arc from EIAV and HIV viruses, respectively; and (2) co-transfection with tetraspanin proteins such as ALIX, CD9, CD81, and TSG101. We then characterized RNA transfer and capsid formation. Overall, we demonstrate that it is possible for Arc to maintain its capsid-forming ability and to traffick RNA when fused with a dCas13 enzyme, as well as other motifs intended for increased capsid release. These preliminary results support the possibility of engineering Arc as a scientific tool for RNA delivery.

Title: Deep brain optical imaging uncovers motivational salience and prediction error encoding by dorsal raphe dopamine neurons

Authors: *J. CHO[1], X. CHEN[1], A. KAHAN[2], D. A. WAGENAAR[1], V. GRADINARU[3]; [1]Caltech, Pasadena, CA; [2]Biol. and Biol. Engin., Caltech, San Marino, CA; [3]Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Increasing evidence shows that DA neurons are functionally heterogeneous from encoding reward or reward prediction error to signaling aversion or salience [1]. DRN DA neurons are anatomically distinct from ventral midbrain DA neurons and respond to salient stimuli regardless of valence, suggesting that they may encode motivational salience [2]. To address this hypothesis, we first performed fiber photometry recordings [3] of DRN DA neurons during appetitive and aversive conditioning tasks where mice learn the association between neutral cues and positive or negative outcomes. Across learning, initially unresponsive DRN DA neurons developed positive response to cues paired with both reward and punishment ($n = 5$ mice, $p < 0.0001$ in two-way ANOVA, $p < 0.01$ in post-hoc Bonferroni tests), suggesting that DRN DA neurons at the population level track motivational salience rather than value [1]. In addition, DRN DA neurons signaled salience prediction error, showing enhanced neural activity in response to unexpected outcomes over expected ones ($n = 5$ mice, $p < 0.05$). However, these neurons did not show activity suppression in response to unexpected omission. The degree of DRN DA salience response was modulated by animal's internal motivational state, as response to reward-predicting cues was diminished after satiety ($n = 5$ mice, $p < 0.05$ in two-way ANOVA, $p < 0.001$ in post-hoc Bonferroni tests). In ongoing work, we are evaluating the VTA DA dynamics in the aforementioned tasks to compare with the DRN DA findings. Finally, we are performing deep brain optical imaging with two-photon microscopy via implanted gradient index lenses during conditioning tasks to investigate the DRN DA neuronal dynamics at the single-cell resolution. Altogether, these data deepen our understanding of the functional

properties of DRN DA neurons and expand on the functional heterogeneity of DA signaling.

Title: VIP neurons in the suprachiasmatic nucleus of female mice underline the bidirectional influence between estrus cycle and circadian rhythm

Authors: *A. KAHAN, G. M. COUGHLIN, V. GRADINARU;
Caltech, Pasadena, CA

Abstract: Female mice ovulate every 4-5 days at the beginning of the dark phase. The temporal specificity of this process points to a role for the circadian clock, and thereby the suprachiasmatic nucleus (SCN), the circadian rhythm pacemaker, in ovulation. One key neuronal population in the SCN expresses vasoactive intestinal peptide (VIP); this signaling peptide has both direct and indirect effects on gonadotropin releasing hormone (GnRH) neurons, the neuronal population

that controls the release of reproductive hormones, such as luteinizing hormone (LH). Although signaling from SCN^{VIP} to GnRH neurons has been hypothesized to control estrous cycle timing, it is not known whether the activity of SCN^{VIP} neurons depends on estrous state. In addition, it is not clear that SCN^{VIP} neurons are the source for VIP peptide release and the exact relevance of SCN^{VIP} neuronal activity for the circadian timing of ovulation is uncertain. To address the first, we recorded calcium dependent fluorescence signal (via fiber-photometry, FP) from SCN^{VIP} neurons in-vivo in both male and female mice. These bulk neuronal activity recordings were supported by single cell resolution imaging using Inscopix miniscopes. We recorded SCN^{VIP} neuronal activity at the transitions from light to dark (ZT12), and two hours before dark (ZT10), which corresponds to the LH surge onset. FP data showed that SCN^{VIP} activity around ZT12 is estrous cycle dependent; at ZT10 these neurons tend to be active at a rate of 0.1 ± 0.02 events/min when recording from females in estrus; lower by factor of 3 to 4 compared to the event rate in other estrous stages. On the other hand, in the first hour of the dark phase (ZT12-13), females in estrus tend to have higher rate (0.38 ± 0.01 events/min), whereas those in other estrous stages and males exhibit a rate of ~0.3 events/min. These results suggest that SCN^{VIP} neurons are under hormonal control, likely involving estrogen and progesterone. To investigate the importance of SCN^{VIP} neurons on the regulation of estrous cycles, we experimentally manipulated the circadian rhythm by: (1) a 'Jet-lag' experiment, by exposing animals to six hours phase advance every 4-5 days (n=7); and (2) ablating SCN^{VIP} neurons through viral-mediated expression of Caspase-3, which triggers cell-autonomous apoptosis (n=5 control, n=6 experimental). In both experiments we observed a significant decrease in estrous cycle regularity and a significant reduction in proestrus events ($P < 0.001$). These experiments provide a direct evidence for the role of SCN^{VIP} neurons as the source of VIP peptide in the circadian regulation of ovulation, and suggest that SCN^{VIP} neuronal activity is affected by the estrous cycle.

York, NY; [4]Dept. of Physics, Univ. of California at San Diego, La Jolla, CA; [5]Dept. of Neurol., UCLA, Agoura Hills, CA; [6]Professor, Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Head-mounted miniature microscopes (Miniscopes) provide a powerful tool for real-time imaging of neuronal activity in freely moving animals that express genetically-encoded calcium indicators (GECIs) (e.g., GCaMP). While current Miniscopes only record a single wavelength of light, a Miniscope capable of recording two separate wavelengths of light would greatly add functional flexibility to allow for imaging different calcium indicators, cell-type specific labeling while imaging and FRET (Fluorescence Resonance Energy Transfer)-based imaging in freely behaving animals. Here, we used our two-channel Miniscope to measure FRET responses *in vivo* from cell-based neurotransmitter fluorescent engineered reporters (CNiFERs) implanted subcortically. CNiFERs are biosensors capable of measuring the release of neurotransmitters or neuropeptides in real-time, and utilize a genetically-encoded FRET-based calcium sensor in conjunction with a specific G-protein coupled receptor. We created a two-channel Miniscope prototype, based on the opensource UCLA Miniscope design, by adding a second optical path and corresponding CMOS sensor. Emission light from the brain passes through an additional dichroic that splits the image into separate wavelengths of light each detected by its own CMOS sensor. The two-channel Miniscope prototype was first validated *in vitr*o by injecting M1 CNiFERs that respond to acetylcholine into agar and measuring changes in the FRET ratio during infusion of acetylcholine. The Miniscope was validated *in vivo* by injecting dopamine sensing D2 CNiFERs directly into the premotor cortex, mounting the scope with GRIN lens, and measuring changes in FRET ratio during electrical stimulation of the substantia nigra. We plan to use the two-channel scope to measure FRET changes in response to endogenous transmitter release in freely behaving mice. Injection of acetylcholine and somatostatin sensing CNiFERs into the CA1 of the hippocampus will allow for the detection of endogenously released acetylcholine and/or somatostatin during free exploration of an open field. In summary, our two-channel Miniscope prototype is capable of measuring changes in FRET. Future refinements and adaptations of this two-channel Miniscope will allow for FRET or any multiplexed recordings of multiple sensors or fluorophores with reduced weight, minimal bleaching, and improved optics.

Title: Minian: An open-source miniscope analysis pipeline with interactive visualization tools

Authors: *Z. DONG[1], Y. FENG[1], W. MAU[2], L. CHEN[1], Z. T. PENNINGTON[1], Y. ZAKI[1], K. RAJAN[1], T. SHUMAN[1], D. AHARONI[3], D. J. CAI[1];

Abstract: Miniature microscopes have gained a lot of traction for *in vivo* calcium imaging in freely behaving animals. However, extracting calcium signals from raw videos is a computationally complex problem and remains a bottleneck for many researchers utilizing single photon *in vivo* calcium imaging. Recently, a few analysis pipelines have been developed and work well on extracting calcium events. However, most analysis packages that are available either have key parameters that are hard-coded or lack detailed documentation on how to set parameters properly. Furthermore, there is a need for a user-friendly tool that offers informative visualization of how altering parameters affect the output of the data. Our open-source analysis pipeline, Minian, facilitates transparency and accessibility of the underlying algorithm of the pipeline. Minian contains interactive visualization tools for every analysis step, as well as detailed documentation and tips on parameter tuning. The visualization tool guides users to explore and select the appropriate parameters which is especially helpful in analyzing different cell-types and brain regions. Minian has been validated to reliably and robustly extract calcium events across different cell types and brain regions. In practice, Minian provides an open-source calcium imaging analysis pipeline with user-friendly interactive visualization to explore parameters and validate results.

Title: FPGA-based real-time processing for integrated electrophysiology and calcium imaging with the UCLA miniscope

Authors: *Z. CHEN[1], G. BLAIR[2], D. AHARONI[3], P. GOLSHANI[3], J. CONG[1], H. T. BLAIR[2]; [1]Computer Sci. Dept., [2]Dept. of Psychology, [3]Dept. of Neurol., UCLA, Los Angeles, CA

Abstract: The UCLA miniscope is an open-source head mounted device that is capable of monitoring the activity of a large population of neurons in freely behaving mice or rats *in vivo*. Here we introduce an accessory real-time processing module (RTPM) for the UCLA miniscope, which processes a standard miniscope video stream at 30 fps with an image resolution of 480x752 and 8-bit pixel intensity. The RTPM is designed on the field programmable gate array (FPGA) of an SoC device to perform the rigid/non-rigid motion correction, image enhancement and calcium trace extraction in real time, and is controlled by a user interface terminal that connects to the RTPM via ethernet from a host computer. The motion correction is accomplished with ~80 μs latency, by using folding to accelerate the contrast filtering, and utilizing unrolling to accelerate FFT operations that are necessary in computing the cross correlation in the frequency domain. The image enhancement is accomplished with <1 ms latency by accelerating morphological operations (erosion and dilation) with dedicated streaming array processing architecture.The modules for calcium trace extraction and cell identification/registration using convolutional neural network inference are under development. In addition to the calcium image processing, the RTPU can also process electrophysiology data in real time by using the compact LSTM inference kernel (CLINK) for filtering and closed-loop feedback (Chen, Blair & Cong, ISLPED 2018). The ultimate goal for the RTPM is to provide flexible hardware for real-time processing and decoding of *in vivo* calcium image and electrophysiology data and to be incorporated it into systems for neurofeedback and closed-loop control of neural activity.

Title: Ccr5 closes the window for contextual memory linking by regulating neuronal ensemble overlap

Authors: *Y. SHEN[1], M. ZHOU[1,2], D. CAI[1,3], Y. CAI[1], A. LAVI[1], D. NECULA[1], A. LIU[1], X. KANG[1], S. HUANG[1], T. SILVA[1], A. J. SILVA[1];

Abstract: Although the mechanisms involved in the encoding, consolidation and retrieval of memory have been widely studied, little is known about the mechanisms that link multiple memories across time. Previous studies in our laboratory showed that when there is substantial overlap between the neuronal ensembles of two memories encoded close in time, recall of one memory increases the likelihood of recalling the other memory, thus linking the two memories across time. Understanding the mechanisms that regulate the temporal window of memory linking is critical for understanding how different memories are either linked or separated across time. Here, we show that that C-C chemokine receptor type 5 (CCR5) plays a key role in closing the temporal window for memory linking. Following contextual conditioning there was a delayed increase in the levels of Ccr5 mRNA in the mouse dorsal hippocampal CA1. When CCR5 activity was measured with the iTANGO-CCR5 system, after learning there was also a delayed increase in neuronal CCR5 activation in a temporal pattern consistent with the hypothesis that these increases in CCR5 expression or activation have an impact on memory linking. Indeed, Ccr5 null mutation resulted in an extension of the window for contextual memory linking, and calcium imaging results with head-mounted fluorescent miniscopes showed that this mutation also extended the temporal window for the overlap between CA1 neural ensembles encoding two separate contextual memories. Aging increases the levels of both Ccr5 and its endogenous ligand Ccl5 in dorsal hippocampus, and importantly, both Ccr5 mutation and CCR5 antagonist reversed the decline in contextual memory linking in aged mice, suggesting that the increase in CCL5/CCR5 signaling in the aged hippocampus contributes to age-related deficits in memory linking. Our results demonstrate that a delayed increase in CCR5 following learning decreases the overlap between the neuronal ensembles encoding two contextual memories acquired distal in time, and therefore close the window for the linking of these memories.

Abstract: Over the past decade, advancements in genetically encoded calcium indicators (GECIs) and head-mounted lightweight imaging devices have enabled researchers to study network dynamics with single cell precision in freely behaving animals. These miniature microscopes (miniscopes) have already provided significant insight into a broad range of neuroscience topics and are likely to continue to be a key technology for investigating neural activity in the context of behavior. When done in parallel with miniscope imaging, electrophysiology recordings can provide complementary information about the brain including high-temporal resolution extracellular spikes and local field potential (LFP) oscillations.
A central goal of our NeuroNex Hub is to design, develop, and implement an electrophyiology integrated miniscope (e-scope) capable of both imaging GECIs as well as recording electrophysiology signals simultaneously in unrestrained animals. We have built a 32 channel e-scope and have successfully tested it in both freely behaving mice and rats. While this system is natively supported by our newest generation of Miniscopes, it also can be easily retrofitted on all previously disseminated Miniscope designs. The ephys electronics interface with the Miniscope imaging electronics requiring no additional cabling between the animal and a data acquisition (DAQ) system. Using a custom flex printed circuit and high density Molex slimstack connectors, the head-mounted ephys electronics can interface with a range of electrodes including single electrodes, tetrodes, and silicon probes. We are now developing 64 and 128 channel e-scopes along with a new generation of DAQ systems.

Here we will present the current status of this project and lay out a roadmap for the coming years.

Title: Eztrack, an open-source video analysis pipeline for the investigation of animal behavior

Authors: *Z. T. PENNINGTON, Z. DONG, R. BOWLER, Y. FENG, L. M. VETERE, T. SHUMAN, D. J. CAI;
Mount Sinai Sch. of Med., New York, NY

Abstract: Tracking small animal behavior by video is one of the most common tasks in the fields of neuroscience and psychology. Although commercial software exists for the execution of this task, this software often presents enormous cost to the researcher, and can also entail purchasing specific hardware setups that are not only expensive but lack adaptability. Moreover, the inaccessibility of the code underlying this software renders them inflexible. Alternatively, available open source options frequently require extensive model training and can be challenging for those inexperienced with programming. Here we present an open source and platform independent set of behavior analysis pipelines using interactive Python (iPython/Jupyter Notebook) that researchers with no prior programming experience can use. Two modules are described. One module can be used for the positional analysis of an individual animal across a session, amenable to a wide range of behavioral tasks including conditioned place preference, water maze, light-dark box, open field, and elevated plus maze, to name but a few. A second module is described for the analysis of conditioned freezing behavior. In addition to a range of

interactive plots and visualizations to confirm that chosen parameters produce results that conform to the user's approval, batch processing tools for the fast analysis of multiple videos is provided, and frame-by-frame output makes aligning the data with neural recording data simple. Lastly, options for cropping video frames to mitigate the influence of fiberoptic/electrophysiology cables, analyzing specified portions of time in a video, and defining regions of interest, can be implemented with ease.

Title: MiniFAST (miniscope with a fast and sensitive image sensor and fast locking baseplate)

Authors: *J. JUNEAU[1], G. DURET[1], A. V. RODRIGUEZ[1], S. MOROZOV[1], D. AHARONI[2], J. T. ROBINSON[1], F. ST-PIERRE[3,1], C. KEMERE[1];

Abstract: In recent years, miniaturized fluorescence head-mounted microscopes have enabled experiments aimed at long-term imaging of cell networks in freely behaving animals. The success of this technology relies on fluorescent neural activity sensors such as calcium indicators (e.g. GCaMP). All fluorescence based neural activity sensors suffer from cell brightness degradation due to photobleaching and thus limit the time of the experimental imaging session (~20-45 minutes for currently available head-mounted microscopes). Photobleaching is caused by microscope excitation light intensity and is directly correlated with image sensor sensitivity and gain levels. Furthermore, new neural activity sensors, such as genetically-encoded voltage indicators (GEVIs), are emerging providing kinetics that can closely match the temporal resolution of action potentials. Presently, GEVIs are significantly dimmer than calcium indicators and require faster frames rates that can match the GEVI's on/off fluorescence kinetics. Due to these technological limitations, imaging of GEVIs with head-mounted microscopes have not been reported. In order to meet emerging neural activity sensor advancements and reduce photobleaching effects, we aim to bridge the gap by improving the technology of head-mounted microscopes.

Here we present the design and *in vivo* results of open-source MiniFAST, a miniaturized fluorescence head-mounted microscope capable of ultra-fast frame rates (> 500 frames per second) and super low-light sensing ability (analog gain up to 30 dB). The design is built upon the open-source Miniscope platform and is compatible with the Miniscope Data Acquisition Board, optical lenses and the single cable serializer/deserializer system. MiniFAST's printed circuit board, with a size of 13 mm by 22 mm, integrates a Sony CMOS image sensor with a total of 2.13 megapixels, 2.9 um pixel size and featuring 1080p video at 30 frames per second. Increased frame rates are achieved by reducing the frame height. The new features of MiniFAST are incorporated into the Miniscope Windows GUI. Additionally, the 3-D printed optics housing is updated for the larger sensor size and provides a fast new easy locking baseplate that maintains stability with animal movement. Without the requirement of tightening set screws, the MiniFAST baseplate design decreases animal handling time from ~2-3 weeks to ~2 days. We demonstrate the camera with *in vivo* imaging of the CA1 region of the hippocampus in freely behaving mice injected with GCaMP6f. Furthermore, we show results from *in vitro* cell patch-clamping and *in vivo* imaging of a genetically-encoded voltage indicator.

Instit, Univ. of California, Los Angeles (UCLA), Los Angeles, CA; [5]Neurosci., Mount Sinai, New York, NY; [6]Dept Neurobiol, UCLA Med. Ctr., Los Angeles, CA

Abstract: Memories are dynamic in nature and a cohesive representation of the world requires memories to be altered over time, linked with other memories and eventually integrated into a larger framework of sematic knowledge. Our laboratory has recently demonstrated that

overlapping ensemble of hippocampal neurons mediate linking of two contextual memories encoded close in time whereby the recall of one can lead to the recall of linked memory (*Cai et al. 2016*). Retrosplenial cortex or RSC is another brain structure that is critical for contextual learning and memory. It is unclear whether memory linking is due to overlap in neuronal ensembles in certain key brain regions, such as hippocampus for contextual memories, or the entire neural circuit involved in contextual memory formation displays this neuronal overlap. We addressed this question by investigating the overlap in neuronal ensembles encoding contextual memories at varying time intervals within the RSC. Using head-mounted miniature microscopes, we imaged GCaMP6f-meadiated calcium dynamics in retrosplenial cortical neurons while the mice explored distinct contexts. We found greater overlap in the neuronal ensemble activated in response to two distinct contexts when the contexts were explored 5h vs. 7d apart. These data indicate that the RSC can mediate temporal memory linking by recruiting a shared neuronal ensemble for memories encoded within a day. We are currently investigating whether manipulating this neuronal overlap in RSC would allow us to manipulate linking of contextual memories. Furthermore, to understand whether such ensemble overlap was driven by neurons encoding spatial information, we performed linear track experiments where RSC calcium transients were imaged using miniaturized microscopes. We found that a subset of RSC cells displayed place cell like dynamics. Furthermore, the same cells could be tracked over repeated linear track sessions and displayed stable firing patterns indicating retention of spatial information over days. We are currently investigating whether reactivation of RSC neurons is influenced by spatial information encoded by these cells. Our data indicate that co-allocation of neuronal ensembles encoding temporally proximate contextual memories may be a general mechanism of memory linking across the brain regions that process spatial and contextual information.

Title: Registration across *in vivo* neuronal imaging modalities: Miniature microscopes to high resolution microscopy

Authors: P. S. XU, S. GULATI, *A. M. STAMATAKIS;
Inscopix, Palo Alto, CA

Abstract: The ability to register data from freely moving imaging experiments to data from high resolution confocal or multi-photon imaging will begin to provide crucial links between activity dynamics and anatomical, molecular, and/or connectivity profiles of distinct neuronal populations. Here, we have developed methodology to register the exact same neurons imaged with the Inscopix nVista miniature microscope to neurons imaged with a Zeiss Airyscan confocal microscope. To ensure we are recording from the same focal plane, we designed a hardware component that allows the experimenter to make the nVista and Airyscan parfocal. Freely-behaving Ca2+ imaging is first performed with the nVista, followed by head-fixed recordings with the Airyscan microscope. After acquiring data from the two imaging modalities, we extract functional cell maps from each Ca2+ imaging data set using Inscopix Data Processing Software. To align the cell maps from both microscopes, we combine cell maps with structural images containing blood vessel patterns and a few shared landmarks. The different scale, rotation, and elastic deformations between the images are then corrected using the bUnwarpJ algorithm in ImageJ. After alignment, the same cells are recognized from the different imaging modalities. Using this hardware and analytical solution, we have demonstrated the feasibility of identifying the same GCaMP neurons imaged in the mPFC with the nVista and Airyscan microscopes. The deformation matrix obtained here can subsequently be applied to other images collected from the corresponding imaging modalities. For example, a static red indicator can be imaged using the confocal microscope, enabling the ability to identify projection-specific, genetically-defined, or activity-dependent subtypes of GCaMP neurons. Importantly, the registration method described here can be expanded to other high-resolution imaging modalities such as two photon or light sheet microscopy.

and Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; [4]Ctr. for Neural Sci., New York Univ., New York, NY; [5]Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: Understanding how populations of neurons and the circuits they create give rise to complex behavior and higher mental function remains a key endeavor of systems neuroscience. Novel imaging tools combined with the development of new Ca^{++} indicators have advanced neuroscience by introducing the ability to (1) monitor large populations of neurons simultaneously, (2) track identified neurons for extended periods of time, and (3) introduce causal manipulations of individual or small groups of molecularly characterized neurons together with recording of population activity. The goal of our work supported by a BRAIN award, is to fill a critical gap in neuroscientific technology by extending microendoscopy imaging approaches, currently used in mice, to macaque monkeys, allowing for the first time imaging experiments for extended periods of time in alert, freely moving monkeys. As a first step toward this aim, we have implemented a novel chamber, grid and manipulator system for implantation in macaque monkeys that allows for targeting of viral injections and precise placement of GRIN lenses for later imaging. Once placed, the manipulator system allows for vertical movement of the GRIN lens with ~25µm resolution, to identify the optimal imaging plane and subsequent permanent placement of the GRIN lens. Our first design allows for the placement of a single GRIN lens and is designed to scale up to hold multiple GRIN lenses for future array recordings. We have also designed a miniaturized microscope optimized for use in macaque monkeys. There are two embodiments of this design which differ in physical size, FOV and working distance. These systems can image a 2mm or 3mm FOV, have adjustable working distances of between 1.5mm and 3mm, and have footprints on the skull of one to two square cm. All tools and devices will be shared through Miniscope.org.

Title: Projection specific medial prefrontal cortex and nucleus accumbens neural dynamics underlying social interactions

Authors: *P. ZHAO[1], X. CHEN[1], W. HONG[2], D. AHARONI[1], A. ARAC[1], P. GOLSHANI[1]; [1]Dept. of Neurol., [2]Dept. of Biol. Chem., UCLA, Los Angeles, CA

Abstract: Deficits in social interactions are the main clinical manifestations of autism spectrum disorder (ASD), yet the neural mechanisms driving social interactions are still poorly understood. While the nucleus accumbens (NAc) is well known for its role in motivation, reward, and drug addiction, it is still unclear whether and how NAc and its connected brain regions like medial prefrontal cortex (mPFC) encode and drive social interaction. Using the UCLA miniature fluorescence microscope (UCLA Miniscope), we recorded neural activity in NAc neurons expressing the calcium indicator GCaMP6f as animals interacted with conspecifics or with an object in a chamber. We extracted neuronal ensemble signal by CNMF-E and performed Receiver Operating Characteristic (ROC) analysis to identify cells that were either significantly excited or inhibited during social interactions or cells that were significantly excited or inhibited by interactions with the object. Overall, 16.8±6.1% of neurons were activated during social interactions while 3.9±3.1% of neurons were inhibited. Conversely, 7.8±4.3% of neurons were excited by interactions with the object while 6.0±2.0% of neurons were inhibited. A Partial Least Squares Regression (PLSR) decoder showed higher performance in predicting episodes of interaction with social target compared to object target. In contrast, far lower proportion of mPFC neurons were activated by social interaction (6.1±1.1%) and the decoder showed lower performance in predicting episodes of interaction with social target when provided mPFC ensemble activity patterns. Using retroAAV-Cre and FLEXed GCaMP6f in mPFC, we are performing recordings of neural activity in mPFC neurons specifically projecting to NAc, mediodorsal thalamus, basolateral amygdala or the ventral tegmental area. Preliminary results show that among these subgroups of PFC neurons, PFC-BLA neurons contain the highest percentage of neurons significantly activated by social interaction. Therefore, social interactions are encoded by a coordinated activation of neurons in multiple brain regions that are differentially activated by interactions with conspecifics. Future work will determine whether these networks are aberrantly activated in models of autism with impaired social interactions.

Title: The aging hippocampus- Loss of learning-induced excitability in CA1

Authors: *L. CHEN[1], S. RAMIREZ[2], R. L. CLEM[1], D. J. CAI[1];
[1]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Psychological and Brain Sci., Boston Univ., Boston, MA

Abstract: With a gradually aging population, the prevalence of age-related neurodegenerative diseases is on the rise; therefore it is essential to identify the mechanisms that underlie the normal age-related cognitive deficits. A remarkable feature of the brain is its ability to "file" and "cross-reference" memories so that they can later be retrieved. We previously showed that two contextual memories become linked when they are learned within a day and they also share a common neural representation in the hippocampus; and this temporal memory-linking process is disrupted in older mice. We further showed that hippocampal CA1 neuronal excitability mediated memory-linking processes, and prior studies suggest that excitability may be altered with aging. In this study, we test the hypothesis that temporal memory-linking deficits observed in older mice are caused by age-related alterations with neuronal excitability in CA1. We used an activity-dependent tagging strategy (cFos tTA + TRE-eYFP virus) to selectively label CA1 neurons that were active during contextual learning with YFP in young adult (3-6 m) and aged (22-24 m) mice, then performed whole-cell current-clamp recording of evoked action potentials in both YFP+ and YFP- neurons. In young adult mice, we found an increase in learning-induced excitability specifically in the ensemble neurons (increased evoked action potentials and reduced inter-spike interval (ISI) of YFP+ neurons compared to YFP- neurons) 5 hours after contextual learning. This increase in learning-induced excitability in YFP+ neurons returned to baseline within 7 days. In aged mice, there was a deficit in specifically the learning-induced excitability, however, baseline excitability of CA1 neurons were no different than in young adult mice. These results suggest that CA1 may be susceptible to learning-induced changes in excitability with normal aging, despite other forms of intrinsic excitability remaining normal. Furthermore, we used *in vivo* calcium imaging with Miniscopes during behavioral linking tasks to test the hypothesis that decreased learning-induced excitability in older mice would disrupt temporal memory-linking. We found aged mice with deficits in learning-induced excitability in CA1 had deficits in temporal memory-linking (both at the circuit and behavioral levels). Aberrations in CA1 neuronal excitability may serve as a cellular mechanism that leads to reduced ensemble overlap in the memory-linking process and to other cognitive deficits during normal aging. Our research also underscores the importance of using ensemble-specific tagging strategies to selectively detect learning-induced changes in the brain.

Title: Large-scale cellular-resolution calcium imaging in 4D during free behavior

Authors: *K. ZITELLI, M. MILLER, S. XU, S. GULATI, A. STAMATAKIS;
Inscopix, Inc., Palo Alto, CA

Abstract: We have developed nVista, a head-mounted miniaturized microscope-based system that enables neuroscientists to record and monitor large-scale Ca2+ dynamics at single-cell resolution in freely behaving rodents over months. To expand upon this system, we have utilized an electronically tunable lens, synchronized to a global shutter image sensor, to enable multi-plane imaging. The fast step-response of the lens (<10 ms) allows for the ability to rapidly move the object plane through a pre-defined volume of brain tissue. We created a video stream containing images of three user-selected focal planes in an interleaved format. With a 60 fps sensor rate, the effective sampling interval per plane is 50 ms with a 16 ms exposure (20 fps) per video frame. To validate this multi-plane imaging approach in a freely behaving animal model, we injected AAV9-CAG-GCaMP6s into the medial prefrontal cortex of mice. During a live imaging session, we selected three focal planes 60 microns apart and recorded Ca2+ activity using this interleaved method. Using a conservative analytical registration approach, we first determined the percentage of cell overlap between imaging planes. After disregarding identical cells that were visibly co-localized in multiple planes, we found that we are able to record from an additional ~50% cells that were unique to their plane. This increase in the number of cells recorded during a single session has several scientific applications, such as improving a behavioral decoder. Other exciting potential applications of this technique remain to be explored, such as imaging multiple sub-nuclei pseudo-simultaneously, or imaging multiple cortical columns through a prism GRIN lens.

Title: SynTagMA: A new tool for mapping active synapses

Authors: *B. C. FEAREY[1], A. PEREZ-ALVAREZ[1], C. SCHULZE[1], R. J. O'TOOLE[3], W. YANG[2], I. ARGANDA-CARRERAS[4], P. J. LAMOTHE-MOLINA[1], B. MOEYAERT[5], E. R. SCHREITER[5], J. S. WIEGERT[2], C. E. GEE[1], M. B. HOPPA[3], T. G. OERTNER[1];

Campus, Ashburn, VA

Abstract: Calcium imaging has given major insights into the function of individual synapses and the mechanisms underlying synaptic strengthening and weakening. Simultaneously measuring functional responses from thousands of synapses across a dendritic tree is possible in two-dimensional culture systems, but not in intact brain tissue: Laser-scanning microscopy is inherently slow when high spatial resolution in 3D is required. To tackle the challenge of functional imaging from thousands of synapses, we employed the photoconvertible calcium integrator, CaMPARI2, by targeting it to either the pre-synapse, preSynTagMA, or to the post-synapse, postSynTagMA (**Syn**aptic **Tag** for **M**apping **A**ctivity). SynTagMA marks synapses according to their internal calcium levels $[Ca^{2+}]_i$ by irreversible photoconversion from green-to-red fluorescence triggered by a brief violet light pulse. Using back-propagating action potentials (bAPs) to activate voltage-gated Ca^{2+} channels in dendrites and spines, we could visualize the attenuation of bAPs along the dendrite. Interestingly, we observed spine-to-spine and branch-to-branch differences in photoconversion, pointing to a heterogeneous distribution of voltage-gated channels. By pairing subthreshold synaptic stimulation and violet light, we labeled a sparse subset of synapses, presumably activated by direct synaptic input. The relatively fast turnover of postSynTagMA affords the opportunity to relabel post-synapses after about two hours, making it

possible to capture multiple activity maps. To find and track thousands of individual synapses over multiple time points, we developed SynapseLocator, a MATLAB-based software package. In summary, SynTagMA is a new tool that allows the user to simultaneously study thousands of synapses in living tissue and to generate exhaustive maps of active excitatory inputs to individual neurons.

Title: Phenotyping mouse sociability using fully-automatic scoring of social interactions

Authors: *C. K. E. JUNG[1], N. SCHWAERZLER[2], A. SCHATZ[2], A. I. ISTUDOR[2], M. RIVALAN[3], Y. WINTER[2];

Abstract: Scoring the social interactions between mice is a necessity for quantifying an individual's social behaviour phenotype. At the same time it is labor intensive and has been difficult to automate. We succeeded by first observing visually identical mice using video and ID chip sensors, and then combining this with the computer-automated algorithmic scoring of social interactions. This gave us an index of sociability for each mouse. We fused sensor information from a video tracker positioned above and an ID sensor grid placed underneath the cage. This allowed us to track individual position and body orientation within pairs of mice, over time durations between hours to days. Using a thermal camera provided independence from mouse fur color and changes in bedding material or illumination. We scored social interactions algorithmically following the approach pioneered by deChaumont et al. (2012). Mice were presented as vectors and the dynamic orientation of one vector towards the other was used to classify contact events, relative position events, and dynamic events. We collected data for mice in different pairings and positively validated the system. Deficits in social interaction in a mouse model of autism were clearly detected. This system is a ready-to-use setup for obtaining an index

of mouse sociability with automation and high time efficiency. We consider it to have great potential as a high-throughput phenotyping technology.

Title: Continuous recordings of whole-body kinematics across the rodent behavioral repertoire

Authors: ***J. D. MARSHALL**[1], D. E. ALDARONDO[1], T. W. DUNN[2], W. WANG[1], G. BERMAN[3], B. OLVECZKY[1];
[1]Harvard Univ., Cambridge, MA; [2]Duke Univ., Durham, NC; [3]Biol., Emory Univ., Atlanta, GA

Abstract: A longstanding goal of neuroscience has been to understand how different brain areas contribute to the acquisition and control of movement. While techniques for large-scale neural recordings are bringing us closer to this goal, complementary techniques for characterizing motor output have been slower to emerge. As a result, experiments probing the relationship between neural activity and movement often do so across a limited set of task-oriented behaviors, preventing a more general understanding of the relationship between movement and brain activity. To extend the range of behaviors and contexts that can be studied, we developed a new behavioral monitoring system, CAPTURE, that combines motion capture and deep learning to track the 3D movement of twenty points on a freely behaving rat's trunk and appendages, continuously over week-long timescales. We validated CAPTURE's ability to identify over 1000 distinct movement elements and describe the known kinematics, sequential organization, and circadian modulation of grooming and locomotor behaviors. Our measurements and analysis revealed unanticipated variability in the kinematics and sequencing of behaviors such as grooming and detected previously undescribed perturbations in movements and behavioral organization following pharmacological challenges and in a rat model of Fragile X syndrome. We then combined CAPTURE with continuous neural recordings in the dorsolateral striatum, a brain region with a known, if debated, role in controlling diverse aspects of movement

kinematics, action selection, and behavioral sequencing. Preliminary analyses of striatal recordings revealed that neurons are active across multiple behaviors, involving disparate poses and appendage movements. However, analyses at longer timescales revealed that striatal neurons are preferentially tuned to individual long-timescale behavioral states, suggesting that behavioral context strongly influences movement encoding in the brain. Overall, CAPTURE should enable new efforts in behavioral phenotyping, studies of behavioral organization, and significantly advance our understanding of how the brain underlies motor behavior.

Title: Simultaneous pupillometry, calcium recording and fMRI to track brain state changes in the rat

Authors: *P. PAIS-ROLDÁN, K. TAKAHASHI, Y. CHEN, H. ZENG, Y. JIANG, X. YU; Max Planck Inst. For Biol. Cybernetics, Tübingen, Germany

Abstract: *Introduction.* The pupil size can inform about arousal or attention. Animal studies have combined pupillometry with electrophysiology and behavior to infer arousal linked to neuronal firing patterns from specific locations. Whole-brain functional magnetic resonance imaging (fMRI) allows tracking the connectivity patterns that emerge upon distinct neurological states. However, fMRI is not compatible with behavior tests. In this work, we merge fMRI with pupillometry and cingulate cortex (Cg) calcium recordings (**Fig. 1A**) to investigate the missing link between the brain state and the whole-brain neural activity. *Methods.* GCaMP was expressed in Cg on 4-week old SD rats. After 3-4 weeks, an optical fiber was implanted on Cg and the anesthetized animals (alpha-chloralose) were transferred to a 14T MRI scanner. An MRI-compatible camera was used to track pupil size changes. fMRI (n=71 trials, 10 animals) was acquired using GE-EPI (TR=1s, TE=12.5ms, resolution=0.4x0.4x0.6mm). Biopac was used to record neuronal activity from Cg. The pupil size was extracted from each video frame using

Matlab. A pupil-fMRI correlation map was obtained from the voxel-wise correlation between pupil dilations and the fMRI signal. *Results.* fMRI revealed negative correlations between the pupil dynamics and most of the brain. The momentary spatial correlation between the pupil-fMRI map and each fMRI volume allowed creating an fMRI arousal time course (fAtc), indicative of the varying arousal level during fMRI (**Fig. 1B**). A region in the brainstem (A5) was positively correlated with dilations, but only under a particular electrophysiological state (during uncoupling of the calcium oscillations) (**Fig. 1C**). The pupil dynamics and the fAtc were negatively correlated with the neuronal activity in the 2-3Hz band (i.e. dilations were associated to less synchronized states) (**Fig. 1D**). *Conclusion.* This new platform (concurrent fMRI + pupillometry + GCaMP) constitutes a powerful tool to track brain state changes from fMRI, which is critical in whole-brain studies investigating consciousness from animal models.

Title: A fully automated location bi-conditional spatial memory task using floor projection

Authors: *V. J. ESTELA, R. D. BURWELL;
Brown Univ., Providence, RI

Abstract: Bi-conditional behavioral assays often require manual manipulation of the subject as well as cues and the apparatus, limiting the number of trials that can be completed in a given session. This is especially problematic when analyzing behavioral correlates of electrophysiology data, as the power of an observed effect can depend on the number of trials. In the field of spatial memory, there is a growing need to maximize both the number of cells recorded and the number of trials per session in a given behavioral paradigm, especially when the task is complex or cells in the target region are sparsely distributed. Here, we present a fully automated location bi-conditional spatial memory task that can be used in conjunction with freely moving *in vivo* electrophysiology, optogenetic or pharmacological neuronal manipulation, and intracranial stimulation as a reward. During training on our 2D floor-projected task, the rat is tracked by LEDs mounted on the electrophysiological implant, facilitating automation of the task and providing precise spatial tracking information including head direction (Figure 1A). We use a bow-tie shaped maze in which the east side is distinguished from the west side by visual and olfactory intramaze cues and visual extramaze cues. Animals learn that one of a pair of 2D objects back-projected to the floor of the maze is correct on the West side of the maze and the other is correct on the East (Figure 1B). Importantly, the presentation of 2D objects on the floor capitalizes on rodents' bias toward using the lower visual hemifield to discriminate objects, while allowing for unlimited options for 2D images to be used as objects. The task is designed such that real-time manipulation of variables allows for animal-specific behavioral shaping, such as correction of side biases, object preferences, and pacing of trials. This paradigm provides the complexity necessary to identify higher-order neuronal representations along with the automation necessary to achieve sufficient power to analyze the resulting complex behavioral correlates.

Title: A novel approach to evaluating social distance processing in rats: Implications for understanding the posterior parietal cortex

Authors: *T. B. WISE[1], R. D. BURWELL[1], V. L. TEMPLER[2];
[1]Brown Univ., Providence, RI; [2]Providence Col., Providence, RI

Abstract: Recent literature points to a potential link between the evolution of complex social behavior and the posterior parietal cortex (PPC) in human and non-human primates. Parkinson and Wheatley (2013) hypothesized that the PPC, an area responsible for evaluating egocentric physical distance, is also implicated in understanding the strength of social relationships, termed "social distance". Thus far, this theory has been overlooked in other highly social animals, such as rats, which may have evolved in a similar way due to social selective pressures. Using experimental lesion approaches and the 3-Chamber Sociability and Social Novelty task, we found evidence implicating rats' PPC in social function (unpublished data). This task, however,

does not directly address the underlying mechanisms of social cognition. To better investigate the potential overlap between physical and social distance evaluations, we developed a novel experimental apparatus designed to permit testing both spatial and social cognition. Using a multi-level apparatus (Figure 1), subjects are trained to discriminate equally familiar conspecifics that are located at near and far physical distances. Once at performance criteria, subjects are then probed for physical to social distance transfer. Subjects are presented with conspecifics that are equally far away but differ in terms of social distance. Our prediction is that rats will complete a physical to social distance transfer. In future experiments, we plan to use this task to examine the role of the rodent PPC in spatial and social distance. This task can also be used to investigate rodent models of human social deficits.

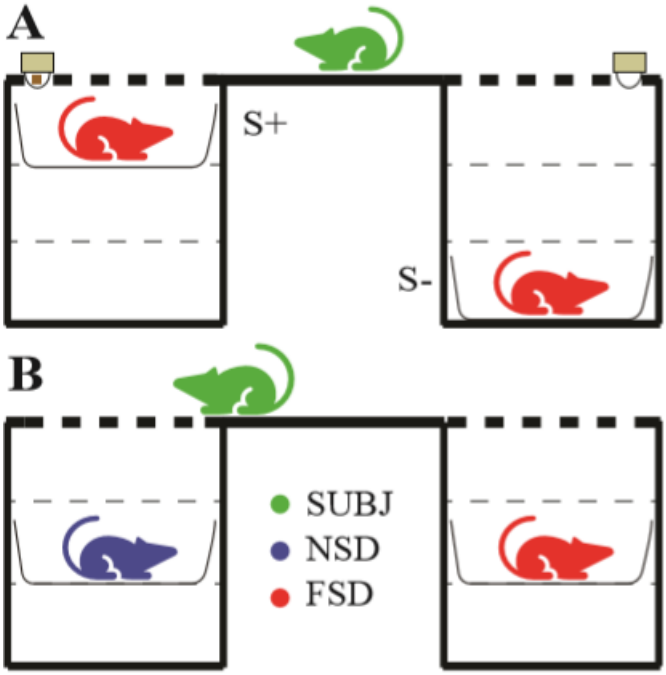

Figure 1. Spatial to social distance task. A) Training: nearest Far Social Distance (FSD) rat is correct (near vs. far correct, counterbalanced across subjects). B) Probe: Subject rats are presented with one Near Social Distance (NSD) rat and one FSD rat, equidistant from subject. We predict subjects will transfer spatial distance to social distance, choosing the NSD rat.

Abstract: The extraction and purification of collagen are of great interest due to its biological function and medicinal applications. Although marine invertebrates are abundants in the animal kingdom our knowledge of their extracellular matrix, which mainly contains collagen, is lacking. The functions of collagen isolated from marine invertebrates remain an untouched source of the proteinaceous component in the development of groundbreaking pharmaceuticals. The composite of marine collagen based biomaterials displays a promising biocompatibility through the dermal wound healing process as well as an evidence of biodegradability. Results suggested that the curcumin incorporated collagen film and chitosan incorporated exhibited excellent wound healing activity (75%) in both full thickness excision and linear incision in rats.

Title: An *in vitro* 3D platform for functional and structural interrogation of neuronal circuits

Authors: *B. MOLINA MARTINEZ[1], P. D. JONES[2], L. JENTSCH[1], P. CESARE[1];
[1]Neuro Microphysiological Systems Group, [2]Microsystems and Nanotechnology
Nanotechnology Engineer, NMI, Reutlingen, Germany

Abstract: In the quest for developing new therapies for neurological disorders, researchers are still largely dependent on 2D in vitro experiments and animal models. Poorly representing the multifaceted nature of neurodegenerative processes in the human brain, these approaches have shown low predictive value in clinical studies.
To fill this gap, several public and private initiatives are focusing on the development of so called organs-on-chips. By combining advanced microfabrication and 3D cell culture technologies, these are expected to better recapitulate the physiology of the brain and capture its complexity at both structural and functional level, which may eventually lead to more relevant in vitro models of human neuronal disorders and consequently to a more efficacious drug discovery process.
However, despite the recent progresses in this field, none of the currently available technologies has the capability to directly measure electrical excitability of individual neurons synaptically connected in 3D neuronal circuits.
To address this need, our group is developing a novel phenotypic platform based on the integration of microfabrication methods, electrode arrays and microfluidics to reconstruct, record and image 3D brain circuits non-invasively in a high-throughput format.
For this purpose, mouse primary hippocampal neurons are grown embedded within hydrogel scaffolds to recreate 3D multicellular architectures inside microfabricated, pumpfree bioreactors. Microelectrode arrays are then integrated into the microfluidic design and used to monitor the electrical activity of enclosed neuronal cells at different time points and in response to a range of neuroactive compounds. In parallel, morphological and 3D structural information of neurons can be collected at high-resolution by confocal microscopy following transduction with AAV particles encoding for fluorescent proteins. To meet the throughput requirements associated to pre-clinical research, up to twelve independent experiments can be carried out simultaneously on a single device having a footprint of only 49 x 49 mm. Future developments may include integration of such technology into a format compatible with multi-well plates.
Collectively, such technology has the potential to introduce a new paradigm in basic and applied neuroscience by providing a novel ground-breaking platform for investigating 3D neuronal circuits in vitro. By enabling a more physiologically relevant disease modelling, this will lead to: i) better understanding of basic neuronal mechanisms; ii) refinement of pre-clinical research methods; iii) reduction in the number of animal studies.

Title: Gauging relevance and reproducibility of human iPSC-derived 3D neuralspheroids for high throughput neuroscience drug discovery and toxicology testing

Authors: A. WHITE, C. CARROMEU, ***B. D. ANSON**, C. CHAPMAN, C. TOMARO-DUCHESNEAU, M. JOHNSON, J. SEELKE, N. PAIDIMUKKALA, F. ZANELLA, M. PERIS; Stemonix, Maple Grove, MN

Abstract: The human cerebral cortex is a highly sophisticated three-dimensional structure which comprises multiple different neural cell types intricately interconnected to form a functional organ. Recent work has focused on the development of *in vitro* models capable of recapitulating brain composition and function. We have developed a three-dimensional human-induced Pluripotent Stem Cell (hiPSC)-derived model amenable to high-throughput drug discovery and toxicology studies. This platform is comprised by neurospheroids measuring approximately 600 µm, populated by cortical neurons and astrocytes. Transcriptional analysis confirms a neuronal expression pattern, immunocytochemistry analysis demonstrates the complex interconnection of cortical neurons and astrocytes and the expression of maturity markers and glutamate transporters typically present in human cortical tissue, and functional analysis demonstrates appropriate neuronal behavior. The functional assays highlight the utility of the platform where it can be used as a phenotypic readout for drug efficacy and toxicity. Specifically, kinetic calcium flux analysis, assayed using a Fluorometric Imaging Plate Reader (FLIPR), provides a measurement of the underlying neuronal activity and highlights the high-throughput capabilities of this platform for the detection and quantification of calcium oscillations both at unstimulated baseline and when exposed to known reference compounds, pathway modulator, and/or toxicants. Variability studies investigating spheroid size, calcium flux and immunocytochemistry, demonstrate the robustness of the platform for high-throughput screening. We also demonstrate that this platform is a highly stable model with a broad assay window of use once differentiated. Taken together, the model described herein provides a highly reliable and stable *in vitro* platform for high-throughput drug discovery and toxicology investigations.

Title: Analyzing individual neuronal connectomes of cultured network using micropattern

Authors: *J. KIM[1], J. RYU[1], W. SUN[2];
[1]Anat., [2]Anat. and Brain Korea 21 Plus Biomed. Sci., Korea University, Col. of Med., Seoul, Korea, Republic of

Abstract: The understanding of connection profile of neural circuits at the cellular level is essential to understand neural function. Nevertheless, the monitoring system for neuronal network has not yet been established due to the complexity of the neuronal circuits. Micro-contact printing is a practical tool to simplify the neuronal circuit architecture in 2D. Recently we developed Semaphorin 3F (Sema3F) dot-surroundings patterning system to guide the axonal growth and confine the area for synaptic formation [Ryu et al., 2016]. In this study, various patterns were investigated to optimize the condition for analyzing circuit structure of cultured neural networks. During the maturation of the cultured network of neurons, axons tend to escape from permissive (poly-l-lysine) to repulsive (Sem3F) zone at the angular point, while dendrites appeared to remain within the permissive area due to relatively short growth. Through a series of such the growth processes on defined patterns, a simplified neuronal circuit was achieved, where most of dendrites and cell bodies were trapped in the permissive region to form receptive field, and axon grew to reach synaptic partners. The extent of axonal growth affected by the size of the pattern and spacing between the patterns was able to adjust the complexity of the network. To separate individual cell morphology, the stochastic multicolor labeling via viral transfection was recruited [Chan et al., 2017]. Combining the synaptic compartmentalization and individual cell labeling allowed to read a whole network structure at cellular level. This new model system is the first experimental model enabling to study neural computation at cellular level in a closed circuit of neurons, allowing to investigate basic characteristics and functional roles of specific types of neurons in neural circuits as well as an *in vitro* testbed to study brain disorder.

Title: Conductive polymer based fiber-eledtrode for bioactivity measurement

Authors: *K. TORIMITSU, K. MIURA;
Tohoku Univ., Sendai, Japan

Abstract: Development of a flexible electrode for bio-activity measurement is important for understanding our physiological conditions. Usage of conductive polymer, a poly(3,4-ethylenedioxythiophene) based compound improved the electrode characteristic and biocompatibility in MEA and/or fiber electrode. We reported previously continuous measurement of chick brain activity using this type of electrode. Here we report the flexible fiber electrodes based on silk and Japanese paper for bioactivity measurement. As the conductive polymer modified fibers allowed us for a higher biocompatibility, we could use this electrode not only for an implantable electrode, but for behavior analysis. Stable signal detection and wireless recordings has been achieved. Application of this electrode for a fabric and furniture as a primary evaluation of behavior analysis is one of our interest.

Title: Synaptic E/I receptor ratio preservation during extremely long post-mortem interval

Authors: *P. SCADUTO[1], D. PANDYA[1], A. LIMON[2];
[1]Neurol., [2]Neurol. and Mitchell Ctr. for Neurodegenerative Dis., UTMB, Galveston, TX

Abstract: The excitation to inhibition balance can be defined as the average amount of depolarizing to hyperpolarizing neuronal synaptic currents (global synaptic E/I ratio or just E/I ratio) in a particular region (Vogels, et al., 2011; PMID: 22075724) and is critical for coherent neural coding (Zhou and Yu PMID: 30334221). Alterations of the E/I ratio have been proposed to underlie neuropsychiatric and neurodegenerative disorders such as schizophrenia and Alzheimer's disease. However, the E/I ratio in humans is poorly understood due to the difficulty to perform electrophysiological studies in postmortem tissue. A critical factor in these studies is the potential degradation, and variability, due to the *post-mortem* interval (PMI), which is the time elapsed from death to the preservation of brain specimens by freezing. Here, we used Microtransplantation of Synaptic Membranes (MSM), a technique that allow us to perform functional studies of synaptic receptors from *post-mortem* brains, and western blotting (WB) to determine the global E/I ratio and the effects of the PMI upon this ratio. By simulating morgue conditions using euthanized rats kept at different temperatures (4° and 21°C) and across different PMIs (0, 6, 16, 24, 48, 120 h) we tested the effect of PMI and temperature on the function of synaptic receptors (glutamate and GABA receptors) and anchor protein levels (PSD-95 and Gephyrin) that determine the E/I ratio. We found that temperature played a larger role than PMI in preserving levels and functions of receptors. Brains kept at 4°C preserved synaptic electrophysiological currents and the E/I ratio up to 120h after death showing no statistical difference from control (One-way ANOVA test for differences in excitatory currents, $p= 0.08$; inhibitory currents, $p=0.5$; and E/I ratio, $p=0.4$). WB analysis showed uniform degradation of PSD95 and gephyrin over time ($p<0.001$ ANOVA for both), maintaining the E/I ratio constant compared to control ($p=0.06$ ANOVA). In contrast, brains kept at 21°C had severe loss of excitatory and inhibitory receptors functionality, which was mirrored by levels of anchoring proteins. Surprisingly, brains kept at 21°C maintained the E/I ratio of currents up to 24h and protein levels after 16h ($p=0.93$ and $p=0.85$, ANOVA Dunnett's test, respectively). Our results indicate that E/I ratio measured by protein quantification or functional assay is preserved at low temperatures and reduced the variability among experiments and within each group. This metric might be useful to investigate the human global E/I ratio while reducing the interindividual variability that characterizes human studies of receptors.

Title: Real time monitoring of the human blood-brain barrier modeled on a microfluidic chip

Authors: *I. MATTHIESEN[1], T. E. WINKLER[1], D. VOULGARIS[1], P. NIKOLAKOPOULOU[2], A. HERLAND[1,2];
[1]KTH Royal Inst. of Technol., Stockholm, Sweden; [2]Karolinska Inst., Stockholm, Sweden

Abstract: The blood-brain barrier (BBB), known to protect the brain from foreign compounds and pathogens, likewise prevents passage of drugs and therapeutics. A better understanding of the BBB is thus needed for design of new brain-targeting drugs (Kesselheim, Nature Rev. Drug Disc., 2015). Currently, BBB studies are mainly performed in animal models with low human translation or *in vitro* in cell cultures which fail to recapitulate physiological BBB function and fluid flow. Moreover, dynamic BBB cellular mechanisms and interactions remain challenging to investigate, since most characterizations and assays are end-point-based. The blood flow that provides sheer force, is important for the characteristics of the endothelial cells of the BBB and studies with microfluidic chips have been shown to give higher BBB like functionality compared to static cultures. Problems such as chip material choices, sensor integration, and continuous monitoring still remain. The most commonly used chip material, polydimethylsiloxane (PDMS), is not suitable for drug studies since it is known to absorb small molecules (Toepke, Lab on a Chip., 2006). We aim to recreate the human BBB on a microfluidic chip, with integrated real time sensors for cell substrate impedance sensing (CSIS) during dynamic flow to monitor the barrier strength. To prevent drug absorption, we use the novel polymer off-stoichiometry thiol-ene-epoxy (OSTE+) (Carlborg, J. Polym. Sci., 2014). The chip, shown below, consists of two layers with channels, separated by a porous polycarbonate membrane, with integrated gold electrodes for the CSIS. The top channel in the device, representing the apical side of the BBB, is seeded with human induced pluripotent stem cell (hiPSC) derived microvascular brain endothelial cells (Stebbins, Methods 2016). Growing on top of the gold electrodes, the cells can be monitored for barrier alternations induced by cellular stress or drug exposure. The bottom channel of the device is seeded with NES-astrocytes (Lundin, Stem Cell Rep., 2018) to recapitulate astrocyte-endothelial interaction of the BBB.

Title: 3D bioprinting of human motor neurons in CELLINK LAMININK

Authors: I. REDWAN[1], J. BLELL[1], N. DUONG[1], E. GATENHOLM[1], K. LAHA[2], ***B. DUNGAR**[3];

Abstract: *In vitro* systems that more closely model the human nervous system are needed for physiological cell models, human disease models, and drug library screening. The use of iPSC-derived human neurons in a three-dimensional (3D) culture can provide a physiologically relevant system that reflects the microenvironment, cell-to-cell interactions, and biological processes that occur *in vivo*. Here we demonstrate 3D bioprinting of BrainXell's human motor neurons using a CELLINK BIO X printer. An appropriate bioink, CELLINK LAMININK, was identified that supported healthy cell growth of motor neurons when printed in small droplets of 15 µl with a cell concentration of 30 million cells/ml bioink. LDH assays over the first two weeks in culture show that cell health is stable. Live/dead staining and visualization by multiphoton microscopy confirmed strong viability and cell morphology similar to that of native motor neurons. Furthermore, motor neurons were co-cultured with astrocytes, demonstrating the potential to print multiple cell-types of relevant interest for modelling the nervous system.

Title: A novel tubular neural electrode with a dissolvable core for adaptable flexibility - biocompatibility aspects

Authors: *J. AGORELIUS[1,2], L. GÄLLENTOFT[1], L. M. PETTERSSON[1,2], C. J. ERIKSSON LINSMEIER[1], P. THORBERGSSON[1], J. SCHOUENBORG[1,2];

Abstract: A big challenge within the field of Brain-Machine-Interface (BMI) is to overcome the tissue reactions to the implanted electrodes. These tissue reactions include glial reactions and loss of neurons nearby which result in an unstable and deteriorating signal quality over time. Our previous studies have shown that microforces between the implanted electrodes and nearby tissue caused by micromotions play a key role in triggering these reactions. In this study, we characterize the tissue reactions to a new type of implantable electrode that is stiff enough to be implanted without support and which transforms into a highly flexible tubular construction after implantation. Methods and materials: Tube electrodes (60-80 um in outer diameter) comprised of a central gold lead (12 um in diameter) covered by dry glucose and insulated with a 4 um thick Parylene C coating, were manufactured using a combination of electrospinning and Parylene C vapor deposition. The distal end of the tubes was cut obliquely with a sharp knife. The entire tube was either coated with a thin layer of dry gelatin (n=8 rats) using dip coating or non-coated (n=8 rats). Control electrodes made of tungsten coated with Parylene C and gelatin with same dimensions as the tube electrodes were also implanted (n=8 rats). The electrodes were implanted in motor cortex in Sprague Dawley rats. The animals were sacrificed after 6 weeks, perfused with PFA and the relevant part of the brain was cut in 16 um thick sections with the tube electrodes resident inside the tissue using a cryostate. The control electrodes had to be explanted before tissue sections. The sections were stained with GFAP, CD68, NeuN and DAPI using immunocytochemistry. Results: The astrocytic and microglial reactions were significantly reduced in both the gelatin coated and non-gelatin coated electrodes as compared to the tungsten control electrodes. There were also significantly more neurons in the inner zone (0-20 um) surrounding the tube electrode as compared to the control electrodes. For all three groups,

neurons were present within 20 um from the tube electrodes and there was no void between tube and tissue.Conclusion: a novel tube electrode with promising biocompatibility has been developed.

Title: Multi dry electrode plate sensor for noninvasive assessment of the role of central nervous system in cardiac autonomic control in response to emotional and physical stressors

Authors: *S. SATO;
Akita Univ. Grad. Sch. of Med., Akita, Japan

Abstract: A novel multi-dry-electrode plate (MDEP) sensor system has been developed to monitor electrocardiogram (ECG) and heart rate (HR) noninvasively in freely behaving mice without the need for device/electrode implantation surgery and a recovery period of 1-3 weeks, which are prerequisite in case of telemetry studies. A mouse can walk around freely on the MDEP sensor, which is a rectangular plate with 15 gold-plated stripe pattern electrodes and detects ECG basically whenever ≥2 paws (footpads) come in contact with the electrodes. The MDEP sensor detected distinct QRS complexes although ECG was fragmented due to locomotion and insufficient perspiration on the footpads. Thereby, HR time courses at every 10 minutes for 1 h were successfully obtained after intraperitoneal injection of drugs. Indeed, isoproterenol and metoprolol injections caused typical responses as a significant increase (+151 ± 15 bpm) and decrease (−77 ± 6 bpm) in HR, respectively, compared to vehicle (saline injection) at 20-60 min postdose. In addition, signal averaging was effective to observe P waves, which were mostly invisible due to the large baseline noise, and to detect ECG intervals such as PR and QT. Meanwhile, no-drug and saline treated mice showed similar HR time courses after being lifted by the tail and released on the MDEP sensor; the HR decreased approximately 200 bpm during the first 30min, which was followed by a resting HR (~500 bpm) with a small variation. Interestingly, the HR at the start of measurement was higher in no-drug group (746 bpm) than that in drug-treated groups (710 bpm; $p < 0.038$), despite the mice were exposed to the stronger

handling stress by holding the scruff of the neck for drug injection. It seems that the stronger stress facilitated both sympathetic and parasympathetic nervous system activities and caused the HR suppression as seen in animals playing death feigning to cope with stressful situations. These results were obtained owing to the complete noninvasiveness of the MDEP-sensor and the simplicity of the measurement protocol, which provides an easy-to-use, high-throughput measurement of ECG/HR, and saves tremendous cost and time. Thus, although the ECG quality still needs to be improved, the MDEP-sensor system would provide an efficient tool to evaluate acute and chronic ECG/HR changes following pharmacological challenges, emotional/physical stressors, and genetic/pathological abnormalities, and also to understanding better the role of the central nervous system that governs the cardiac autonomic control in response to a variety of stressors including pharmacological intervention.

Title: Polymer modified carbon-fiber microelectrodes for the simultaneous detection of neurotransmitters

Authors: *A. G. ZESTOS, D. RAJU, P. WONNENBERG;
Chem. and Ctr. for Behavioral Neurosci., American Univ., Washington, DC

Abstract: Our laboratory has developed novel methods to detect neurotransmitters and their metabolites. Traditionally, carbon-fiber microelectrodes (CFMEs) have been utilized to detect dopamine, serotonin, and other important neurotransmitters. However, this method is limited due to a poor limit of detection of these sensors to detect physiologically relevant concentrations of these neurotransmitters. Carbon nanotube and polymer modified microelectrodes will be utilized to detect physiologically low levels of neurotransmitters that also resist surface fouling and have high temporal resolution to detect fast changes of neurotransmitters. Furthermore, novel electrode coatings and waveforms will also be utilized to detect several neurotransmitter metabolites such as 3,4-dihydroxy-benzeneacetaldehyde (DOPAL), 3-methoxytyramine (3-MT), homovanillic acid (HVA), and 3,4 dihydroxyphenylacetic acid (DOPAC). Currently, dopamine is thought to be an important neurotransmitter concerning several disease states such Parkinson’s

disease, drug abuse (amphetamine, cocaine, etc.), and even for gambling and sex-disorders. However, dopamine is metabolized on a subsecond timescale, and studies have pointed to the importance of neurotransmitter metabolites in these disease states apart from dopamine. Presently, there is no method to selectively measure these neurotransmitter metabolites of dopamine utilizing voltammetry. Through several waveform modifications and polymer electrode coatings, we develop a novel method for dopamine metabolite detection utilizing fast scan cyclic voltammetry, which will help differentiate the cyclic voltammograms of dopamine and dopamine metabolites through the shapes and positions of their respective cyclic voltammograms. This will help develop a method for detecting and differentiating several dopamine metabolites.

Title: Amygdalo-cortical networks revealed by high-field fmri during infrared neural stimulation of amygdalar subnuclei in the macaque monkey

Authors: *Y. RUI[1], A. XU[1,2], J. WANG[1,2], S. SHI[1], A. EDATHODATHIL[1], K. M. GOTHARD[3], A. W. ROE[1];
[1]Interdisciplinary Inst. of Neurosci. and Technology, Zhejiang Univ. Sch. of Med., Hangzhou, China; [2]Key Lab. of Biomed. Engin. of Ministry of Education, Col. of Biomed. Engin. and Instrument Science, Zhejiang Univ., Hangzhou, China; [3]Univ. Arizona, Col. Med., Tucson, AZ

Abstract: In nonhuman primates, the amygdala is central to different processing loops important for cognitive behavior: (1) Sensory loops that connect the amygdala to uni- or multisensory sensory cortical areas, (2) Evaluation loops that connect the amygdala to areas that process the intrinsic and learned value (or salience) of sensory stimuli, and (3) Action observation and action planning loops, important coordinatingthe actions of others with actions of self. Currently, we lack sufficient anatomical knowledge about these networks at whole brain scale, especially as they relate to the mm-scale subnuclei within the amygdala.
Here, we used a novel network mapping technique (INS-fMRI, Xu et al 2019 Science Advances,

DOI: 10.1126/sciadv.aau7046), which maps locations of hemodynamic response induced by infrared neural stimulation (INS) delivered via a fine 200 μm fiber optic to selected locations in the brain. By systematically stimulating different amygdalar targets and mapping in a Siemens 7T MRI, we were able to map associated networks with high precision and at whole brain scale. We established that the laser stimulation was reliable, consistent, and intensity dependent. Significant voxels at connected sites in multiple brain areas were detected using a general linear model.
Confirming activation of sensory loops, we found that stimulating some nuclear targets in the amygdala revealed activations in visual, tactile, auditory, gustatory, and olfactory cortical areas. Consistent with evaluative loops, other stimulation sites activated areas in the orbital, medial, and lateral prefrontal cortex, areas of subgenual and anterior cingulate, and areas of the anterior insula. Finally, amygdala stimulation also activated multiple components of the action observation network, including frontal premotor, motor, and parietal areas.
These patterns of activation were congruent with and further extended previous track-tracing studies. The power of this laser-fMRI method is evident, as whole brain networks associated with submillimeter stimulation sites are revealed at high spatial resolution *in vivo*. We are currently evaluating the degree of segregation and overlap between these multiple amygdalar networks.

Title: Human iPSC-derived neural 3D cultures provide a novel high-throughput screening platform for drug discovery

Authors: *C. B. ANDERSEN, A. FENTON, T. CHU, R. GORDON, F. ZANELLA, O. GUICHERIT, C. CARROMEU;
Stemonix, San Diego, CA

Abstract: Spheroid-based cellular platforms are considered to enable more complex, biologically relevant, and predictive assays for compound screening, safety evaluation and toxicity studies. Thus, here we deployed a high throughput spheroid co-culture of cortical glutamatergic and GABA-ergic neurons as well as astrocytes, more closely resembling the tissue constitution of native human brain tissue. Whole genome RNAseq profiling demonstrated neural tissue expression patterns with high content imaging validating neuronal and astrocytic cell

populations while showing highly reproducible spheroid size across 96 and 384-well plates. Functional neuronal circuitry was confirmed with MEA recordings and visualized under high-throughput conditions as robust spontaneous, synchronized calcium oscillations with reproducible baseline activity patterns across wells and plates.
In order to validate the capabilities of the platform for compound profiling and discovery, a library of 1622 FDA approved compounds was screened in single point at 10μM final concentration using Ca^{2+} oscillations as a functional phenotypic readout. The library included drugs covering a wide spectrum of targets such as oncology, cardiology, anti-inflammatory, immunology, neuropsychiatry and analgesia. DMSO was used as control and showed a standard deviation of 9% across all plates and a Z'of 0.73 was observed for the whole screen. Hits were identified as responses that were at least 3 standard deviations from DMSO control responses. As expected, the highest number of hits arrived from targets associated with neuronal signaling (serotonin, dopamine, GABA and adrenergic receptors). Interestingly, several compounds leading to higher cAMP accumulation lead to increase in peak count similar to what is noted using 4-AP, a known pro convulsant. Hit confirmation in 7 point dose response and exploration of pathways is currently ongoing. In conclusion, high throughput functional assays using the human iPSC-derived 3D neuronal spheroids platform deployed in this study demonstrated the ability to identify a wide range of hits spanning multiple target areas. Thus this model may serve as phenotypic and target-based platform for identifying new starting points for novel CNS discovery.

Title: Human 2D neural cells and 3D brain organoids resembling neuronal networks for high throughput assays

Authors: *J. FAN, A. WANG, T. ZOU, Q. LIU, F. REN, Y. YAN, Z. LU, J. XU;
Hopstem Biotech. Co. Ltd., Houston, TX

Abstract: Using RONA method reported in Xu et al., 2016, large amount of high purity and multipotent human neural stem cells and progenitor cells can be stably derived from human pluripotent stem cells including patient induced Pluripotent Stem Cells (iPSCs). Due to the lack

of structure/size consistency, stability and mature function of 3D brain organoids produced by most methods, it is hard to compare developmental and structure differences between organoids, not to mention carrying out high throughput screens. Based on the needs, we have developed a robust, stable and low-cost method to produce functional 3D brain organoids that resemble the prefrontal cortex. These cerebral organoids contain excitatory (70-80%) and inhibitory (20-30%), including subtypes of inhibitory neurons that are critical in the neural development, maturation and balanced functions, such as PV, nNOS, SST interneurons. These organoids have 6 layers of cortical markers, astrocyte (~50%) and oligodendrocytes at about 80 days *in vitro*. They have synchronized spontaneous firings starting 20 days *in vitro* and can be maintained for years and up to 6mm diameters. Smaller organoids can also be generated with small variations between organoids for high throughput assays including viability, MEA, high content imaging with clearing and immunohistochemistry etc. Microglia invaded 3D brain organoids are also generated for studies involving neuroinflammation. This novel method will provide great aid to the mechanism study and drug discovery using *in vitro* hiPSC models for neurological disorders, including autism, schizophrenia, epilepsy, and even AD or PD.

Title: *In vivo* monitoring of cholinergic neurotransmission with a microelectrochemical choline biosensor

Authors: S. DOYLE[1], M. M. DORAN[1], K. L. BAKER[1], C. CUNNINGHAM[2], *J. P. LOWRY[1]; [1]Chem., Maynooth Univ., Maynooth, Ireland; [2]Sch. of Biochem. and Immunol., Trinity Col. Dublin, Dublin, Ireland

Abstract: Acetylcholine acts as a key neuromodulator within the central nervous system, capable of altering neuronal excitability and coordinating neuronal firing patterns. Conversely, cholinergic neurotransmission plays a crucial role in a variety of cognitive functions, including the encoding of new memories. Cholinergic neuronal loss, and the resulting drop in cholinergic neurotransmission (collectively referred to as hypocholinergia), is closely associated with cognitive dysfunction in a number of chronic neurodegenerative disorders including Alzheimer's

disease. However, conventional analytical techniques for monitoring *in vivo* cholinergic neurotransmission lack the spatiotemporal resolution required to accurately detect endogenous cholinergic dynamics. Here we validate in mice a Pt-based electrochemical biosensor for selective monitoring of choline, a verified marker of cholinergic transmission. Enzymatic choline biosensors (modified with choline oxidase) were sterotaxically implanted in the medial prefrontal cortex (mPFC) and contralateral dorsal hippocampus (dHPC) of female C57Bl6J mice. Real-time choline current recordings over a period of several days revealed circadian fluctuations in both regions, with extracellular choline levels highest during light phases. Administration of pharmacological compounds known to induce central acetylcholine release, scopolamine (1mg/kg) and amphetamine (4mg/kg), evoked a robust increase in choline current. In contrast, peripheral injection of the reversible acetylcholinesterase inhibitor, donepezil (3mg/kg), produced a marked decrease in recorded choline current. The induction of systemic inflammation with bacterial lipopolysaccharide (LPS; 500µg/kg) produced characteristic 'sickness behaviour' in mice and evoked a tonic rise in central choline levels in both the mPFC and dHPC. Furthermore, the induction of hypocholinergia in selected mice was preformed via intracerebroventricular injections of murine-p75-saporin immunotoxin (1.2µg). Evoked cholinergic neurotransmission was dramatically attenuated in lesioned (hypocholinergic) mice. Collectively, the data suggests that microelectrochemical choline biosensors may serve as a powerful tool for monitoring cholinergic neurotransmission across a number of behavioural and disease states.

Title: Skin-brain biomarkers

Authors: *R. A. NORMAN[1], M. JIMENEZ-CAPDEVILLE[2], I. RODRÍGUEZ-LEYVA[3]; [1]Neuro-Dermatology, Robert A. Norman, D.O., P.A., Ft. Lauderdale, FL; [2]Ctr. de Investigación en Ciencias de la Salud y Biomedicina, Univ. Autónoma de San Luis Potosí, San Luis Potosí, Mexico; [3]Dept. de Neurología, Hosp. "Ignacio Morones Prieto", San Luis Potosí, Mexico

Abstract: Skin-Brain Biomarkers have been underutilized when identifying neurological diseases. Skin and oral mucosa have been used as biomarkers to screen for proteinopathies in cognitively impaired patients. Our study using p-Tau quantification by flow cytometry supports using skin-brain biomarkers as excellent neurologic disease detection tools. (Frontiers in Neurology 2017)
The purpose of our study was to determine whether there is a differential Tau expression in oral mucosa cells according to cognitive impairment. Eighty-one subjects were enrolled in the study and classified per Mini-Mental State Examination test score into control, mild cognitive impairment (MCI), and severe cognitive impairment (SCI) groups. More positivity was present in subjects with cognitive impairment than in control subjects, both in the nucleus and cytoplasm, in a speckle pattern. These findings demonstrate the higher presence of p-Tau and Tau transcript in the oral mucosa of cognitively impaired subjects when compared with healthy subjects. The feasibility of p-Tau quantification by flow cytometry supports the prospective analysis of oral mucosa as a support tool for screening of proteinopathies in cognitively impaired patients.
Although proteinopathies have previously been assumed to be exclusive to the central nervous system (CNS), several recent studies demonstrate their presence in peripheral tissue. These findings strongly suggest that proteinopathies are systemic diseases whose fingerprints could be tracked in an accessible peripheral tissue.

Title: Non-invasive peripheral nerve interfacing platform for reliable and quantitative tracking of nerve function

Authors: A. HARRISON, E. BROWN, A. M. MELEHAN, A. J. PREYER, M. SONNTAG, A. HECKERLING, ***I. P. CLEMENTS**;
BioCircuit Technologies, Atlanta, GA

Abstract: Improved capabilities for sensing and manipulation of nerve and muscle activity would advance clinical diagnostics, including the ability to precisely quantify and reliably track biomarkers of disease. Here we describe a non-invasive, automated platform for targeted monitoring and manipulation of human peripheral nerves and muscles. Flexible arrays of transcutaneous electrodes are coupled to a custom, miniaturized recording platform, providing 32 or more channels of simultaneous stimulation and recording. Array-based stimulation enables on-target measurement and stimulation selectivity accounting for patient-to-patient anatomical differences. Array-based recordings enable 2D mapping of neural propagation and practical, longitudinal tracking of nerve function between sessions. Ultimately, this platform will facilitate advancements in both neuromuscular research and medical device development, with applications in electrodiagnostics, practical tracking of disease-specific biomarkers, neural prosthetics, and bioelectronic medicine.

Title: Sensitivity of the MRI water proton resonance to myelin

Authors: *S. FOXLEY[1], G. WILDENBERG[2], V. SAMPATHKUMAR[2], P. BRUGAROLAS[4], B. J. POPKO[3], N. B. KASTHURI[2];
[1]Radiology, Univ. of Chicago, University of Chicago, IL; [2]Neurobio., [3]Neurol., Univ. of Chicago, Chicago, IL; [4]Radiology, Harvard Med. Sch., Boston, MA

Abstract: Dysmyelinating diseases are characterized by abnormal myelin formation and function; Shiverer mice are a common model used to demonstrate this devastating condition. Microstructural abnormalities in myelin such as this have been demonstrated to produce measurable effects on the MRI signal. How myelin effects the MRI signal has been described using theoretical models that predict its frequency dependence, however empirical evidence supporting spectroscopic results produced with these models have not been shown. This work describes using a high-resolution 3D-multi-gradient echo (3D-MGE) pulse sequence to measure changes in the water spectrum in both postmortem control (n=5) and dysmyelinated (homozygous shiverer, n=4) mouse brain. All brains were perfusion fixed with gluteraldehyde. Prior to imaging, samples were submerged in fluorinert to susceptibility match the tissue with its surroundings and preserve the tissue over long scan durations. All MRI data were acquired using a 9.4T, small bore MRI scanner (Bruker Biospin). 3D-MGE data were acquired with 0.1mm isotropic spatial resolution over 192 echoes with 1.9ms echo spacing. These data were Fourier transformed along the time dimension to produce voxel-wise water spectra with 2.7Hz spectral resolution. High-angular resolution DTI data were also acquired to estimate the principle diffusion direction of white matter. T2* weighted images were made by identifying the voxel-wise peak signal magnitude from the spectra produced from the 3D-MGE dataset. These high fidelity images demonstrate that grey/white matter contrast is significantly mitigated in the shiverer mouse brain relative to that of the control ($p<0.1$, one-way Student's t-test). Voxel-wise spectral shape was quantified by measuring the asymmetry of the resonance about the peak. This is done by integrating the negative frequency half of the spectrum, subtracting that from the integral of the positive frequency half, and normalizing by the total area under the curve. Spectra from white matter in control brains were shown to produce a larger average asymmetry that those from the shiverer mice. Moreover, the asymmetry in control brain was shown to be dependent on the orientation of the underlying axons relative to the main magnetic field (B0). This is consistent with modeling and suggests that the water spectrum shape is sensitive to both myelin concentration as well as its orientation relative to B0 (Xu et al., Magn. Reson. Med.

2018). These results suggest that the water spectra measured with 3D-MGE are sensitive to the presence of myelin and could serve as a potential MRI biomarker of dysmyelinating disease.

Title: An MR tractography-based study of the impaired white matter integrity along medial longitudinal fasciculus in MS patients with internuclear ophthalmoplegia

Authors: *A. GHAYOOR[1], X. WANG[1], K. KANHAI[2], O. R. THON[3], J. HESTERMAN[1], A. VERMA[4], G. J. GROENEVELD[2], K. C. EVANS[5];
[1]Invicro, LLC, Boston, MA; [2]Ctr. for Human Drug Res., Leiden, Netherlands; [3]Drexel Neurosciences Inst., Drexel Univ. Col. of Med., Philadelphia, PA; [4]Precision for Med., Boston, MA; [5]Biogen, Cambridge, MA

Abstract: BACKGROUND
The medial longitudinal fasciculus (MLF) connects the paramedian pontine reticular formation and abducens nerve to the contralateral oculomotor nerve, enabling horizontal saccades. MLF lesions, that are common in multiple sclerosis (MS), might lead to internuclear ophthalmoplegia (INO), which causes slowed or absent adduction of the ipsilateral eye. Accurate characterization of MLF tissue integrity via diffusion tensor imaging (DTI) holds promise to inform research efforts in MS but has proven to be challenging.
The study objective is twofold: 1) Develop an imaging biomarker of axonal and myelin integrity of the MLF in MS patients with INO using DTI and brain tractography. 2) Test for correlation between DTI findings and INO severity.
METHODS
Twenty-three patients (11 Female/12 Male with a mean age of 49±10.6 years) with MS and unilateral or bilateral INO were enrolled. Versional dysconjugacy index (VDI) was measured by oculography (using Eyelink1000) to grade INO severity.
T1W, T2W/PD, DTI (b=750, 24 directions) were acquired on a 3T GE MR750. Analysis was performed using a DTI tractography pipeline in Nipype. DTI was preprocessed, susceptibility artifacts corrected, then subjected to a two-tensor tractography algorithm to identify the MLF. MS lesions within and adjacent to the MLF were manually segmented based on abnormal

hyperintensity on T2W and PD images.
DTI scalars (fractional anisotropy (FA), mean, and radial diffusivity (MD, RD)) were estimated for entire MLF tract, and lesion/non-lesion MLF segments, and then two-sample t test were performed between the affected (N=36) vs. unaffected (N=10) eyes. Pearson's correlation of DTI scalars with severity (VDI) was performed within the INO group.

RESULTS

Measures of MS lesion length/load were similar between INO and non INO eyes. However, INO-affected eyes showed significantly higher MD and RD values on the ipsilateral MLF compared to the un-affected eyes. FA values were lower on the ipsilateral MLF of INO-affected eyes, but only significantly lower when considering the whole (bilateral) MLF. Though, none of the DTI scalars were significantly correlated with VDI, after controlling for age, and MS duration.

CONCLUSIONS

The DTI profile within the MLF of INO-affected eyes was consistent with diminished white matter integrity, which we speculate was due to demyelination and tract degeneration associated with MS. Although we failed to detect a significant correlation between DTI scalars and VDI, this novel approach to MLF tractography could allow for better characterization of the MLF integrity than previously published DTI reports of INO in MS that had relied upon registration-based approaches.

Title: Magnetic resonance imaging corresponds to worsening behavior and gross demyelination in MOG_{35-55} induced experimental autoimmune encephalomyelitis

Authors: C. L. PATEL[1], M. D. MEADOWCROFT[2], *P. J. MCLAUGHLIN[3];
[1]Neural & Behavioral Sci., The Pennsylvania State Univ. Col. of Med., Hershey, PA; [2]Neurosurg., The Pennsylvania State Univ. - Col. of Med., Hershey, PA; [3]Neural & Behavioral Sci., Penn State Univ. Coll Med., HERSHEY, PA

Abstract: Experimental autoimmune encephalomyelitis (EAE) is a well-established model for multiple sclerosis (MS) that is characterized by spinal cord pathology progressing in a caudal to

cranial direction. Currently, demyelinated lesions are visualized in mice utilizing Luxol fast blue staining. However, in humans, magnetic resonance imaging (MRI) is routinely used to monitor patient progression. Recently, diffusion MRI has come to the forefront because it utilizes a different approach to the traditional anatomical imaging by visualizing the movement of water molecules. In this study, we have combined anatomical and diffusion MRI to ascertain the feasibility and accuracy of using fMRI studies to characterize EAE pathology. C57BL/6J mice were immunized with MOG_{35-55} and received daily intraperitoneal injections of 10 mg/kg Opioid Growth Factor (OGF), ([Met^5-enkephalin) or saline. Daily composite behavior scores were recorded over a 28-day period based on tail tone, gait, righting reflex and limb strength. EAE mice receiving IP saline treatments had composite behavior scores that differed significantly from normal mice ($p<0.05$). OGF mice demonstrated a reduction ($p<0.05$) in clinical severity from EAE-saline mice at peak disease, day 18. *In vivo* and *ex vivo* MRIs were performed at baseline, day 7, day 18, and day 28 using a 7T magnet system. Following humane euthanasia, spinal cords were removed, sectioned and stained with Luxol fast blue. Preliminary diffusion data from day 28 showed an overall decrease in functional anisotropy (FA) in both saline and OGF mice when compared to baseline with caudal regions more affected than cranial regions. Diffusion images on day 28, showed an increase in overall mean diffusion in both OGF and saline treated mice when compared to baseline. Changes in the MRIs were restricted to the caudal aspects of the spinal cord. In conclusion, these studies suggest that changes in both functional anisotropy and mean diffusion in EAE mice can be identified using MRI. In particular, the increased mean diffusion suggests an increased rate of water molecule diffusion through the tissue that could result from either radial demyelination or longitudinal white matter tract damage. The reduction in functional anisotropy suggests a potential reorganization of the spinal cord architecture, and together with staining or immunohistochemistry will facilitate more accurate assessment of EAE progression.

Title: Improved experimental autoimmune encephalomyelitis mice recovery by intravenous injection of conditioned culture medium of induced mesenchymal stem/stromal cells derived from human iPSCs

Authors: *R. DENG[1,2,3], A. LAW[2], Q. DU[1], K. R. BOHELER[3], G.-F. CHAN[2], J. SHEN[1]; [1]Sch. of Chinese Med., [2]Dept. of Paediatrics and Adolescent Med., [3]Stem Cell & Regenerative Med. Consortium, The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Multiple sclerosis (MS) is a progressive autoimmune disease of the CNS. Conditioned culture medium of mesenchymal stem/stromal cells (MSCs-CM) was reported to be a potential therapeutics for MS. MSCs are multipotent cells, which not only can differentiate into various cell types but also have modulation functions on immune response. However, *ex vivo* expansion of human primary MSCs is limited due to senescence. Therefore we generated induced MSC-like cells (iMSCs) from human iPSCs. We investigated these iMSCs on surface specific markers, differentiation related gene transcriptional levels and cytokine release levels *in vitro*, and immunomodulating effects *in vivo* on an experimental autoimmune encephalomyelitis (EAE) mouse model. We found iMSCs were the same as primary human MSCs by flow cytometry analysis, which are $CD44^+$, $CD90^+$, $CD73^+$ and $CD105^+$ and $CD11b^-$, $CD19^-$, CD45-, $CD14^-$, $HLA\text{-}DR^-$. The RNAseq results also showed these iMSCs were closely similar to primary human MSCs. Furthermore, we compared the protein profiles of secreted cytokines and cell lysates between primary MSCs and iMSCs using Human XL cytokine array. Cells from the same donor were used to reduce variants caused by individual differences. Results showed that secretion profiles were similar between the primary MSCs and iMSCs. At last, we tested the immunomodulating effect of iMSCs-CM and MSCs-CM by intravenous injecting the conditioned medium into EAE mice at the peak time of disease progress (17, 19 and 21 dpi). We found that both iMSCs-CM and MSC-CM improved EAE recovery compared to EAE control mice while the blank culture medium induced EAE mice death (n=5-6). CM treated EAE mice had significantly reduced demyelination and inflammatory infiltrations. The clinical score was below 0.5 after treatments compared to the EAE control maintained at around 1.5 after 30 dpi. In conclusion, we propose these iMSCs can be considered as *ex vivo* cultured MSCs which have potential to be used for therapeutic purposes for MS.

Title: Advancing Alzheimer's disease and related dementias research via a multiple-pronged human biospecimen collection initiative

Authors: *M. W. VONDRAN[1], S. SHAD[1], Z. MOURELATOS[2], G. KOPEN[1], T. J. BELL[1]; [1]Natl. Dis. Res. Interchange, Philadelphia, PA; [2]Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstract: Human biospecimens are essential to advance our understanding of pathogenesis and treatment of neurological disease, including Alzheimer's disease and related dementias (AD/ADRD). AD/ADRD are multi-factorial, genetically complex and heterogeneous diseases that progress over approximately two to three decades of life. Access to a diverse range of human biospecimens and donors is essential to support the escalating nature of scientific questions and experimental techniques that investigators are pursuing. More comprehensive AD/ADRD human tissue resources suitable for a wide range of experimental analyses are needed. To address this gap, here we report our results on providing human biospecimens for AD/ADRD research. The National Disease Research Interchange (NDRI) is a non-profit organization that specializes in using a project-specific approach to provide scientists with experimental-specific human biospecimens for their studies. Using this approach, NDRI is developing a new, NIH-funded resource, AD/ADRD Human Biospecimen Resource (ADBR). The ADBR is a comprehensive human biospecimen resource that provides biospecimens from two distinct AD/ADRD cohorts, patients and post mortem donors. ADBR's methods to provide human biospecimens for rigorous experimental methods such as RNAseq is presented along with the supporting neuropathological case report data. The advantages of the ADBR's multi-pronged approach are 3-fold. 1) The post mortem donations permit the collection of AD/ADRD and control (non-diseased) human biospecimens with a neuropathological review and case report to confirm the presence or absence of AD/ADRD pathology. 2) The living patient collection enables acquisition of biospecimens that could capture unique time points, such as different stages of the disease or the patients' responses to given treatment protocols. 3) Standardization of donor eligibility and biospecimen collections will yield more accurate and reproducible data. Collectively, ADBR will provide the AD/ADRD research community an unmatched resource to advance basic research evaluating the etiology of AD/ADRD, as well as translational research assessing effective diagnostics and therapies.

Title: Structure based design and molecular docking studies for phosphorylated tau inhibitors in Alzheimer's disease

Authors: *J. PRADEEPKIRAN, P. HEMACHANDRA REDDY;
Intrnl. Med., Texas Tech. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The purpose of our study is to identify phosphorylated tau (p-tau) inhibitors In Alzheimer's disease (AD). P-tau has recently received great interest and alternative potential therapeutic target in AD. The continuous failure of Aβ-targeted therapeutics recommends an alternative drug target to treat AD. There is an increasing evidence of tau, which plays a central role in AD pathophysiology, including neurofibrillary tangles, paired helical filaments formation in AD neurons. Abnormal activation, imbalanced phosphatases/kinases, is initiated by p-tau aggregation in AD neurons. In the present study, we performed computational pharmacophore models, molecular docking, and simulation studies for p-tau in order to identify kinase regulated hyperphosphorylated sites in AD. We found multiple serine/threonine sites that altered the R1/R2 repeats flanking sequences in the tau protein, affecting the microtubule stability of tau. The proposed ligand molecules exhibited the p-O ester scaffolds with inhibitory and/or blocking actions against serine/threonine residues of p-tau. Molecular docking studies showed high docking scores and optimal protein-ligand interactions of p-tau. Our docking results revealed that five ligands binds at major tau phosphorylated kinases like glycogen synthase kinase-3beta (GSK-3β), cyclin-dependent kinase-5 (CDK5) positions. These ligands showed the best pharmacokinetic properties, including good absorption, distribution, metabolism, and excretion (ADME) and non-toxic with admetSAR tests. The p-tau pharmacophore based drug discovery models provide the best comprehensive and rapid drug interventions in AD, and tauopathies. We are expected to be the prospective future therapeutic approach in AD.

Title: Apelin reduces amyloid β generation by attenuating endoplasmic reticulum stress-induced BACE1 expression

Authors: *Y. WU[1], X. WANG[2], H. LU[1], Q. ZHAO[1], Y. ZAI[1];
[1]Jining Med. Univ., Jining, China; [2]Jining Med. Univ., Shandong, China

Abstract: Neuritic plaques are the major pathological hallmark of Alzheimer's disease (AD). Amyloid β (Aβ) is the major component of neuritic plaques, and BACE1, a β-secretase, mainly contributes to Aβ generation. Increased Aβ plays a major role in the pathogenesis of AD. Growing evidence showed that ER stress constantly exists in AD brains, which promotes Aβ generation and BACE1 upregulation. Our recent work showed that apelin protects neurons from apoptosis by attenuating ER stress in ischemic stroke. However, the role of apelin in Aβ generation remains elusive. Here we showed that constant ER stress exists in AD models, whereas apelin attenuates ER stress. Moreover, apelin markedly reduces Aβ generation and BACE1 expression. Our work indicates that apelin might inhibit Aβ generation by attenuating ER stress-induced BACE1 expression.

Title: Cerebrospinal fluid ecto-GPR37 in Parkinson's disease

Authors: *F. CIRUELA[1], X. MORATÓ[1], P. GARCIA-ESPARCIA[1], V. FERNÁNDEZ-DUEÑAS[1], I. FERRER[1], P. SVENNINGSSON[2];
[1]IDIBELL-Universitat de Barcelona, Barcelona, Spain; [2]Dept. of Clin. Neuroscience; Karolinska Institutet, Stockholm, Sweden

Abstract: In Parkinson disease (PD) management, reliable diagnostic and prognostic biomarkers are needed. GPR37, also known as parkin associated endothelin-like (Pael) receptor, is an orphan G protein-coupled receptor, which suffers a defective parking ubiquitination in autosomal recessive PD that promotes its endoplasmic reticulum aggregation and stress, neurotoxicity and neuronal death. In addition, aggregated GPR37 species have been identified in Lewy bodies (LBs) from sporadic PD or LB dementia postmortem brains. Importantly, this orphan receptor is

a partner of dopamine D_2 and adenosine A_{2A} receptors (D_2R and $A_{2A}R$, respectively). Accordingly, GPR37 has emerged as an important modulator of dopaminergic and adenosinergic transmission in the striatum. Here, we revealed the presence of the N-terminal domain of GPR37 (ecto-GPR37) in human cerebrospinal fluid (CSF). Thus, we engineered a nanoluciferase-based ELISA to evaluate ecto-GPR37 in CSF from healthy and PD subjects. First, by means of immunoblot and mRNA determinations we confirmed an increased GPR37 expression in postmortem substantia nigra from PD subjects. Next, we demonstrated the presence of ecto-GPR37 in CSF from wild-type, but not from $GPR37^{-/-}$, mice, thus validating our homemade ELISA system to monitor ecto-GPR37 expression in biofluids. Subsequently, we assessed the relative abundance of ecto-GPR37 in CSF from healthy controls (n=42) and PD (n=42) subjects. Interestingly, we found that ecto-GPR37 was significantly increased ($P = 0.0002$) in the CSF from PD patients, with no differences between male and female subjects. Importantly, CSF immunoprecipitation mass spectrometry results supported the analytical validity of our ELISA to measure ecto-GPR37 in human CSF. Overall, these results open exciting perspectives and encourage further systemically studies to confirm the clinical validity and utility of ecto-GPR37 as a potential PD diagnostic/prognostic biomarker.

Title: Identification of dopamine and 5-S-cysteinyl-dopamine as Parkinson's disease biomarkers in complex simulated body fluids and their detection by surface enhanced Raman spectroscopy

Authors: *I. BADILLO-RAMÍREZ[1], J. M. SANIGER[1], A. MÜHLIG[2,3], D. CIALLA-MAY[2,3], J. POPP[2,3];
[1]Inst. de Ciencias Aplicadas y Tecnología, Univ. Nacional Autónoma de México, Mexico City, Mexico; [2]Spectroscopy/Imaging, Leibniz Inst. of Photonic Technol., Jena, Germany; [3]Inst. of Physical Chem. and Abbe Ctr. of Photonics, Friedrich-Schiller-University Jena, Jena, Germany

Abstract: Parkinson´s disease (PD) is the second most common neurodegenerative disorder. Researching in PD biomarkers may open the access to accurate diagnosis of the disease.

Dopamine (DA) metabolism, through the formation of oxidized metabolites, has been related to contribute in the physiology of PD. 5-S-Cysteinyl-Dopamine (5SCDA), a thio-catecholamine product in the dopamine oxidative pathway, induces cell vulnerability and neural death. 5SCDA has been detected in increased concentration in brain samples and fluids of PD patients, indicating that 5SCDA might be a suitable biomarker for PD. Accurate biomarker detection with high sensitivity is highly desirable in routine diagnosis. Surface Enhanced Raman Spectroscopy (SERS), combining the advantages of Raman spectroscopy with plasmonic enhancement of the vibrational signal, allows for the detection of molecules at very low concentration with high sensitivity in a very short time frame, in comparison with standard chromatographic methods. The aim of this study was to show the feasibility of SERS for the detection of DA and 5SCDA in simulated complex body fluids. For this purpose, colloids of silver nanoparticles (AgNPs) were mixed with DA or 5SCDA, at different concentrations, in pure water and in two prepared simulated body fluids, cerebrospinal fluid (CSF) and simulated urine (SU). SERS measurements were performed in cuvette through a Raman microscope with an excitation wavelength of 488 nm. In this investigation we show that SERS is suited very well for the reliable detection of DA and 5SCDA in pure water and simulated CSF. However, only 5SCDA could be detected in SU. The limits of detection (LOD) for DA in pure water and CSF were $1x10^{-6}$M and $1x10^{-7}$M, respectively, while the LOD for 5SCDA in water, CSF and SU were at $1x10^{-7}$M, $5x10^{-11}$M and $1x10^{-6}$M, respectively. 5SCDA was detected in lower concentration than DA. This variation in the detection sensitivity, was attributed to the different Raman cross sections of the two analytes, the molecular orientation relative to the surface of the AgNPs and the type of ions and their concentration in the different simulated fluids. It was found that the composition of CSF improves the SERS detection sensitivity of both analytes DA and 5SCDA. In conclusion, in this work we show that 5SCDA has a lower LOD, in comparison to DA. In simulated complex fluids the SERS sensitivity becomes higher than in pure water. Therefore, as proposed by other authors [Goldstein et al. 2016], 5SCDA might be a better biomarker for PD than DA. Furthermore, it was shown that SERS as a simple, fast and accurate strategy might be a powerful tool for the detection of 5SCDA and other physiological biomarker metabolites.

Title: Development of a novel positron emission tomographyradioligand for neuroimaging in preclinical Parkinson's disease

Authors: *S. SUBBURAJU[1], A. W. SROMEK[2], P. SEEMAN[3], J. L. NEUMEYER[2]; [2]Medicinal Chem. Program,Division of Basic Neurosci., [1]McLean Hospital, Harvard Med. Sch., Belmont, MA; [3]Departments of Pharmacol. and Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract: The dopaminergic system, especially the D_2 receptor, is affected in various neurological disorders, including Parkinson's disease (PD). Here, the loss of dopaminergic neurons causes a shift of D_2 receptors into the high affinity state (D_2^{high}), the functional or active form of the receptor to which dopamine (DA) binds. Medications for the treatment motor dysfunction, a hallmark symptom of PD, specifically target the D_2^{high} receptor. Unfortunately, PD is difficult to diagnose in early, preclinical stages. Thus, the availability of a selective D_2^{high} agonist as a diagnostic tool could enable early diagnosis and ensure timely onset of treatment. Recently, we described the synthesis and pharmacological evaluation of a series of fluorinated aporphines and identified several high affinity D_2^{high} ligands, which have potential for development as a ^{18}F PET radiotracer. We evaluated two lead radioligands, [^{3}H] MCL-524 and [^{3}H] MCL-536, in saturation and competition binding studies to human D_{2long}. In a competition binding assay between [^{3}H] MCL-536 and the agonist R-(-)-N-n-propylnorapomorphine (NPA), NPA had a *K*i binding affinity of 0.16 nM. When [3H] MCL-524 was used, NPA was found to have a Ki value of 0.9 nM. Co-incubation with guanylylimidodiphosphate abolished binding to D_2^{high}. Next, we evaluated radioligands [^{3}H] MCL-524 and [^{3}H] MCL-536 for biodistribution in brain and peripheral tissues in rats. Peak radioactivity levels were detected in the striatum vs. cerebellum between 15-30 minutes post-administration. In the periphery, binding was highest in liver and kidney, and elimination from the brain and peripheral organs evident at 60 min. *Ex vivo* brain autoradiography with [^{3}H] MCL-524 or [^{3}H] MCL-536 in controls and amphetamine-sensitized rats (a model for elevated D_2^{high}) showed elevated binding in regions of interest (striatum, substantia nigra pars compacta, nucleus accumbens and olfactory tubercules) vs. controls. Replication studies in rhesus monkey confirmed and extended earlier results from cynomolgus monkeys that ^{18}F MCL-524 selectively label the striatum, with a peak ratio of striatum vs. other brain tissues at 30-45 min post administration. Metabolic stability in liver microsome was reasonable for both ligands. In summary, [^{3}H] MCL-524 and [^{3}H] MCL-536 show high selectivity and affinity for the D_2^{high} receptor, ability to cross the blood-brain barrier, fast on and off kinetics and low non-specific binding to tissues, indicating they are suitable D2 receptor ligands for development as an ^{18}F PET tracer. The first proof-of-concept studies in human volunteers are planned in the near future.

Title: Assessment of disease progression in early onset Parkinson's disease (EOPD) patients using transcranial sonography (TCS) and hemisphere specific neuropsychological testing

Authors: *S. RAVI[1], **B. MULLEN**[2], V. SHIVKUMAR[6], D. WAGNER[3], D. DANG[3], M. P. SUBRAMANIAN[4], T. GILMOUR[7], J.-L. WANG[3], P. ESLINGER[3], K. VENKITESWARAN[5], T. SUBRAMANIAN[4];

Abstract: Early onset Parkinson's disease (EOPD) is defined by the onset of motor symptoms between the ages of 40 to 60. EOPD detection and monitoring for disease progression is critical since these patients are at an increased risk for developing motor and non-motor complications. Neuropsychological testing has revealed subclinical, cognitive deficits in PD that can lead to mild cognitive impairment (PD-MCI) and possibly Parkinson's disease associated dementia (PDD). In our previous research, data indicated the MRT as a valid neuropsychological test to distinguish visuospatial deficits between left and right-onset EOPD (MLPD and FLPD n = 19, MRPD and FRPD n = 24; p = 0.040). Within the same cohort, left-onset EOPD patients scored significantly better (p = 0.021) on the Total Repetitions of the Delis Kaplan Executive Function Verbal Fluency (DKEFS-VF) Test compared to right-onset EOPD patients. To compare these subclinical differences to clinical assessments of PD, we correlated MRT and DKEFS-VF Total Repetition scores to the UPDRS (Parts I-III Total Score). The findings were weak, negative correlations in both neuropsychological tests (MRT, r = -0.210 ; DKEFS VF Total Repetitions, r = -0.121). Transcranial Sonogrpahy (TCS) has been indicated to monitor disease progression in PD, which precedes the onset of motor symptoms between stage I and stage II based on Substantia Nigra Hyperechogeneceity (SN+). SN+ has been shown to remain stable with an area >0.2cm^2 in advanced PD patients (≥H&Y stage II). 44 EOPD patients in Hoehn and Yahr (H&Y) Stage I as determined by the UPDRS were followed every 6 months. A video z-stack of each SN was obtained and largest area of SN+ was quantitated on de-identified clips by a blinded

technologist. SN+ >0.2cm^2 were classified as significant on each side. At V1, SN+ that met >0.2cm^2 was found exclusively on the contralateral SN of all 44 subjects. Mean contralateral and ipsilateral SN+ was 0.268 ± 0.0582 cm^2 and 0.146 ± 0.0493 cm^2, respectively. By 540 days after V1, 67.57% of the patients (n=37) displayed SN+ >0.2cm^2 ipsilaterally and 13.51% of the patients (n=37) were classified as Stage II. Of the 37 individuals who have attended follow-up visits through 720 days from V01, we report bilateral SN+ in all subjects, whereas only 17 of the 37 subjects had clinically progressed to stage II via H&Y Scoring. Our current study aims to associate SN+ with performance on the MRT and DKEFS-VF Total Repetitions measurement. We plan to associate the MRT, DKEFS-VF Total Repetitions, and SN+ to observed PD subtypes such as akinetic-rigid, tremor dominant and equivalent. These subtypes have been shown to have a varied disease progression of motor and non-motor symptoms.

Title: Longitudinal magnetic resonance imaging of an alpha-synuclein pathology mouse model

Authors: *W. T. CHU[1], J. C. DESIMONE[2], C. J. RIFFE[3], H. LIU[4], P. CHAKRABARTY[5], B. I. GIASSON[5], D. E. VAILLANCOURT[2];
[1]Biomed. Engin., Univ. of Florida, Gaineville, FL; [2]Applied Physiol. and Kinesiology, [4]Biomed. Engin., [5]Neurosci., [3]Univ. of Florida, Gainesville, FL

Abstract: Background and Purpose: Aggregation of alpha-synuclein (aSyn) is the hallmark pathology for multiple neurodegenerative diseases such as Parkinson's disease (PD) and dementia with Lewy bodies (DLB). The objective of this study was to test how MRI-based biomarkers relate to aSyn pathology progression in a mouse model. **Methods:** 37 human A53T

transgenic M83$^{+/-}$ mice were given bilateral intra-muscular (IM) injections of either 10μg of aSyn fibrils or phosphate buffered saline (PBS). Multi-shell diffusion MRI scans were collected for each mouse at 4 time points: pre-injection, 1 month, 2 months, and 3 months post-injection. The Neurite Orientation Dispersion and Density Imaging (NODDI) model was applied to the diffusion MRI scans to estimate bulk neurite morphology characteristics such as neurite density (NDI), orientation dispersion (ODI), and isotropic volume fraction (ISO). Maps of diffusion metrics such as fractional anisotropy (FA) and mean diffusivity (MD) were also calculated. Average values of each metric were calculated within anatomical regions of interest (i.e. cerebellum, vermis, medulla, posterior pons, thalamus, and striatum). Between-group t-tests (aSyn-injected vs. PBS-injected) were performed with a p-value threshold of 0.05. **Results:** It was confirmed that, pre-injection, no significant between-group differences existed for any of the metrics in all the examined regions. At 1 month post-injection aSyn-injected mice had reduced FA in the cerebellum, vermis, medulla, and posterior pons, reduced MD in the cerebellum, medulla, posterior pons, and striatum, increased NDI in the posterior pons, thalamus, and striatum, and increased ODI in the cerebellum, vermis, medulla, posterior pons, thalamus, and striatum compared to controls. No significant differences in ISO were found. At 2 months post-injection aSyn-injected mice had increased ODI in the thalamus compared to controls, however, no significant differences were found for the other metrics in the examined regions. At 3 months post-injection the aSyn-injected group had reduced FA in the vermis, reduced MD in the medulla, and reduced ISO in the medulla, however, no significant differences were found for the other metrics in the examined regions. **Conclusion:** Our results show that multi-shell diffusion MRI combined with the NODDI diffusion model can resolve subtle longitudinal changes in brain tissue microstructure that result from alpha-synuclein pathology. These findings have direct applications in pre-clinical drug-screening and has the potential to inform future applications of NODDI to human PD and DLB populations.

Title: Development of a novel ELISA methods for quantification of phosphorylated S^{129}-α-synuclein in biological samples

Authors: *K. BIGGS[1], S. HORNUNG[1,4], S. DUTTA[1], G. BITAN[1,2,3];
[1]Neurol., [2]Brain Res. Inst., [3]Mol. Biol. Inst., UCLA, Los Angeles, CA; [4]Div. of Peptide Biochem., Tech. Univ. of Munich, Munich, Germany

Abstract: Synucleinopathies are a group of neurodegenerative diseases including Parkinson's disease (PD), multiple system atrophy (MSA) and Dementia with Lewy bodies (DLB). They are characterized by the aggregation and deposition of the protein α-synuclein (α-syn) in Lewy bodies (LBs). In healthy brains only ~4 % of α-syn is phosphorylated at Ser^{129} (pS^{129}-α-syn), whereas over 90% pS^{129}-α-syn is found in LBs. There is currently no ELISA available to measure pS^{129}-α-syn. The development of a robust biochemical method to reliably measure low pg/mL levels of pS^{129}-α-syn addresses an urgent need for research and clinical applications. We evaluated different combinations of capture antibodies and detection antibodies on two different platforms, an electrochemiluminescent ELISA platform (Meso Scale Discovery) as well as a traditional chemiluminescent sandwich ELISA using a biotinylated detection antibody. Semisynthetic pS^{129}-α-syn and unphosphorylated α-syn (as a negative control) standards were measured in a concentration range from 0.76 pg/mL to 100,000 pg/mL. Further, mouse brain lysate, human serum, cerebrospinal fluid (CSF), saliva, and brain-derived exosomes were tested in this assay. Using the biotinylated monoclonal antibody EP1536Y and the SULFO-Tag anti-human α-syn antibody (MSD) resulted in the most sensitive measurement of pS^{129}-α-syn standards in the MSD platform. Whereas using EP1536Y capture antibody and biotinylated MJFR1 detection antibody resulted in the most sensitive measurement in the traditional sandwich ELISA. The assays show a wide dynamic range from single pg/mL to tens of ng/mL and does not detect unphosphorylated α-syn up to a concentration of 50 ng/mL. pS^{129}-α-syn could be detected in all the mouse and human tissues tested. Our results demonstrate that these novel ELISAs are highly sensitive and specific for pS^{129}-α-syn. The MSD platform can detect pS^{129}-α-syn at low pg/mL level and the traditional ELISA at a slightly higher minimum concentration but at a lower cost. Both assays achieve these results with high intra- and inter-experimental reproducibility. The traditional ELISA will be useful for high throughput animal studies and other situations where the sensitivity of the MSD platform is not required. The MSD platform assay will be useful for detecting pS^{129}-α-syn in limited volumes of patient samples and can offer new opportunities for diagnostic biomarkers, monitoring disease progression, and quantifying outcome measures in clinical trials.

Title: A mobile platform to assess cognition in amyotrophic lateral sclerosis

Authors: *T. KANGARLOO[1], A. GUPTA[2], S. PAGANONI[2], S. CHEW[2], E. COLLINS[2], A. STEINMAN[1], J. SEVERSON[3], J. BERRY[2], J. D. COSMAN[1];

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease characterized by the death of upper and lower motor neurons. These motor neurons degenerate over time and result in muscle atrophy, and thus a majority of the research in ALS focuses primarily on the functional consequences of this process on respiratory and movement symptoms. However, ALS patients often face marked cognitive impairment, especially in aspects of executive control. However, evaluations in the clinic to assess cognitive decline are performed infrequently using screening tests (e.g., ALS-CBS) rather than functional psychological tests. To this end, we developed a mobile application to enable self-administration of objective psychological tests in ALS patients at home and at the point of care that can be used to supplement data collected via current screening tools. The application was developed in iOS for the Apple iPhone to assess cognition (Trailmaking A/B and Digit-Symbol-Substitution Test) in patients with ALS and age-matched healthy comparisons. Participants completed two in-clinic visits spaced one week apart in which they performed the cognitive battery on the app. During the one-week period between clinic visits patients completed the cognitive tasks at-home at least twice. Data collection is ongoing and results of the cognitive tests versus standard in-clinic screening assessments will be discussed.

Title: RNA sequencing of cerebellar white matter reveals a potential role of APP and endothelial cell genes in cerebellar multiple system atrophy pathogenesis

Authors: *I. S. PIRAS[1], C. BLEUL[1], I. SCHRAUWEN[2], J. S. TALBOOM[1], M. DE BOTH[1], M. NAYMIK[1], G. M. HALLIDAY[3], J. HOLTON[4], G. E. SERRANO[5], L. I. SUE[5], T. G. BEACH[5], M. J. HUENTELMAN[1];

Abstract: Multiple System Atrophy (MSA) is a rare adult-onset neurological disorder that is pathologically typified by α-synuclein inclusions in glial cells. MSA clinically presents as either Parkinsonian (MSA-P) or Cerebellar-type (MSA-C). Little is known about the molecular mechanisms associated with MSA or what may distinguish the two subtypes. To address this, we performed RNA sequencing of the cerebellar white matter (CWM) from two independent cohorts of MSA patients (n = 66) and healthy controls (HC; n = 66). RNA samples from bulk brain and from oligodendrocytes (Od) obtained by laser capture microdissection (LCM) were sequenced . Differentially expressed genes (DEGs) were determined using DESeq2 and classified according to their expression in brain using an informatics approach developed by the co-authors.
We detected the highest number of DEGs in the MSA-C group (n = 747), and only a single gene in the MSA-P patients, highlighting the much larger transcriptional change in the MSA-C patient's CWM. The LCM study yielded 187 DEGs in Od, with the top genes involved in myelination. The PPI network revealed enrichment for "collagen genes" (in MSA patients as a whole, adj $p < 0.01$), "cytoskeleton organization" and "cell death" (MSA-C patients, adj $p < 0.01$), and "chaperone folding" (in LCM Od from 6 patients, adj $p < 0.05$). The APP gene (amyloid precursor protein, downregulated in MSA-C) was identified as a top ranked hub gene in both MSA-C and the LCM Od networks. The cell-classification of MSA-C DEGs revealed a downregulation of Od genes and upregulation of microglia (M), astrocyte, endothelial cell (Ec), and neuron genes. M genes were enriched for "NF-kappaB signaling" (inflammation, adj $p < 0.01$). Finally, Ec genes were enriched for angiogenesis (adj $p < 0.01$), a process also reported to be dysregulated in other neurodegenerative diseases.

This is the largest RNA profiling study ever conducted in MSA patients. We were able to define specific transcriptional signatures for MSA-C and detect several candidate genes that may shed additional light onto possible therapeutic approaches. We also report the association of Ec specific transcriptional changes that may affect angiogenesis in the CWM. Several results point to a β-amyloid (Aβ) independent role for APP in MSA. An analogous mechanism has been proposed in Alzheimer's disease and is related to altered metabolism of APP and accumulation of APP C-terminal fragments rather than the more typical Aβ production. This suggests that these two diseases may share a common molecular origin.

Title: Immune response in ischemic stroke and intracerebral hemorrhage in neutrophils and whole blood

Authors: *P. CARMONA-MORA, B. P. ANDER, G. JICKLING, X. ZHAN, B. KNEPP, F. HAMADE, H. HULL, E. FERINO, H. AMINI, F. R. SHARP, *B. STAMOVA;
Univ. of California, Davis Sch. of Med., Sacramento, CA

Abstract: Differentiating intracerebral hemorrhage (ICH) from ischemic stroke (IS) can be challenging when imaging is not available. Ruling out ICH is essential for early thrombolytic or endovascular IS therapy to be initiated. Understanding transcriptome differences between both and between IS etiologies, can lead to a better knowledge of the molecular and cellular pathways involved in the response to acute brain injury caused by ICH and IS. In this study we sought to characterize the transcriptomic profiles in blood from cases with ICH and different IS etiologies to identify acute molecular changes in isolated neutrophils and in whole blood.
Peripheral blood was drawn from cases with diagnosed ICH (6) and IS (33) (cardioembolic,

large vessel disease and lacunar) in the first 30 ± 20 hours after the onset of symptoms. We performed whole-genome RNA sequencing of whole blood (WB), and of isolated neutrophils. Control cases (10) with vascular risk factors (diabetes and/or hypertension and/or hypercholesterolemia) were included (VRFC). A linear regression model including diagnosis, sample subtype and their interaction with FDR<0.05 or p<0.05 overlap with FDR<0.2, and |fold-change|>1.2 was used for identifying differentially expressed (DE) genes. Gene ontology and pathway enrichment were performed for investigating their biological context. In addition, we delineated gene networks significantly associated with each diagnosis using Weighted Gene Co-expression Network Analyses (WGCNA). The significant co-expression modules were further studied to provide more insights in the pathways associated to ICH and IS. Transcriptional changes are distinguishable between both diagnoses in neutrophils and WB and also between stroke etiologies. For example, ICH vs VRFC 549 were DE in neutrophils, and 672 in WB. 389, 378, 694 genes were DE between cardioembolic IS, large vessel IS and lacunar IS compared to VRFC in neutrophils. Most of the changes are cell-type specific and involve cell-specific pathways, along with different signal transduction and immune response pathways. For ICH compared to VRFC, about half of the over-represented pathways were unique to neutrophils. 65% of the pathways over-represented in WB were not over-represented in neutrophils. Additional analyses will also allow us to demonstrate alternative splicing differences between to further refine the molecular signatures of both diseases. The unique molecular signatures in neutrophils underscore their involvement in IS and ICH pathophysiology. The large number of unique pathways in whole blood not detected in neutrophils signifies the contribution of other cell types to the ICH and IS responses.

Abstract: With new therapies being regularly developed for pediatric neurodegenerative disorders, there is a critical need to longitudinally track the progression of these diseases through utilization of noninvasive methods in both clinical and animal studies. Using a similar platform that was developed utilizing an animal model of CLN6-Batten disease, a multifaceted approach tracking relevant biomarkers of disease progression was performed on a preclinical mouse model for CLN2 Batten disease. Having accelerated disease advancement including visible, hyperactive tremors and early death, the *Cln2*$^{R207X/R207X}$ nonsense point mutation mouse model is ideal for testing a platform that incorporates the findings of noninvasive testing into one, comprehensive "disease score." Using a range of conventional neuroimaging tests and kinematic gait analysis, this approach tracks 144 parameters over the course of the model's lifespan to ultimately quantify key factors that contribute to disease progression and behavioral deficits. The tangible and quantifiable benefit of an application of this type has both clinical and therapeutic relevance.

Title: Exogenous flupirtine and flupirtine aromatic carbamate derivative as a potential treatment for CLN3 disease

Authors: *J. MAKOUKJI[1], K. MAALOUF[1], S. SAAB[1], B. VAIDYA[2], A. CARMONA[2], P. C. TRIPPIER[2], R.-M. BOUSTANY[1];
[1]American Univ. of Beirut, Beirut, Lebanon; [2]Texas Tech. Univ. Hlth. Sci. Ctr., Amarillo, TX

Abstract: Objective: Neuronal Ceroid Lipofuscinoses (NCL) are fatal, childhood neurodegenerative diseases characterized by seizures, blindness, cognitive and motor decline. CLN3 disease is the most common form. Hallmarks include brain atrophy, retinitis pigmentosa, accelerated apoptosis and ceramide elevation. Treatment regimens are symptomatic, disease-modifying drugs are urgently needed. Flupirtine and its novel aromatic carbamate derivative

(compound 6) exert anti-apoptotic and neuroprotective effects, *in vitro,* in neuronal precursor PC12 cells and human NCL cell lines. This study aims at investigating, *in vivo*, beneficial effects of orally supplied flupirtine and its allyl carbamate derivative (compound 6) in *Cln3*$^{\Delta ex7/8}$ knock-in mice. **Methods**: Flupirtine and compound 6 were tested by establishing growth curves, in neuronal precursor PC12 cells following siRNA knockdown of *CLN3* gene, and in patient-derived NCL lymphoblasts, using trypan blue and JC-1 staining. Ceramide levels were determined in human NCL lymphoblasts before and after treatment. Expression levels of *BCL-2, Caspases 3/8/9,* and ceramide synthesis enzymes (*CERS2/CERS6/SMPD1/DEGS2*) were compared in treated vs. untreated CLN3-deficient PC12 cells by quantitative real-time PCR (qRT-PCR). As a next step, 80 WT and *Cln3*$^{\Delta ex7/8}$ mice (40 males and 40 females) received flupirtine, compound 6 or vehicle for a period of 15 weeks. Effect of flupirtine or compound 6 on *Cln3*$^{\Delta ex7/8}$ mice is determined by performing behavioral tests (open field, pole climbing, Morris water maze, rotarod, wire suspension test), measuring ceramide in brains and sera, assessing impact on longevity, subunit C storage, astrogliosis and neuronal cell counts. Impact of flupirtine and compound 6 on apoptosis markers (BCL-2, caspases...) and ceramide synthesis/degradation enzymes levels is also investigated by qRT-PCR and Western Blot. Global gene expression patterns in *Cln3*$^{\Delta ex7/8}$ mouse brain treated with flupirtine or compound 6 is identified. **Results**: Flupirtine and compound 6 were neuroprotective in CLN3-defective PC12 cells and rescued human NCL lymphoblasts from accelerated apoptosis. Flupirtine and compound 6 decreased ceramide level in human NCL lymphoblasts. Increased *BCL-2,* decreased *Caspases 3/8,* and decreased ceramide synthesis enzyme expression were established in CLN3-deficient PC12 cells treated with flupirtine or compound 6. Based on these results, *in vivo* experiments were conducted to assess their effect on *Cln3*$^{\Delta ex7/8}$ mice. **Conclusion**: These findings establish that compounds analogous to flupirtine demonstrate anti-apoptotic activity with potential for treatment of NCL disease.

Title: Magnetization transfer imaging in the adrenomyeloneuropathy spinal cord shows potential suitability as a longitudinal biomarker for clinical trial

Authors: *B. R. TURK[1], R. LAWLESS[2], M. KAUFMAN[1], J. L. KELLER[1], K. M. ZACKOWSKI[1], G. V. RAYMOND[3], A. J. BASTIAN[1], A. FATEMI[1], S. A. SMITH[2]; [1]Kennedy Krieger Inst., Baltimore, MD; [2]Vanderbilt Inst. of Imaging Sci., Nashville, TN; [3]Penn State Children's Hosp., Hershey, PA

Abstract: Adrenomyeloneuropathy (AMN) is the non-fatal phenotype affecting ~60% of patients with Adrenoleukodystrophy (ALD), an X-linked inborn error of metabolism due to a mutation of the ABCD1 gene. MRI of the AMN spinal cord shows atrophy at all cervical levels, due to a dying-back axonopathy in long tracts. Our group has previously shown that magnetization imaging (MT) normalized to patient's own CSF levels (MTCSF) shows significant increase in dorsal column signal, and that MTCSF correlates to clinical and sensory motor measurements.

Currently, there is no FDA approved therapeutic compound for AMN. However, multiple therapeutic compounds are in different stages of the development pipeline. One main challenge is a lack of a longitudinal imaging marker for the AMN spinal cord. This study explored secondary imaging outcomes the longitudinal potential of MT as a biomarker from an ALD clinical trial from 2005-2009. Analyses were performed on the spinal cord vertebral level C2. Mirroring our previous findings in other populations, MTCSF was cross-sectionally significantly higher in the dorsal column of the AMN spinal cord versus heterozygote female carriers (Fig A) (n=147, AMN=74,Het=73). Interestingly, cross-sectionally, atrophy measured by spinal cord/column ratio and MTCSF showed a significant linear correlation only in AMN patients with further disease progression, stratified by the expanded disability status scale (EDSS) above 3.0 (Fig B). Longitudinally, MTCSF in AMN shows progression after one year and further progression after 2 years (Fig C). These data indicate that MT may be a suitable biomarker for clinical trial.

Figure caption: A) Violin plot depicting distribution (wings) and quartiles (center) of MTCSF of the spinal cord C2 dorsal column between Males (AMN) and female heterozygote carriers. B) MTCSF vs spinal cord/column ratio, by EDSS (point size and hue) and gender (Male = Blue, Red = Female), with linear regression on data points for EDSS above 3.0 C) Longitudinal delta change of MTCSF in AMN C2 dorsal column over one and two years

Abstract: New advances in synthetic and data driven immune engineering antibody discovery are enabling new neuroscience antibody therapeutics to be discovered and engineered in weeks rather than years. Here, we review ten years of progress in computational optimization of antibody discovery libraries through the lens of high-throughput data collection technologies, with specific case studies of modern repertoire design principles applied to neuroscience targets. We emphasize the case studies of TfR, CD19, and amyloid-beta, where computationally optimized libraries generated thousands of unique anti-brain target antibodies, including picomolar binders, mouse/cyno/human triple cross-reactive epitopes, antagonists, agonists, and saturated epitope coverage of the neuroscience target.

Title: Improved multi-objective optimization for large-scale neuron models

Authors: *A. ABOUZEID, W. KATH;
Engin. Sci. and Applied Mathematics, Northwestern Univ., Evanston, IL

Abstract: Today's rapid growth of open source neural modeling tools, data sharing platforms, and computational resources presents rich opportunities for in silico hypothesis generation and testing to support experimental findings. However, large-scale neuron models with realistic dendritic morphologies can require extensive tuning to match data. Previous work has shown that multi-objective evolutionary algorithms (MOEAs) can help to partially automate the task, but specific difficulties arise when these methods are applied to neural models. We address these shortcomings with a new technique that substantially improves the performance of such methods.
One difficulty is that neural models often have a large number of parameters, and properly determining them requires multiple experimental recordings. As a result, the number of objective functions required to constrain the model can be large. However, it is well-documented that some of the most commonly used MOEAs fail to converge on problems with more than two or three objective functions, making them ill-suited for use on neural models.
Secondly, due to the highly nonlinear dynamics associated with spiking, errors in these objective functions can be large, even within a bounded parameter range. Tests reveal that most MOEAs also perform poorly when the range of objective function values is not bounded.
We show that these challenges can be overcome by projecting objective values into a bounded space. The resulting method substantially improves the fitting of neural models with multi-objective evolutionary algorithms.

Title: Minimum number of voltage-gated channels in a biophysical conductance-based model that can predict spike-timing in neurons with short-term adaptation

Authors: *A. R. ASILADOR[1], R. RATNAM[2];
[1]Neurosci. Program, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Sch. of Arts and Sciences, Biol. and Life Sci., Ahmedabad Univ., Ahmedabad, India

Abstract: In a spike-time code, the time of occurrence of a spike is assumed to carry information about its input. This has led to computational models that can predict the time of each spike, with the most successful model being the adaptive or moving threshold model. With few exceptions

(e.g., Abarbanel and co-workers) nonlinear biophysical conductance-based models (Hodgkin-Huxley or H-H type) have been poor at predicting spike-times because of the difficulty in estimating the large number of model parameters. There is thus a significant gap in exploring biophysical models of spike-timing which have predictive power, i.e., which can be used to predict the spike-times from experimental data. At the biophysical level, it is know that outward potassium currents regulate spike-timing. Further, they are responsible for the adaptive or moving threshold that persists from ten to hundreds of milliseconds causing firing-rate adaptation. This work has two goals: 1) determine a conductance-based model with the smallest number of ion channels that can predict the spike-times observed experimentally, 2) establish the role of outward potassium currents in adaptation. Using publically available intracellular data from L5 pyramidal neurons in the rat somatosensory cortex (the INCF Spike Time Prediction Challenge, 2009), and a parameter estimation procedure developed by Abarbanel and co-workers, we show that only five ion channels are needed to obtain a good fit to the membrane potential and to predict spike times: the three classical H-H type channels (a leak channel, a transient Nav, and a Kv delayed rectifier but with inactivation), a non-inactivating outward M-current (Kv7), and a persistent Na+ current. The predicted spike-time coincidence with experimental data is 0.47 (about 63% of the experimentally reported coincidence). In comparison, the best-fit obtained using a multiscale adaptive threshold model (Kobayashi and co-workers) was about 0.57 (or 76%). Increasing the number of channels does not improve the fit. We verify that the estimated parameters are within the biophysically plausible range, and show that the M-current produces the adaptation observed in the data, and that this adaptation is not long-lasting (10-30 ms). The model mimics the spike-initiation region (the axonal initial segment or AIS) as it does not include voltage-gated channels found elsewhere in the soma or dendrites. Finally, we show that the M-current, but not the delayed rectifier, regulates the spike-rate (proportional to energy consumption). These results support the idea that the AIS may be critical for regulating spike-timing, spike frequency adaptation, and the neuron's energy consumption.

Engin. and Computer Sci., [4]Electrical & Computer Engin., Univ. of Missouri Columbia, Columbia, MO

Abstract: Neuronal models are of different types spanning the range from phenomenological to detailed biophysical types. These models attempt to capture the key signatures of neuronal responses, depending on the application. Such neural signatures include resting membrane potential, input resistance, membrane time constant, subthreshold oscillations, threshold potential, and frequency-current (F-I) curves. Biophysical models of neurons typically include either simplified or detailed morphology of soma and dendrites modeled as cylinders into which are embedded different current channels, and synapses.
Several approaches have been proposed to develop biophysical models ranging from hand-tuning to automated algorithms that can search large databases. Here we propose automated approaches to construct biophysical models of neurons with different numbers of neural signatures, using both analytic and machine learning components. In the first category, we consider a biophysical model structure for simple spiking neurons with only a few signatures: resting potential, input resistance, membrane time constant and F-I curve. In the second category, we consider neurons with additional signatures such as low- and high- threshold oscillations and bursting. Such approaches are important to speed up the development of network models and also free up the neuroscientist from having to devote time away from science to learn complex technical details.

Title: Combined biophysical and statistical modeling pipeline for investigating roles of ion channels in stimulus encoding

Authors: ***N. G. GLASGOW**[1], Y. CHEN[2], A. KORNGREEN[4], R. E. KASS[3], N. N. URBAN[1]; [1]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [2]Ctr. for Neural Basis of Cognition, [3]Carnegie Mellon Univ., Pittsburgh, PA; [4]Bar-Ilan Univ., Ramat-Gan, Israel

Abstract: To understand single neuron computation, it is necessary to know how specific ion channel conductances affect neural integration and output. Knowledge of these relationships is

critical in understanding how changes in biophysical properties affect stimulus encoding. Here we present a computational pipeline combining biophysical and statistical models to provide a link between variation in functional ion channel expression and changes in single neuron stimulus encoding. Biophysical models provide mechanistic insight, whereas statistical models provide insight into what spiking actually encodes. We used published biophysical models of two morphologically and functionally distinct projection neuron cell types: mitral cells (MCs) of the main olfactory bulb, and layer V cortical pyramidal cells (PCs). We first simulated MC and PC responses to pink noise stimuli while scaling individual ion channel conductances and then fit point process regression models (generalized linear models; GLMs) to the resulting spike trains. This provides both stimulus effects (the stimulus filter) and spike-history effects (the history filter). Although we find interesting differences for several channel types in each model, we focus here on high-voltage-activated Ca^{2+} channels (Ca_{HVA}) as an example of our pipeline. Changing Ca_{HVA} conductance converts our MC and PC models from regular firing to burst firing or vice versa. These changes are reflected predominantly in changes of the GLM history filter and early components of the stimulus filter. Through stimulus reconstruction, we find that increasing Ca_{HVA} conductance in MCs reduces coherence of low and medium frequency stimulus components, but not high frequency components. In contrast, varying Ca_{HVA} conductance in PCs has moderate effects on coherence of low and medium frequency components, but substantial reductions in coherence of high frequency components. Thus, we can predict how differences in individual conductances affect encoding of specific stimulus features. Our computational pipeline provides a way of screening all channel types to identify those channels that most strongly influence single neuron computation in any cell type of interest.

Title: Using convolutional neural networks to predict ion-channels densities in single neuron biophysical models

Authors: *R. BEN-SHALOM[1], J. BALEWSKI[3], V. BARATHAM[4], A. SITHTHARANJAN[4], H. KYOUNG[4], K. KIM[4], K. J. BENDER[2], K. E. BOUCHARD[2];

Abstract: Conductances generated by ion channels distributed along neuronal membranes contribute markedly to neuronal activity. To better understand the underlying mechanisms of neuronal activity, we need to model single neurons accurately, including spatial densities of different ion channels along the membrane. Currently, it is quite difficult to accurately measure these densities. This makes it difficult to constrain these parameters in compartmental models. Instead, a common approach is to treat these ion channel densities as unknown parameters that are then estimated to allow for accurate recapitulation of *in vitro* recordings from target neuronal datasets. This is traditionally done using optimization algorithms like Multi Objective Optimization (MOO), which seeks to minimize differences between model output and target data using defined criteria - the objectives of the optimization. One central shortcoming of this approach is that MOO often returns different parameters depending on the chosen objectives. Recently, CNNs, which have been applied in a range of dynamical systems fields, have been shown to be advantageous for such complex systems. Here we ask whether CNNs can predict ion channel densities from membrane potentials across a spectrum of neuronal models. We trained CNNs with a simulated dataset of known ion channel densities and their resultant voltage outputs in response to a stimulus. Following training, we tested CNNs with novel voltage outputs generated from a new complement of ion channel densities and asked whether the CNN could determine these densities from the voltage outputs alone. In contrast to MOO-based fitting, where each optimization fit one voltage trace to one set of parameters, a trained CNN was able to provide channel density predictions for all voltages created by the neuronal model, albeit with varying prediction errors. After CNNs are trained, we generate a report for how well each parameter can be constrained and how individual parameters correlate with each other. For simple models, CNNs were able to accurately predict all parameters with relatively small error (less than 4%). For more complex models, we found that some parameters were well predicted, whereas for others CNN predictions were poor. This is presumably because those parameters with higher error had little influence on overall voltage output, at least at the soma. We are currently exploring whether these parameters could be better fit by simultaneous recordings from the soma and other neuronal sites (e.g., axon or distal dendrite). Finally we discuss several ways to reduce the dimensionality of the free parameters to increase accuracy of the predictions.

Title: Identifying and mitigating statistical biases in neural models of tuning and functional coupling

Authors: *P. SACHDEVA[1], M. DOUGHERTY[2], S. BHATTACHARYYA[3], K. E. BOUCHARD[2];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Biol. Sci. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA; [3]Statistics, Oregon State Univ., Corvallis, OR

Abstract: Neural activity is a function of factors in the external world (i.e., tuning) and other neurons, some of which may be simultaneously measured and analyzed (i.e., functional coupling), while others are not observed and contribute both shared variance and private noise. Statistical models (e.g., generalized linear models) have been used to describe neural responses using tuning and functional coupling with high predictive accuracy and a set of interpretable parameters. These fitted parameters provide insight into which internal and external factors are important and their relative importance. For example, past studies have demonstrated that the inclusion of coupling greatly improves predictive performance while decreasing the magnitudes of the tuning parameters. Thus, the implication is that neural activity, while shaped by tuning, is largely determined by coupling. However, extracting conclusions about neural activity from model parameters requires that their estimates are unbiased. We demonstrate that correlated variability can introduce the simultaneous equations bias (a phenomenon studied in econometrics) in statistical models of coupling and tuning, potentially biasing parameter estimates and jeopardizing past conclusions about neural computation. We present a novel method, Iterated Two-Stage Factor Analysis (ITSFA), that alleviates the simultaneous equations bias in a common model of neural activity. We show that ITSFA consequentially corrects tuning curves in both single-unit recordings from monkey motor cortex and micro-electrocorticography recordings from rat auditory cortex. We highlight a connection between the increase or decrease of tuning and the distribution of noise correlations. Together, our results shed light on how noise correlations can result in adversarial statistical biases, and provide a novel algorithm to mitigate that bias.

Title: Striatal population models of ionic conductances reveal mechanisms for conversion among healthy, disease, and drug-treated phenotypes

Authors: *S. ALLAM, T. RUMBELL, T. M. HOANG TRONG, J. KOZLOSKI;
IBM Res., Yorktown Heights, NY

Abstract: The variability in electrophysiological signatures of neurons describe phenomena characteristic of the neuron's physiological states. The principal neurons of the striatum, responsible for motor co-ordination and cognition exhibit varied active and passive properties in healthy and Huntington's disease phenotypes. While the manifestation in electrophysiological properties due to disease or drug treatment is an outcome of underlying biochemical pathway modifications, it is difficult to quantify the causation and correlation of these outcomes through single experimental models alone owing to the heterogeneity of the cell population divergent across species, wild-type and disease phenotypes. Here we show, by constructing large populations (using evolutionary algorithms and parameter optimization) of such heterogenous striatal projection neuron models comprising of Hodgkin Huxley type ion channel and non-linear leak conductances constrained by trans-membrane ionic concentrations, robust linear controllers of these active and passive properties of neurons could be revealed. With cannonical correlation analysis, we then provide insights into how the landscape of specific potassium and sodium channel conductances are oriented in healthy population, altered in disease phenotypes and partially restored though drug treatment of the sub-cellular pathways. Our methods provide a way to linearly characterize the effects of various drugs aimed at multiple downstream targets of the dopamine receptor pathways within the striatal principal neurons and predict the effects of such drugs on the disease states within the striatal network

Title: Investigation of factors affecting burst firing patterns of a thalamocortical neuron: Computational NEURON model study

Authors: *S. PARK, S. LEE, J. CHO, Y. HUH;
Catholic Kwandong Univ., Incheon, Korea, Republic of

Abstract: The thalamus is a structure which relays and modulates sensory information before reaching the cortex. The unique ability of a thalamocortical (TC) neuron to switch between the high frequency firing (burst firing) and single spike firing (tonic firing) have been implicated to be involved in pain modulation. Of the two firing modes, previous studies demonstrated that the properties of TC burst firing, e.g. intervals between burst spikes in a burst, are key components in modulating behavioral nociceptive responses. Therefore, investigating the factors that influence the temporal dynamics of thalamic bursts would offer important insight into understanding the mechanism of sensory modulation. In this study, using full-morphology thalamocortical NEURON model, we investigated how the balance, timing, and intensity of excitatory and inhibitory inputs influences the dynamics of TC bursting patterns. We found that burst firing patterns changed more dynamically under weak inhibitory input conditions compared to strong inhibitory input conditions. To reflect a more realistic condition, we repeated the same analysis with excitatory inputs delivered at different dendritic locations: proximal, intermediate, or distal. Interestingly, we found that an excitatory input into a distal dendrite had the strongest influence on shaping the temporal pattern of TC bursts than the closer intermediate or proximal dendrites. Overall, our results demonstrate that several factors interplay to model the temporal dynamics of a burst firing pattern and provide insight into understanding the factors that contribute to sensory modulation.

Title: Dopamine neuron population modeling and intracellular pathway modulation in a nigrostriatal model

Authors: *T. RUMBELL[1], T. M. HOANG TRONG[1], S. ALLAM[1], J. KOZLOSKI[2];
[1]IBM Res., Yorktown Heights, NY; [2]IBM - TJ Watson Resch Ctr., Yorktwn Hghts, NY

Abstract: Dopaminergic neurons (DAs) of the rodent substantia nigra pars compacta (SNc) display varied electrophysiological properties *in vitro*. Despite this, projection patterns and functional inputs from DAs to other structures are conserved, so *in vivo* delivery of consistent, well-timed dopamine modulation to downstream circuits must be coordinated. Here we show robust coordination by linear parameter controllers, discovered through powerful mathematical analyses of data and models, and from which consistent control of DA *in vitro* spontaneous firing patterns emerges. We used evolutionary unbiased parameter search and dimensionality reduction to produce a unique population of models that show good generalization to channel blockade and compensatory intracellular mechanisms, and blanket the empirically observed range of electrophysiological profiles. Incorporating these heterogenous models of this neural population into a previously published striatopallidal circuit model (Corbitt et al., J. Neuroscience, 2016), and in combination with similar population modeling of striatal projection neurons (SPNs), we model the reciprocal connection between dopamine release in striatum and GABAergic input onto nigral DAs. We also incorporate existing canonical systems biology models of the intracellular pathway linking dopamine receptor activation to SPN excitability through the DARPP-32 biochemical pathway. This multiscale approach facilitates investigation of the role of both dopamine and drugs in modulating striatonigral circuit activity patterns and basal ganglia oscillations in health and disease.

Abstract: The activity patterns of neurons are governed by nonlinear interactions of their internal state and synaptic inputs; these interactions can be predicted using quantitative models. Since NEURON 7.4, the NEURON simulator has supported models coupling 3d intracellular -- necessary for understanding microdomains near spines or the morphology variations where dendrites meet the soma -- and electrophysiological kinetics, however computational overhead imposed practical limits on models that can be studied this way. The recently released NEURON 7.7 features completely redesigned 3D voxelization and parallel simulation algorithms, drastically reducing the compute time -- expanding the set of simulatable models -- without requiring changes to model implementation code. We are able to run a 4-thread 300ms simulation of a propagating wave on approximately 750k voxels near the soma of a virtual neuron with a reconstructed morphology in approximately 258s. Conversion of point-diameter neuron traces to 3D volumes follows the CTNG heuristic (McDougal et al., 2013) but extended so that discretization time scales with the volume of the neuron not the volume of the bounding box. Simulation uses an adaption of the parallel Douglas-Gunn algorithm (Newton et al., 2018) that runs on irregular domains. Reactions are JIT compiled and are exportable to SBML. Currents always enter and are computed based on surface voxels. We demonstrate scaling and simulation using models of the circadian oscillator, propagating calcium waves at the soma, and diffusion near spines.

Title: Particle swarm optimization of a nonlinear cable model of an autonomic c-fiber axon

Authors: *B. THIO, N. A. PELOT, D. CATHERALL, W. M. GRILL;
Duke Univ., Durham, NC

Abstract: Computational models of large myelinated somatic axons have been well characterized. However, the vagus nerve is primarily comprised of unmyelinated C-fiber axons, and the responses of small unmyelinated autonomic axons to stimulation have not been modeled. We implemented a non-linear cable model of an autonomic c-fiber axon containing a complement of ion channels with properties derived from voltage clamp data and ionic pumps with Michaelis-Menten kinetics derived from the concentrations of intracellular Na+ and extracellular K+. In addition to non-linear ionic conductances, we implemented ion accumulation mechanisms in a 30 nm-thick periaxonal space. We used multi-objective particle swarm optimization (PSO) to identify an optimal set (i.e., optimal particle) of ion conductances, maximum pump currents, and intracellular resistance (12 dimensions) such that model responses matched characteristics compiled from in vivo recordings in literature. The PSO was initialized with 30 12-dimensional particles set to random values with realistic bounds. At each generation, each particle's performance was evaluated using the conduction velocity, chronaxie, action potential duration, presence of a long-duration (>500 ms) subnormal period (increased threshold during the recovery cycle), and presence of a short-duration (<50 ms) supernormal period (decreased threshold during the recovery cycle). All nondominated conductance sets influenced the update of the conductance sets of all other particles. The PSO converged in 1005 generations which required 10.5 days on 400 cores. The conduction velocity and chronaxie were largely influenced by the NaV1.7 conductance and intracellular resistance, action potential width was most influenced by NaV1.8 channels conductance, and the recovery cycle dynamics were influenced primarily by the ion accumulation dynamics. The optimized c-fiber model had conduction velocities of 0.8 and 1.6 m/s and chronaxies of 1.43 and 1.08 ms for 0.5 and 2 μm fiber diameters, respectively, which are within the literature ranges of 0.45 to 1.76 m/s for conduction velocity and 0.75 to 1.5 ms for chronaxie. PSO enabled optimization of a non-linear cable model of an autonomic c-fiber axon with responses matching those measured in vivo, and the resulting model provides a valuable tool for analysis and design.

Title: Modulation of slow gating kinetics of ion channels causes a gradual change in neuron excitability

Authors: *J. A. BROEK[1], G. DRION[2];
[1]Electrical Engin. and Computer Sci., Univ. Liege, Liege, Belgium; [2]Electrical Engin. and Computer Sci., Univ. of Liege, Liege, Belgium

Abstract: The physiology of a neuron can exhibit different kinds of spiking behaviour, which are classified as Type I and Type II excitability. Type I has a continuous gain function in the frequency-current (FI) curve and is therefore able to generate low firing frequencies depending on the strength of the applied current. Type II has a non-continuous FI curve, which reflects the threshold behaviour, i.e. the abrupt move from quiescence to fast spiking. The properties of Type I and Type II have consequences for information processing and computational processes such as thresholding and gain scaling. Excitability types have long been classified based on the type of bifurcation associated to equilibrium points: a saddle-node on invariant cycle (SNIC) bifurcation represents Type I excitability and a Hopf bifurcation a Type II excitability. These bifurcations are often related to the shape of the current-voltage (I-V) curve, where Type II excitability reflects a monotonically increasing I-V curve with one equilibrium, whereas a non-monotonically increasing I-V curve reflects Type I excitability and has three equilibriums. Likewise, both excitability types have been associated to specific phase portrait configurations in reduced neuron models. Here, we analyse how excitability types are affected by neural dynamical properties. In particular, we analyse the influence of timescale separation modification on the type of bifurcation in the situation with three equilibriums, without modifying the I-V curve or the phase portrait. We show that increasing timescale separation leads to the occurrence of a Hopf bifurcation before collision with the saddle, hence changing the excitability type from Type I to Type II. As a consequence, in the singular limit, where timescale separation is infinite, no configuration of a classical phase portrait can lead to SNIC bifurcation, and therefore Type I excitability. However, a SNIC bifurcation that persists in the singular limit can be achieved by incorporating the slow regenerative variable in the classical phase portrait.

Title: Computational model of neural recordings in dorsal root ganglia

Authors: *M. KADWANI[1,2], R. D. GRAHAM[1,2], Z. J. SPERRY[1,2], S. F. LEMPKA[1,2,3], T. M. BRUNS[1,2];
[1]Biomed. Engin., [2]Biointerfaces Inst., [3]Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Dorsal root ganglia (DRG) are neural tissue bulges outside the spinal cord, where the soma of sensory neurons are clustered. DRG are an attractive target for neural interfacing, such as for monitoring organ or limb state for closed-loop neuroprostheses. A greater understanding of this interface may inform the design of new electrodes and lead to less dependence on animal models. Therefore, we developed a computational model of neural recordings from a microelectrode implanted within the DRG. The first model component was a finite element model (FEM) of a microelectrode implanted within the DRG. We also performed simulations for a point electrode placed within an infinite homogeneous medium. To simulate the membrane currents generated by neurons within the DRG, we created a multicompartment model of an Aβ-fiber neuron (80 µm ellipsoid soma diameter; 11.5 µm peripheral axon diameter, 10 µm central axon diameter, 8.7 µm stem axon diameter). We created three versions of this neuron model: one with a straight initial glomerulus (IG) of the stem axon, one with a slightly curved IG, and one with a highly coiled IG to simulate the tortuous path often observed in anatomical studies. We used a reciprocity-based solution to simulate the microelectrode voltage recordings generated by the Aβ-fiber neuron. We calculated the final voltage recording as the sum of the time-dependent voltages generated by each compartment within the neuron model. The model-based intracellular action potentials (APs) matched those reported in the literature. The FEM-based extracellularly-recorded waveforms were similar in shape to recordings with the point electrode, but with smaller amplitudes. APs near the axons were narrower and APs near the soma were wider. The peak-to-peak voltage (V_{pp}) varied from 5 µV to 400 µV for electrode-to-neuron distances of 150 µm to 5 µm, respectively. V_{pp} was larger than 30 µV (typical *in vivo* noise floor) if the microelectrode was within 25 µm of the axon and if within 150 µm from the soma. For the coiled IG neuron, we observed multi-phasic AP waveforms depending on electrode position, similar to *in vivo* observations. In conclusion, our model was able to predict waveforms and amplitudes similar to those observed experimentally. In future work, we will incorporate additional features, such as additional nearby neurons to simulate background noise and

additional neuron types, to better mimic *in vivo* conditions.

Abstract: The vagus nerve (VN) connects critical periphery organs with different integrative areas in the brain to maintain homeostasis, and electrical stimulation of the VN has been long recognized to have therapeutic effects. However, the origin and fiber type localization in the VN is poorly understood and electrical stimulation is performed in the entire nerve causing undesirable side effects, including hoarseness and voice alterations resulting from off-target activation of large myelinated axons that innervate the recurrent laryngeal nerve (RLN). Current models of the rat VN are limited by the lack of published data on its ultrastructure organization, and the assumption of homogenous random distribution of all axon types. In this study we evaluated the left cervical VN of 12 adult Sprague-Dawley rats using electron microscopy and observed axon clustering of myelinated fibers. We then utilize custom multi-contact electrode cuffs in the left VN of the rat to restrict the volume of depolarizing stimulation to selectively activate afferent axons, while avoiding efferent motor fibers. Electrical stimulation was performed using 50 μsec biphasic pulses at at 1 Hz and variable pulse amplitudes. Electrophysiological recordings of VN and RLN were processed using Matlab. The compound action potentials evoked by electrodes located either in the left (L-E) or right (R-E) side of the

VN, revealed selective activation of A-alpha or A-beta fibers under certain stimulation conditions. Selective depolarization of A-beta, and A-delta afferents in the proximal VN was achieved, without depolarizing A-alpha fibers innervating the laryngeal muscles. DiI labeling was used in some studies to mark the position of the L-E relative to the position of fibers within the nerve, so that the evoked activity was correlated to the anatomical distribution of axon types near the stimulating electrodes. Significant differences in the RLN/VN activation ratio between R-E and L-E configurations were noted. The newly established anatomical, histological, functional, and electrophysiological data allowed the development of sophisticated computational (coupled electromagnetic-neuronal dynamics) models of superior realism, which can be used to gain mechanistic insights and further optimize the electrode design and stimulation protocols. These novel contributions (implant, nerve characterization, computational model) combine to form a powerful platform for neurological investigations.

Title: Agent based modeling of neural development with NeuroMaC

Authors: *E. DE SCHUTTER, M. KATO;
Okinawa Inst. of Sci. and Technol., Tancha, Japan

Abstract: NeuroMaC was initially developed to simulate how interactions between growing neurons shape their dendritic trees (Torben-Nielsen and De Schutter 2014). It implements a stochastic, agent based representation of growth cones - fronts - in a Python multi-core computing environment to efficiently simulate the concurrent growth of hundreds of neurons. An extensive rewrite and expansion of NeuroMaC now offers additional simulation options, a better user interface and improved performance. Extensive documentation combined with examples and exercises help the novel user to discover the rich modeling environment. Model behavior is defined as a Python module that implements several front methods. Models can be run in jupyter notebooks or as Python processes from the terminal. Cell birth, migration and apoptosis combined with a phenomenological approach to attraction and repulsion by chemical cues allow for simulation of the development of complex neural tissues. Synapses can be established between neurons, causing the intracellular release of signaling molecules. Stochastic

diffusion of signaling molecules inside dendrites or axons can promote their extension or retraction.
We are using NeuroMaC to simulate the development of a small volume of murine cerebellar cortex during the first postnatal weeks. The massive downward migration of thousands of granule cells along Bergmann glia and the growth of granule cell axons - the parallel fibers - combined with the early development of Purkinje cell dendritic trees make the cerebellar cortex a very crowded environment. Investigating how evolution has solved these challenges by detailed simulation improves our understanding of this important developmental stage of the cerebellum and suggests additional experiments.

Title: Homeostasis and spreading depolarization in multiscale simulation of in ischemic stroke

Authors: *A. J. H. NEWTON[1,2,3], M. L. HINES[1], W. W. LYTTON[3,4,5], R. A. MCDOUGAL[1,2]; [1]Dept. of Neurosci., [2]Ctr. for Med. Informatics, Yale Sch. of Med., New Haven, CT; [3]Dept. of Physiol. and Pharmacol., [4]Dept. of Neurol., SUNY Downstate, Brooklyn, NY; [5]Dept. of Neurol., Kings County Hosp. Ctr., Brooklyn, NY

Abstract: Ionic homeostasis in neurons is essential for maintaining stable electrophysiological properties and a disruption of homeostasis is a characteristic of several pathologies including ischemia and epilepsy. Ionic homeostasis also provides an additional constraint on model parameters. Modeling and simulation of homeostasis with few ions or single compartment neurons can be analyzed mathematically, however for detailed neuronal morphology with multiple charge carrier a numerical approach is required.
Recent developments and performance improvements in the NEURON (neuron.yale.edu) reaction-diffusion module (rxd) allow us to model multiple relevant concentration in the intracellular and extracellular space. We modeled a morphologically detailed hippocampal pyramidal neuron and combine rxd with evolutionary algorithms (BluePyOpt) to obtain parameters that produce realistic electrophysiological responses while maintaining homeostasis of K^+, Na^+, Ca^{2+}, Cl^- and glutamate. We use this model to simulate spreading depression

following ischemic stroke.
We developed multiscale models of spreading depolarization in ischemic stroke, coupling electrophysiology and intracellular molecular alterations and bulk tissue alterations mediated by tortuous extracellular diffusion. We simulated spreading depolarization by placing biophysically detailed models of pyramidal neurons in the penumbrae, with reduced pump conductances. We used this model to explore the hypothesis that individual neurons show a pattern of susceptibility to damage due to morphology and physiology, such as the surface area to volume ratio or the intracellular calcium dynamics. In morphologically simplified cells, excessive intracellular Ca^{2+} produced greater susceptibility in proximal compared to distal dendrites.

Title: A multiscale modeling framework to understand and optimize ultrasound neuromodulation

Authors: *T. LEMAIRE[1], E. NEUFELD[2], S. MICERA[1];
[1]Translational Neural Engin. Lab., Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]Computat. Life Sci., IT'IS Fndn., Zuerich, Switzerland

Abstract: *Low-Intensity Focused Ultrasound Stimulation* (LIFUS) emerges as an attractive technology for noninvasive modulation of neural circuits, yet the underlying action mechanisms remain unclear.
We recently developed a *multi-Scale Optimized Neuronal Intramembrane Cavitation* (SONIC) model [1], that goes beyond the complex neuronal intramembrane cavitation excitation theory [2] by offering interpretability in terms of effective channel dynamics, for which a wide range of established neuroscientific approaches exist.
Using this model, we systematically explored the LIFUS parameter space to predict cell-type-specific spiking behaviors in cortical and thalamic neurons, and explained transitions between different behavioral regimes (tonic firing, bursting, silencing...) using a phase-plane analysis of differential variables evolving at quasi-steady state.
Moreover, taking advantage of the resulting reduced computational cost, we developed multi-compartmental representations incorporating the SONIC model to predict LIFUS

neuromodulatory effects at various scales in a more reliable manner. (i) A nanoscale model was used to predict how local intracellular currents mediate a synchronized neural response across a cell membrane having a heterogeneous responsiveness to LIFUS; (ii) morphological-scale models of peripheral axons were used to study the fundamental differences in action potential initiation and propagation in myelinated and unmyelinated fibers upon LIFUS.
This computational approach is part of an effort to build a multiscale simulation framework that couples modeling of LIFUS-neuron interaction with that of acoustic propagation in (personalized) anatomical models. The framework is expected to be valuable in supporting mechanistic investigation, device optimization, and personalized treatment planning.

Title: Modular software for drift diffusion model tested with striatal neuronal populations

Authors: *E. LARA-GONZALEZ[1], M. DUHNE[2], **M. GARCÍA-MATA**[3];
[1]Univ. Nacional Autónoma de México, Ciudad de Mexico, Mexico; [2]Neurociencia Cognitiva, Inst. De Fisiologia Celular UNAM, Mexico DF, Mexico; [3]Facultad de Ciencias, Univ. Nacional Autónoma de México, Ciudad de México, Mexico

Abstract: Motivation: Cellular transmembranal potential mathematical models are a handy tool for analysis of excitable cell behavior. They allow us to perform experiments in silico to explain transmembrane potential dynamics that can not be done *in vitro* electrophysiologic because of physical or technological limitations. Most of the mathematical models have several equations to model different ionic channels making it difficult to reproduce different types of cells with the exact same model. However, the drift-diffusion model (Herrera-Valdez, 2018) proposes a general equation to describe the transmembranal flux, which describes the traffic through ion channels, pumps or exchangers. This will make the modeling of different cellular kinds easier.Methods: We implemented the drift-diffusion model in python using object-oriented programming paradigm. The development has such a structural organization that allows further updates and upgrades as concurrent programming or graph structure implementation.

Additionally, we created a friendly user interface in pyQt. To test the model whole-cell patch clamp recording of striatal neurons *in vitro* was used. Results: We successfully modeled transmembrane voltage dynamics of spiny projection, fast spiking, and cholinergic murine striatal neurons. We compared the action potential width and amplitude. We found no statistical difference between electrophysiologically recorded and the modeled action potentials for all cell types.Conclusion: Object-oriented programming proved to be an adequate paradigm to model different neurons. The drift diffusion model allows the use of a single equation for different channels. This implementation maximizes its versatility by making the modeling of different neuronal types simple.

Title: State-dependent effects of electrical stimulation on populations of excitatory and inhibitory neurons

Authors: *C. CAKAN, K. OBERMAYER;
Technische Univ. Berlin, Berlin, Germany

Abstract: Electrical stimulation of neural populations is a key tool for understanding neural dynamics and developing treatments. To investigate the effects of external stimulation on a basic cortical mass model, we analyse the dynamical properties of a low-dimensional mean-field model of two coupled populations of excitatory and inhibitory adaptive exponential integrate-and-fire (AdEx) neurons with biophysically interpretable parameters and validate the results using large network simulations. Bifurcation diagrams establish a close dynamical relationship between predictions from mean-field theory and the underlying ground truth neural network. The dynamical landscape and all attractors are retained in the mean-field approximation. The diagrams reveal asynchronous up- and down-states, bistable regions and limit cycles corresponding to fast excitation-inhibition oscillations in the gamma frequency range and slow adaptation-excitation feedback loops in the delta range. The effect of an external electrical stimulus critically depends on the current dynamical state of the unperturbed system which itself is determined by the mean inputs to the excitatory and inhibitory populations. External stimuli can cause attractor switching such as turning on and off oscillations. Oscillatory stimuli can

frequency-entrain and phase-lock endogenous oscillations to the external input. We show that these effects can be found in the mean-field approximation as well as in the detailed network model, further underpinning the utility of low-dimensional neural mass models.

Title: Employing support vector machines to identify functionally distinct fMRI resting state networks

Authors: *R. T. PHILIPS[1], S. TORRISI[2], M. ERNST[1], C. GRILLON[1];
[1]NIH, Bethesda, MD; [2]UC Berkeley and Advanced MRI Technologies, LLC., Berkeley, CA

Abstract: Functional connectivity (FC) is defined as the temporal similarity between fMRI signals from distinct brain regions. FC has been shown to reflect anatomical connectivity. However, traditional FC analyses have a few limitations, including: 1. Temporal delays between signals (order of seconds) are ignored; 2. Methods that distinguish important brain regions and networks with distinct FC are inadequate. Here, we propose a new approach to address these limitations, utilizing dynamic time warping (DTW) within a machine learning framework. As a proof of concept, the cortical FC patterns of two spatially nearby but functionally distinct subcortical regions, namely the Substantia Nigra Pars Compacta (SNc) and Ventral Tegmental Area (VTA), are explored. Whole brain resting state fMRI scans from 40 healthy participants, collected using a Siemens Magnetom 7T MRI (32-ch head coil, TR of 2.5s, TE=27ms, 1.2mm isotropic, multiband factor 3), are preprocessed and aligned to a standard template. Two subcortical regions of interests (ROIs) and 360 cortical target parcels are defined based on the CIT168 Atlas and the Glasser HCP Atlas, respectively. The correlations between the each of the 2 subcortical ROIs and the 360 cortical parcels are computed using: 1. standard Pearson correlations (PC), 2. DTW followed by Pearson's correlations (DTW-PC). These correlations serve as inputs to a Support Vector Machine (SVM). The separability of the SNc-cortical and VTA-cortical networks is assessed using Leave One Out Cross Validation (LOOCV). In addition, SVM-Recursive Feature Elimination (RFE) yields the most important features (cortical parcels). Results reveal that the SVM-LOOCV separates the SNc-cortical and VTA-cortical networks with 68.75% and 96.25% accuracy on using PC and DTW-PC, respectively. The top 20

SVM-RFE features (cortical parcels) are sufficient to account for the accuracy levels. Only half of these features survive the Bonferroni-Holm correction with PC inputs; whereas, all the 20 survive with DTW-PC inputs ($p<0.05$). Dynamic time warping based functional correlations in conjunction with recursive feature elimination, within a support vector machine framework, appears to be a viable strategy to separate brain networks and identify important ROIs.

Title: A comprehensive biophysical model of substantia nigra pars compacta cells for understanding Parkinsonian neurodegeneration

Authors: *V. R. MUDDAPU, S. V. CHAKRAVARTHY;
Dept. of Biotech., IIT Madras, Chennai, India

Abstract: Parkinson's disease (PD) is the second most prominent neurodegenerative disease around the world. Although it is known that PD is caused by the loss of dopaminergic cells in substantia nigra pars compacta (SNc), the decisive cause of this inexorable cell loss is not clearly elucidated. We hypothesize that "Energy deficiency at sub-cellular/cellular/systems level can be a major cause for SNc cell loss in PD." Here, we propose a comprehensive computational model of SNc cell which helps us to understand the pathophysiology of neurodegeneration in PD. The proposed model includes a rich vein of molecular dynamics related to SNc neurons such as ion channels, active pumps, ion exchangers, dopamine turnover, energy metabolism, calcium buffering mechanisms, alpha-synuclein aggregation, Lewy body formation, reactive oxygen species (ROS) production, levodopa uptake, and apoptotic pathways. The proposed model was developed and calibrated based on experimental data. The influx of glucose and oxygen into the model is controlled, and the consequential ATP variation is observed. Apart from this, the dynamics of other molecular players (alpha-synuclein, ROS, calcium, and dopamine) known to play an important role in PD pathogenesis are also studied. The aim of the study is to see how deficits in supply of energy substrates (glucose and oxygen) lead to a deficit in ATP, and furthermore, deficits in ATP are the common factor underlying the pathological changes in alpha-synuclein, ROS, calcium, and dopamine. The model with its biophysical framework shows four regimes of ATP dynamics by varying glucose and oxygen: (A) Unperturbed (no change in

Basal ATP Concentration (BAC)), (B) adaptation (initial drop and a subsequent return to initial BAC), (C) no adaptation (initial drop and stabilized at a lower BAC) and (D) oscillating (BAC fluctuates). The model suggests that hypoglycemia plays a more crucial role in leading to ATP deficits than hypoxia. We believe that the proposed model provides an integrated modeling framework to understand the neurodegenerative processes underlying PD.

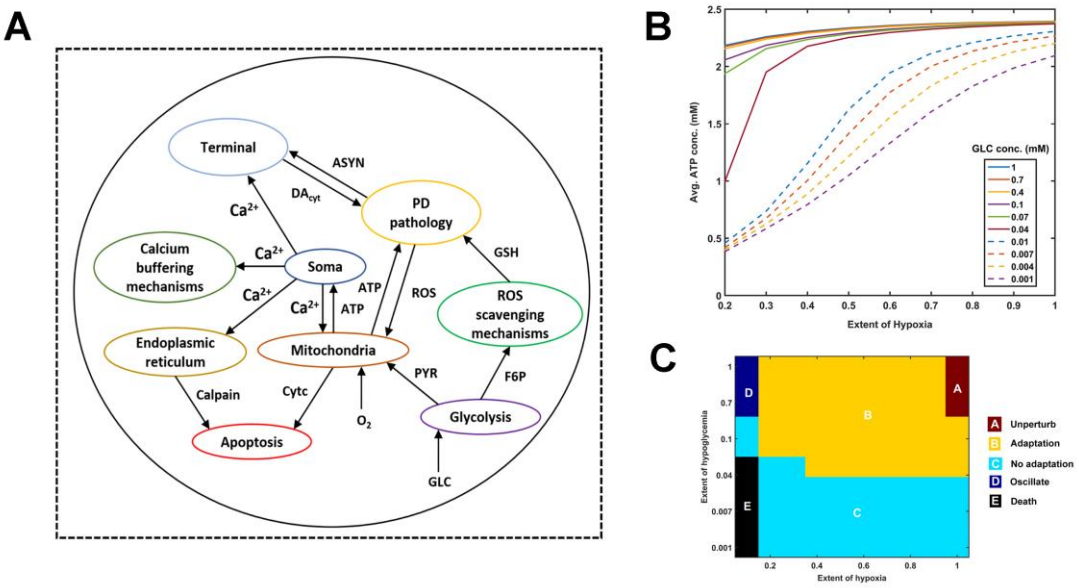

Figure 1 (A) Molecular pathways included in the proposed model of SNc neuron (B) Profile of available ATP for different glucose concentrations across the extent of hypoxia (C) Different model response regimes for the different extent of hypoglycemia and hypoxia.

Title: Computational modeling of neural activation during transcranial photothermal stimulation

Authors: *M. BHATTACHARYA, A. DUTTA;
Univ. at Buffalo, Buffalo, NY

Abstract: INTRODUCTION Transcranial Near Infrared Stimulation(tNIRS) has proved to be a powerful tool to modulate cortical excitability. Moreover, photothermal stimulation can be a powerful tool to map brain-wide networks [1]. We developed a computational model to investigate photothermal effects of tNIRS. METHODS Tetrahedral mesh was generated through Delauney Tetrahedralization from the MRI-based digital phantom of Colin27 head atlas. The computation of Finite Element Analysis on the tetrahedral mesh of the head model was performed to solve Radiative Transfer Equation by Diffusion Approximation at near-infrared wavelengths (630nm, 700nm, 810nm) coupled with Bioheat Transfer due to absorbed optical power. We stimulated at the Cz position at the scalp surface using a point source of light of power density 0.5mW/cm^2[2]. We derived the temperature profile across the layers of scalp, skull, CSF, Gray Matter, and White Matter along a line through Cz. To understand cortical excitability alterations, Hodgkin Huxley model of the pyramidal neurons needs to be simulated. RESULTS Temperature change at the gray matter did not show any significant increase to cause any neuronal excitability. We see a change of temperature of around 0.04 degree C, whereas, a change of around 1-2 degree C is suggested for changes in excitability [3]. DISCUSSION Longer wavelengths will be better choice for photothermal stimulation due to lower scattering and stronger water absorption.

Title: Multiplicative modulations enhance unique hue representation in V4

Authors: *P. MEHRANI, A. MOURAVIEV, **J. K. TSOTSOS**;
Electrical Engin. and Computer Sci., York Univ., Toronto, ON, Canada

Abstract: Which region in the brain represents unique hues is unknown. We introduce a hierarchical model inspired by neural mechanisms in the visual system for local hue representation and with computational simulations suggest that cells in V4 have the capacity to encode unique hues. Our network of single-opponent color and hue-selective cells differs from that of [1, 2] as it models cells in each of LGN, V1, V2, and V4 areas and explicitly reveals how the contributions of each participating area can lead to a hue encoding. Our network receives cone activations as input and gradually increases nonlinearities in terms of cone responses as observed by [3]. Specifically, single-opponent LGN responses are obtained by linearly combining cone activation. Half-wave rectification keeps V1 tunings similar to those of LGN cells [4] while nonlinear in terms of cone inputs. De Valois et al. [1] suggested that additive/subtractive modulation of cone-opponent cells with S-opponent cell responses rotates the cone-opponent axes to red-green and blue-yellow directions. To achieve this rotation in V2, in addition to single-opponent cells, we propose multiplicative modulations of V1 L- and M-opponent cell activations with V1 S-opponent responses. Multiplicative modulations increase nonlinearities and mix color channels. Moreover, unlike additive/subtractive modulations with little impact on tuning bandwidths, multiplicative modulations reduce tuning bandwidths. Finally, V4 responses are obtained by linearly combining V2 activations with weights determined based on tuning peak distances of V2 cells to the desired V4 neuron tuning peak. Our results indicate that multiplicatively modulated V2 cells play an important role in the representation of hues along intermediate directions in the MacLeod-Boynton diagram [5]. Similarly, these cells have substantial input weights compared to single-opponent V2 cells to V4 neurons selective to unique green and blue hues. Moreover, we observed a gradual decrease in distance of tuning peaks to unique hue angles reported by [6] from our model LGN to V4. Our results show that responses of our network neurons resemble those of biological color cells.

Title: The BEL model, a literature data-based approach with a new concept of target identification

Authors: *K. BORNEMANN[1], M. VON HEIMENDAHL[1], N. LAWLESS[1], T. SCHWEIKARDT[1], A. EMON[2], D. DOMINGO-FERNANDEZ[2], S. SPRINGSTUBBE[2], M. HOFMANN-APITIUS[2], B. HENGERER[1];

Abstract: Identifying new targets for therapeutic interventions is becoming more challenging. In order to manage an increasing portfolio of biomedical literature based data, we used a big-data approach, tied with an understanding of mechanistic aspects and the molecular basis of depression, a psychiatric disease. We have picked the Biological Expression Language (BEL) model for the identification of new targets and developed a prototype model of a psychiatric condition, focused on anhedonia, a core symptom domain of depression, combined with projection models and DTI/MRI data. We generated a matrix (platform), allowing the identification of new targets via novel interacting neuronal circuits in their functional context and environment. The core of the platform is a connectivity network viewer, consisting of nodes and edges (links, relations), which contains the relevant information from biomedical literature (PubMed) comprising citations, evidence and annotations, thereby revealing the linkage between nodes. The major challenge of this project was to define appropriate key and search terms to handle the huge number of potential abstracts and obtain the most relevant publications to code them as BEL language and integrate to the model. Our platform is composed of two additional modules, a brain projection and human brain connectome viewer, derived from functional neuroimaging of healthy persons. Both modules enable us to link maps of brain projections and connections with neuronal circuit functions from our core module, thereby revealing novel interaction partners that may otherwise have gone unnoticed. Our BEL model relies on the current PubMed knowledge base and requires regular new data entering to keep it up to date. In summary, we have generated a prototype of a combined gene to phenotype network, aimed at modeling a symptom domain, hosted in a matrix tool to identify new targets. The BEL model is also augmentable to other symptom domains and therapeutic indications.

Title: Model-based multivariate mapping of the visual hierarchy with image synthesis

Authors: *J. D. WAMMES[1], D. L. K. YAMINS[3], K. A. NORMAN[4], N. B. TURK-BROWNE[2]; [2]Psychology, [1]Yale Univ., New Haven, CT; [3]Stanford Univ., Stanford, CA; [4]Princeton Univ., Princeton, NJ

Abstract: Given the dramatic individual differences in neuroanatomy, the use of cognitive tasks as functional localizers remains an indispensable tool for neuroscientific inquiry. Localizers allow regions of interest for a particular cognitive function to be identified independent of both the experimental question and anatomical landmarks. Here, we present a novel functional localization approach, which attempts to employ features from convolutional neural networks (CNNs) to exhaustively map levels of complexity along the visual hierarchy. Our approach synthesizes sets of images — using a combination of deep dreaming and feature correlation optimization — wherein the features at all model layers match an experimenter-specified similarity structure, operationalized as the correlations between patterns of unit activity. In preliminary work, our aim was to target higher-order object-selective regions such as lateral occipital (LO) and inferior temporal (IT) cortex, by manipulating higher model layers. Pairs of images were synthesized using a CNN, pre-trained for object recognition. The pairs were matched in similarity at early model layers, while varying in later model layers coding for higher-order visual features. We validated the approach behaviorally by instructing participants to sort the synthesized images according to visual similarity. Model-defined visual similarity was significantly correlated with the resulting pairwise distances. We then selected eight pairs of images, varying parametrically in higher model-layer similarity, and participants viewed the images while being scanned using high-resolution fMRI. Patterns of voxel activity were extracted for each of the 16 images. A searchlight analysis revealed a reliable cluster in LO where neural pattern similarity tracked our predefined model similarity. Together these results

indicate that we were able to synthesize images to elicit a particular representational structure in a higher-order visual region. Although this image set manipulated similarity at only one layer and across only two images at a time, it is possible to synthesize entire representational spaces that are unique at every model layer. We are now conducting follow-up studies using fMRI to determine whether these synthesized representational spaces can be used to localize each consecutive level of visual complexity using just one set of images.

Title: An ultra-low complexity of the transcriptional profile of the human brain

Authors: *J. HUA, Z. YANG, T. JIANG, S. YU;
Inst. of Automation, Chinese Acad. of Sci., Beijing City, China

Abstract: The transcriptional profile of the human brain is a complex structure with the orchestrated expression of tens of thousands of genes. Previously we demonstrated that the complexity of genes' expression patterns can be reduced from exponential ($\sim 2^N$) to polynomial ($\sim N^2$). In this work, we aimed to examine if an even lower dimensional space with linear ($\sim N$) complexity can represent the transcription patterns observed in the human brain. To this end, we analyzed microarray transcription data from Allen Institute, obtained from 6 subjects, in over 3000 sites distributed across the human brain cortex. Specifically, three properties of the gene expression pattern were utilized: 1) the mean expression rate of individual genes (MR), i.e., the proportion of brain regions in which a specific gene expresses actively; 2) the distribution of population expression rate (PR), i.e., the proportion of actively expressing genes in a specific brain area; and 3) the coupling of each gene to the whole genome (CG), which measures the correlation between single gene's expression and that of the whole genome. We found that the three properties can accurately predict the transcription profile of the whole genome, which reduced the complexity of the transcriptional profile of human brain to ~N. In addition, we also found that CGs played an important role in predicting the pair-wise interaction between genes and were diverse across different genes. High/low CG genes, i.e., genes strongly/weakly coupled with the whole genome, tended to have different biological functions, with high CG genes more involved in signal transduction and low CG genes more associated with DNA binding. Together, we revealed an ultra-low dimensional space that determines the transcriptional profile of the

human brain, which provides new insights into how transcription of tens of thousands of genes is orchestrated in the human brain.

Title: Contribution of noise, chaos and network topology to the emergence of multi-stable dynamics in neuronal networks

Authors: ***P. ORIO**[1,2], C. CORONEL[2], J. PALMA-ESPINOSA[2], M. GATICA[2], S. CASTRO[2]; [1]Inst. de Neurociencia, Univ. De Valparaiso, Valparaiso, Chile; [2]Ctr. Interdisciplinario de Neurociencia de Valparaiso, Univ. de Valparaiso, Valparaiso, Chile

Abstract: Multi-stable behavior of the brain dynamics is actively being studied as a landmark of ongoing ('resting') cerebral activity, reported in both fMRI and M/EEG recordings. This consists on a continuous switching between different partially synchronized states, in the absence of external stimuli. Multi-stability is thought to be an important mechanism for dealing with sensory novelty and to allow for efficient coding of information in an ever-changing surrounding environment. There is some understanding about how network topology, connection delays and noise can contribute to building this dynamic, but a systematic exploration of the interplay between these factors is still missing. We are studying the emergence of dynamical Functional Connectivity (dFC) in simulations of biophysically inspired neurons and neural masses, characterizing how local chaotic and stochastic influences the switching between different network states, and how this interacts with topological features. We calculate the Functional Connectivity (FC) matrices that describe the pair-wise phase synchronization or correlation in a moving window fashion. Then, the FCs are compared by angular distance to obtain the Functional Connectivity Dynamics (FCD) matrix and clustered into states. In deterministic simulations, the networks show multi-stable dynamics in a certain range of global connectivity strength and. When the network is composed of nodes that have chaotic dynamics, we observe a richer dFC with more and more diverse states. We also characterized the multi-stable dynamics when the networks are, in addition to chaotic, subject to ion channel stochasticity in the form of

multiplicative (channel) or additive (current) noise. Moderate noise can enhance the multi-stable behavior that is evoked by chaos, resulting in more heterogeneous synchronization patterns, while more intense noise abolishes multi-stability. In networks composed of nonchaotic nodes, moderate noise can induce multi-stability in an otherwise synchronized, nonchaotic network. Finally, we are studying how the effects of noise and chaos are maintained under different network topologies, including the Structural Connectivity of the Human Connectome. Preliminary results show that Small-World Networks sustain the multi-stability in a larger global coupling range. However, the Human Connectome contains a core of nodes that facilitate the appearance of multiple states, enabling a richer dynamic. Our results aim towards understanding the origins of the dFC, enabling a fine tuning of the dynamics in artificial systems and dealing with neuropathologies associated to the disruption of dFC.

Title: Semibalanced networks and inhibitory plasticity implement nonlinear computations

Authors: *C. BAKER[1], R. ROSENBAUM[2];
[2]Applied and Computat. Mathematics, [1]Univ. of Notre Dame, Notre Dame, IN

Abstract: Recent work in modern computational neuroscience has focused on replicating the properties of artificial neural networks (ANNs) using purely biophysical principals. Many of these studies prioritize adapting ANN architectures to account for spiking dynamics and firing rates as a first top-down approach to making biologically realistic ANNs. Instead, we take a bottom-up approach starting from a biologically realistic network of sparse, recurrently connected adaptive exponential integrate-and-fire neurons (AdEx) in an asynchronous irregular state with balanced excitation and inhibition. We show how simple ANN architectures may be explicitly instantiated in terms of subpopulation averaging, and how more complex self-generating activation functions can arise from strong heterogeneous external input patterns. These patterns naturally lead to inflation in the number of non-spiking neurons, but maintain balance within the spiking portion of the population, hence leading to a semi-balanced operational state. We then show how combining these networks with well-established inhibitory synaptic plasticity (ISP) stabilizes the firing rate activity of the network in response to familiar

stimuli, as well as creating a mechanism of surprise detection.
For comparative analysis, we show how to utilize these methods to solve classification problems involving nonlinear computations such as the exclusive OR (XOR) operator, radial basis transformations, as well as their analogues in higher-dimensional spaces. We then hedge the performance of our biological networks against true ANNs with identical numbers of computing units and layer structure. Our comparison shows that such biologically realistic networks can indeed impart high-quality nonlinear computational power on par with fully-connected ANN structures.

Title: Hierarchical levels of predictive coding play different roles in second-language learning

Authors: *Z. TANG[1], K. ZHOU[2], W. HE[3], M. XU[1];
[1]Shenzhen Univ., Shenzhen, China; [2]Beijing Normal Univ., Beijing, China; [3]Educational Res. Ctr. of Nanshan Educ. Bureau, Shenzhen, China

Abstract: A considerable amount of literature has indirectly investigated the link between language learning and predictive coding accounts through beta and gamma oscillatory neural dynamics. However, it remains unclear as to how predictive coding processing directly affect language learning, and no previous study has investigated the different impact of predictive coding processing between first-language learning (Chinese) and second-language learning (English). To answer these questions, we adopted behavioral measure (associative learning task) and computational modeling in primary school children (n = 67) in the present study. Behavioral measurements indicated that the higher second-language learning level, the bigger the surprise, but the correlation of first-language learning level and surprise were not significant. A hierarchical Bayesian model suggested a positive correlation between the perceptual parameter ω_2 at the second level and second-language learning level, but not first-language learning level. The perceptual parameter ω_3 at the third level were not significantly correlated with those two languages learning level. To further examine the effect of predictive coding processing, the subjects were divided into high and low achievement groups according to their second-language

learning level. We found that the low achievement group updated the learning rate at the third level more than the high achievement group. This result is similar to that of autism study. This study offers insights into the behavioral, algorithmic mechanisms in the relationship between predictive coding processing and language learning and the different impact of predictive coding processing between those two languages learning.

Title: An autoregressive mathematical model for reproducing neuronal responses with respect to various types of spiking

Authors: *S. HIRAI[1], A. MASAOKA[3], T. KOHAMA[2];
[1]Kindai Univ., Wakayama, Japan; [2]Kindai Univ., 930 Nishimitani, Kinokawa, Wakayama, Japan; [3]Tamagawa Univ., Machida, Japan

Abstract: Higher-order brain functions such as visual cognition are extremely complex. Recent studies have shown that constructive approaches help understand such brain mechanisms. Masaoka & Kohama described a neuron network model that reproduces the attentional modulation in several brain regions using an autoregressive mathematical representation (Masaoka & Kohama, 2018). This model is configured with several functional units that correspond to specific brain regions. These regions are constructed by networks of many individual neurons. However, the Masaoka & Kohama model is a macroscopic expression of the regional brain activity and does not include individual neuronal responses. In this study, we proposed a modified Masaoka & Kohama model to reproduce various types of spiking of individual neurons that could share mathematical expressions between macroscopic and microscopic brain functions. We modified the Masaoka & Kohama model for the following three functions: (1) delay in the connection between neurons, (2) self-inhibition to reduce the firing rate of spikes, and (3) spiking probability at a certain time, which controls the firing rate of each neuron. We compared the output of our model to that of the Izhikevich model, which shows high reproducibility of neuronal responses. The results showed that our model sufficiently reproduces the various spiking responses of neurons. The responses of the proposed model were compared to the outputs of the Izhikevich model (Izhikevich, 2003), which showed high reproducibility of neuronal responses with respect to the following types of spiking: regular, fast, low-threshold, intrinsically bursting, and chattering. The results showed that the proposed model reproduced the

outputs of the Izhikevich model, which suggested that our model was also able to reproduce the various types of neuronal responses.

Title: A rapid online learning network derived from biological olfaction

Authors: *A. BORTHAKUR[1], T. A. CLELAND[2];
[1]Computat. Biol., [2]Psychology, Cornell Univ., Ithaca, NY

Abstract: The mammalian olfactory system learns from very few examples, presented in unpredictable online sequences, and then recognizes these learned odors under conditions of substantial interference without exhibiting catastrophic forgetting. Moreover, it achieves this performance despite encountering odorant stimuli at widely differing concentrations and in unpredictable backgrounds. This combination of properties - particularly the capacity for rapid, online, lifelong learning - to date has not been matched by artificial systems. We here present a spike timing-based network model based on the architecture and functionality of the mammalian olfactory bulb that exhibits rapid, online learning of arbitrary high-dimensional input vectors (such as odorants) and, based on very small training sets, recognizes and classifies test inputs across concentrations and in the presence of substantial interference. A limitation of conventional computational neuroscience modeling in this context is that networks typically are presented with problems that are already recognized, thereby neglecting the potential problem of overfitting. To counter this, we tested the network with data gathered from physical sensor systems, including gas sensor arrays (machine olfaction), hyperspectral cameras, and the acoustic features of anuran calls. These datasets include challenges such as sensor drift, hierarchical classifications, unknown within-groups variance, changing environments, and unpredictable odorant concentrations. To enable a single instantiated network to perform well under these diverse conditions - a challenge termed “learning in the wild” - we developed a series of preprocessors and heterogeneities that condition diverse sensory inputs into a regularized statistical structure. Interestingly, one critical signal conditioning step depended on the indirect

afferent excitation of mitral cells via external tufted cells; this network motif may present a solution to a previously unrecognized sensory sampling problem in the biological system. Thus, in addition to its performance characteristics as an artificial system, this multi-layer network serves as a computational model embedded in the wild, enabling assessment of the in vivo utility of fast oscillatory dynamics, spike timing regulation, and the architectures of olfactory bulb network connectivity and plasticity motifs.

Title: Exploring the redundancy of resting-state functional network connectivity

Authors: *K. M. OUDYK, Z. QI, R. MARKELLO, E. DUPRE, B. MISIC, J. POLINE; Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada

Abstract: INTRODUCTION
Investigating the features of resting state networks can help elucidate the functional organization of the brain. Here, we explore the redundancy of resting state networks, in order to determine whether there is redundancy and if so, what is the nature and location of the redundancy.
METHODS
To this end, we applied the Yeo resting-state functional networks [1] to functional Magnetic Resonance Imaging (fMRI) on 69 subjects [2]. We calculated the mean functional connectivity of each set of within- and between-network connections (from now on, 'connections'), and then explored the predictability and predictive role of each connection using general linear models with leave-one-out prediction on connections.
RESULTS AND DISCUSSION
Within-network connections were generally better predicted by between-network connections than by other within-network connections. Further, we found strong reciprocality in the

predictive roles of pairs of connections, that is, connection AB's role in predicting CD was similar to CD's role in predicting AB. However, this reciprocality decreased with increasing strength of the predictive roles. Further, reciprocality was related to the nature of the pair of connections: to whether the pairs share a network and whether the connections are within- or between-network connections. For example, a network's connection to another network was more predictive of it's within-network connectivity than vice versa. This was particularly the case for some connections between higher- and lower-level networks and connections within lower-level networks. For example, the dorsal attention & visual networks' connection was more predictive of the visual-visual within-network connection than vice versa. This top-down resemblance will be discussed in the context of other known characteristics of the resting state networks.

Title: Deep learning based activity recognition of daily livings with wearable sensors for stroke survivors and non-disabled controls

Authors: *S. KIM[1], Y. SHIN[1], S.-A. CHOI[1], J. LIM[2], Y. OH[3];
[1]Physical Therapy, Jeonju Univ., JeonJu, Korea, Republic of; [2]Dankook Univ., Youngin, Korea, Republic of; [3]Neurosci., Samsung Electronics, Suwon, Korea, Republic of

Abstract: Individuals with stroke often show decreased use of the more-affected arms even if they have capability to use them. Recently, to assess real-world use of the more-affected arm, wearable sensors such as accelerometers or mobile devices have been widely used, and the success of these wearable devices depends on accuracy of recognizing daily activities of individuals with stroke. Previous research on human activity recognition has suffered from inaccuracy and inability to generalize a trained model due to various factors, such as insufficient data and not fine-controlled design of activities that often includes only gross movements, such as walking, jumping, or sitting. Here in this study, we attached five inertia measurement units on

subjects' upper extremity and trunk, and collected data from thirty young non-disabled subjects and ten individuals with stroke while they performed eighty daily activities of living including washing dishes, folding tower, and applying make-up lotions, etc. Each activity was segmented and labeled manually, and then the labeled data was trained in deep-learning based models for activity classification. We applied techniques to improve cross-subject generalization including data augmentation and transfer learning. Our model showed that applying deep learning methods improves accuracy of activity recognition of daily living for both non-disabled subjects and stroke survivors. Our work can be applied to generate a daily and/or weekly activity profile of patients, analyze patterns of habitual use of the upper extremity in post-stroke, and provide online visual or tactile feedback if they do not use their more-affected arms and hands for various daily activities.

Title: Biophysical model of IL-BLA network to study DBS-induced changes in theta coherence

Authors: *Z. CHEN[1], Z. CHEN[2], F. FENG[1], E. BLACKWOOD[3], M.-C. LO[3], A. S. WIDGE[3], S. S. NAIR[1];
[1]Electrical & Computer Engin., [2]Electrical Engin. and Computer Sci., Univ. of Missouri Columbia, Columbia, MO; [3]Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Neurostimulation is increasingly used as a treatment for neuro-psychiatric disorders. This direct brain intervention is thought to function at a network level. From invasive deep brain stimulation (DBS) to low-energy interventions such as transcranial electrical stimulation, applying energy to a brain region changes not just that target, but a broad network of regions coupled to the target. Further, a major effect of stimulation appears to be changes in neural synchrony, i.e. the coordinated firing of neural ensembles within and between brain regions. Synchrony is often reflected in the presence of oscillatory activity in the electro-encephalogram or local field potential (LFP), in consistent oscillatory phases (coherence) between regions, and nesting of oscillations (cross-frequency coupling) within regions.
The Widge laboratory recently demonstrated stimulation approaches that specifically affect networks. Electrical pulse sequences were shown to increase or decrease both frequency-limited coherence and broad-band synaptic connectivity between brain regions, without changing oscillatory power or other intrinsic features of the individual regions. The effects are repeatable within and across subjects and lasted for hours after stimulation offset.

We developed a scaled down 1680-cell detailed biophysical computational model of the basolateral amygdala (BLA) and the infralimbic cortex (IL) using biological estimates of connectivity and synaptic neurophysiology. Background input is used to match baseline *in vivo* firing rates and LFP. A module for realistic electrical stimulation is being developed for incorporation into the overall *in silico* framework. As a parallel study, plasticity is selectively 'dialed-in' into suitable model IL and BLA synapses to mimic stimulation effects and explore post-stimulation synaptic weight configurations that might replicate *in vivo* post-LFP data. The model can thus assist with screening of multiple hypotheses related to the contrasting effects of *in vivo* stimulation on synaptic potentiation and on inter-regional theta coherence between IL and BL. Preliminary results indicate that modest changes in synaptic weights between excitatory IL and BLA connections can explain the alteration of *in vivo* single-pulse evoked potential response (ERP) in BLA from stimulation in IL. However, potentiation of solely excitatory model synapses in IL and BL could not reproduce the changes in theta coherence found post-stimulation in *in vivo* studies. This suggests that differential plasticity, including of the inhibitory type may be needed, and a systematic evaluation of such scenarios is the focus of on-going studies.

Title: *In vivo* swine model for developing and validating acoustoelectric brain imaging: Towards noninvasive, real-time 4D electrical brain mapping

Authors: C. WILHITE, A. ALVAREZ, A. BURTON, C. PRESTON, D. MUSTACICH, A. FUGLEVAND, K. GOTHARD, S. COWEN, ***R. S. W. WITTE**;
Univ. of Arizona, Tucson, AZ

Abstract: Our vision is to develop a noninvasive technique for electrical mapping of the human brain at higher resolution than electroencephalography. Acoustoelectric (AE) brain imaging (ABI) uses pulsed ultrasound to transiently modulate tissue resistivity and can be used to map current densities in 4D and at high spatial and temporal resolutions (millimeter, millisecond).

This study describes a setup for developing and validating ABI in the somatosensory cortex of swine *in vivo*. Following craniotomy, the right or left snout was electrically stimulated (100 µs pulse at 0.5 Hz, 1-15 mA) using two, horizontally spaced needle electrodes (2-3 cm separation) while evoked activity across the contralateral rostrum somatosensory area was mapped with a 16-channel electrocorticography array. The stimulating electrode pair was repeatedly inserted along the dorsoventral axis of the snout (1 cm increments, 5 sites) to create a somatotopic map of activation across the cortical rostrum area. Surface electrophysiological mappings revealed strong evoked potentials (0.2-0.9 mV peak) that were spatially confined (5-55 mm^2 FWHM) to the area of cortex represented by the receptive field of the stimulation site. Consistent with similar topographic studies, dorsal to ventral stimulation of the snout corresponded to a caudal to rostral progression of activation across the rostrum somatosensory cortex. In a separate experiment, evoked EEG signals were also detected across the skull and scalp. We then integrated our custom ABI platform with ultrasound transducer (0.6 MHz) placed over somatosensory cortex to generate AE signals during snout stimulation for current density reconstruction. ABI displayed concentrated current densities at the rostrum somatosensory area after snout stimulation with spatial and temporal correlations between evoked potentials and AE signals. Using this model, we are capable of evoking robust, scalable, and spatially selective neuronal currents in pigs for quick and reliable *in vivo* testing of ABI in large animals. This initial study (n = 4 pigs) is an important step towards validating ABI for noninvasive, high-resolution electrical mapping of the human brain to help diagnose, monitor, and treat a variety of neurological conditions with electrophysiological signatures.

Title: Human brain-to-brain entanglement states during eye contact

Authors: *R. LEE;
Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY

Abstract: INTRODUCTION: Human eye contact induces mutual perceptions and mentalization [1]. Such interactions may yield the correlated dyadic brain states. Some of these states may only co-exist in the dyadic minds - the state changes in one brain result in simultaneous changes in another. Although the monadic perspectives of eye contact have been

widely studied, its dyadic perspectives of the co-dependent brain-states just emerged recently [2]. Computationally speaking, these dyadic brain states may or may not be decomposed to two monadic brain states. Borrowing a concept from quantum communication [3], these non-decomposable states may represent bi-partite entanglement states. **METHOD**: To describe a dyadic fMRI experiment [4] in quantum formation, two individual brain's correlation matrices among their activated parcellates can be orthogonalized by PCA and form two Hilbert spaces (A and B) respectively. The Hilbert space C for the coupled brains can be generated from the tensor product of the A and B. Meanwhile, the overall dyadic activation can be further decomposed into independent components which represent different communication channels during eye contact. For each channel, the density matrix of dyadic brains was empirically derived from the distance correlation matrix of the time series of dyadic activation vertices in Hilbert space C. Based on each channel's density matrix, (1) its quantum discord [3] can be computed; (2) its quantum computational circuits can be modeled using Monte Carlo method. **RESULTS:** As the average results from 19 dyadic datasets, the ten channels' quantum discords are 0.0, 0.82, 0.8, 2.3, 0.44, 1.28, 1.16, 1.34, 0.05, and 0.73 qubit respectively. Also, the circuit model in one channel reveals OR-XOR logic. Both results suggest entanglements in some dyadic brain states during eye contact. **CONCLUSIONS**: This is the first experimental evidence that the dyadic brain entanglement states exist during eye contact, which could offer an unprecedented method to quantify human social interaction and communication. **REFERENCES:** [1] Itier, R. et al, Neuroscience and Biobehavioral Review (2009) 33, 843. Title: Optimal force production via flexible neural control of motor units

Authors: *N. J. MARSHALL, L. ABBOTT, M. M. CHURCHLAND;
Neurosci., Columbia Univ., New York, NY

Abstract: Roughly 10^2–10^3 motor units (MUs) control each muscle, providing myriad ways to generate a particular force profile. Nevertheless, MUs are believed to obey an orderly recruitment process, the 'size principle' (SP), wherein small MUs are recruited before larger MUs. Intriguingly, several studies report deviations from the SP during dynamic movements, but whether such deviations represent instances of a broader phenomenon remains unclear. We used mathematical optimization to develop predictions regarding optimal MU recruitment strategies. We tested those predictions using a new experimental paradigm and novel spike-sorting methods. Finally, we asked whether cortical recruitment of MUs extends beyond the single degree of freedom associated with the SP.

Predictions were derived from the recruitment strategy that best matched actual force to desired force. We modeled an idealized motor pool of five MUs of varying size. As observed empirically, larger MUs had briefer twitch responses. Optimization predicted that recruitment should obey the SP for steady forces, but deviate from the SP for rapidly changing forces. Specifically, there should be preferential recruitment of larger MUs, whose briefer twitch responses are better suited for rapid force fluctuations.

We trained a monkey to generate a variety of force profiles (steps, ramps, sinusoids, and chirps) via isometric contractions of the anterior deltoid, whose activity we recorded using 8 modified percutaneous electrodes. We leveraged Bayesian nonparametrics and optimal filtering to decompose EMG into the spike times of single MUs. For steady forces, MU activity lay on a 1-dimensional nonlinear manifold (as predicted by the SP), but departed from this manifold for higher frequency (>1 Hz) forces. MU activity in both steady and dynamic regimes were consistent with our model.

Our theoretical and empirical results suggest that MU recruitment depends both on instantaneous and future force commands. The need to consider the future suggests supra-spinal structures may play a role in recruitment. To test this, we used microstimulation of sulcal motor cortex, via a 32-channel linear array, combined with simultaneous EMG recordings as described above. Microstimulation produces artificial activation under experimenter control, yielding the potential to reveal degrees of freedom that are available but rarely used, and might be difficult to otherwise observe. We found that stimulation recruited MUs in ways that often deviated from the 1-dimensional manifold observed during steady force production. Thus, MU recruitment is flexible, force-profile specific, and can be influenced by descending control.
