Title: The systemic administration of histamine H_1 receptor antagonist chlorpheniramine to pregnant rats impairs offspring nigrostriatal dopaminergic innervation and function

Authors: *B. M. VALADEZ[1], G. AQUINO-MIRANDA[2], M.-O. QUINTERO-ROMERO[3], H. PAPACOSTAS-QUINTANILLA[1], C. LOPEZ-RUBALCAVA[4], N.-F. DÍAZ-MARTÍNEZ[3], J.-A. ARIAS-MONTANO[5], A. MOLINA-HERNÁNDEZ[3];

Abstract: The dopaminergic and histaminergic systems are the first to appear during central nervous system development. During embryo development histamine increases deep cortical layer neurogenesis through H_1 receptor (H_1R) activation, while reducing the dopaminergic phenotype in the ventral mesencephalon. Furthermore, the intrauterine or systemic injection of the H_1R antagonist/inverse agonist chlorpheniramine, decreases FoxP2 cortical phenotype neurons at embryo day (E) 14, and increases the dopaminergic markers tyrosine hydroxylase (TH) and Pitx3 in the ventral mesencephalon at E16. Although the short-term effect of histamine and H_1R pharmacological blocking has been reported, the postnatal functional implications have to be stablished. To do so, here the H_1R antagonist/inverse agonist chlorpheniramine was systemically administered (5 mg/kg, i.p.) to pregnant Wistar rats from gestational days 12 to 14 and, male and female offspring were evaluated at postnatal day 21 for changes in nigro-striatal innervation and function. The administration of chlorpheniramine to pregnant rats promotes a decrease in TH-immunoreactivity in the substantia nigra pars compacta (SNpc) and dorsal striatum in 21-day-old offspring compared to the controls. The reduction on TH correlates with 26 % lesser TH^+ cells in the SNpc, with a substantial increase of 77 % in ectopic TH^+ cells, compared to control animals. Furthermore, the striatal dopamine content and depolarization-evoked [^{3}H]-dopamine release in the striatum were reduced in pups of chlorpheniramine-treated rats. To explore if the changes observed in 21-day-old pups may have functional relevance, total motor activity was evaluated in an open field under basal and metha-amphetamine stimulated

dopamine release. Interestingly, the motor activity of stimulated pups of chlorpheniramine-treated rats was decreased. These results in addition to the increased dopamine neurogenesis reported by chlorpheniramine at embryo stages, suggests that the impaired nigro-striatal innervation and function may be due to migration defects of the dopamine neurons during embryo development to correctly form the SNpc. This information may have clinical relevance since first-generation antihistamine drugs are still used during pregnancy.

Title: Mismatched Sox: differential partner proteins & downstream targets of Sox11 in neural development

Authors: *K. S. SINGLETON[1], P. SILVA RODRIGUEZ[2], E. M. SILVA[2];
[1]Interdisciplinary Program in Neurosci., [2]Biol., Georgetown Univ., Washington, DC

Abstract: Neural development involves the progression of proliferating cells to mature neurons in order to form a complete and precisely functioning central nervous system. Transcription factors (TFs) maintain the balance of proliferating and differentiating cells, and Sox TFs, in particular, are key regulators of neural development. Along with partner proteins, Sox TFs control the production, differentiation and maturation of cells in the nervous system. Sox11, a member of the SoxC family, has been shown to play a critical role in every step of neural development including: establishment of neuronal identity, promotion of neural differentiation, and axon development. Deficits in Sox11 function have been linked to various neurodevelopmental disorders, focal temporal lobe epilepsy and malformations in the neural tube, cortex and spinal cord. However, little is known about the molecular mechanism underlying Sox11 function. Our previous work revealed that despite high evolutionary conservation and similar temporal and spatial expression, *Xenopus laevis* (frog) and *Mus musculus* (mouse) Sox11 cannot substitute for one another in neuronal differentiation. To further investigate the cause of this functional difference, we us co-immunoprecipitation to identify partner proteins that directly bind frog Sox11. In parallel, we performed RNA-seq to identify novel Sox11 targets during neurogenesis. Our results indicate that frog and mouse Sox11 partner

with different proteins and regulate different downstream targets in order to promote neuronal differentiation. Additionally, by using Sox11 deletion constructs, we were able to establish which domains are necessary and sufficient for Sox11 function during neural development. Collectively, this data demonstrates how Sox11 function, but not mechanisms, is evolutionarily conserved in the process of neural development.

Title: Possible implication of histamine H1 receptor on impaired motor cortex cytoarchitecture and function in diabetic rat offspring's

Authors: *R. VALLE-BAUTISTA[1,2], G. HERRERA-LOPEZ[3], E. GRIEGO-MELO[3], E. GALVÁN[3], N. DÍAZ[1], J. ARIAS-MONTAÑO[2], A. MOLINA-HERNÁNDEZ[1];

Abstract: Gestational diabetes mellitus has been related to cognitive dysfunction in children, probably due to impaired neocortical embryo development. In rodents maternal diabetes decreases proliferation and increases differentiation during early corticogenesis. Interestingly, histamine H_1 receptor (H_1R) regulates the differentiation of FoxP2 projection neurons in the deep layers V and VI, and is overexpressed in the cortical neuroepithelium of embryos from diabetic rats at E12, its ligand is also increased at E14. The above suggests that changes in the transitory histaminergic embryo system under high glucose may be involved in the increased deep layers neurogenesis that will lead to postnatal changes in the cytoarchitectonic pattern. The aim of this study was to evaluate the effect of maternal hyperglycemia on postnatal motor cortex cytoarchitecture and function, and under this condition to evaluate the effect of embryos exposure to an H_1R antagonist. Hyperglycemia was induced by a single intraperitoneal injection of streptozotocin to pregnant rats at day 5 of gestation for the diabetic experimental group (Db), while buffered citrate solution was administrated to the control (Ctrl), the Db group was further divided in chlorpheniramine-treated and non-treated animals. Offsprings were sacrificed at postnatal days (P) 0, 5 and 21, and the frontal cerebral cortex was obtained to evaluate HA

content and H_1R density, by ELISA and binding assays respectively. The laminar localization of H_1R, reelin and Satb2 was evaluated by immunofluorescence, while the expression of *H_1R*, *FoxP2* and *Tbr1* was evaluated by qRT-PCR at P0. Furthermore, P21 cortical cytoarchitecture was assessed using Golgi-Cox stain and the functionality of pyramidal neurons was evaluated by electrophysiology. Results at P0 showed that the neonates from diabetic rats presented significant increases in *H_1R*, and in the deep cortical markers *FoxP2* and *Tbr1*, as well as, altered reelin and Satb2 laminar expression. Interestingly chlorpheniramine from E12 to E14, prevented the changes in *H_1R* and *FoxpP2*, observed at P0 in the diabetic group. Important changes were also observed in P21 pups from diabetic rats, such as: increased HA content, decreased dendritic complexity, alterations in cell polarity, and changes in passive and active electrophysiological properties of projection neurons. Overall, our results suggest that maternal hyperglycemia during corticogenesis affects postnatal motor cortex cytoarchitecture and function, and suggest a possible participation of that H_1R and HA in early neuronal differentiation and migration in cerebral cortex development in health and disease.

Title: The transcription factor Sp9 represses the identity of the D1 MSN and promotes the identity of the D2 MSN in the striatum

Authors: *H. DU, Z. LI, Z. XU, Y. YOU, Z. ZHANG, Z. YANG;
State Key Lab. of Med. Neurobiology, Inst. of Brain Sci., Fudan Univ., Shanghai, China

Abstract: Striatal medium-sized spiny neurons (MSNs), composed of striatonigral dopamine receptor DRD1-expressing neurons (D1 MSNs) and striatopallidal dopamine receptor DRD2-expressing neurons (D2 MSNs), are derived from radial glial cells in the ventral lateral ganglionic eminence (LGE). Previously, *Sp9* constitutional and conditional loss-of-function analyses demonstrate that *Sp9* is required for the development of D2 MSNs in the striatum. Here, *Sp9* conditional gain-of-function analyses show that SP9 represses the identity of the D1 MSNs and promotes the identity of the D2 MSN. We generated a Sp9 conditional overexpression (*Rosa-Sp9-OE/+*) line, in which Sp9 expression is triggered by mating *Dlx5/6-Cre-ires-EGFP* (*Dlx5/6-CIE*) or *Sp9-Cre* driver lines. Upon Sp9 is overexpressed in the LGE, we observed that the expression of D1 MSN marker genes, such as Drd1 and Tac1, was greatly downregulated, whereas the expression of D2 MSN marker genes, such as Drd2 and Adora2a, was upregulated.

In *Dlx5/6-CIE; Rosa-Sp9-OE/+* or *Sp9-Cre; Rosa-Sp9-OE/+* mice at P20, we observed that most D1 MSNs have become D2 MSNs. RNA-Seq analysis confirmed this observation. Finally, using ChIP-Seq analysis, we show that SP9 directly binds to the promoter and/or enhancers of MSN-enriched genes, such as *Bcl11a, Bcl11b, Gad1, Gad2, Foxp1, Foxp2, Ebf1, Isl1, Drd1, Tac1, Drd2, Gpr88, Grik3, Ptprm, Nt5e,* etc. Thus, Sp9 is crucial for the development of both D1 and D2 MSNs.

Title: Trim71 links an ancient microrna pathway to neural stem cell development and human congenital hydrocephalus

Authors: *D. Q. PHAN[1], S. WEISE[3], B. JUX[3], E. LAKE[1], L. T. FERNANDEZ[3], Y. YANG[1], D. FOSTER[4], F. SLACK[4], T. CONSTABLE[1], H. LIN[1], W. KOLANUS[3], K. KAHLE[2];

Abstract: Congenital hydrocephalus (CH), the most common brain malformation that affects 1:1000 live births, remains poorly treated owing to incomplete understanding of disease pathogenesis. Identification of novel CH disease genes is a powerful approach to understanding the molecular genetics of CH. Whole exome sequencing in humans has identified *TRIM71* as a *bona fide CH* disease gene. Trim71 is the major target of the ancient *let-7* pathway that famously regulates cell differentiation and organismal development via microRNA-mediated gene silencing in *C. elegans*. Previous works have implicated Trim71 in the regulation of embryonic neural stem cell (NSC) fate, yet its cellular and molecular function in NSCs remain poorly understood. To gain a better understanding of *Trim71* as a paradigm of neural stem cell involvement in CH, we have generated a mouse model that harbors the point mutation in *Trim71* that results in human CH (R595H) using CRISPR-Cas9. We found that a subset of mice

heterozygous for the *Trim71* R595H mutant allele developed severe communicating hydrocephalus with accompanying macrocephaly by four weeks of age. Mice homozygous for the mutant allele were embryonic lethal and exhibited profound neural tube by embryonic day 9.5. Investigation into the function of *Trim71* and its CH-causing mutations using our novel mouse models presents outstanding opportunities to increase understanding of human NSC regulation, brain development, and CH pathogenesis.

Title: R-loops as mechanisms governing neural differentiation and cell-type specific transcription

Authors: *E. A. LAMARCA[1], S. ESPESO-GIL[2], N. M. TSANKOVA[1], K. BRENNAND[2], S. AKBARIAN[2];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Schizophrenia, bipolar disorder, and major depression together affect over 16% of the worldwide population, but their etiologies are poorly understood. Gene expression variation is a common attribute of these disorders, so research to identify and target aberrant mRNA regulation may provide novel therapeutic benefit. mRNA can anneal to template DNA during transcription, forming a DNA/RNA hybrid known as an R-loop. New genome-wide mapping strategies have identified a connection between R-loops and transcriptional regulation, suggesting a role for R-loops in gene expression variation. However, R-loops have never been characterized on a genome-wide scale in human brain cells, precluding research exploring their role in neuropsychiatric illnesses. Here, using DNA/RNA immunoprecipitation followed by deep sequencing (DRIP-seq), we show that R-loops are abundant in human neural cells and display a distinctive distribution relative to non-neural cells. We find evidence that R-loops may be poising genes for transcription, particularly those genes involved in neural differentiation and cell type-specific function. We predict that aberrant R-loop regulation may be involved in the pathophysiology of neuropsychiatric illness, and our future studies will test this hypothesis by

directly manipulating R-loop formation and examining the phenotypic consequences in neural cells both in vitro and in vivo.

Title: Classification, diversification and maturation of mouse retinal ganglion cells using single-cell transcriptomics

Authors: *K. SHEKHAR[1], I. E. WHITNEY[2], W. YAN[3], Y.-R. PENG[4], X. ADICONIS[1], J. Z. LEVIN[1], A. REGEV[1], J. R. SANES[5];
[1]Broad Inst. of MIT and Harvard, Cambridge, MA; [2]Mol. and Cell. Biol., [3]FAS, [4]Ctr. for Brain Science, Dept. of Mol. and Cell. Biol., [5]Harvard Univ., Cambridge, MA

Abstract: Retinal ganglion cells (RGCs) represent a diverse class of neurons, all of which project axons through the optic nerve and communicate distinct visual features to the rest of the brain. Using high-throughput single-cell RNA-seq (scRNA-seq), we profiled >35,000 RGCs from adult mice (post-natal day 56, or P56) and assembled a comprehensive atlas of this class, identifying 45 molecularly distinct types. We used histological approaches to match molecular identity to morphology for many types, and to validate new markers for known types. We next investigated the diversification RGCs by profiling them at 4 developmental timepoints, from embryonic day (E) 14, when they are newly postmitotic, through P5. Using the mathematical framework of Optimal Transport (OT) (Schiebinger et al., Cell, 2018), we identified lineage relationships between developing RGC and their mature counterparts. OT analysis predicted an asynchronous diversification across RGC subclasses and types, with certain subclasses (e.g. Opn4+ RGCs) specified as early as E14, while others (e.g. Neurod2+ RGCs) emerging as a distinct group only at P0. Altogether, >95% of types are fully diversified by P5, with type-specific transcriptional distinctions at this stage exhibiting a 1:1 correspondence with their adult counterparts. While we detected ~700 differentially expressed genes between P5 and adult RGCs, these were largely shared across types, and corresponded to transcriptional programs representing neuronal maturation (axon guidance, cell adhesion, and ion channel activity). Lastly, we asked if molecular maturation of RGCs was intrinsic or dependent on visual experience, by examining the transcriptomes of adult RGCs in mice that were either dark reared,

or possessed a mutation (Rd1) that leads to early and rapid photoreceptor degeneration. In both cases, all RGC types were present, and were transcriptomically far more similar to control adult RGCs than to P5 RGCs. Taken together, our results suggest that visual input plays a relatively minor role in the diversification and maturation of this neuronal class in the retina.

Title: The neurodevelopmental consequences of genomic stress

Authors: *N. MICHEL[1], U. B. MAJUMDAR[3], J. LANNIGAN[2], M. MCCONNELL[1]; [1]Biochem. and Mol. Genet., [2]Univ. of Virginia, Charlottesville, VA; [3]Icahn Sch. of Med., Mount Sinai, New York, NY

Abstract: Somatic mosaicism is a common consequence of normal development. DNA repair is simply not perfect, and each cell's genome incurs continuous DNA damage as a consequence of transcription, replication, and other cell biological stressors. Brain somatic mosaicism is particularly noteworthy because the vast majority of an individual's neurons are with that individual for life and neural circuits give rise directly to behavioral phenotypes. Brain somatic mosaicism, now revealed and tractable due to advances in single cell 'omic approaches, has emerged as an intriguing and unexplored aspect of neuronal diversity. Furthermore, the study of DNA damage during early neurodevelopment, when the rate of mutagenesis is high, is the perfect starting point to understand the origins of brain mosaicism. Flow cytometry is a highly efficient technique to study cell cycle and intracellular proteins of interest; particularly those related to DNA damage, but lacks the high resolution of microscopy to examine the localization of these proteins. In this study we outline a novel single-cell approach to quantify DNA Double-Strand Break (DNA DSB) dynamics during early human neurodevelopment by applying imaging flow cytometry (IFC) to human-induced pluripotent stem cell derived neural progenitor cells (NPCs) undergoing neurogenesis. We establish an increase of DNA DSBs by quantifying γH2AX foci in mildly stressed NPCs using various single-cell approaches in addition to IFC including fluorescent microscopy, conventional flow cytometry, and measuring DNA DSBs with

the comet assay. We demonstrate the dose-dependent sensitive detection of γH2AX foci through IFC and reveal the dynamics of DNA DSBs in proliferating and differentiating neural cells in early neurogenesis.

Title: Global effects of Parkinson's disease risk-SNP rs356182 at the SNCA locus

Authors: *J. D. PRAHL, T. TYSON, S. PIERCE, J. VANDERSCHANS, G. COETZEE; Van Andel Inst., Grand Rapids, MI

Abstract: Genome wide association studies (GWAS) have revealed 92 independent genetic risk signals associated with Parkinson's disease (PD). Most single-nucleotide polymorphisms (SNPs) identified by GWAS occur in non-exonic regions, making functional characterization difficult. Here we investigate the most significantly associated PD-risk SNP, rs356182. Its proximity to *SNCA* has led to the assumption that rs356182 confers risk through allele-dependent differences in alpha-synuclein expression. However, preliminary evidence suggests that the genetic enhancer encompassing rs356182 (referred to here as SNCA-ENH1) impinges on the expression of many genes across the genome, and mediates a phenotype not typically ascribed to SNCA. Together these data indicate that rs356182 may relate to PD in an unexpected way. To determine the biological mechanism(s) linking PD with rs356182 we employ LUHMES cells and induced pluripotent stem cells (iPSCs) as models of normal dopaminergic neurons (DANs) in a mature or still developing human brain. To examine possible roles of SNCA-ENH1 we are measuring its temporal activity by performing chromatin immunoprecipitation (ChIP) for histone H3 lysine 27 acetylation (H3K27ac; marker of active enhancers and promoters) at time points during DAN differentiation. We are also examining transcription factor (TF) binding at rs356182 by predicting candidate TFs based on expression and known binding motifs, and then verifying these TFs using ChIP. Finally, we are investigating the allele-specific differential gene expression due to the risk (G) or protective (A) alleles at rs356182. We speculate that the rs356182 risk allele could increase the likelihood of PD by changing TF occupancy during a key step in DAN differentiation (compared to the protective allele), resulting in repression of key differentiation genes and reduction in the mature DAN population. Subsequent stresses leading to neuronal death are then more likely to result in Parkinsonian symptoms compared to an individual with a larger neuronal cell population.

Title: Accelerated expression of functional NMDA receptors on mature hiPSC-derived neurons

Authors: *J. B. RUDEN[1], M. DIXIT[2], L. L. DUGAN[3];
[1]Vanderbilt Univ., Nashville, TN; [2]Med., [3]Dept Medicine/Geriatrics & Vanderbilt Brain Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: NMDA receptors are glutamatergic receptors that come late in development and are critical for neurotransmission of higher-order CNS function. They are necessary for LTP, memory entrainment, and many other neural processes. Many protocols to derive cortical neurons from human neural progenitor cells produce neurons that exhibit excitatory postsynaptic potentials and/or AMPA receptor activity. A limited number of protocols can produce glutamatergic neurons with functional NMDA receptors from human inducible pluripotent stem cells (hiPSCs), but the process is time-consuming. We wanted to develop an accelerated protocol to derive mature cortical neurons that have functional NMDA receptors in order to test several neuroinflammatory factors *in vitro*. Here, we derived neurons from commercially available hiPSC-derived neural progenitor cells that exhibit increased cytoplasmic calcium translocation in response to NMDA, demonstrating that they have functional NMDA receptors. We were able to derive these mature neurons with functional NMDA receptors in approximately six weeks. The presence of NMDA receptors was confirmed with RT-PCR and Western blot. These mature neurons can be used to address many scientific questions beyond our specific questions.

Title: The effects of metformin on early cortical development

Authors: *W. ALSANIE, H. HABEEBALLAH, O. BAHRI, M. ALHOMRANI, A. GABER, K. ALSWAT;
Taif Univ., Taif, Saudi Arabia

Abstract: Metformin is widely used as an antidiabetic drug to treat patients who have been diagnosed with type 2 diabetes mellitus. Although it is known to cross the placenta, it is one of only two oral medications that can be prescribed for pregnant diabetic women. To date, the effects of metformin on the development of human neurons, particularly cortical neurons in the fetus, have not been evaluated in any study. Human pluripotent stem cells (hPSCs) are considered an invaluable tool in studying of normal development and drug testing in vitro. Thus, the effects of metformin on cortical neurons derived from hPSCs were evaluated in the current study. Metformin has been added to cortical differentiation cultures established from hPSCs to examine whether metformin has an effect on this early developmental process. The expression of several genes and transcription factors were evaluated at different time points throughout the differentiation. Metformin was shown to increase the differentiation of PAX6-positive early cortical progenitors into TBR2-positive intermediate progenitors ($p = < 0.050$). In agreement, the expression of several cortical progenitor genes were increased significantly in metformin treated cultures in comparison with the control cultures ($p = < 0.050$). During maturation, an increase in the number of CTIP2-positive neurons, which normally reside in the deep layers of the cerebral cortex, was evident in the metformin-treated differentiation culture compared to the control differentiation culture ($p = < 0.050$). By contrast, there was no difference observed in the number of TBR1-positive neurons identified in the two differentiation cultures. The delay in differentiation in the metformin-treated culture was found to be due to the activation of the adenosine monophosphate-activated protein kinase (AMPK) signaling pathway on further analysis. By inhibiting the AMPK signaling pathway in the metformin-treated cultures, differentiation of the human cortical neurons therein was similar to that in the control group. To the best of our knowledge, this is the first study to have demonstrated the effect of metformin on human cortical development in vitro. Further studies are warranted to examine the effects of metformin on the morphogenesis and synaptogenesis of cortical neurons.

Title: Premature birth results in dysmaturation of dentate granule neurons and cognitive deficits

Authors: *D. R. SHARMA[1], B. CHENG[1], D. SINGH[1], N. PARIKH[1], S. MAMTANI[1], S. YADAV[1], M. K. JAISWAL[2], P. BALLABH[1];
[1]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Psychaitry, Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Every year ½ million infants are born prematurely in the US and 15 million worldwide. Preterm-born children suffer deficits in memory and learning, which suggests disruption in hippocampal development. As dentate gyrus develops perinatally, premature-birth can impact its maturation. Preterm infants are deprived of safe intrauterine environment and reared in the stressful environment of Neonatal Units. However, the effect of premature-birth on dentate gyrus development is obscure. We hypothesized that premature-birth and non-maternal care would disrupt the structure and function of dentate gyrus and induce cognitive deficits. To test our hypotheses, we compared preterm (E28.5) and term (E32) rabbit kits at an equivalent post-conceptional age (P28). Preterm kits were reared in an infant incubator and were gavage fed, whereas term kits were reared by mother rabbit. Neurobehavioral tests included open field test, object placement test and Barnes Maze test, using ANY-maze video tracking system. Granule cells were immunostained with NeuN, and Calbindin, and interneurons with GABA, parvalbumin and somatostatin antibodies. Neurons in dentate gyrus were stereologically quantified. Granule cell were also assessed in Golgi-stained sections. Synapses were quantified in PSD95 and Vglut2 immunostained sections. Markers of stress, glucocorticoid receptor (GR) and p-GR were assessed by western blot analyses. Object placement test revealed that preterm kits spent less time exploring the moved object compared to term kits. Modified Barnes maze showed that preterm kits had longer-latency and made more errors in finding food relative to term kits. This suggests reduced spatial memory and learning in preterm kits. Stereological Quantification showed that both $NeuN^+$ granule cells and interneurons--$GABA^+$, $Parvalbumin^+$ and $somatostatin^+$ cells--were higher in number in the dentate gyrus of preterm kits compared to term controls. However, $calbindin^+$ neurons were reduced in preterm relative to term kits. Accordingly, Golgi stained sections showed more abundant granule cells in preterm compared to term kits. Despite granule cells were larger in number in preterm kits, VGlut2-$PSD95^+$ synaptic puncta in the molecular layer of dentate gyrus were reduced in preterm compared to term kits.

Moreover, phospho-glucocorticoid-receptor expression was higher in preterm relative to term kits. Hence, dysmaturation of dentate granule neurons in premature kits results in reduced synaptic connectivity, and contributes to poor memory and learning. Strategies to enhance maturation of granule cells might improve the cognitive outcome of premature infants.

Title: Dual-specificity phosphatase 15 (DUSP15) modulates notch signaling through enhancing the stability of notch protein

Authors: *N. BHORE, B.-J. WANG, P.-F. WU, Y.-W. CHEN, Y.-F. LIAO;
Inst. of Cell. and Organismic Biol., Academia Sinica, Taipei, Taiwan

Abstract: Dual-specificity phosphatases (DUSPs) are a unique group of phosphatases which are involved in protein dephosphorylation at both phospho-serine/threonine and phospho-tyrosine residues. A preliminary RNAi screen led us to identify DUSP15, whose downregulation significantly affected the interaction between Notch and presenilin-1, thus hinting at potential modulation of Notch signaling. Accumulated evidence has suggested that Notch signaling is a conserved pathway essential for cell fate determination and development, and is also upregulated in cortical regions of patients with Alzheimer's disease (AD). Thus, we sought to determine the underlying molecular mechanism of this DUSP15-mediated alteration of Notch processing. Our data suggest that over-expression of DUSP15 increases the steady-state levels of recombinant Notch (extracellular domain-truncated Notch, NΔE) protein and concomitantly its cleaved product, Notch intracellular domain (NICD), in a dose-dependent manner. Consistently, the overexpression of DUSP15 effectively increased the levels of endogenous NICD in cultured cellular models. However, the overall ratio between Notch substrate and the cleaved product was unchanged in response to overexpression of DUSP15, suggesting that γ-secretase activity is not significantly affected by DUSP15. Previous studies have shown that ERK phosphorylation is positively correlated with the levels of Notch protein. Our results also confirmed that overexpression of DUSP15 increases the phosphorylation of ERK in a dose-dependent manner,

suggesting that DUSP15 could regulate the levels of Notch protein through an ERK-dependent pathway. We will determine whether this DUSP15-ERK-Notch pathway could play a role in neuronal differentiation, and provide proof-of-principle evidence validating that DUSP15 could be a novel therapeutic target for neurodevelopmental and neurodegenerative diseases.

Title: Automated neonatal and adult mouse brain dissociation and magnetic isolation of neurons increases efficiency and sensitivity for single-cell gene expression profiling

Authors: S. REISS[1], R. KLÄVER[1], S. TOMIUK[1], J. SOYKA[1], M. DELSO VALLEJO[1], C. JONES[2], *A. BOSIO[1], M. JUNGBLUT[1];

Abstract: Single-cell RNA sequencing has emerged as a powerful technology for the analysis of cell types with high resolution during the last years. Especially in case of the huge heterogeneity of neural cells, the technology can help to better understand their phenotype and function by deciphering the transcriptome of different subtypes. A prerequisite for single-cell analysis of tissue derived cells is the preparation of single-cell suspensions with high cell viability and a minimum of cell debris, which is particularly challenging in case of highly sensitive neurons. To improve cellular analysis of neural cells, we established an elaborated technology for the automated dissociation of neonatal and adult mouse brain tissue, which is based on the combination of an ideal mechanical dissociation using the gentleMACS™ Octo Dissociator with Heaters (Miltenyi Biotec) and an optimized enzymatic treatment. After tissue dissociation, neurons were isolated using the Neuron Isolation Kit (Miltenyi Biotec) to increase the percentage of target cells for single cell genomics. Gene expression profiling of adult unsorted cells and isolated neurons was performed using the Chromium Single Cell 3′ Reagent Kits v3 (10x Genomics) for preparation of Single-cell RNA-seq libraries. In detail, 16000 cells per samples were loaded into the Chromium Chip B Single Cell and processed according to the manufacturer's instructions. Furthermore, we compared single cell sequencing data from manually and automatically dissociated neonatal mouse brain loading 8000 cells per sample. All Single-cell RNA-seq libraries were pooled and sequenced using two Next Seq 500 High Output Cartridges on the NextSeq 500 Instrument (Illumina). For processing and visualization of the single cell RNA sequencing data, the Seurat package (v3.0.0) was used. The analysis resulted in the identification of 5800-10800 cells per sample with an average of 15000 reads per cell.

Results showed that isolation of neurons led to substantial enrichment in the number of target cells and allowed for the identification of different neuronal subpopulations that could not be distinguished in the unsorted brain fraction. Comparison of automatically and manually dissociated neonatal mouse brain tissue led to the identification of the same neural cell clusters, proving that the automated gentleMACS based dissociation did not have any negative influence. In summary, we showed that an optimized automated dissociation protocol based on the gentleMACS octo Dissociator and magnetic isolation of neurons significantly improves sensitivity and resolution of single cell sequencing for characterization of neuronal subtype complexity.

Title: Novel roles of BMP signalling in cerebellar granule cell neurogenesis

Authors: *V. ROOK[1,2], R. J. WINGATE[2], T. BUTTS[3,1];
[1]Sch. of Biol. and Chem. Sci., Queen Mary Univ. London, London, United Kingdom; [2]Ctr. for Neurodevelopmental Disorders, King's Col. London, London, United Kingdom; [3]Sch. of Life Sci., Univ. of Liverpool, Liverpool, United Kingdom

Abstract: Cerebellar granule cell precursors (GNP) are the most abundant neuronal progenitor population in the brain, making them a good model for studying principles of neurogenesis. GNPs are born at the rhombic lip and migrate tangentially to form a transiently proliferative layer that covers the cerebellar anlage; the external granule layer (EGL). GNPs undergo massive proliferation in the EGL influenced by Sonic Hedgehog (SHH) secreted by underlying Purkinje neurons. Mutations in SHH are implicated in medulloblastoma; the most common paediatric brain cancer. However, triggers for termination of GNP proliferation are poorly understood. Whilst BMP signalling has been implicated at various stages of cerebellar development, data from *in vitro* and transgenic mouse studies has been conflicting. In this study we show, by *in ovo* genetic manipulation of the embryonic chick hindbrain, the role of BMP signalling changes as the local signalling environment of the developing cerebellum changes. In the absence of BMP signalling the EGL fails to form at embryonic day 7 (E7), but GNPs are nevertheless specified and migrate away from the rhombic lip and immediately differentiate, sending axonal projections

into the molecular layer of the cerebellum. In contrast, with the misexpression of an activated form of the intracellular mediator of BMP signalling, Smad1, GNPs are recruited to the EGL or differentiate and migrate away from the pial surface. Following the onset of proliferation at E8, Smad1 misexpression only induces radial migration and premature differentiation. In conclusion, our data suggests that the correct level of BMP signalling is required to regulate the developmental chorography, but not the ultimate fate of granule cell neurons. These data unify previous conflicting observations surrounding the role of BMP signalling in the granule lineage and uncover an important function of BMP signalling in late cerebellar development that is developmentally pliable, and may explain variation in foliation between species, as well as identify potential avenues to treat medulloblastoma.

Title: Bisphenol A induces neurite extension in PC12 cells

Authors: ***K. SHIMOKE**, K. MATSUURA, H. MARUOKA;
Kansai Univ., Osaka, Japan

Abstract: Bisphenol A (BPA) is included in plastics as a plasticizer widely. BPA is an endocrine disrupting chemical (EDC) that promotes a female-inducing phenotype in genital organs via estrogen receptors. We have found that BPA and other alkylphenol compounds can cause apoptosis in PC12 cells when we add relatively high dose. This mechanism was classified as endoplasmic stress (ER)-mediated apoptosis due to involvement of accumulation of unfolded proteins with upregulation of glucose-regulated protein 78 (GRP78) / BiP (immunoglobulin heavy-chain binding protein), a marker of ER stress. In cell-based assays, we also discovered that BPA is an inducer of neurite outgrowth in PC12 cells when we add lower dose. Contrary to expectations, we also found that the neurites are unique compared with those induced by nerve growth factor (NGF). This suggests that BPA may have a direct function in differentiation of neurons. This evidence was obtained using neuronal marker proteins. In addition to formation of neurites in PC12 cells. A molecular analysis showed that acetylation of specific amino acids in histones, which induces expression of the orphan nuclear receptor nur77 gene, an immediate early gene, leading to epigenetic regulation of gene expression. Based on these results, we suggest that intracellular signaling caused by BPA is mediated via the specific gene expression epigenetically to extend the neurites.

Abstract: Depression is a neuropsychiatric disorder that courses with alterations in behavior and brain plasticity in regions belonging to the limbic system. Several reports have indicated that stress plays a significant role to precipitate depression. In order to reverse the alterations occurring at the behavioral and brain plasticity levels several pharmacological interventions have

been used. However, there are clinical evidences supporting the effects of repetitive transcraneal magnetic stimulation (rTMS) as a non-invasive intervention that may impact brain plasticity to reverse depression. However, the mechanisms that underlay the effects of rTMS are unknown. Thus, in this study we analyzed the impact of rTMS in female Balb/C mice exposed to chronic mild stress (CMS). Here, we found that rTMS (5Hz) applied for 28 days during the CMS protocol, reverses depressive-like behavior and produces positive changes in the cellular populations of the dentate gyrus. Moreover, rTMS increases BDNF inmunoreactity in the dentate gyrus. The data of this study strongly support the beneficial effects of rTMS and its effects on the generation of new neurons in the dentate gyrus.

Title: Rhoa functions in late embryonic apical neural stem cells in the mammalian cerebral cortex

Authors: *A. COSSARD, Y. JOSSIN;
Lab. of Mammalian Develop. & Cell Biol., Univ. Catholique De Louvain, Bruxelles, Belgium

Abstract: Excitatory neurons, the major type of neurons in the cerebral cortex, are produced by Neural Stem Cells (NSCs) located in a region called the ventricular zone (VZ). Initially NSCs mainly self-renew, resulting in an expansion of their number. They then progressively switch into another type of proliferative cells called radial glia cells or apical NSCs (aNSCs) and start producing basal progenitors and neurons. The maintenance of the balance between proliferation, self-renew and differentiation is crucial to the formation of a normal cortex. Disruption of the molecular and cellular mechanisms that regulate these processes can lead to serious cortical malformations (neuronal heterotopy, microcephaly ...).
The small GTPase RhoA plays key roles in fundamental functions such as regulation of actin cytoskeleton, microtubule movement, and regulation of gene expression. It is highly expressed in the VZ of the developing cerebral cortex and its Conditional deletion in early NSCs of the

cerebral cortex induces a loss of adherens junctions associated with massive disorganization of the tissue and over-proliferation of NSCs. However, nothing is known about its function in later stage. Since early NSCs mostly self-renew while late aNSCs divide asymmetrically to produce postmitotic cells, we hypothesized that RhoA function might not be the same at different developmental stages. In this project, we investigate RhoA functions during late neurogenesis by means of an alternative approach that only affects a subset of cells in a cell autonomous manner. Using *in utero* electroporation and molecular techniques, we found that RhoA positively regulates proliferation and controls differentiation into basal progenitors or postmitotic neurons in the cerebral cortex before and therefore independently to the occurrence of tissue disorganization.

Title: Pax6 regulates the development of morphology and electrophysiological properties of the mouse embryonic prethalamic neurons

Authors: *T. TIAN, I. QUINTANA-URZAINQUI, Z. KOZIć, T. PRATT, D. PRICE;
Ctr. for Discovery Brain Sci., Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: The transcription factor Pax6 is a pleiotropic player during neural development. In the central nervous system, Pax6 is mostly expressed by neural progenitors, where its functions have been most extensively studied. However, in the anterior diencephalon, the prethalamus, Pax6 is expressed in both neural progenitors and post-mitotic neurons. This distinctive expression pattern of Pax6 makes the prethalamus a unique place in which to explore the functions of Pax6 and its mechanisms of action during development.
Gene ontology analysis on our RNAseq data, which showed significant transcriptional changes of genes in the prethalamus when Pax6 is lost, indicated that Pax6 seems to regulate the process of neuronal morphogenesis. To further explore this, we dissociated the prethalamus at embryonic day 13.5 and cultured the primary prethalamic neurons for 1-9 days *in vitro* (DIV). We found that Pax6-null prethalamic neurons constantly displayed fewer neurites and a disturbed rate of neurite elongation. Additionally, we discovered that the axon initial segments (AISs) of these neurons were shorter and located further away from the soma. The AIS is where the neurons

generate action potentials, and its location and molecular composition can determine the amplitudes and firing frequencies of the neurons. We found that the components of the AISs seemed to have been altered as increased amount of voltage-gated sodium channels and AnkyrinG was found in the AISs of the Pax6-null prethalamic neurons. Therefore, our analysis suggested that the Pax6-null prethalamic neurons might display different electrophysiological properties. Whole-cell patch recording is currently underway to further confirm whether and how the electrophysiological properties are changed in the absence of Pax6.
Our results thus revealed novel and distinct functions of Pax6 in the post-mitotic cells of the mouse embryonic prethalamus- regulating neuronal morphogenesis and functionality in a cell-autonomous manner.

Title: Novel mediators of prenatal alcohol effects in neural stem cells: Gag-like proteins as RNA chaperones for intercellular communication

Authors: *M. PINSON, A. TSENG, V. NAIR, R. C. MIRANDA;
Neurosci. & Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr, Col. of Med., Bryan, TX

Abstract: Extracellular vesicles (EVs) are nanometer-sized, membrane-bound vesicles released by cells that may serve as a means of intercellular communication by transporting biological information between cells. Recently the Gag-Like Protein (GLP) Arc was identified in neuron-derived EVs, and found to transport its own mRNA between neurons. This raises the possibility that other members of the brain-enriched GLP family may function like Arc, and the ancestral retrovirus Gag protein, in their ability to interact with mRNA and self-target for membrane bound export in EVs. GLPs may chaperone RNA in intercellular transport and therefore, serve as a means for programming the multipotency and differentiation of neural stem cell (NSC) ensembles. GLPs may also mediate effects of alcohol in developing tissues. In line with this reasoning, we evaluated the expression of GLP mRNAs in neural development under basal and ethanol exposure conditions by using qRT-PCR and of proteins using immunoblot. The GLPs PEG10 and PNMA2 were knocked-down (KD) and the impact on NSC differentiation was determined by qRT-PCR and immunoblot. Furthermore, effect of KD of GLPs on cellular

metabolic activity was determined by MTT assay, on cell cycle progression Click-iT EdU flow cytometry, and apoptotic activity by Caspase-Glo 3/7 assay. Results show that transcript expression of PNMA2 increased during differentiation, suggesting a role in NSC maturation. Furthermore, ethanol exposure resulted in a dose related-increase in mRNA and protein for GLPs, PEG10 and PNMA2. Ongoing studies are evaluating the effect of GLP KD on NSC differentiation, cell cycle progression, and apoptotic activity. These data support a hypothesis that GLPs mediate compensatory mechanisms for cell survival or maturation following ethanol exposure. Further understanding how GLPs mediate and coordinate neural development may lead to interventions that moderate the harmful effects of prenatal alcohol exposure.

Title: Neuron-specific alternative mRNA splicing is required for SYNGAP1 protein expression

Authors: X. FENG[1], *X. ZHANG[2];
[1]Deptment of Human Genet., The Univ. of Chicago, Chicago, IL; [2]Dept. of Human Genetics, and the Grossman Inst. for Neurosci., Univ. of Chicago, Chicago, IL

Abstract: Synaptic RAS GTPase-activating Protein 1 (SYNGAP1), a major component in the post-synaptic density, is crucial for synaptic plasticity. Mutations in SYNGAP1 are leading causes (1%) of non-syndromic intellectual disability and frequently associated with autism and epilepsy. Although *SYNGAP1* mRNA is widely transcribed in different tissues and cell types, SYNGAP1 protein is specifically expressed in the nervous system. This post-transcriptional expression difference is particularly striking during neural development, but the regulatory mechanism remains unknown. Here, we report that the polypyrimidine tract binding proteins (PTB) repress the expression of SYNGAP1 by promoting an alternative 3' splicing site usage. This mammal-conserved alternative splicing event leads to nonsense-mediated mRNA decay (NMD) in non-neural tissues and ensures neuron specific expression of SYNGAP1 protein. Our study highlights the importance of cell type specific alternative splicing in neural development.

Title: Early neurogenesis in the human cephalic ectoderm and the cranial sensory placodes

Authors: *I. BYSTRON;
Univ. of Oxford, Oxford, United Kingdom

Abstract: The preplacodal cephalic epithelium is continuous with the prosencephalic epithelium prior to the fusion of the anterior neuropore. We report here a previously unknown early neuronal population in the human cephalic ectoderm, which is distinct from the neurons originated in the cranial sensory placodes and the neural crest. Human embryos from Carnegie stages (CS) 10-17 (29-41 days post-conception) were obtained from the Human Developmental Biology Resource UK. We used a number of cell-specific and proliferative markers to reveal the phenotypic characteristics and migratory pathways of the first neurons in the cephalic ectoderm and mesenchyme. We developed a new approach to reconstruct cells in sections of the human ectoderm, diencephalon, cortical wall, and retina by rapid, high-resolution volume rendering of multichannel 3D confocal data sets from a Zeiss LSM 710 confocal microscope. The majority of precocious TU-20-positive ectodermal neurons appear to migrate tangentially within the ectoderm, and some delaminate from the epithelium to coalesce within the mecenhyme surrounding the rostral telencephalon. The fibers of the neurons in the oral ectoderm formed a dense network along the basement membrane adjacent to the ventral hypothalamus by CS13. Some neurons in the optic mesenchyma extended non-axonal processes through the prospective pigment epithelium into the neural retina. Others invade the presumptive cortical wall, perhaps providing additional signalling information to the local stem cell niche. Pioneer olfactory neurons constitute a distinct migratory population at CS 13-14. Their processes penetrate the cerebral wall by CS17. Thus the human cephalic epithelium adjacent to the forebrain contain hitherto unrecognized stem cell niches generating the first migratory neurons.

Title: The generation of the mystery cells of the male depends on HLH-3 function in C.elegans

Authors: *L. PEREZ, L. MARQUEZ, Z. IBRAHIM, A. ALFONSO;
Univ. of Illinois at Chicago, Chicago, IL

Abstract: The Mystery Cells of the Male (MCMs) are a newly discovered pair of neurons derived from a pair of glia in *C. elegans*. The generation of these sex-specific neurons in *C. elegans* is remarkable because it is the first documented case in which a non-epithelial cell, nor blast cell, gives rise to a neuron, and is a sexually dimorphic event occurring during L4 lethargus development. Functionally this pair of neurons integrate environmental cues to promote mating with hermaphrodites, or sexual conditioning. Our laboratory has data to suggest that *hlh-3*, which encodes a bHLH Class II proneural-like protein, has a role in the terminal differentiation of sex-specific neurons, including all sex-specific neurons of the hermaphrodites, HSNs and VCs, and a set of male specific neurons, CEMs. Since the ventral pair of CEMs are sister cells of the amphid socket glia and cousins to the MCMs, and we know that the differentiation of ventral CEMs is most affected, it seemed logical to address whether there is any defect in the generation and differentiation of the MCMs. Our analysis on markers for both MCMs and the amphid socket glia reveal abnormalities in the position and quantity of each cell type between wild type males and *hlh-3(lf*) males. Overall, we find that *hlh-3* has a role in the generation and differentiation of MCMs and that MCM-mediated male mating behavior is also compromised.

Title: Effects of the organophosphorus insecticide chlorpyrifos on neuronal differentiation of the SH-SY5Y cell line: Involvement of cannabinoid type 1 receptors

Authors: S. W. TODD[1], E. W. LUMSDEN[1], W. R. RANDALL[2], B. K. KRUEGER[3], E. X. ALBUQUERQUE[1], ***E. F. R. PEREIRA**[1];
[1]Div. of Translational Toxicology, Dept. Epidemiology and Publ. Hlth., [2]Pharmacol., [3]Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The acute toxicity of the organophosphorus insecticide chlorpyrifos (CPF) results primarily from the irreversible inhibition of acetylcholinesterase (AChE). However, via mechanisms that remain poorly understood, developmental exposures to CPF levels insufficient to inhibit AChE have been associated with neurological deficits in children and animal models. This study was designed to test the hypothesis that, acting via AChE-independent mechanisms, CPF disrupts neuronal differentiation, a process that shapes the nervous system structurally and functionally from the earliest stages of embryogenesis through adulthood. To address this hypothesis, SH-SY5Y cells, a neuronal cell line used to study neuronal differentiation *in vitro*, were exposed to CPF (0.3-100 μM) for 24 h or 7 days. To minimize experimental bias and maximize rigor, we use a randomized, blind design. Each assay was done in triplicate using 3 independent cultures. Two- or three-way ANOVA followed by Tukey post-hoc test was used to statistically analyze the data. Following 24-h exposure to CPF concentrations that caused significant AChE inhibition (≥30 μM), cell viability was significantly reduced. On the other hand, following 7-day exposure to CPF concentrations that caused no detectable inhibition of AChE (1-3 μM), there was a significant reduction in the expression of nestin, a marker of neuroprogenitor cells, and a significant increase in the expression of NeuN, a marker of mature neurons. When examined by immunofluorescence, cultures exposed to these low concentrations of CPF exhibited a lower percentage of $NeuN^{-}nestin^{+}$ cells and a higher percentage of $NeuN^{+}nestin^{-}$ cells than did cultures exposed to vehicle. Since previous studies reported that CPF can interact with components of the endocannabinoid system (rev. in J Neurochem 142:162, 2017), experiments were then carried out to determine whether the effects of CPF on neuronal differentiation were mediated by cannabinoid receptor type 1 receptors (CB1Rs). In cultures that were co-treated with CPF and the CB1R antagonist AM4113, NeuN and nestin expression levels were comparable to control. CPF increased phosphorylation of a number of mitogen-activated protein kinases, including p38 - a downstream signaling pathway linked to CB1Rs. In the presence of the p38 inhibitor SB203580, CPF had no effect on nestin expression or on the percentage of $NeuN^{-}Nestin^{+}$ cells. This is the first demonstration that, acting at least in part via CB1Rs and p38, CPF induces neuronal differentiation. These findings provide a framework for future studies to determine how disruption of neurogenesis contributes to the developmental neurotoxicity of CPF.

Title: *In vitro* modeling of the disruptive effects of the organophosphorus insecticide chlorpyrifos on synaptic transmission in the developing hippocampus

Authors: *E. W. LUMSDEN, R. D. BURKE, E. X. ALBUQUERQUE, E. F. PEREIRA;
Div. of Translational Toxicology, Dept. of Epidemiology and Publ. Hlth., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The acute toxicity of the organophosphorus insecticide chlorpyrifos (CPF) results from the irreversible inhibition of acetylcholinesterase (AChE). However, prenatal exposures to levels of CPF that do not cause substantial AChE inhibition have been associated with neurodevelopmental disorders in children, particularly boys. Preclinical studies have also reported that developmental exposures of rodents to low levels of CPF result in sexually dimorphic learning and memory impairments (rev. in J Neurochem 142:162, 2017). Since similar

impairments can be caused by drugs that act as positive allosteric modulators of $GABA_A$ receptors, the first part of this study was designed to test the hypothesis that cognitive deficits observed in male guinea pigs prenatally exposed to subacute doses of CPF (25 mg/kg/day, gestation days 53 to 62) correlate with an increase of GABAergic transmission in hippocampal CA1 pyramidal neurons. Electrophysiological experiments revealed that the frequency of spontaneous inhibitory postsynaptic currents (IPSCs) was significantly higher in the CA1 pyramidal neurons of CPF- than vehicle-exposed male guinea pigs (n = 13 animals/group). This increase positively correlated with learning deficits the animals presented in the Morris Water maze and could not be accounted for by an increase in the number of interneurons. The second part of this study was designed to model *in vitro* the CPF-induced increase in GABAergic transmission observed *in vivo*. To this end, primary hippocampal cultures were exposed for 5-7 days to CPF (0.03-30 µM) or vehicle starting at different times after cells were plated. Seven days after the end of the exposures, synaptic activity was recorded from hippocampal neurons. A randomized, blind design was used to minimize experimental bias and maximize scientific rigor. Statistical analysis of the electrophysiological results considering treatment and cultures as independent factors revealed that the frequency of IPSCs was significantly increased in cultures that had been exposed to CPF at a time when neuroprogenitor cells (i.e., nestin-immunoreactive cells) prevailed in the system. Thus, this *in vitro* model becomes unique for studies aimed at identifying the mechanisms that underlie the developmental neurotoxicity of CPF.

Title: Characterization of fiber layers in the developing cerebral cortex of ferrets and mice

Authors: *K. SAITO, K. MIZUGUCHI, T. HORIIKE, T. A. DINH DUONG, Y. SHINMYO, H. KAWASAKI;
Dept. of Med. Neuroscience, Grad. Sch. of Med. Sci., Kanazawa Univ., Ishikawa, Japan

Abstract: Changes in the cerebral cortex of mammals during evolution have been of great interest. Ferrets, monkeys, and humans have more developed cerebral cortices compared with mice. Although the features of progenitors in the developing cortices of these animals have been intensively investigated, those of the fiber layers are still largely elusive. By taking the advantage of our in utero electroporation technique for ferrets, here we systematically investigated the cellular origins and projection patterns of axonal fibers in the developing ferret cortex. We found that ferrets have 2 fiber layers in the developing cerebral cortex, as is the case in monkeys and humans. Axonal fibers in the inner fiber layer projected contralaterally and subcortically, whereas those in the outer fiber layer sent axons to neighboring cortical areas. Furthermore, we performed similar experiments using mice and found unexpected similarities between ferrets and mice. Our results shed light on the cellular origins, the projection patterns, the developmental processes, and the evolution of fiber layers in mammalian brains.

Title: Nanodendrimer-n-acetylcysteine enhances survival and *in vivo* migration of transplanted allogeneic glial restricted precursor cells

Authors: *S. N. TOMLINSON[1], C. L. NEMETH[1,2], M. ROSEN[1], A. WOLFE[1], A. SHARMA[3], R. SHARMA[3], M. V. JOHNSTON[1,2], R. M. KANNAN[3], S. KANNAN[4,2,3], A. FATEMI[2,1]; [1]Hugo W. Moser Res. Sch. of Med., Baltimore, MD; [4]Anesthesiol. and Critical Care Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Oligodendrocyte replacement is a promising avenue for the use of glial restricted precursor cells (GRPs); however, limited cell survival reduces integration and functional recovery. Nanotherapeutic approaches can facilitate stem cell delivery while concurrently delivering factors aimed at enhancing and nourishing stem cells en route to, and at, the target site. Here, survival and migration of GRPs was assessed in a mouse model of neonatal white matter injury with different methods of G4 PAMAM dendrimer nanoparticle support. GRPs isolated from embryonic day 13.5 mice expressing eGFP were purified by A2B5 selection. Three groups of preterm equivalent (post-natal day; P5) CD-1 mice underwent right common carotid artery ligations followed by 1) a vehicle injection at P10 and an intracallosal (IC) injection of 100,000 GFP-expressing GRPs at P22; 2) a single dose of dendrimer conjugated to the antioxidant/anti-inflammatory N-acetylcysteine (D-NAC; 10 mg/kg, intraperitoneal) at P10, followed by IC GFP-GRP at P22; or 3) a vehicle injection at P10 and IC GFP-GRPs pretreated for 12h with D-NAC at P22. At 8 weeks post-transplant, GRPs were detected in 82% of mice receiving GRPs alone, 94% of mice receiving D-NAC at P10 and GRPs, and 100% of mice receiving D-NAC pretreated GRPs. Migratory capacity improved as GRPs from P10 D-NAC treated mice traveled 25% farther than untreated mice while D-NAC pretreated GRPs traveled a 75% greater distance. GRPs were also more likely to differentiate *in vivo* when combined with D-NAC. To interrogate the area of these combinatorial effects, injured animals were treated with GRPs with a fluorescent dendrimer given as a cell pre-treatment or intraperitoneally. At one-week post-transplant, intraperitoneally injected dendrimer colocalized at sites of injury, while dendrimer was detected outside pre-treated GRPs suggesting the potential for combination therapies to enhance the environment surrounding injury independent of administration route. These studies demonstrate that D-NAC nanoparticles enhance transplanted progenitor cell survival and migration, and suggest that such combinatorial therapies may allow long term engraftment without overt use of immunosuppression.

Title: Growth cone molecular machinery in development vs. regeneration: Subcellular transcriptome mapping in corticospinal neurons

Authors: *A. K. ENGMANN, J. HATCH, J. KIM, C. WINTER, J. D. MACKLIS;
Dept of Stem Cell and Regenerative Biology, and Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Neurons of the central nervous system (CNS) grow axons over long distances during development, generating exquisitely precise functional circuitry. The same neurons, however, fail to regenerate following injury. Despite current knowledge about factors that prevent regeneration, including inhibitory extrinsic cues and failure to activate intrinsic growth machinery, no causal treatment exists for traumatic injuries to the CNS.
Neurons are uniquely polarized cells with extreme spatial expanse. In development and regeneration, growth cones (GCs) are the subcellular units effecting axonal growth, guidance, and circuit assembly. Until very recently, molecular states of GCs *in vivo* were experimentally not accessible. New experimental and analytic approaches developed recently in our lab enable direct access to the molecular machinery of subtype- and stage-specific GCs directly from the mouse brain. We combine specific labeling, biophysical fractionation, and newly developed fluorescent small particle sorting to purify GCs of interest. The application of this quantitative 'subcellular RNA-proteome mapping' approach to callosal projection neurons of the developing mouse cortex identified hundreds of GC-enriched RNAs/proteins [Poulopoulos *et al.*, Nature 2019].
Subcerebral projection neurons send their axons over remarkably long distances to the midbrain, brainstem and spinal cord, and play key roles in several clinical conditions. Insight into their local GC- and soma-specific transcriptomes would not only be informative but also highly translationally relevant. Due to their limited number, however, they have so far not been accessible to subcellular molecular mapping. Recent technological advancement now enables nearly full-depth RNA sequencing from as little as 100,000 GCs, collected not only in a subtype-specific manner, but also with spatial resolution across a variety of developmental stages. This

facilitates deep investigation of the molecular machinery of corticospinal GCs and somata *in vivo*. We are currently investigating the molecular states of corticospinal GCs across distinct developmental stages, generating deep data about the local changes in proteome and transcriptome that enable precise navigation of GCs all the way from the cortex caudally to the spinal cord. Additionally, we are expanding this work to regenerative GCs following spinal cord injury, aiming to identify similarities and differences between the local molecular controls of developing (growth-permissive) and regenerating (growth-abortive) corticospinal GCs.

Title: Rat adipose stem cells: Relevance of VEGF signalling for pain relief

Authors: *A. VONA, L. DI CESARE MANNELLI, L. MICHELI, C. GHELARDINI, P. FAILLI;
Univ. of Florence, Firenze, Italy

Abstract: In oxaliplatin-induced neuropathy, vascular endothelial growth factor (VEGF) was increased in plasma. VEGF antibodies and adult rat adipose stem cells (RASCs) administration reduced neuropathic pain (Di Cesare Mannelli - Neuropharmacology, 2017). Therefore, we decided to investigate: 1) the presence of VEGF receptors (VEGFRs), 2) the intracellular signal induced by VEGF in RASCs and in "*in vitro"* neuron-like cells differentiated from RASCs.
Methods: RASCs were isolated from retrosternal fat and used at passages P1-P4. Rat endothelial cells (RCE) acted as positive control. Western blot was performed in cell homogenates. Intracellular calcium dynamic was measured using FURA-2 imaging analysis. RASCs were transformed in neuron-like cells by incubating with growth factors.
Results: 1) in RASCs and RCE the VEGFR1 was well expressed in control condition. One hour after $VEGF_{165b}$ administration (1ng/ml), VEGFR1 and trunked form of VEGFR1 (sFlt1) expression decreased in RASCs.
2) VEGF (100ng/ml) induced a small increase in intracellular calcium in RASCs and RCEs, whereas ATP induced a vigorous, oscillatory calcium signal in both cell lines. The rise of the intracellular calcium induce by VEGF was somehow slow and not synchronized in all analysed cells. Responsive cells were almost at the culture serial passage P2 (40%).
On the contrary, the rise of intracellular calcium induced by ATP was rapid and the maximum was synchronised in all cells. Moreover, ATP was very effective in RASCs at P2-P3 (76% - 81%

respectively) whereas P1 cells were less responders (8%).
RASCs can differentiate in neuron-like cells under special culture condition. Differentiated cells showed DCX and Tuj-1 positivity and GFAP negativity. Neuron-like cells presented electrically-evoked Ca^{2+} transients upon 0.1 Hz field stimulation, 100 mV voltage and 50 ms width duration in control solution. The dynamic of cytosolic Ca^{2+} increase presented Ca^{2+} transient characterized by very rapid, steeply increase and a slow return to basal Ca^{2+} levels.
Conclusion: VEGFR1 is well expressed RASCs and it stimulation can induce sFlt1 release as suggested by the decrease in soluble receptor content.
The small increase in intracellular calcium induced by VEGF suggests VEGF receptors are actively linked to intracellular calcium movement. Experiments are in progress to characterized other intracellular signaling responsible to the anti-neuropathic effect of RASCs in oxaliplatin induced pain.
Studies are in progress to better understand ionic channels at the basis of calcium transient measured in neuron-like cells and the therapeutic application of differentiated cells in different type of neuropathic pain.

Title: Light-induced inhibition of human primary neurons by human stem cell-derived GABAergic neurons *in vitro*

Authors: *A. GONZALEZ-RAMOS, E. WALOSCHKOVA, M. LEDRI, M. ANDERSSON, M. KOKAIA;
Clin. Sci., Epilepsy Centre, Lund Univ., Lund, Sweden

Abstract: Gamma-aminobutyric acid (GABA)-releasing interneurons are responsible for the modulation of neuronal network activities in the brain by inhibiting other neurons. The alteration or absence of these cells disrupts the balance between the excitatory and inhibitory processes in the neuronal networks, leading to neurological disorders such as epilepsy. In this regard, a cell replacement-based therapy may be an alternative therapeutic approach, in particular for those epilepsy cases that currently lack effective treatment. To address this issue, a single-step method was used to generate a highly-enriched population of functional GABAergic interneurons from

human embryonic stem cells (hESCs). Using lentiviral vectors, we induced the expression of the transcription factors Ascl1 and Dlx2, that are key factors for this lineage determination. In addition, the cells were transduced by another lentiviral vector with channelrhodopsin-2 (ChR2) gene. After 35 days *in vitro* (DIV), hESC-derived GABAergic neurons showed mature electrophysiological properties and spontaneous synaptic currents that could be enhanced using 460 nm blue light to activate ChR2. We then co-cultured these cells at 14 DIV with human primary neurons to investigate whether these cells received functional afferent synapses. Thereby, we could test if the activity of the cultured primary neurons was inhibited by using blue light, which would indicate that hESC-derived GABAergic neurons do integrate into the neuronal network. This study opens the possibility to develop a new potential treatment by means of the transplantation of these inhibitory cells to obtain a precise temporal control of the neuronal network excitability in diseases like epilepsy.

Title: A novel pseudogene-encoded long noncoding RNA mediates fetal alcohol effects

Authors: *N. A. SALEM[1,2], A. M. TSENG[1], A. H. MAHNKE[1], C. GARCIA[1], H. JAHROMI[1], R. C. MIRANDA[1,2];

Abstract: Prenatal alcohol exposure is a leading cause of neurodevelopmental disability. We previously found that ethanol exposure caused a loss of neural stem cells (NSCs) due to premature maturation. We asked whether ethanol could inhibit NSC self-renewal capacity, as an explanation for their ethanol-induced depletion. We assessed the regulation of the homeobox transcription factor, Oct4/POU5F1, which is important for maintaining stem cell renewal. Ethanol treatment resulted in a dose-related decrease in Oct4/Pou5f1 protein in NSCs. The Oct4 family includes a number of transcribed pseudogenes. Only one member of the murine Oct4 pseudogene family is expressed in NSCs as a long non coding-RNA lncRNA (Oct4pg9). We assessed Oct4pg9 lncRNA expression in neurospheres, along with mRNA transcripts for Oct4 and associated stem cell fate markers. We report that Oct4pg9 is expressed in NSCs at

significantly higher levels than the parent Oct4 mRNA transcript, its expression in the nucleus is ten-fold higher than in the cytoplasm. Ethanol exposure resulted in a dose-related increase in Oct4pg9 lncRNA expression. Oct4pg9 overexpression resulted in increased GLAST, DCX, NeuN and GFAP transcripts. This effect was mimicked by ethanol exposure. In contrast, Oct4pg9 knockdown results in elevated Oct4, and REST mRNA transcripts, but downregulation of DCX mRNA. These data suggest that ethanol-mediated elevation of Oct4pg9 shifts NSCs towards a neuronal/oligodendrocytic fate. Oct4pg9 overexpression decreased Oct4 3'UTR-controlled luciferase expression indicating that Oct4pg9 influences translation regulation at the Oct4 3'UTR. Our data show that Oct4pg9 associates with the miRNA chaperone, Ago2 and that capture of native Oct4pg9 resulted in preferential recovery of three miRNAs, miR-328-3p, miR-744-5p and miR-642a-5p suggesting that Oct4pg9 is a miRNA sponge. Overexpression of Oct4pg9 resulted in decreased expression of miR-328 (effect size= -0.93), an identified suppressor of tumor cell proliferation. Oct4pg9 overexpression and ethanol exposure may both increase cell proliferation in part by sequestering miR-328. Our results suggest that a novel lncRNA may regulate NSC renewal and mediate some of the teratogenic effects of ethanol through translation-regulatory mechanisms.

Title: Activation of innate immune responses inhibits neurogenesis

Authors: *P. XU[1], J. GAO[1], C. SHAN[2], X. XIE[2], T. DUNN[1], N. VASILAKIS[3], P. SHI[2], S. WEAVER[4], P. WU[1];

Abstract: Objective: Globally Zika virus (ZIKV) outbreaks and their strong link to microcephaly have raised public health concerns. Studies have shown that ZIKV disrupts neural progenitor development, leading to microcephaly in mice. In human cerebral organoids, ZIKV depletes neural progenitors through activation the innate immune receptor Toll-like-Receptor 3 (TLR3). Using human neural stem/progenitor cell (hNS/PC) lines, our lab has reported that ZIKV inhibits neuronal differentiation in a cell-strain-dependent manner, which is well correlated with the alteration of global gene expression patterns, including the innate immune pathways. Nevertheless, how these immune factors affect neurogenesis is largely unknown. In this project, we sought to determine the role of innate immune genes/pathways in the hNS/PC line-dependent reduction of neurogenesis after TLR3 activation. Methods: Three hNS/PC lines were treated by ZIKV (PRVABC59) or TLR3 agonist poly(I:C) at the proliferating, priming or early differentiating stage. The mRNA levels of genes in the TLR3/IFN/MHC pathway and neurogenesis transcription factors were measured by qRT-PCR. The protein levels of pSTAT1, STAT1 and Beta-2-Microglobulin (B2M) were measured by Western blot. Newly differentiated neurons and astrocytes were detected by several makers through immunostaining. Results: Poly(I:C) robustly induced genes transcription in the TLR3/IFN/MHC pathway (TLR3, IRF7, IRF3, STAT1 and B2M) in K048 and K054 hNS/PC lines, but in G010 hNS/PC line only marginally. Moreover, these genes were transcribed in a stage-dependent manner, as they were only activated when Poly(I:C) was used in the priming and differentiating stages, but not in the proliferating stage. Correspondingly, the K048 and K054 showed a significant reduction in newly differentiated neurons, especially in the priming stage, whereas the G010 was not affected at any stage. Similarly, ZIKV (PRVABC59) robustly promoted genes transcription in the TLR3/IFN/MHC pathways in hNS/PCs, and this alternation was observed in both the proliferating and priming stages. Conclusion: TLR3 activation in neural stem cells induces innate immune responses and impairs neurogenesis in a cell-strain-dependent and a time-dependent manner.

Title: Studying functional neurogenic plasticity from genes to spikes on a-multiscale-CMOS-chip

Authors: *H. AMIN[1], G. KEMPERMANN[1,2];
[1]German Ctr. for Neurodegenerative Dis. (DZNE), Dresden, Germany; [2]Ctr. for Regenerative Therapies Dresden (CRTD), Technische Univ. Dresden, Dresden, Germany

Abstract: Adult neurogenesis provides a continuous influx of new neurons to invigorate the brain's plasticity to adapt and change with experience. These newly-generated cells add unique properties to existing networks and contribute to particular computational functionalities of memory formation and learning process. Neuronal activity regulates genes controlling neuronal development and plastic modifications within mature networks. However, the interplay of molecular mechanisms supporting electrophysiological functions remains undefined. We report here that increasing in synaptic input conferred by heightened network-wide firing activity induces immediate-early genes (*NPAS4*, *Fos*, and *Egr1*) responses in newly neurons integrated into a resident network. We implemented a human-based on-a-chip system combined with quantitative real-time polymerase chain reaction, calcium imaging to systematically decipher the multiscale functional and molecular role of newly-generated neurons in resident networks. Indeed, this functional plasticity coordinated gene expression program is significant to experience-driven synaptic changes associated with information processing thus has implications for healthy aging and neurodegeneration.

Title: Identification and characterisation of authentic dopaminergic neurons at single cell resolution in human ventral midbrain patterned organoids

Authors: *M. BIRTELE, A. FIORENZANO, Y. SHARMA, J. NELANDER, B. MATTSSON, M. P. PARMAR;
Lund Univ., Lund, Sweden

Abstract: Parkinson's disease (PD), one of the most common neurodegenerative disorders, is characterized by a progressive loss of dopamine (DA) neurons in the ventral midbrain (VM). The inability of two-dimensional (2D) *in vitro* cultures to recapitulate the complexity of the

architecture and cell composition has made the study of human VM challenging. Despite intensive research efforts, the molecular mechanisms controlling both the development and functional maturation of DA neuron subtypes remains largely unknown.In this study, we designed a new method for expanding and differentiating human fetal cells dissociated from the VM of 7-9 weeks old human embryos. We developed athree-dimensional (3D) organoid culture system with the aim to better preserve authentic and functional DA neurons *in vitro*. Using fetal-derived organoids as valuable reference, we also conducted a comparison between fetal-derived and human embryonic stem cell(hESC)-derived VM organoids.Using single cell RNA sequencing (scRNA-seq) we compared human fetal cells from 2D and 3D *in vitro* culture systems. Despite the analysis showing that both cell preparations initially gave rise the same culture composition, the 2D system promoted proliferation of glial and oligodendrocyte progenitors, with limited surviving neuronal populations. On the contrary, 3D organoids could sustain the maturation of the neuronal population, and importantly maintained the dopaminergic neuronal compartment.Intriguingly, we have also found clear differences between fetal and hESC-derived organoids at the single cell resolution. While both cell preparations gave rise to neurons, we found that astrocytes and oligodendrocytes were detected only in fetal organoids whereas a barrier forming fibroblast-like cell type normally present in the brain was identified as a unique component of hES-derived organoids during late stage differentiation.Taken together these results represent an important step in characterizing both fetal derived- and hESC-derived authentic dopaminergic neurons through the use of novel 3D-culture conditions which better recapitulates the features of human ventral midbrain.

Title: Sex differences in ethanol's effects on fetal neural stem and progenitor cells

Authors: *A. H. MAHNKE, H. M. AL-MUHISEN, A. M. TSENG, N. A. SALEM, R. C. MIRANDA;
Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Prenatal alcohol exposure can result in growth and neurodevelopmental deficits, collectively termed 'Fetal Alcohol Spectrum Disorders'. We have found that ethanol reprograms neural stem and progenitor cells to favor premature maturation and decrease self-renewal. Recent evidence has shown that genetic sex is an important determinant gene expression and lineage progression in the adult ventricular-subventricular zone. Here, we investigated sex differences in the developing neural stem cell niche *ex vivo*, using neurosphere cultures derived from murine dorsal neuroepithelium at GD 12.5. Separate suspension cultures were prepared from male and female tissue samples based on the qPCR assessment of the presence of the Y Chromosome (YMT region). Female neurospheres were more stem-like than male neurospheres, with higher rates of secondary neurosphere formation. In contrast, male neurospheres showed fewer secondary neurospheres but with a higher number of viable cells. This increased cell number in males is associated with a larger proportion of cells in mitotic S-phase and higher rates of DNA synthesis, indicating that male neurospheres were enriched for more lineage committed, transit amplifying-like populations. Sex-segregated neurospheres were exposed to ethanol for 5 days and were assessed for the expression of markers of neural stem cells and differentiation lineages using qPCR. Control male and female neurospheres had similar levels of stem cell and differentiation markers, with the exception of progenitor/gliogenic GFAP mRNA which was higher in the male neurospheres. Ethanol exposure at low doses (60 mg/dL) affected mRNA transcript levels only in female neurospheres, which had increased mRNA expression of stem/progenitor marker nestin mRNA and decreased expression of neurogenic and gliogenic transcripts. Ethanol exposure at chronic alcohol use levels (320 mg/dL) decreased neural, astrocytic, and oligodendrocytic markers in male neurospheres while the female neurospheres exhibited a moderate reduction in oligodendrocytic markers. Preliminary analysis of RNAseq data indicates a monotonic relationship between the number of transcripts altered at a large effect size and ethanol dose. These data provide evidence of sex differences in neural stem and progenitor cell dynamics in the developing cortex. Ethanol exposure alters the neurosphere transcriptome and further work will elucidate the contribution of sex to these ethanol-induced alterations. More research is needed to understand how these interactions between sex and alcohol shape cortical development and neurobehavioral deficits following prenatal alcohol exposure.

Title: Alcohol effects on the proteome of fetal neural stem cell-derived extracellular vesicles

Authors: *D. CHUNG[1], A. TSENG[1], M. PINSON[1], L. DANGOTT[2], S. WEINTRAUB[3], R. C. MIRANDA[4];
[1]Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Texas A&M Univ., College Station, TX; [3]UT Hlth. San Antonio, San Antonio, TX; [4]Neurosci. & Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr, Col. of Med., Bryan, TX

Abstract: Prenatal alcohol exposure can result in craniofacial abnormalities, growth deficits, and is the leading cause of neurodevelopment disability worldwide. Neural stem cells (NSCs) are particularly vulnerable to alcohol (ethanol) exposure during the late first through the second trimester, when they are most extensively involved in neurogenesis. NSCs reside in a complex microenvironment rich in extracellular vesicles (EVs), which are shown to traffic protein, lipid, and RNA cargo between cells, that can serve as a mode of intercellular communication. Using fetal mouse derived cortical neuroepithelium, cultured ex-vivo as non-adherent neurosphere cultures, we previously found that ethanol exposure resulted in significant alterations of miRNA cargo in EVs.
To further assess the extent to which ethanol influenced the EV cargo, we investigated the impact of genetic sex on the proteome of EVs secreted by NSCs. EVs were isolated by ultracentrifugation from basal and ethanol-treated male and female derived NSCs, maintained as neurosphere cultures, and their proteome was assessed by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Sample data were analyzed using Mascot (Matrix Science, London, UK; version 2.6.0). Scaffold (version 4.8.5, Proteome Software Inc., Portland, OR) was used to validate MS/MS based peptide and protein identifications. From our EV samples, we found over 2700 total proteins, with about 1400 proteins being represented in all the samples. For the top 25% most abundant proteins on the ratio intensity plot, the majority of proteins are within the 2-fold protein ratio of female to male. The top 100 most abundant proteins were expressed at similar levels across all samples. However, a number of proteins were expressed uniquely in male or female-derived EVs, suggesting that there may be sex-specific control over the behavior of the neurogenic niche during early fetal development. Through gene enrichment analysis, we found that our EV proteins were enriched for genes that are used for cell-cell recognition, protein

translation and transport. Based on my preliminary proteomic analysis, I also identified several RNA binding proteins (RBPs) in EVs secreted from NSCs. A number of these RBPs (e.g., HSP90AB1, HSPA8, HSP1A, and HSPD, Hsc70 and Hsp90) belong to the heat shock protein family that plays an important role in miRNA-mediated gene silencing. Consequently, our observation that ethanol elevated microRNA levels in NSC-derived EVs may be explained by alterations in miRNA binding RBPs, or alternately the miRNA binding capacity of RBPs, which are predicted to increase the loading of associated miRNAs.

Title: Effects of cocaine on an *in vitro* model of human pluripotent stem cell derived ventral midbrain neurons

Authors: *K. THANGAMANI[1], J. A. GOMEZ[1], C. HUTCHINSON[1], A. M. MAROOF[2]; [2]Dept. of Biol., [1]Univ. of Texas San Antonio, San Antonio, TX

Abstract: Addiction can be defined as a drug induced neural plasticity that leads to compulsive seeking of reward. To combat drug addiction effectively we must elucidate the cellular mechanisms that are involved upon exposure to drugs. Midbrain dopaminergic neurons are involved in acute and chronic responses to drugs. Even though this region has been studied in, much of what's been learned has not been studied in human counterparts. Therefore, the question arises, do human dopamine neurons express the pathophysiological phenotypes observed in rodent dopamine neurons when exposed to cocaine? To address this, I generated and isolated putative ventral midbrain neurons from human pluripotent stem cells (hPSCs). After characterizing these cells generated under defined differentiation conditions, I co-cultured them with primary glia to accelerate maturation of the derived neurons. After establishing stable conditions to accelerate maturation, I exposed these neurons to cocaine and determined these cell's spike rate is higher than saline treated . This model serves as a novel platform to study substance abuse in human neurons.

Title: Diversity of inhibitory neurons and glial cells in human cortical organoids generated from stem cell-derived single neural rosettes

Authors: *L. A. BELL, Y. WANG, C. RUSSELL, Y. WU, C. ARMSTRONG, G. YANG, A. SHCHEGLOVITOV;
Univ. of Utah, Salt Lake City, UT

Abstract: The neocortex is a highly complex brain structure with many human-specific features of development and function. Remarkably, this structure organizes from a pool of neuroepithelial cells organized in a tube-like structure called the neural tube. The cortex further develops to comprise a multitude of neural cell types including glutamatergic excitatory neurons and GABAergic inhibitory neurons together with a variety of glial and mural cell-types including astrocytes, oligodendrocytes, and pericytes. While excitatory neurons of the cortex arise from the dorsal pallium of the embryonic telencephalon, inhibitory neurons are traditionally thought to arise from the ventral subpallium and undergo migration to more dorsal areas. In order to study human corticogenesis, we have developed a system to generate 3D cortical organoids from a single neural rosette, a neural tube-like structure *in vitro.* Using a combination of single-cell RNA sequencing (scRNA-seq) and immunohistochemistry, we characterized the populations of cells in single rosette-derived cortical organoids (SRCOs) at different developmental stages (1 and 5 months post induction). We observed that 1-month-old SRCOs produce a variety of neural progenitors and both excitatory and inhibitory neurons. Using developmental trajectories, we identified the specific transcriptional programs that lead to the production of inhibitory neurons in SRCOs even in the absence of SHH agonists and Nkx2.1-expressing cells. After 4 months in culture, we find that SRCOs show maturation and radial organization of a variety of neural cell types including deep and superficial cortical excitatory neurons, a variety of inhibitory neurons, astrocytes, oligodendrocytes, and mural cells. Together, our results provide novel insights into

the molecular programs that are activated during different stages of human cortical development and could be disrupted in patients with developmental disorders.

Title: Ruta graveolens stimulates neural plasticity of human and mouse embryonic mesencephalic neuronal cell progenitors

Authors: *G. CIMAGLIA, M. T. GENTILE, O. PASTORINO, L. COLUCCI-D'AMATO; DiSTABiF, Lab. of Mol. Neuropathology, Univ. of Campania "Luigi Vanvitelli", Caserta, Italy

Abstract: Neural stem cells (NSCs) proliferation and differentiation play a pivotal role in the generation of functional neuronal networks. However, NSCs as they develop and acquire the features of a mature neuronal phenotype progressively lose their ability to proliferate. Here we demonstrate that *Ruta graveolens* aqueous extract (*R. graveolens* a.e.), already shown to own selective activity on neural cells, it is capable to induce a pro-proliferative effect and to promote neural plasticity on neurons generated from two embryonic neuronal mesencephalic cell progenitors stem cell lines (mouse mes-c-myc A1 (A1) and its human counterpart ventral mesencephalic immortalized stem cell line). Both cell lines were exposed to *R. graveolens* a.e. treatment according to their experimental protocols. Both cell lines respond with an increase of neuronal cell number as shown by positivity to neuronal markers such as βIII tubulin and/or MAP-2. Even though the treated cells were fully differentiated they were still able to increase Ki67 a marker for active proliferation. Furthermore, morphologic analyses on A1 cells shown that *R. graveolens* a.e. besides enhancing the number of mature neurons also increased neurite outgrowth. Molecular analysis shows that *R. graveolens* a.e. treatment, induces expression of genes belonging to neural stem cell lineage such as rest/nrsf, nestin and light neurofilament. Therefore, we suggest that *R. graveolens* a.e. treatment might represent a powerful tool to both induce cell cycle re-entry of mature neurons and promote neural plasticity in pathological conditions were is lost.

Title: Micrornas and histone deacetylase inhibition mediated differentiation of human mesenchymal stem cells into neuronal lineage

Authors: ***S. JANG**[1,3], H.-S. JEONG[1,3], H.-H. CHO[2,3], S. PARK[1], J.-S. PARK[1,3], S.-H. PARK[1]; [1]Physiol., Chonnam Natl. Univ. Med. Sch., Hwasun-gun, Korea, Republic of; [2]Otolaryngology and Head and Neck Surgery, Chonnam Natl. Univ. Med. Sch., Gwangju, Korea, Republic of; [3]CNUH Biomed. Res. Inst., Gwangju, Korea, Republic of

Abstract: Histone deacetylase (HDAC) inhibitors play important roles in the cell homeostasis and cell cycle progression and have potentials to enhance self-renewal abilities and directed differentiation of stem cells. We previously identified a set of HDAC inhibitors can induce neurogenic differentiation of human adipose tissue-derived mesenchymal stem cells (MSCs) through canonical- and non-canonical Wnt signaling pathways. In the present study, we hypothesized that the HDAC inhibition-mediated neurogenic differentiation is regulated by the microRNAs (miRNAs) in human MSCs. By performing a miRNA-mRNA paired microarray screening, we identified and selected two candidates (miR-124 and miR-133b) among the most upregulated miRNAs after HDAC inhibitor treatment (MS275, sodium butyrate, trichostatin A, or valproic acid). After selection of the miRNAs, we investigated the ability of neurogenic differentiation of miRNAs in human MSCs by a quantitative PCR. The expressions of *TUJ1* and *MAP2* were highly increased following miRNAs treatment compared with control medium. In addition, the expression of most of the Wnt-related genes was highly increased following treatment of miRNAs. Further, the protein level of canonical- and non-canonical Wnt was upregulated after miRNAs treatment, based on western blot analysis. Using bioinformatics and functional assay, we confirmed that miR-124 and miR-133b potentially regulated Wnt signaling pathway. These findings suggest that the HDAC inhibitors enhance the neurogenic differentiation of human MSCs via the miR-124 and miR-133b and activate the neuronal gene expression and Wnt signaling pathway. In conclusion, we demonstrate a possible new

mechanism by which HDAC inhibition-induced miRNAs are required to regulate Wnt signaling and control neurogenic differentiation of human MSCs.

Title: Effects of CO1, an active compound from Chinese medicine, on modulating neural stem cells fate decision via mitochondrial metabolism

Authors: *Q. DU, R. DENG, C. GAO, J. SHEN;
The Univ. of HK, Hong Kong, Hong Kong

Abstract: Numerous researches demonstrate that mitochondria are central regulators of fate decision of neural stem cells (NSCs). NSC are regarded as a promising therapeutic approach to protecting and restoring damaged neurons in neurological disease. However, new research suggests that NSC reprograming is required to make this strategy effective. Here, we found one potential drug CO1, an active compound from Chinese Medicine, could modulate stem cell fate decision through mitochondrial metabolism. We tested the impact of CO1 on embryonic stem cell (ESC) proliferation and mitochondrial structural and function parameters, such as membrane potential and ATP synthesis, as well as oxidative stress indicators. The results indicated that CO1 dose-dependently increases ATP concentration, mitochondrial membrane potential, and ROS synthesis to inhibit the ESC proliferation and promotes it reprogramming into NSC. Therefore, we concluded that CO1 could efficiency develop ESC into NSC via mitochondrial activity promotion.

Title: Slc52a3 gene disruption affected the development of cerebral cortex in mice

Authors: *C. JIN[1,2], A. YONEZAWA[1,2], H. YOSHIMATSU[1,2], S. IMAI[1], M. KOYANAGI[1,2], K. YAMANISHI[1,2], S. NAKAGAWA[1], T. OMURA[1], T. NAKAGAWA[1], K. MATSUBARA[1]; [1]Dept. of Clin. Pharmacol. and Therapeut., Kyoto Univ. Hosp., Kyoto, Japan; [2]Grad. Sch. of Pharmaceut. Sci., Kyoto Univ., Kyoto, Japan

Abstract: Background: Riboflavin transporter 3 (RFVT3), encoded by the SLC52A3 gene, is highly expressed in the small intestine, kidney, testis and placenta. Mutations in SLC52A3 were associated with a rare neurological disorder, Brown-Vialetto-Van Laere syndrome. Our previous studies demonstrated that Slc52a3 knockout (Slc52a3-/-) mice exhibits neonatal lethality, riboflavin deficiency and metabolic disorder. Here, we investigated the inference of Slc52a3 gene disruption to embryonal development of brain using Slc52a3-/- mice. Methods: Slc52a3-/- mice were obtained from Knockout Mouse Project repository. Brains were dissected at embryonic day 13.5 (E13.5) and immediately after delivery (P0). Morphological changes in the whole brain at P0 were observed by histochemistry. Expressions of neuron and intermediate neural progenitors (INPs) makers (Tuj1 and Tbr2) were evaluated by immunohistochemical analysis. Riboflavin concentrations were measured by HPLC. Results: Brain riboflavin levels were decreased in Slc52a3-/- mice compared with WT mice. Histological and immunohistochemical analysis of brains in Slc52a3-/- newborn pups showed hypoplasia and global reduction of cerebral cortex. Slc52a3-/- pups have normal cortical lamination, but the thickness of cortical layers was significantly reduced. Evaluation of Slc52a3-/- embryos at E13.5 indicated that Tuj1-positive neurons and Tbr2-positive INPs were significantly decreased, compared with WT mice. Conclusions: Disruption of Slc52a3 gene reduced the production of INPs and neurons during the embryonic period and could influence the development of cerebral cortex in mice.

Title: Visualizing neural correlates of Tourette's-like motor tics in brain slices with genetically encoded voltage indicators

Authors: *J. RHEE[1,2], B. J. BAKER[1,2];
[1]Ctr. for Functional Connectomics, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]KIST Sch., Korea Univ. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: For some cases of Tourette's, Deep brain stimulation (DBS) of thalamic nuclei may be the only way to alleviate the patients' symptoms. Currently, however, there is neither a comprehensive understanding of the neural circuitry involved in Tourette's nor how DBS corrects the dysfunction. To explore whether Arclight-derived genetically encoded voltage indicators (GEVIs) can be used to detect activity resembling the neural correlates of Tourette's-like motor tics, the motor cortex was imaged to visualize both the neuronal excitation and inhibition during bath application of bicuculline in an in vitro brain slice preparation. Ensemble firing of neurons resulting in an oscillation in the motor cortex was detected, using wide-field fluorescence microscopy with 3 different GEVIs consisting of different kinetics and voltage sensitivities. All 3 GEVIs were capable of detecting oscillations: Arclight in the 5-15 Hz, Bongwoori-R3 and Bongwoori-pos6 in the 5-25 Hz range. Oscillations arose spontaneously, and correlated pixels of an oscillation showed varying patterns with no clear spatial origin.

Title: Sexually-dimorphic dopamine signaling dictates the penetrance and behavioral trajectory of human dopamine transporter coding variation as revealed in studies of DAT Val559 mice

Authors: *A. STEWART[1], R. GOWRISHANKAR[1,4,5], R. PEART[2], M. J. RABIL[1], K. SPIESS[1], M. K. HAHN[1,3], R. D. BLAKELY[1,3];
[1]Biomed. Sci., [2]Honors Col., [3]Brain Inst., Florida Atlantic Univ., Jupiter, FL; [4]Neurosci. Grad. Program, [5]Intl. Scholars Program, Vanderbilt Univ., Nashville, TN

Abstract: Virtually all neuropsychiatric disorders display sex bias, with the prevalence, age of onset, and clinical symptomology differing significantly between males and females. Amongst the most strongly skewed are Attention-Deficit/Hyperactivity Disorder (ADHD) and Autism Spectrum Disorder (ASD) for which the ratio of male:female diagnoses hovers at 4:1. Accumulating evidence indicates that genetic/gonadal sex influences a number of brain functions including the release, reuptake, and signaling response to dopamine (DA), a neurotransmitter implicated in ADHD and ASD. In an effort to identify penetrant genetic changes in DA signaling that drive ADHD risk, and generate construct-valid animal models of the disorder, the Blakely lab screened for coding variation in the DA transporter (DAT) in ADHD subjects, identifying the Ala559Val substitution in two brothers. The DAT Val559 variant has also been found in a girl with bipolar disorder and two unrelated boys with ASD. Though capable of clearing DA, the DAT Val559 mutant exhibits spontaneous outward DA leak, leading to homeostatic DA disruptions in DAT Val559 mice. We now report profound, sex-dependent phenotypic divergence in DAT Val559 mice that derives, at least in part, from circuit-specific DA D2 receptor (D2AR)-DAT coupling. In male DAT Val559 mice, presynaptic nigrostriatal D2ARs are constitutively-activated, driving enhanced DAT surface trafficking, an effect is absent in DAT Val559 females. However, females show constitutive D2AR activation of presynaptic mesolimbic D2ARs. These findings are paralleled by sex-specific differences in extracellular DA clearance as assessed by *in vivo* chronoamperometry. These sex differences in DA biology translate into a differential impact of the mutation on behavior and psychostimulant action. Male DAT Val559 mice exhibit blunted amphetamine-induced locomotion, aberrant social interaction in the tube test, and decreased spontaneous alternation in the Y-maze, phenotypes absent in their female counterparts. The DAT Val559 mutation also resulted in enhancement of amphetamine-induced c-Fos activation in the dorsal striatum of females whereas this effect is seen in the ventral striatum of males. When the rewarding properties of cocaine were assayed, male DAT Val559 animals displayed delayed conditioned place preference extinction whereas extinction was accelerated in DAT Val559 females. Overall, these studies provide striking evidence of a sexually dimorphic impact of functional DAT coding variation and reveal an important opportunity to gather insights into the sex-dependence of behavioral trajectories that attends neuropsychiatric disease risk.

Title: Characterisation of William's syndrome zebrafish mutants: fzd9b and baz1b

Authors: *J. TORRES PEREZ, C. H. BRENNAN;
Sch. of Biol. and Chem. Sci., Queen Mary Univ. of London, London, United Kingdom

Abstract: Rationale and research objective: William's Syndrome (WS) is an autosomal dominant developmental disorder affecting around 1 every 7500-10000 individuals. It is caused by an haploinsufficiency on the chromosome 7 covering some 28 genes. Neurological impairments among people with WS include difficulty with visual-spatial tasks and with large number discrimination, attention deficit disorders and elevated anxiety. From the genes missing in this microdeletion, two seem key for the neurodevelopmental phenotype: frizzled class receptor 9 (fzd9) and bromodomain adjacent to zinc finger domain 1B (baz1b). Fzd9 encodes for a 7 transmembrane protein receptor from the Wnt signalling pathway. Neuronal deficiency of fzd9 leads to longer dendrites, increased number of spines and altered network connectivity. Baz1b encodes for a transcription factor which acts as neuroepigenetic switch for migration and neuronal maintenance during neurodevelopment. Deletion of this gene also leads to increased dendrite arborization and altered neuronal linkage. **Methods and results:** Here, we generated two knockout mutant zebrafish (*Danio rerio*) lines for fzd9 receptor b (fzd9b) and baz1b using the CRISPR-Cas9 technology to explore their behavioural and molecular phenotypes. All experiments were carried out in accordance with the Animals (Scientific Procedures) Act, 1985, under guidance from the Queen Mary Animal Care and Use Committee and the UK Home Office. Based on power calculations, we aimed to use around 20 larvae from each line for shoaling assay and/or for the light/dark test. Furthermore, few animals were PFA-fixed at different stages to assess the expression pattern of fzd9b and baz1b via wholemount *in situ* hybridization. Our results suggest that fzd9b and baz1b play a key role on zebrafish neurodevelopment and specially in the WS phenotype. **Conclusions:** We generated viable loss-of-function lines that show distinct phenotypes covering aspects of the WS. These lines provide a robust animal model for future research into the neurobiology of WS.

Title: Structural integrity of cholinergic neurons in the NBM-cortical pathway following behavioral intervention in adulthood in a rodent model of fetal alcohol spectrum disorders (FASD)

Authors: *K. A. MILBOCKER[1], N. K. GINN[1], Z. H. GURSKY[2], A. Y. KLINTSOVA[3]; [2]Dept. of Psychological & Brain Sci., [3]Psychological and Brain Sci., [1]Univ. of Delaware, Newark, DE

Abstract: One in twenty infants in the United States are affected by prenatal alcohol exposure (PAE) resulting in a range of disorders categorized as Fetal Alcohol Spectrum Disorders (FASD). PAE during late-stage pregnancy can produce lasting deficits of cortical-dependent behaviors in affected individuals (executive function, i.e. decision-making and inhibitory control). Evidence from human cases and animal models of FASD suggest that cognitive impairments could be mitigated by non-invasive intervention such as choline supplementation (Fuglestad et al., 2013; Idrus et al., 2017). However, it is unknown if environmental stimulations can produce changes in cholinergic function paralleled by morphological changes in cholinergic neurons.

Our study examines the effects of adult exposure to two behavioral interventions on the integrity of cortical-projecting cholinergic neurons from the nucleus basalis of Meynert (NBM) to the prefrontal cortex in a rat model of FASD. Male Long-Evans rats were exposed to binge-like alcohol (5.25 g/kg/day) on postnatal days (PD) 4-9. Control groups included sham-intubated (SI) and suckle-control (SC) rats. Pups were weaned into same-sex cages of three on PD23 (social housing, SH). On PD30, rats were either: 1) given free access to a running wheel (WR), 2) exposed to “super-intervention” consisting of twelve days of WR followed by four weeks of housing in a complex environment (EC), or 3) remained in SH from PD30-72. Immunocytochemical visualization of ChAT+ neurons in NBM was performed on brain tissue collected at PD72. Preliminary analyses of unbiased stereological estimates show a significant increase in the number of cholinergic neurons ($F(1, 27) = 6.63$, $p = 0.02$; interaction with treatment $p = 0.08$) and volume of NBM ($F(1, 27) = 4.65$, $p = 0.04$) following super-intervention. However, it appears that the intervention affects postnatal treatment groups differently, indicating decreased neuroplasticity in AE rats long-term. Chronic exercise intervention had no effect on the number or size of cholinergic neurons in the NBM in both control and AE rats.

Finally, a Hedreen and Bacon modified Karnovsky Roots histochemical stain was used to visualize AChE+ axon fibers in prelimbic medial prefrontal cortex (Cg2) of rats from all intervention groups at PD72. Neither behavioral intervention significantly altered cholinergic axon length (as measured with the Spaceballs stereological probe) or volume of Cg2 in animals of all three postnatal treatment groups. Our study suggests that cholinergic neuron integrity is largely conserved following neonatal alcohol exposure and behavioral intervention in adulthood along the NBM-cortical pathway.

Title: Understanding the neurodevelopment basis of DDX3X syndrome

Authors: *D. C. UNG[1,2,3], A. BOITNOTT[1,2,3], D. MENDONCA[1,2,3], K. NIBLO[1,2], E. DRAPEAU[1,2], S. DE RUBEIS[1,2,3];
[1]Psychiatry, Icahn Sch. of Med., New york, NY; [2]The Seaver Autism Ctr. for Res. and Treatment, New York, NY; [3]The Mindich Child Hlth. and Develop. Inst., New York, NY

Abstract: DDX3X syndrome is a recently identified rare intellectual disability (ID) caused by mutations in the DEAD-box helicase 3 X-linked (*DDX3X*) gene. In addition to ID, affected individuals present with behavioral problems including Autism Spectrum Disorder, movement disorders, and brain anomalies including cortical malformations. Most affected individuals are females with *de novo* mutations in *DDX3X*; only a few affected males have been reported. DDX3X is an RNA helicase which regulates mRNA translation in non-neuronal cells. To date, the exact functions of DDX3X in neurons and at synapses is poorly understood. The objective of this study is to understand the molecular and cellular mechanisms of DDX3X during neurodevelopment (corticogenesis and synaptogenesis) and to explore its impact on behavior. We have generated a novel conditional knockout mouse recapitulating DDX3X syndrome. We study the effect of *Ddx3x* deficiency on corticogenesis by examining cortical lamination using immunostaining techniques with layer-specific markers at postnatal day 3 (P3) and by using a retrograde virus to label corticofugal projection neurons at P21 in *Ddx3x*-deficient ($Ddx3x^{+/-}$) and control ($Ddx3x^{+/+}$) female mice (n=6 mice/genotype). We investigate the impact of *Ddx3x*

deficiency on physical, motor, and sensory behaviors by assessing developmental milestones (P1-P21) and by testing cognitive and social behavior at the adult stage of our *Ddx3x* mouse (n=10 mice/genotype/experiment). We also apply biochemical methods to dissect the complexes mediating DDX3X-dependent translational using synapses from mouse cortices and perform an innovative method to map mRNA targeted by DDX3X (vTRAP-seq) (n=6).To study synaptogenesis, we use our mouse model to assess synapse morphology in single-embryo neuronal cultures modelling the genetics of DDX3X syndrome using a CRE-LOX strategy (n=8 embryo/genotype). We found that *Ddx3x* null male mice (*Ddx3x*$^{-/y}$) die *in utero*, compatible with the dearth of boys affected by DDX3X syndrome. *Ddx3x*-deficient females (*Ddx3x*$^{+/-}$) are viable, have reduced DDX3X protein expression in the cortex compared to controls, and have delayed developmental milestones compared to control females. DDX3X is expressed in glutamatergic projection neurons in the developing cortex and we are characterizing cortical connections and synaptogenesis in *Ddx3x*-deficient mice. In conclusion, we have generated a mouse model with construct validity for DDX3X syndrome that shows initial evidence for face validity through behavioral analyses. Through these approaches we expect to expose, with molecular and cellular resolution, the core neurobiology of DDX3X syndrome.

Title: Age and sex differences in behaviors relevant to schizophrenia and addiction

Authors: *E. R. CULLITY, A. A. GUÉRIN, H. B. MADSEN, C. J. PERRY, J. H. KIM; Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia

Abstract: Dopamine receptors 1 (D1) and 2 (D2) are important for neurodevelopmental disorders. We have shown previously that in the insula cortex, the density of D1 expressing neurons compared to D2 expressing neurons (D1:D2 ratio) is lower in adolescent male mice when compared to adolescent female, and adult male and female mice. Since addiction and schizophrenia are male dominant disorders which often have an adolescent onset, this reduced

D1:D2 ratio may be relevant in understanding the neurobiological basis of these disorders. Using a methamphetamine (meth) conditioned place preference (CPP) paradigm, I examined potential age and sex differences in meth-induced hyperactivity- relevant to psychosis in schizophrenia- as well as meth-induced place preference- relevant to addiction. Brains were perfused to investigate activation of D1- and D2-expressing cells within the insula cortex following these behaviors. I hypothesized that psychosis-like and addiction-related behaviors would be associated with a reduced D1:D2 ratio in the insula cortex, and that adolescent males would form a stronger meth CPP compared to adolescent females and adult males and females. Meth at 3 mg/kg increased locomotor activity in all mice (*n*=19-27 per age and sex group), and this effect was enhanced in adults compared to adolescents; no effects were found at 0.1 mg/kg. At 0.1 mg/kg, a higher proportion of male adolescents formed a preference to meth compared to male adults. In contrast, at 3 mg/kg, a higher proportion of male adults formed an aversion to meth compared to male adolescents. There were no age differences in females at either dose. These results suggest there is an age effect in the development of meth-induced hyperactivity, and that more male adolescents showa preference for meth compared to male adults. Collection of brain data is ongoing.

Title: The role of Crb complex in hydrocephalus pathogenesis

Authors: *M. LEE, S.-H. CHO, S. KIM;
Shriners Hosp. Pediatric Res. Center, Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: Hydrocephalus is a condition in which the intracerebral ventricles are engorged because cerebrospinal fluid (CSF) is obstructed, overproduced, or inadequately reabsorbed. Among the most common neurodevelopmental disorders, it can be caused by genetic mutation, infection, or brain injury. Without timely surgical intervention, it produces devastating intellectual and motor disability. However, the cellular and molecular mechanisms of hydrocephalus pathogenesis are not well understood, which precludes development of preventive

treatments. Previous genetic studies point to the importance of adhesion molecules, such as L1, and tight junction-associated proteins, such as MPDZ, in the pathogenesis of hydrocephalus in humans. Mutations in Crb2 also evoke hydrocephalus in humans, emphasizing the pathogenetic importance of the Crb complex, which includes Crb1/2/3, MPDZ/Patj and Pals1. To understand the mechanism by which Crb2 causes hydrocephalus, we developed a mutant mouse with nervous system-specific deletion of Crb2. We found that Crb2 deletion causes aqueduct stenosis with obvious hydrocephalus at birth and additional abnormalities in cerebral cortex, including periventricular heterotopic neurons. Analyses using cell-specific markers revealed that these heterotopia are primarily composed of late born neurons and astrocytes. Importantly, ependymal cells lining the ventricular aqueduct do not develop in the absence of Crb2, leading to the fusion of ventral aqueduct neuroepithelium. Together our results demonstrate that mouse Crb2 CKO recapitulates important features of human brain pathology and emphasize the important, but previously unrecognized, function of Crb2 in ependymal cell development.

Title: Glia characterization in BLOC-1 deficient mice

Authors: *J. WEBSTER[1], J. LARIMORE[2];
[2]Biol. and Neurosci. Dept., [1]Agnes Scott Col., Atlanta, GA

Abstract: Schizophrenia (SZ) is a chronic mental disorder characterized by hallucinations, disorganized speech, memory deficits, and an emotionless demeanor. It has been reported that dysbindin, a subunit of the octameric BLOC-1 complex, is reduced in the hippocampus of patients with SZ. Dysbindin regulates endosomal trafficking and has also been localized to the astroglial endfeet and endothelial cells that line capillaries in the cerebellum. Microglial activation has been implicated in neurological disorders and may regulate SZ progression. However, further characterization of glial cell function in SZ is necessary. This study will examine glia cell markers in dysbindin deficient mice in an effort to further understand disease progression in SZ.

Title: RHEB1 activating mutations can cause aberrant neuronal development, cortical malformations and epilepsy in mouse models generated using *in utero* electroporation

Authors: *M. PROIETTI ONORI[1,2], Y. ELGERSMA[1,2], G. M. VAN WOERDEN[1,2]; [1]Neurosci., Erasmus MC, Rotterdam, Netherlands; [2]ENCORE Expertise Ctr. for Neurodevelopmental Disorders, Rotterdam, Netherlands

Abstract: RHEB1 (ras homolog enriched in brain) is a member of the GTP-binding protein family which is well known for being a key regulator of the Ser/Thr protein kinase Mammalian Target of Rapamycin (MTOR). A fine-tuned regulation of this pathway is a key determinant for proper brain development and function, and hyperactive MTOR in mouse models can lead to seizures and behavioral abnormalities. However, RHEB1 itself has never been linked to neurodevelopmental disorders in humans before. Recently, we identified a de novo mutation in the RHEB1 gene (RHEB1p.P37L) in patients with intellectual disability, macrocephaly and epilepsy, which indicates that RHEB1 might play a prominent role in neurodevelopmental disorders (Reijnders MRF, Kousi M, van Woerden GM et al., 2017). Our goal in this current research is to study the effect of RHEB1p.P37L in neuronal in vitro and in vivo assays to understand the potential role of RHEB1 in neurodevelopmental disorders and epilepsy. We made use of a screening which comprises both in vitro (mouse hippocampal cultures and multielectrode arrays (MEAs)) and in vivo (in utero electroporation and Local Field Potential measurements) techniques to assess the effect of RHEBp.P37L on neuronal development, migration and physiology. We showed that RHEBp.P37L causes hyperactivation of the mTOR pathway and we also observed, using a lentiviral approach in MEAs, that overexpression of the RHEBp.P37L mutant causes an aberrant neuronal development in vitro, with an overall increase in mean bursting rate activity (MBR: 16.2 Hz ± SEM 1.6, N=4) and burst duration (BD: 302.4 ms ± SEM 14.9, N=4) during early developmental stages, compared to control primary neuronal cultures (MBR: 6.7 ± 1.1, N=4; BD: 206.8 ± 8.9, N=4). Furthermore, using in utero electroporation, we generated a mouse model that upon overexpression of RHEBp.P37L in the somatosensory cortex at E14.5, shows the appearance of severe cortical malformations with dysplastic neurons and the presence of heterotopic nodules adjoining the ventricles. Starting from three weeks of age, all successfully targeted mice show the occurrence of spontaneous seizures (measured by electroencephalogram and local field potential), giving us the opportunity to study the involvement of RHEB1 in cortical malformations and epilepsy. This study shows

that RHEB1 activating mutations can cause intellectual disability and epilepsy, thereby making RHEB1 a potential critical therapeutic target for neurodevelopmental disorders.

Title: Early postnatal alcohol exposure at both high and moderate doses reduces neuron, but not glial, number in thalamic nucleus reuniens of rat

Authors: *Z. H. GURSKY, A. Y. KLINTSOVA;
Psychological & Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Individuals diagnosed with FASDs often possess cognitive deficits, with frequent impairment in "executive function" (EF) behaviors. Many behaviors included under EF umbrella require coordination of neuronal activity between the prefrontal cortex (PFC) and hippocampus (HPC). Recent non-human primate and rodent studies have demonstrated that the midline thalamic nucleus reuniens (Re) is essential in coordinating PFC-HPC activity, as selective Re inactivation impairs PFC-HPC synchrony and behavioral performance on HPC- and PFC-dependent tasks. Given its critical role in coordinating PFC-HPC activity, we initially examined immunofluorescently-labeled neurons (NeuN+) and cell nuclei (Hoechst33342-stained) in adult female Long-Evans rats exposed to 5.25 g/kg/day AE on postnatal days (PD) 4-9. We observed a significant loss of neurons in Re and reduction in volume, but no change in non-neuronal cell number. All of these measures were unaffected in the neighboring rhomboid nucleus, suggesting specificity of this damage to Re within midline thalamus. We next explored whether there is a dose-dependent loss of neurons in the nucleus reuniens. In this experiment, either "high-dose" 5.25 g/kg/day (BAC ≈340 mg/dL) or "moderate-dose" 3.00 g/kg/day (BAC ≈145 mg/dL) alcohol was delivered to male and female rats via intragastric intubation. The data suggest that both doses of alcohol produced significant neuronal (NeuN+ cell) loss in adulthood (intubated control = 67905 neurons, moderate-dose AE = 40058 neurons, high-dose AE = 38178 neurons). Neither dose resulted in altered number of microglia (immunofluorescent labeling of Iba1 protein). High-dose AE resulted in reduced Re volume (confirming the findings in previous study), but moderate-dose AE did not alter Re volume. These data indicate that moderate-dose AE is

sufficient to induce lasting damage in Re. Taken together, our data suggest that Re is highly vulnerable to AE in development, and is selectively damaged within midline thalamus, resulting in significant neuron loss at both high and moderate doses. AE at this time in development does not appear to alter the number of glial cells (i.e., non-neuronal cells or microglia) throughout life.

Title: Unraveling how gut microbiota influence form and function in the developing enteric nervous system of zebrafish

Authors: *M. A. ODEM[1], N. PEREZ-SOTO[1], S. DOWNING[2], L. THOMPSON[1], E. SINGLETON[2], A.-M. KRACHLER[1], R. A. URIBE[2];
[1]Microbiology and Mol. Genet., McGovern Med. Sch. at UTHealth, Houston, TX; [2]BioSciences, Rice Univ., Houston, TX

Abstract: The enteric nervous system (ENS) is a network of intrinsic nerve plexuses innervating the muscle layers of the gut that regulate motility, hormone secretions, water balance, and modulation of satiety via the vagal nerve. Functional maturation of the ENS is dependent on migration and differentiation of neural progenitors along the gut, and may be influenced by the luminal microenvironment. However, how the gut microbiota influence ENS form and function during early phases of development is poorly understood. The vertebrate model organism zebrafish (*Danio rerio*) may offer powerful insights into this process; the goal of this study was to investigate how absence of the gut microbiota in zebrafish affects differentiation of the ENS and to characterize potential dysfunctional phenotypes using a novel gut motility assay. First, gut motility was characterized in wild type *AB* larvae at 5-7 days post-fertilization (dpf) using novel event-detection algorithms that quantify fluorescently-contrasted muscle contractions along the regions of the gut. Next, transgenic larvae *Tg(-8.3bphox2b:Kaede)* expressing the *Kaede* fluorescent protein in enteric neuron precursors, and differentiated neurons, were used to determine how absence of the gut microbiota affects enteric neuron innervation of the gut and motility. Results from germ-free (GF) and conventionally-raised (CONV) *phox2b:Kaede* larvae suggest that enteric neurons do not properly innervate variable regions of the gut, in particular the midgut, in GF larvae at 5-7 dpf, when compared with CONV controls. Functionally, the GF larvae exhibited abnormal, irregular patterns of motility in the midgut region, suggesting absence

of the gut microbiota may negatively affect gut function, in addition to innervation. Collectively, these results suggest that microbiota may play a critical role during developmental maturation of the ENS in the midgut.

Title: TAF1-gene editing alters the morphology and function of the cerebellum

Authors: *U. JANAKIRAMAN[1], Y. JIE[2], M. AUBIN[2], S. BATCHELOR[1], A. ANNADURAI[1], K. RAJESH[2], M. NELSON[1];
[1]Pathology, [2]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: TAF1/MRSX33 intellectual disability syndrome is an X-linked disorder caused by loss-of-function mutations in the TAF1 gene. How these mutations cause dysmorphology, hypotonia, intellectual and motor defects is unknown. Mouse models which have embryonically targeted TAF1 have failed, possibly due to TAF1 being essential for viability, preferentially expressed in early brain development, and intolerant of mutation. Novel animal models are valuable tools for understanding neuronal pathology. Here, we report the development and characterization of a novel animal model for TAF1 ID syndrome in which the TAF1 gene is deleted in embryonic rats using clustered regularly interspaced short palindromic repeats (CRISPR) associated protein 9 (Cas9) technology and somatic brain transgenesis mediated by lentiviral transduction. Rat pups, post-natal day 3, were subjected to intracerebroventricular (ICV) injection of either gRNA-control or gRNA-TAF1 vectors. Rats were subjected to a battery of behavioral tests followed by histopathological analyses of brains at post-natal day 14 and day 35. TAF1-edited rats exhibited behavioral deficits at both the neonatal and juvenile stages of development. Deletion of TAF1 lead to a hypoplasia and loss of the Purkinje cells. We also

observed a decreased in GFAP positive astrocytes and an increase in Iba1 positive microglia within the granular layer of the cerebellum in TAF1-edited animals. Immunostaining revealed a reduction in the expression of the CaV3.1 T-type calcium channel. Abnormal motor symptoms in TAF1-edited rats were associated with irregular cerebellar output caused by changes in the intrinsic activity of the Purkinje cells. This animal model provides a powerful new tool for studies of neuronal dysfunction in conditions associated with TAF1 abnormalities and should prove useful for developing therapeutic strategies to treat TAF1 ID syndrome.

NEUROFARBA, Univ. of Florence, Firenze, Italy; [5]Inst. of Neurosci., CNR, Pisa, Italy

Abstract: CDKL5 deficiency disorder (CDD) is a neurodevelopmental disorder characterized by a severe global developmental delay, early-onset seizures and, notably, visual abnormalities often clinically diagnosed as Cortical Visual Impairment. Animal models of the disease have been recently generated, giving the possibility to test new therapeutic strategies as long as quantitative and longitudinal biomarkers are available. CDD mouse models display visual deficits analogous to patients and cortical visual responses can be used in mice as a robust and minimally invasive biomarker. However, a quantitative measurement of the predictive power of the visual biomarker on general behavioral cognitive dysfunctions is still missing. Moreover, the

involvement of cortical as opposed to subcortical circuits in the origin of the symptoms is poorly understood. To address these questions, we first developed a custom, automated chamber for operant conditioning to assess the impact of CDKL5 lack in the learning of a simple task. We found that mutant mice initiated significantly more trials and responded to the initiation of the trial with shorter reaction times compared to wild-type littermates. This perseveration phenotype was quantitatively correlated with the visual biomarker.We then assessed which are the circuits underlying the described visual deficits in two ways: first, we performed an in-depth morphological analysis of the visual pathway, from the retina to the primary visual cortex (V1), of CDKL5 null mice. We found that CDKL5 lack produced no alteration in the organization of retinal circuits, but, conversely, it reduced density and altered morphology of spines and decreased excitatory synapse marker PSD95 in the dorsal Lateral Geniculate Nucleus and in V1. Second, using a conditional KO model, we showed that selective cortical deletion of CDKL5 from excitatory cells is sufficient to produce abnormalities of visual cortical responses, demonstrating that the normal function of cortical circuits is dependent on CDKL5. In summary, this work proposes cortical function as a critically important target for studying CDD.

Abstract: Angelman Syndrome (AS) is a rare neurodevelopmental disorder caused by loss of *UBE3A* (ubiquitin-protein ligase E6-AP) expression in the brain, typically due to a deletion of

the maternal 15q11-q13 region. Symptoms of the disorder include developmental delay, impaired receptive and expressive communication skills, ataxia, motor and balance deficits, poor attention, intellectual disabilities, microcephaly, and seizures. Recent advances in genetic rat models have allowed for the development and utilization of clinically-relevant assays to quantify sophisticated outcome measures of relevance to AS across a developmental time course. We aimed to use innovative and clinically-relevant outcome measures of social communication, motor behavior, and learning and memory to identify AS-relevant functional phenotypes in the *Ube3a* mutant rat. Juvenile social communication was assessed in *Ube3a m-/p+* (with a maternally inherited deficiency) and *m+/p+* (control) rats using a heterospecific play ("tickling") assay during which subjects were manipulated by the experimenter in a standardized manner mimicking species-typical play while ultrasonic vocalizations of both low and high frequency categories were recorded. Nuanced social interaction behaviors were quantified via a separate 10 min juvenile reciprocal social interaction test in which subject rats were allowed to freely interact with a sex- and age-matched wildtype control animal. The open field test of locomotion and the rotarod test of motor learning were used to assess motor behavior, gait was analyzed using the automated DigiGait system (Mouse Specifics, Inc.), and fine motor ability was tested with an adhesive removal task. Additionally, learning and memory were assessed with the novel object recognition task as well as cued and contextual fear conditioning. This study discovered altered social communication and reciprocal social interactions in the *Ube3a m-/p+* rat model of AS. Learning and memory, as measured by the novel object and fear conditioning tasks, was undisturbed and gait parameters are currently undergoing analysis. The results herein lend support for the important role of Ube3a in social behavior and for the use of this rat model as a tool to study the neurobiology underlying the behavioral phenotypes of AS, as well as to test potential therapeutics in future experiments.

Title: Latrophilin-3 (LPHN3) knockout and heterozygous Sprague Dawley rats show hyperactivity, response to ADHD medication, and cognitive deficits

Authors: *S. L. REGAN[1], C. SUGIMOTO[2], M. T. WILLIAMS[3], C. V. VORHEES[4];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Cincinnati Childrens Hosp., Cincinnati, OH; [3]Div. Neurol (MLC 7044), Cincinnati Children's Res. Found, Cincinnati, OH; [4]Div. of Neurol., Cincinnati Children's Hosp & Univ. of Cincinnati, Cincinnati, OH

Abstract: Attention deficit hyperactivity disorder (ADHD) is a heterogeneous neurodevelopmental disorder affecting ~10% of children in the United States. Latrophilin-3 (LPHN3) is a brain specific G-protein coupled receptor that has been associated with increased risk of ADHD and cognitive deficits. CRISPR/Cas9 was used to generate a constitutive knockout (KO) rat of *Lphn3* by deleting exon 3, and this model was used to investigate the lack of LPHN3 in ADHD-related behavior, and cognition. *Lphn3* KO rats show hyperactivity, an attenuation to common ADHD medication, and significant cognitive deficits. In a second experiment we tested KO, heterozygous, and WT rats to understand if there was a gene-dose response to the behavioral phenotype. We tested the rats in home cage at P35 for 7 days and again at P50 for 9 days. On the last two days of P50 testing, rats are challenged with 0.75 mg/kg of methylphenidate (MPD) to determine if it reduces the hyperactivity of KO rats. We also tested these rats in the Morris water maze (MWM), and Cincinnati water maze (CWM) to understand if there were cognitive deficits. Results showed that KO and HET rats are hyperactive compared with the WT controls, and that this effect may be slightly attenuated by low-dose MPD. KO and HET rats also showed cognitive deficits in the MWM and CWM. The data suggest that *Lphn3* KO rats exhibit a hyperactive phenotype with severe cognitive deficits and may be a useful model to better understand one of the genetic contributions to ADHD. (Supported by a grant from the LIFE Foundation).

Abstract: Serotonin is a critical player in brain development whereby serotonin neurotrophic actions can be regulated through maternal-fetal interactions. Hence, maternal rather than offspring's serotonergic genotype may determine variation in serotonin levels in the early fetal brain, which might result in downstream effects on the development of the brain and potentially influencing behavior. Indeed, serotonin has been shown to be involved in psychiatric disorders such as autism, anxiety, and depression, but the nature of its etiology so far is unclear.
In our first study, we investigated whether changes in extracellular serotonin levels due to serotonin transporter (SERT) availability (SERT rat model) in the mother influenced the maternal care. Maternal care is a major constituent of early life environment and seems to be related to offspring's behavior and serotonin levels. We observed that one of the most prominent forms, licking-grooming their offspring, is significantly less often performed by SERT knockout (KO) dams then SERT wildtype (WT) dams. Thus, variation in licking-grooming behavior seems to be determined by maternal serotonergic genotype.
To delineate whether maternal serotonergic genotype influences offspring's development through changes in fetal serotonin levels and/or through changes in licking-grooming behavior, we set up a breeding such that both these two questions could be answered. In this study, the offspring was subjected to several behavioral assessments. Our data showed that a decrease in fetal forebrain serotonin levels (KO mother) and a decrease in licking-grooming behavior (KO care) synergistically strengthen their impact on brain morphology and behavior. More specifically, in adult offspring from SERT KO mothers, which received SERT KO care we observed a diminished anxiety (elevated plus maze test), which correlated with an increase in mineralocorticoids receptor mRNA expression in the infralimbic cortex. In addition, these offspring showed a diminished anhedonia (sucrose consumption test), which correlated with a decrease in GAD65 and BDNF VI mRNA expression in the infralimbic cortex.
These findings indicate that genetically induced increases in maternal extracellular serotonin levels has a beneficial effect on offspring's behavior via modulations of key genes involved in the functionality of the hypothalamic pituitary adrenal (HPA) axis, GABAergic transmission, and neuroplastic mechanisms. For this reason, maternal SERT genotype, influencing fetal forebrain serotonin levels and maternal care, seems to be involved in the development of psychiatric disorders.

Title: Characterization of a novel porcine model of CLN3 Batten disease

Authors: *T. B. JOHNSON[1], P. NEGRAO DE ASSIS[1], V. SWIER[1], K. A. WHITE[1], D. A. STURDEVANT[1], A. V. DRACK[3], S. BHATTARAI[3], C. ROGERS[4], J. D. COOPER[5], D. A. PEARCE[2], J. M. WEIMER[1];

Abstract: CLN3 Batten disease is an autosomal-recessive neurodevelopmental disorder that results from mutations in *CLN3*. In the vast majority of cases, disease onset occurs in early childhood and is characterized by progressive loss of vision, seizures, failure in psychomotor development and is universally fatal by the third decade of life. Several mouse models of CLN3 disease have been developed that have provided insight into the pathological progression of this disease including early glial activation followed by neuronal loss, however, many aspects of the disease are not recapitulated in these mouse models. The development of an animal model that more closely recapitulates the clinical manifestations of CLN3 disease in humans is a crucial step toward implementing successful therapies for CLN3 patients. Porcine models hold the promise of a more accurate disease model given the similarities that pigs and humans share in terms of development, anatomy, and physiology, and in particular, similarities in brain development such as perinatal growth spurt and brain structure. Furthermore, the shared characteristics of the human and porcine visual system make the pig a useful resource for studying macular-associated retinal diseases that are not possible in mice. Additionally, the size of the pig would allow for the use advanced neuroimaging techniques such as MRI, CT and/or PET to model *in vivo* changes within the CNS longitudinally and track the success of potential therapeutics. Recently, we have developed a novel $CLN3^{\Delta ex7\text{-}8/\Delta ex7\text{-}8}$ porcine model of CLN3 Batten disease. Here we present initial characterization results showing behavioral, pathological, and visual deficits that mirror changes seen in human patients.

Title: Effects of developmental alcohol exposure on brain activation and functional connectivity

Authors: S. TANG[1,3], A. TARASIEWICZ[2], R. P. GULLAPALLI[1,3], *A. E. MEDINA[2];
[1]Dept of Diagnos. Radiology & Nuclear Med., [2]Pediatrics, Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Ctr. for Advanced Imaging Res. (umCAIR), Univ. of Maryland, Baltimore, MD

Abstract: Children with fetal alcohol spectrum disorders (FASD) often have deficits associated with multisensory processing. Because ethanol disrupts activity-dependent neuronal plasticity, a process that is essential for refining connections during cortical development, it may have an effect on normal development of sensory regions and brain networks. In this study, we used a ferret model to test whether early alcohol exposure alters the activation of brain regions involved in multisensory processing using resting-state functional magnetic resonance imaging. In addition, we assessed alterations of the brain network organization.
Ferret pups were given 3.5g/Kg ethanol or saline every other day between postnatal day 10 to 30, which is similar to the 3rd trimester of human gestation regarding cortical development. 23 control (Ctr, 10 males, 13 females) and 21 ethanol-exposed (Eth, 11 males, 10 females) ferrets were imaged in juvenile. 17 Ctr (8 males, 9 females) and 15 Eth (7 males, 8 females) animals were imaged in young adulthood. The functional connectivity of the lateral rostral suprasylvian sulcal area (LRSS, an auditory-tactile area) and the rostral posterior parietal cortex (PPr, a visual-tactile area) involved in multisensory processing were assessed. Fractional amplitude of low frequency fluctuation (fALFF) and regional homogeneity (ReHo) were calculated to estimate brain activity. Graph analysis was performed to assess the network organization using a home-made ferret atlas with 60 cortical regions of interest. The effects of ethanol, age and their interaction were assessed with two-way ANOVA in males and females. Increased functional connectivity between LRSS and tactile areas was observed only in Eth males. Functional connectivity between PPr and visual regions was increased in Eth juvenile males but decreased in Eth juvenile females. ReHo of tactile regions increased only in Eth males. Eth males showed increased network clustering coefficient, local efficiency and decreased characteristic path length in juvenile, indicating increased network segregation and decreased integration. In summary, our

results indicate that early alcohol exposure alters the regional activity/interaction within sensory systems and alters the brain network organization.

Title: Dissecting the mechanism and function of DNMT3A in neural development and disease

Authors: *D. CHRISTIAN[1], D. Y. WU[1], R. LIU[1], J. MARTIN[1], A. CLEMENS[1], J. R. MOORE[1], J. DOUGHERTY[2], D. WOZNIAK[3], H. W. GABEL[1];
[1]Neurosci., [2]Genet., [3]Psychiatry, Washington Univ. In St. Louis, St. Louis, MO

Abstract: Human genetic studies have linked disruption of genes encoding epigenetic regulators of transcription to autism and related neurodevelopmental disorders, but little is known about how causative mutations disrupt protein function to lead to disease. DNA methyltransferase 3a (DNMT3A) catalyzes the addition of methyl groups to cytosines in DNA, and mutations in DNMT3A are associated with neurodevelopmental disorders, including autism and intellectual disability in Tatton-Brown-Rahman Syndrome (TBRS). Though DNA methylation is classically thought to occur in mammalian cells in the CpG context, neurons have high levels of a recently-discovered form of methylation in non-CpG contexts that is established by DNMT3A. This non-CpG methylation, primarily occurring at CA dinucleotides (mCA), is critical to proper neuronal development and establishment of neuronal cell-type-specific transcription. Though mCA plays an important role regulating neuronal gene expression, little is known about how loss of DNMT3A and mCA relate to neurodevelopmental disease. We have studied disease mutations identified in patients with TBRS and Autism Spectrum Disorder and analyzed how these mutations differentially affect the ability of DNMT3A to methylate neuronal DNA through protein-domain specific mechanisms. Additionally, we have utilized several genomic, molecular, and behavioral assays to investigate how loss of DNMT3A in mice alters neuronal DNA methylation and changes neuronal function. Furthermore, we have generated mice carrying a

disease mutation identified in TBRS and we show a similar loss of disruption of DNA methylation in the brain. Together, this work defines several molecular mechanisms that may be leading to neurological disease and provides insight into the functional domains of DNMT3A. In addition, these analyses elucidate the function of DNMT3A and mCA in nervous system development and functionally link disruption of DNA methylation to neurodevelopmental disease.

Abstract: Low birth weight and preterm birth proposed as risk factors for developing schizophrenia and other forms of psychosis, later in life. Administration of magnesium sulfate (MgSO4) as a neuroprotective agent to women at high risk of imminent preterm birth has become the most common clinical practice. However, the molecular mechanism of MgSO4 as a neuroprotective agent has not been fully elucidated. The NRG1-ErbB4 signaling plays a critical role in embryonic brain development, in the biology of dopaminergic and GABAergic systems and in schizophrenia, therefore, we hypothesize that pathway is associated with the neuroprotection role of MgSO4. Here, we investigate the effect of MgSO4 at either early (GD16) or late (GD20) on the expression of the ErbB, dopaminergic and GABAergic signaling pathways in maternal immune activation (MIA) embryos. Two cohorts of 20 pregnant dam rats randomly assigned into four different treatment groups: saline/saline, LPS/saline, saline/MgSO4, and MgSO4/LPS. Experimental groups were first treated i.p. with LPS or saline, and then with

MgS04 or saline every 20 minutes for four hours. Fetal brains were collected for RT-qPCR measurement. The expression of NRG1 and D2R at both gestational days were significantly elevated in the MgSO4/saline and in MgSO4/LPS groups. However, ErbB4 receptor mRNA levels at 16 GD, but not at 20 GD, were significantly elevated in the MgSO4/LPS group. The expression of NRG3, NRG2, and NRG4 at 16 GD was significantly downregulated in MgSO4/saline and MgSO4/LPS groups. Together, our preliminary results suggest that the NRG-ErbB and the D2R pathways possibly involved in the neuroprotection mechanism of MgSO4.

Title: Inflammation exacerbates intrauterine growth restriction-induced cognitive deficits in juvenile rats

Authors: *L.-W. FAN[1], L.-T. TIEN[3], J. W. LEE[1], S. LU[1], N. DANKHARA[1], V. PRAKASH[1], I. ARGUELLO[2], Y. PANG[1], A. J. BHATT[1], R. D. SAVICH[1], N. B. OJEDA[1];

Abstract: Epidemiological and experimental studies suggest that intrauterine growth restriction (IUGR) is associated with neurodevelopmental impairments. Our previous studies demonstrated that systemic inflammation during pregnancy induced the priming activation of microglia and elevated levels of pro-inflammatory cytokines, which may contribute to behavioral dysfunction in offspring. This study was designed to further examine whether maternal inflammation via lipopolysaccharide (LPS) exposure enhances cognitive deficits associated with IUGR in juvenile rats. LPS (100 µg/kg) was administered intraperitoneally into pregnant rats on day 13 of gestation (E13) and the reduced uterine perfusion (RUP) surgery was performed on day 14 of gestation (E14) to generate IUGR rat offspring. One offspring from each sex from each litter was included in each experimental group. Four groups of 8 pups per group were included in the following treatments: Saline+Sham, Saline+RUP, LPS+Sham, and LPS+RUP. The control rat offspring were from the pregnant rats which had been administered saline injection followed by

sham surgery (Saline+Sham). The body weight and locomotion of offspring were determined on postnatal day 14 (P14) and P21, and the cognitive tests were determined by Y maze (P23) and passive avoidance on P23 and P24 in a double-blind manner. To ensure scientific rigor the molecular assays and histological assessment were evaluated by triplicate, and the sample sizes were calculated to reach a statistical power of at least 0.85 for a $P<0.05$. All animals were from the same strain and same vendor. Data were analyzed by two-way ANOVA followed by the Student-Newman-Keuls test. Our results show that offspring from dams exposed to either LPS or RUP showed significantly lower birth weight compared to controls at P21. Exposure to LPS during gestation exacerbated IUGR-associated motor disturbances including increases in rearing events in juvenile rats as well as cognitive deficits including short-term memory, learning and long-term memory. Significant difference was observed between male and female rats within the same treatment group. The current study suggests that exposure to LPS during gestation enhances IUGR-associated cognitive deficits including learning and memory in both male and female juvenile rats. This model may be useful for studying mechanisms involved in the development of children's neurodevelopmental delays associated with exposure to inflammation and growth restriction during gestation, and could help to develop future potential therapeutic strategies.

Title: Role of serotonin in synaptic signaling and plasticity in tuberous sclerosis

Authors: *R. SRINIVASAN[1], W. FRANCESCONI[3], F. BERTON[4], R. KIRCHNER[5], K. P. KOSTER[2], J. BENEDICT MICHAEL[6], A. YOSHII[7];

Pharmacol., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [5]Biostatistics, Harvard Chan Sch. of Publ. Hlth., Boston, MA; [6]Univ. of Illinois, Chicago, IL; [7]Dept of Anat. & Cell Biol., UIC, Chicago, IL

Abstract: Tuberous sclerosis complex (TSC) is an autosomal dominant genetic disorder caused by mutations in TSC1 or TSC2. While it is a multi-organ disease, neurological symptoms are prominent and include epilepsy, intellectual disabilities, and autistic behaviors. Dysregulated synapse formation and plasticity is likely to play a major role in the pathophysiology of TSC. TheTSC-1 and -2 proteins form a complex that downregulates the mammalian target of rapamycin(mTOR) pathway, and a gene mutation results in mTOR over activation. mTOR is a critical regulator of protein synthesis as well as synaptic plasticity. Consequently, suppression of mTOR by rapamycin or its derivatives is one way to correct the pathophysiology of TSC. However, mTOR pathway has multiple roles and rapamycin neither specifically nor completely cures all neurological symptoms. A greater understanding of dysregulated synaptic function will enable identification of specific therapeutic targets for epilepsy and cognitive disabilities in TSC.To identify potential causes of abnormal synaptic activity, we conducted RNA-seq analysis in wild-type vs. neuron-specific TSC1 -/- and found an excess of transcripts associated with the serotonin signaling pathway in TSC1 -/- brain. Immunoblots confirmed that levels of the serotonin receptor 5-HT2C were higher and its intracellular distribution was altered in pyramidal cells ofthe TSC1 -/- cortex. We next used calcium imaging and found that TSC1 -/- cultured cortical neurons had frequent Ca 2+ bursts throughout the soma and dendrites that depended on a specific serotonin pathway while WT neurons showed random and scattered transients mostly within dendritic spines. Furthermore, daily injection of the serotonin pathway antagonist rescued the premature death of the mutant pups. Our results indicate synaptic dysregulation in TSC can be corrected by modulating serotonergic pathway and set the stage for developing a new therapeutic approach. TSC is associated with a wide range of cognitive, behavioral, and psychiatric manifestations.TSC- Associated Neuropsychiatric Disorders (TAND) is often treated with risperidone, the first FDA- approved drug indicated for behavioral problems in autistic patients. Risperidone is not only a dopamine antagonist but also possesses anti-serotonergic properties. Thus, 5HT2C inhibition as a novel, specific therapeutic strategy for neurological symptoms of TSC.

Sch. of Med., Indianapolis, IN; [4]Dept. of Pediatrics, Herman B Wells Ctr. for Pediatric Research, Indiana Univ. Sch. of Med., Indianapolis, IN; [5]Psychiatry, IU Sch. of Medicine,, Indianapolis, IN

Abstract: RASopathies are syndromes arising from genetic mutations that result in dysregulation of the RAS pathway, a ubiquitous molecular pathway involved in cellular survival, growth, and division. Neurofibromatosis type I (NF1) is a well-studied RASopathy that is caused by an inactivating mutation in a single gene (neurofibromin) responsible for RAS pathway inhibition. Patients with NF1 often possess learning or cognitive difficulties, and one third of these patients meet criteria for autism spectrum disorder (ASD). Recent studies show that a substantial number of individuals with NF1 demonstrate disruptions in communication that are independent of their attention and learning problems, in line with current and past ASD criteria. Our previous studies have shown that mice haploinsufficient for *Nf1* (*Nf1*$^{+/-}$ mice) possess long-term social memory deficits due to RAS hyperactivation. Adult mice produce ultrasonic vocalizations (USVs) in specific social contexts, and studies demonstrate that these “songs” communicate information to a partner. USVs can be reliably elicited during courtship trials and can be used as an indicator of social communication in mice. Here, we explored social communication during courtship behavior in adult male *Nf1*$^{+/-}$ and wild-type (WT) mice. Additionally, we aimed to identify male mouse brain regions involved in the male-female social communication network. We have recorded and analyzed the USVs of WT and *Nf1*$^{+/-}$ mice. Following a 5 minute habituation, male mice were allowed to interact for eight minutes with an ovariectomized WT female mouse primed with estrogen and progesterone while USVs and video were recorded. Twenty minutes following female-induced USVs, the male mice were perfused and their brains were collected for immunohistochemistry (IHC). Slices were stained using dual immunohistochemistry for phospho-ERK (pERK), a marker of cellular activity, and NeuN, a marker for mature neurons. *Nf1*$^{+/-}$ mice exhibited a reduced number and duration of USV calls, as well as a reduced complexity of syllables compared to WT. Additionally, blinded dual IHC revealed alterations in pERK activation following exposure to a receptive female in several brain regions important for social behaviors, such as basolateral amygdala and nucleus accumbens. These data will provide additional information about the neural circuits and underlying mechanisms associated with RAS-related ASD-like social communication deficits.

Title: Effect of developmental alcohol exposure on layer 2/3 neurons in primary visual cortex

Authors: *D. KEUM[1], T. E. KRAHE[2], N. S. PULIMOOD[1], A. E. MEDINA[1];
[1]Dept. of Pediatrics, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Pontifical Catholic Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Children with FASD (fetal alcohol syndrome disorder) can have deficits in visual-spatial learning and visual-motor coordination as well as display amblyopia-like visual impairments even in absence of optical and oculomotor abnormalities. Studies from our lab have demonstrated in ferrets and mice that developmental alcohol exposure leads to a long lasting deficit in neuronal plasticity in the visual cortex. However, the effects of development alcohol exposure on neuronal responses in this area remain elusive. Here we use whole-cell patch clamp to characterize neuronal responses in Layer 2/3 of the visual cortex of a mouse model of "third trimester" alcohol exposure. C57/BL6 mice from both sexes received 5g/Kg of alcohol (25% i.p.) or control saline on postnatal days (P) 5, 7 and 9. Another group of mice from the same litter remained undisturbed (Naïve). Animals were euthanized between P25-P38 and slices prepared for electrophysiology and recorded in excitatory neurons layer 2/3 of primary visual cortex. Under current clamp we analyzed the numbers of spikes reduced by 25% in alcohol exposed and 17% in saline injected mice compared to naïve animal. However, properties of cell membrane (cell capacitance, input resistance, and resting membrane potential) and spikes (threshold, half duration, rising and decay time) were not changed significantly. AMPA/NMDA ratios were analyzed under voltage clamp but there was no difference between groups. Then we analyzed spontaneous post synaptic current. Our data showed that the early exposure to alcohol significantly reduced the frequency of sPSC but did not alter the amplitude. These findings suggest that impairment in neurotransmitter release in the visual cortex may cause the deficits in neuronal plasticity previously demonstrated in this model. Stress of the injection itself also seems to affect numbers in evoked action potentials by larger current (> 200pA) range.

Title: Moderate prenatal alcohol exposure and housing manipulations alter spatial navigation behavior in adult rodents

Authors: *C. M. MAGCALAS[1], S. DAVIES[2], D. D. SAVAGE II[2], D. A. HAMILTON[1]; [1]Univ. of New Mexico, Albuquerque, NM; [2]Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM

Abstract: Prenatal alcohol exposure (PAE) is associated with structural and physiological changes that impact the central nervous system and can result in persistent negative consequences in a broad spectrum of cognitive and behavioral domains including deficits in motor behavior, social behavior, and behavioral flexibility. Previous studies have characterized the influence of PAE on spatial navigation and behavioral flexibility through various behavioral paradigms including the Morris water task (MWT). The current study focuses on examining the behavioral consequences of PAE on directional and place navigation through the use of the MWT. Pregnant rat dams voluntarily consumed saccharin (SAC) water containing 0% or 5% ethanol (EtOH) for 4 hours per day during the entire gestational period. Same sex pups were pair-housed with a partner of the same prenatal treatment (Same; Sac-Sac or EtOH-EtOH) or the different prenatal treatment (Mixed; Sac-EtOH). In order to assess directional and place navigation the animals were tested in a 2-day hidden platform protocol. Day 1 of the hidden protocol consisted of 12 training trials and 1 pool shift test. Day 2 consisted of 8 training trials, 1 pool shift test (opposite of the first test), 4 training trials, and 1 probe trial. The pool shift test consisted of moving the pool to a secondary position. The platform either moves with the pool to a relative location in the pool (directional navigation) or stays in the absolute location in the room (place navigation). There were no significant differences between prenatal treatment, sex, or housing conditions in the hidden training trials. In the hidden variant there was a significant interaction in the females between preference for the absolute or relative location and PAE. This interaction was only significant in the mixed housed females and was not present in the same housed females. The SAC female rats displayed a preference for the relative platform location, which is consistent with previous findings, while EtOH female rats displayed a preference for the absolute location. Additionally, the mixed housed males showed some preference for the relative location while the mixed housed males showed almost not preference for either goal location. These outcomes suggest that animals may have distinct search patterns that may be sex specific

and can be influenced by PAE and housing manipulations. [Supported by grant AA019462 to DH].

Title: Altered patterning and HLH transcription factors that control neurogenesis and gliogenesis in retinoic-acid-induced spina bifida in rat model

Authors: *M. ORIA, Z. LI, B. PATHAK, K. BAKRI, J. L. PEIRO;
Ctr. for Fetal and Placental Res., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: During spinal cord development, multipotent progenitor cells generate three major cell lines; neurons, oligodendrocytes and astrocytes at precise time and position. Normally, neurogenesis occurs in early embryonic stage and astrocytes and oligodendrocytes later. However there have been studies indicating of astrocyte differentiation in early embryonic stages of spina bifida aperta. To date the pathophysiological mechanisms related to astrocyte differentiation with reactive astrogliosis of spina bifida aperta are poorly understood. This study characterizes the development of these reactive astrocytes from Pax6 and Olig2 multipotent progenitor cells. In comparing 20 rat spinal cords in retinoic-acid (RA) induced spina bifida and 6 sham controls at three gestational times (E15, E17, E20) we observed differentially expressed genes using standard RNA seq approach and RT-qPCR not only the transcription factors Pax6, Olig2 and Nkx2.2, but also the HLH transcription factors, Mash1, Ngn2, ID1 and ID2 that regulates the spatiotemporal neurogenesis and gliogenesis. We have also identified the presence of Olig2+ and Pax6+ multipotent progenitor cells in GFAP+ reactive astrocytes during gestation and increased numbers in the neural tissue exposed to amniotic fluid. Together, our observations demonstrate altered neurogenesis and astrogenesis patterns that contribute to neuronal dysfunction, injury, and neural loss in spina bifida aperta after birth.

Title: Complex behavioral assessment of preterm brain injury models

Authors: *D. BAKALAR, H. LACAILLE, C. M. VACHER, J. O'REILLY, J. SALZBANK, P. KRATIMENOS, S. SEBAOUI, A. PENN;
Children's Natl. Hlth. Syst., Washington, DC

Abstract: Preterm birth increases the risk of attentional deficits, but the neurological basis of this process is unknown. Our lab has previously shown that pre- and post-natal inflammatory insults work synergistically, leading to interneuron subtype alterations. This includes Parvalbumin-expressing (PV) interneurons, implicated in human Attention Deficit Disorder. Here, two preterm brain injury models are compared, one resulting from external environmental insults (a two hit model combining prenatal maternal inflammation with postnatal hypoxia) and the other resulting from intrinsic environmental factors (Akr1c14-Cyp19Cre mouse which has a placental deficit of the anti-inflammatory hormone Allopregnanolone). We screened mice for behavioral deficits using an IntelliCage (an automated group behavioral testing platform) and custom analysis pipeline focused on attention and inhibition. Module 1 assessed activity levels, anxiety, circadian rhythm, and working memory. Module 2 assessed Place Learning and Reversal Learning. Module 3 used the Simple Reaction Time Task, previously validated against the 5-Choice Serial Reaction Time task, to assess attention, impulsivity, and compulsivity. Finally, a Delay Discounting task was used to measure impulsive choice and reward motivation. A custom-written Python analysis program cleans the data, extracts relevant values and produces a pandas DataFrame on which statistics can be run, allowing for full automation of all modules. Preliminary data in both mouse models show no changes in baseline behavior, and intact place learning and memory. However, attentional deficits are evident, implicating the medial prefrontal cortex. This region will be assessed at a molecular and cellular level with a specific focus on inflammatory processes and PV-interneurons.

Title: Deficiency of Amotl1 leads to schizophrenia-like phenotype in mice

Authors: J. KRZEMIEN, K. O. ROJEK, M. WINIARSKI, P. BOGUSZEWSKI, E. KNAPSKA, ***T. J. PROSZYNSKI**;
Nencki Inst. of Exptl. Biol. PAS, Warsaw, Poland

Abstract: The Angiomotin family comprises of three scaffold proteins Amot, Amotl1, and Amotl2 that have been implicated in the regulation of cell polarity, migration, and proliferation. We have recently reported that Amot together with Yap1, the Hippo pathway transcription co-activator, are critical for proper dendritic arborization and mice locomotor coordination (Rojek KO, et al. (2019) PLoS Biol 17(5): e3000253). However, the function of two other Angiomotins, Amotl1 and Amotl2 in neurons has not been investigated.
In the present study, we show that Amotl1 localizes to the synaptic compartments in neurons. In contrast to Amot mutants, mice with systemic or neuron-specific knockout (KO) of Amotl1 do not show impairments of motor coordination. Instead, Amotl1 mutants exhibit hyperactivity in the open field (n=10) and decreased anxiety reflected by the time spent in the center of the open field and reduced digging in the marble burying test (n=9). Amotl1 ablation causes alteration in mice sociability, which was assessed by a three-chamber experiment (n=8), and mice nesting behavior (n=6). Abnormal social behavior was independently studied in the Eco-Hab experiment (n=10), in which behavior of individual animals within the larger group is measured over prolonged time and analyzed in an automatic manner (Puścian A., et al. (2016) eLIFE 5: e19532). Amotl1 mutants, however, did not show tendency to increased repetitive behavior (e.g. self-grooming). Morphological analysis of Amotl1 KO brains by MRI and histochemical methods revealed a 50% increase in volume of lateral ventricles and cerebrospinal fluid (n=4). Similar features are observed in animal models of schizophrenia.
We identified a novel synaptic protein Amotl1, the deletion of which causes behavioral deficits thus it could be a potential molecular target for the development of new therapeutics for neurological disorders.

Title: The effects of maternal high fat diet on ultrasonic vocalizations during maternal separation by BTBR and B6 mouse pups

Authors: Y. NIE, R. FEINGOLD, *K. K. CHADMAN;
NYS Inst. Basic Res., Staten Island, NY

Abstract: The etiology for most cases of autism spectrum disorder (ASD) is unknown at this time. There is strong evidence for the genetic role in ASD but environmental factors also have a modifying role. One potential environmental factor is the maternal diet during fetal development. Obesity before and during prenatal development increases the vulnerability of affective disorders including schizophrenia and ASD. Prenatal maternal obesity has been shown to be a risk factor for ASD and other developmental disabilities (Krakowiak et al. *Pediatrics* 2012; 129; e1121). BTBR $T^{+ tf}$ Itpr/J (BTBR) mice have been used as a model for ASD because of low sociability and high levels of repetitive behaviors. These experiments examined the effects of a maternal high fat diet on pup ultrasonic vocalizations (USV) in C57BL/6J and BTBR offspring on P4, 6 & 8. Female C57BL/6J and BTBR mice were placed one of three diets (regular mouse chow, high fat diet, control diet) for 2 weeks prior to mating and remained on each diet throughout these experiments. One male and female pup per litter were tested for USVs for 5 min. Overall, the BTBR pups made more calls compared to the B6 pups. Across all three time points, the high fat diet BTBR pups made more calls than the pups from the control and chow diets. Across all 3 diets, BTBR pups made longer calls compared to B6 pups, regardless of diet. Differences in prenatal nutrition led to minor differences in pup vocalization behavior.

Title: Comprehensive profiling and localization of gene expression in the cerebral cortex and striatum of BTBR mice, a mouse model of autism spectrum disorder by comparing with those of C57BL6/J, a highly social mouse strain

Authors: *S. MIZUNO[1], J. HIROTA[1], H. IWASAKI[2], S. OKABE[3], Y. SANO[1], T. FURUICHI[1];
[1]Dept. of Applied Biol. Sci., Tokyo Univ. of Sci., Noda, Chiba, Japan; [2]Dept. of Anat. and Cell Biol., Gunma Univ. Grad. Sch. of Med., Maebashi, Gunma, Japan; [3]Dept. of Cell. Neurobio., Grad. Sch. of Medicine, Univ. of Tokyo, Tokyo, Japan

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder, of which prevalence rate is approximately 1%, and that is characterized by two core symptoms: 1) impaired social interaction and communication, and 2) restricted and repetitive behavior. Genetic factors strongly contribute to the risk for ASD. Recent studies reported that ASD have high degree of genetic heterogeneity and are probably caused by complex interaction between multiple genes. However, it is unclear how a combination of different gene variations causes a common mind symptom. Here, we compared brain gene expression between two mouse strains BTBR T+tf/j (with low sociability and used as a model for ASD) and C57BL/6J (B6) (with high sociability). For this purpose, we applied DNA microarray analysis (Agilent, SuperPrint G3 Mouse Gene Expression Microarrays: 27,122 genes, 4,578 lncRNAs) to perform genome-wide expression profiling in the cerebral cortex and striatum because of the possible involvement of the corticostriatal pathway in ASD core symptoms. As a result, we could identified 1,081 downregulated genes and 359 upregulated genes. Among these genes, 45 genes have already been reported as ASD gene candidates (ASD-linked genes registered in AutDB), and 268 genes are non-coding RNA (ncRNA). First, we focused on Fmr1 and Cpeb4 (RNA-binding protein genes known candidate for ASD) and searched their binding target genes among 45 ASD-related genes differently expressed between BTBR and B6. The results showed that there were 4 and 15 targeted genes for Fmr1 and Cpeb4, respectively in ASD-related genes differently expressed in BTBR. Second, we investigated functional interaction networks of ncRNAs using a database starBase v3.0 in which 19 ncRNAs among those differently expressed in BTBR were registered in this program. The results showed that these 19 ncRNAs possibly interact with 135 target genes including 6 ASD candidate genes and thereby may affect their expression and/or function. Third,

we performed gene ontology (GO) enrichment analysis using DAVID 6.8. The results highlighted 96 annotations (GO terms) including neuron/synapse, immune, chromosome/DNA-related ones. Lastly, we performed clustering of ASD candidate genes differently expressed in BTBR based on their spatial gene expression profiles in mouse brain regions using the Allen Brain Atlas tool. The results showed that many genes were classified into a region cluster including prefrontal, motor and temporal cortex. Taken together, our comprehensive gene expression study indicates a transcriptomic feature that distinguishes between BTBR and B6 mice, which may contribute to their difference in sociability.

Title: Overexpression of metabotropic glutamate receptor 5 in the striatum and prefrontal cortex of BTBR mouse model of autism spectrum disorder

Authors: F. MATRISCIANO[1], V. LOCCI[1], E. DONG[1], ***D. R. GRAYSON**[2], A. GUIDOTTI[1]; [1]Psychiatry, Univ. of Illinois Chicago, Chicago, IL; [2]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Autism Spectrum Disorder (ASD) is a complex neuropsychiatric syndrome for which there is not presently a cure. The metabotropic glutamate receptor 5 (mGluR5) is involved in synaptic plasticity and learning and memory mechanisms during development and represents a suitable target for neurodevelopmental disorders associated with intellectual disabilities such as ASD. Our study focused on the expression, function, and signaling of mGluR5 using the BTBR T+tf/6J (BTBR) mice that exhibit behavioral endophenotypes relevant to the behavioral symptoms associated with ASD. C57BL/6J (B6) mice were used as controls. First, we measured the mGluR5 mRNA levels in selected brain regions of BTBR mice involved in cognition and motor programing such as frontal cortex, hippocampus, striatum and cerebellum. Both mRNA and protein levels of mGluR5 were significantly higher in striatum of BTBR compared to B6 mice. Higher levels of mGluR5 mRNA and protein were also detected in frontal cortex. The striatum of BTBR mice was characterized by decreased levels of mGlu2 receptors which are neuroprotective against excitotoxicity mechanisms induced by high levels of glutamate. Other mGluR mRNAs were unchanged. Because the canonical signaling pathway associated with the activation of mGluR5 coupled receptors is Pi hydrolysis, we also performed measurements of PI hydrolysis. Compared to controls, and we found significantly higher basal levels of inositol-

monophosphate accumulation in the striatal tissue of BTBR mice after systemic *in vivo* lithium exposure. In addition, we found increased levels of the early inducible gene *Mef2c,* and *Arc* which are responsible for AMPA receptor endocytosis at dendrites. Behaviorally, BTBR mice showed deficits in novel object recognition, social interaction and stereotypic behavior, such as self-grooming, which is one of the major behavioral features of these animals. A single injection of the selective allosteric glutamate antagonist MTEP (10 mg/kg, i.p) fully reversed the stereotypic behavior and reduced the high levels of Arc mRNA. A higher variability in the response to MTEP was observed in the social interaction test, suggesting that in addition to altered expression of mGluR5, additional mechanisms may be involved in the control of altered social behavior. Our results showed that in BTBR mice, which exhibit biochemical, behavioral and pharmacological endophenotypes reminiscent of those observed in ASD subjects, that mGluR5 receptor expression is elevated and likely responsible for some of these behaviors.

Title: Perinatal fluoxetine exposure results in social deficits and reduced monoamine oxidase gene expression in mice

Authors: C. M. BOND, **J. C. JOHNSON**, V. CHAUDHARY, M. L. MCWHORTER, *N. S. WOEHRLE;
Wittenberg Univ., Springfield, OH

Abstract: BACKGROUND Currently, 8.7% of pregnant American women fill antidepressant prescriptions, and approximately 80% are for selective serotonin reuptake inhibitors (SSRIs). Perinatal antidepressant drug exposure increases risk for autism spectrum disorder, yet the molecular and neurobehavioral effects of maternal antidepressant drug use on offspring remain poorly understood. METHOD In this study, we examined social interaction behavior and whole brain monoamine oxidase A (*MAOA*) gene expression in the offspring of female mice administered the SSRI fluoxetine non-invasively throughout gestation and early lactation. We tested mice in the three-chambered social test (TCST) as juveniles and again as young adults. Gene expression was measured using droplet digital PCR (ddPCR). RESULTS We found deficits in sociability and social novelty-seeking behavior in the juvenile offspring of SSRI-

treated mice, and these behaviors persisted into young adulthood. Furthermore, we found decreased *MAOA* expression in the brains of offspring of SSRI-treated mice. CONCLUSIONS Our findings suggest that exposure to antidepressants during the prenatal and early postnatal period negatively affects social development. Moreover, reduced *MAOA* expression may play a role in the mechanistic pathway linking SSRI exposure and behavioral deficits symptomatic of autism.

Title: The role of cerebellar granule cells in autism spectrum disorder related behaviors

Authors: *B. DENTEL, E. GIRMASH, E. OH, L. ANGELES-PEREZ, C. REN, P. TSAI; Neurol., UT Southwestern, Dallas, TX

Abstract: Autism Spectrum Disorder (ASD) affects 1 in 59 children and is a heterogenous disorder for which there are no targeted therapies. Individuals with ASD not only experience the 2 core deficits in social and repetitive behaviors but also experience severe comorbid conditions including anxiety. The underlying neural substrate underlying these behavioral disruptions in ASD are not well understood. Accumulating evidence has increasingly implicated the cerebellum in patients with ASD, including many studies which demonstrate significant changes in cerebellar volume in individuals with ASD. While previous studies have highlighted the vital modulatory role of Purkinje cells of the cerebellum in ASD-related behaviors, granule cells (GCs) make up the majority of cerebellar volume, while many ASD-linked genes are exclusively expressed in GCs. However, as little is known about the contribution of GCs to ASD-related behaviors, we hypothesize an important role for cerebellar GCs in the regulation of ASD-relevant behaviors. To investigate this hypothesis, we generated a GC-specific deletion of *Tsc1*, one of the genes mutated in Tuberous Sclerosis, a neurodevelopmental disorder associated with high rates of ASD in an *Atoh-1*^{creER2}*Tsc1*$^{fl/fl}$ mouse. We first assessed recombination of this mouse by crossing an *Atoh-1*^{creER2}*Tsc1*$^{fl/fl}$ mouse to a *Rosa* cre TdTomato Reporter mouse. All pups were injected on p0 with 350mg/kg tamoxifen. At 6 weeks of age, we examined animals for behaviors relevant to ASD (tests performed from least to most stressful). The experimenter was blinded to genotype during all behavioral testing with only males tested in this cohort. Mutants

were compared with Cre negative, tamoxifen-exposed littermate controls (n=13 per cohort). We examined ASD-relevant behaviors and whereas we identified no social deficits or repetitive behaviors, mutants' performance in reversal learning was significantly worse than control littermates, pointing to deficits in behavioral inflexibility. Upon further investigation we also found that mutant mice displayed anxiety-like behaviors in the open field and light/dark box testing. Acute slice recordings were also performed on GCs. Mutant cells were less excitable and had decreased excitatory postsynaptic currents (EPSCs). This model demonstrates that hypofunction of GCs in the cerebellum contributes to ASD-related behaviors.

Title: Impacts of social and environmental deprivation on fine motor development in mice: Implications for ASD

Authors: S. PICKERNELL, K. CLARK, A. PELLE, *D. P. DEVINE;
Psychology, Univ. of Florida, Gainesville, FL

Abstract: People with Autism Spectrum Disorder (ASD) present with many co-morbid features, which include sensori-motor integration deficits. As children with ASD fail to interact appropriately with their social and physical environment, we used a rodent model to investigate the potential that inadequate environmental engagement may impair development of sensori-motor integration and fine motor skills. We raised 170 C57Bl6 mice from weaning in physically and socially enriched environments, or environments that were physically impoverished, but included social mates, or environments that were both physically and socially impoverished. The mice were then tested in a vermicelli handling task to assess the impact of impoverishment on development of sensori-motor integration. The total amount of pasta consumed was scored for each mouse and a defined set of fine motor handling behaviors was assessed. The enriched mice ate significantly more pasta and exhibited greater fine motor dexterity than did the mice in both the impoverished housing environments. Overall, these results support the theory that social and environmental deprivation leads to failures in sensori-motor development.

Abstract: Non-human primate (NHP) translational models are critical for understanding social deficits in neurodevelopmental disorders, such as Autism Spectrum Disorder (ASD). Development of primate infant attachments/bonds depends on the mother and are necessary for the maturation of social competency. The goal of this study was to identify early social predictors shaping later social competence and to map the developmental trajectories of social reward and salience neurocircuits that support the maturation of early prosocial behaviors and attachments in infant rhesus macaques.
Longitudinal structural MRI scans were acquired at 2, 4, 6, 8, 12, 16, 20, 24 wks from 25 male macaques living with their mothers in social groups, and again at 12 months in a subset of 4 animals. T1- and T2-MRI images were acquired using a 3T MRI scanner and analyzed for volumetric changes in social reward and salience brain regions, i.e. amygdala (AMY), nucleus accumbens (NACC), anterior cingulate cortex (ACC), orbitofrontal cortex (OFC), ventromedial prefrontal cortex (vmPFC) and insula (INS). Measures of infants' social development were collected from a subset of subjects (n = 4), using: (1) a rhesus ethogram, (2) rating scales of atypical social behaviors (adapted from the Social Responsiveness Scale used for ASD diagnosis

in humans) and (3) maternal rating scales (to examine the contribution of maternal care to developmental outcomes).
AMY volume -core region for social salience- increased rapidly from 4-8 and after 16 wks. The INS -crucial in social cognition and in mapping interoception that initiates processing of salient emotional information and explicit motivation- showed rapid gray matter volume increase from 4-8 wks, and sharp white matter (WM) volume decrease from 4-12 wks. These neural changes were paralleled by a decline in frequency and duration of mother-infant affiliative behaviors (including face-to-face interactions and contact) by 8 wks, when infants increase independence-seeking behavior and engage in social play with peers. We are currently analyzing changes in other brain regions in these networks (ACC, OFC, NACC) and increasing the sample size.
Our findings suggest that during the first 24 wks, particularly the first 8 wks, social salience and reward brain networks undergo robust structural changes, presumably to support the infant's adjustment to independence and increasing emotional awareness of appropriate social interaction. Understanding how normative social behavior and the underlying social brain networks develop can help elucidate the roots of brain-behavior pathogenesis of human social deficits.

Title: A new objective electrophysiological technique as a measure of central auditory processing in a rat model of autism spectrum disorder

Authors: R. SINHA[1], D. MISHRA[2], **R. MITTAL**[2], D. SHAHAL[2], J. MITTAL[2], *S. A. PENA[1], J. BOHORQUEZ[4], A. A. ESHRAGHI[3];
[1]Otolaryngology, Univ. of Miami Miller Sch. of Med., Miami, FL; [2]Otolaryngology, [3]Otolaryngology, Neurolog. Surgery and Biomed. Engin., Univ. of Miami Miller Sch. of Med., MIAMI, FL; [4]Biomed. Engin., Univ. of Miami, Miami, FL

Abstract: Objective: Autism Spectrum Disorders (ASD) comprise complex neuropsychiatric disorders associated with high healthcare burden. One of the most commonly reported sensory processing impairments in individuals with ASD is the abnormalities in central auditory processing (CAP). ASD patients consistently exhibit atypical behaviors in response to auditory stimuli and central auditory processing disorder (CAPD), which refers to a complex and

heterogeneous group of auditory-specific disorders. There is still not a reliable electrophysiological technique to determine CAPD in ASD patients. The aim of this study was to develop an electrophysiological technique that can be used as an objective measure of CAP in anesthetized rat model.
Methods: We developed a method to determine the Objective Gap Detection Threshold (OGDT) in rats. Quasy steady state response (QSSR) elicited by noise modulated by 40Hz gaps of different durations were analyzed in time and frequency domains using wild-type (WT) and rat model of ASD. The detection was performed in frequency domain, by applying the Hotelling's T2 test to the 40Hz complex fundamental frequency component. The OGDT is estimated by analyzing the confidence ellipses of the 40Hz spectral component.
Results: Our results suggest that WT rats were able to detect noise gaps as low as 2 ms. On the other hand, we observed that the rats with ASD phenotype were detecting noise gaps of 12, 10 and 8ms and not detecting thresholds lower than the 6ms gap. We also observed the "vanishing" of response into the background noise when a 4ms noise gap is applied. The 6ms OGDT result was verified by the statistical T2 test and is consistent with the previous animal studies with awake rats. The OGDT values were significantly increased in our rat model of ASD in agreement with findings observed in humans having ASD.
Conclusions: We have developed an electrophysiological method to determine OGDT as a measure of CAPD in an anesthetized rat model. This technique eliminates the need for being alert and awake during the test bringing a new dimension especially in animal experiments regarding central auditory evaluation. The availability of novel objective techniques to determine CAPD will help in its early detection in patients diagnosed with ASD or suspicion of being on the spectrum leading to early intervention and hence better clinical outcomes.

Title: The role of Foxp1 and Foxp2 in striatal D1 spiny projection neurons

Authors: *N. I. AHMED, A. G. ANDERSON, G. KONOPKA;
Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Speech and language deficits and autism spectrum disorder have been observed in individuals with mutations in either *FOXP1* or *FOXP2*. These transcription factors can work together to regulate gene expression and one part of the brain where they are co-expressed is the striatum. Heterozygous reduction of *Foxp1* in mice results in hyperexcitability of dopamine 2 receptor spiny projection neurons (D2 SPNs) of the striatum without a significant effect on dopamine 1 receptor SPNs (D1 SPNs). Furthermore, behavioral studies have found motor learning impairments upon the conditional deletion of *Foxp1* from D2, but not D1, SPNs. We therefore hypothesize that *Foxp1* and *Foxp2* may be able to compensate for each other in the D1 SPNs. To test this hypothesis, we have deleted *Foxp1*, *Foxp2*, or both from the D1 SPNs in mice and are examining the effects of loss of these transcription factors on behavior and gene expression. We have found that D1 specific conditional knockout mice of *Foxp1* or *Foxp2* alone do not show deficits in motor learning as assessed by a rotarod assay. However, deleting both *Foxp1* and *Foxp2* from D1 SPNs leads to significant impairments in this assay. Ultrasonic vocalization recordings of these mice at early postnatal time points also show a trend in decreased bout number in the double conditional knockouts. Using single-nuclei RNA-sequencing, we are examining cell type-specific effects on gene expression that include non-cell-autonomous molecular changes with loss of these genes. These data offer novel insights into the extent to which *Foxp1* and *Foxp2* can coordinate molecular pathways important for striatal function and may provide a better understanding of the molecular underpinnings of speech and language impairments associated with *FOXP1* or *FOXP2* mutations.

Abstract: We investigate how the immune system can modulate ASD-like behavior using a mouse model of neurodevelopmental disorders in which offspring are exposed to maternal

immune activation (MIA) during embryogenesis, resulting in deficits in sociability in adulthood. We demonstrate that the social behavior deficits of MIA mice can be modulated through the immune system. At the neural level, increasing immune activities produced a reduction in neural activity in the dysgranular zone of the primary somatosensory cortex (S1DZ). S1DZ hyperactivity was previously implicated in the manifestation of MIA behavioral phenotypes. At the molecular level, we demonstrate that modulation of blood brain-barrier (BBB) permeability, potentially allows immune molecules to act directly upon the brain. Our data suggest that peripherally-induced immune molecules can affect the expression of neurodevelopmental disorders by abrogating hyperactivity in the central nervous system.

Title: Altered RNA processing in CHD8 haploinsufficient mice

Authors: *A. A. WADE, C. P. CANALES, I. ZDILAR, A. L. GOMPERS, L. SU-FEHER, A. S. NORD;
Psychiatry & Behavioral Sciences; Neurobiology, Physiology, & Behavior, Univ. of California, Davis, Davis, CA

Abstract: CHD8 is a chromatin remodeler encoded by a high-risk autism gene. Studies in mouse models show that CHD8 has important roles in gene regulation, but mechanisms underlying this function have yet to be fully elucidated. While significant data point to the role of this protein in maintaining open chromatin for transcription, new evidence shows *Chd8* haploinsufficiency has downstream consequences on co-transcriptional RNA processing. We used RNA sequencing in mouse brain to further test how gene isoform expression is altered with heterozygous mutation to *Chd8*. We also used chromatin immunoprecipitation followed by liquid chromatography with tandem mass spectrometry in wild-type mouse cortex to profile Chd8 interaction partners and propose explanations for how Chd8 function could be related to RNA processing. In our

transcriptomic analysis, we found several alternatively-spliced RNA transcripts in *Chd8* mutant mice. Furthermore, differentially-spliced transcripts commonly encode synapse-relevant proteins, suggesting a relationship between perturbed splicing and synaptic dysfunction with *Chd8* haploinsufficiency. Preliminary proteomic data also suggest a physical association between Chd8 and splicing proteins, further implicating a relationship between Chd8 and co-transcriptional gene regulation. These studies offer a novel mechanism for pathology associated with heterozygous *Chd8* mutations but warrant additional *in vivo* validation and characterization before definitive conclusions can be made. As *Chd8* haploinsufficiency could represent generalized convergence of synaptic dysfunction and abnormal gene regulation in autism, understanding these perturbations could provide insight into the biological underpinnings of neurodevelopmental disorders.

Title: Altered gene expression in the embryonic rat brain following maternal poly I:C exposure during pregnancy

Authors: E. KAMIMURA[1,2,3], H. ZHU[1], A. SAEFULLOH[1,3], S.-I. HORIKE[2,3], ***S. YOKOYAMA**[1,3];
[1]Res. Ctr. for Child Mental Development, Kanazawa Univ., Kanazawa, Japan; [2]Advanced Sci. Res. Center, Kanazawa Univ., Kanazawa, Japan; [3]Div. of Socio-Cognitive-Neuroscience, United Grad. Abstract: Maternal immune activation (MIA) during pregnancy with various infectious agents has been reported to increase risk for offspring's neurodevelopmental disorders, such as schizophrenia and autism spectrum disorders (ASD). Previous studies have established several rodent MIA models that manifest various abnormal behaviors characteristic of these disorders. In particular, offspring from the polyriboinosinic-polyribocytidilic acid (poly I:C) model has been demonstrated to exhibit the core symptoms of ASD including impairments in social communication and repetitive behavior, as well as schizophrenia-like behaviors including deficits in sensorimotor gating, working and social memory, and increased anxiety. However, little is known about the molecular and cellular mechanisms underlying these abnormal behaviors. In the present study, we therefore studied changes in gene expression of embryonic

brain obtained from the poly I:C model. Pregnant Wister rats at embryonic day 12 (E12) were injected intravenously with poly I:C (4 mg/kg) or saline. After 3 or 7 days (at E15 or E19), rats were deeply anesthetized with isoflurane, and embryonic brains were removed; the experimental procedures approved by the Guideline for the Care and Use of Laboratory Animals in Kanazawa University. Total cellular RNA was then extracted and subjected to microarray analysis. We compared gene expression differences between E15 and E19. Overall 610 common up-regulated genes and 529 common down-regulated genes were identified. Further analysis revealed that significant (fold change of at least 2.0, $p < 0.05$) changes were observed in 194 genes: 153 for up-regulation and 41 for down-regulation. Gene ontology analysis showed that genes representing the olfactory pathway are enriched: 30 up-regulated and one downregulated genes encoded olfactory receptors. These results suggest that poly I:C treatment alters multiple pathways other than immune-related genes, thereby increasing risk for neurodevelopmental disorders.

Title: Dysregulation of the blood-brain barrier and neurovasculature induced by prenatal immune disturbances

Authors: *H. MOON, B. A. BABINEAU, J. UMANS, H. NGUYEN, T. D. PALMER; Stanford Univ., Stanford, CA

Abstract: Dysfunction of the blood-brain barrier (BBB) and neurovasculature has been implicated in the etiology of neurodevelopmental disorders such as autism spectrum disorder (ASD) and schizophrenia (SCZ). At a cellular level, BBB-associated endothelial cells regulate selective movements of ions, nutrients, metabolites, and immune cells. Prior genetic profiling from SCZ patient-derived endothelial cells uncovered dysregulation of the angiogenic pathways. Elevated peripheral neuroinflammatory biomarkers and immune cell infiltration in SCZ patients' brains suggested aberrant BBB permeability. Downregulation of *Claudins* and *Occludin*, BBB-associated tight junction proteins, has been detected in the SCZ brains. Genetic studies also

confirmed that a *CLAUDIN-5* SNP is linked to SCZ psychosis and *CLAUDIN-5* haploinsufficiency is associated with 22qDel syndrome. Intriguingly, BBB abnormalities in rare ASD cases were reported in a recent GWAS study identifying *LAT-1* mutations. Together, these previous findings suggest that BBB dysfunction may underpin the pathogenesis of neurodevelopmental disorders. However, the exact cellular mechanisms by which BBB disruptions cause the neuropathology of aforementioned diseases have not been elucidated. We hypothesized that neuroinflammation may result in endothelial cell dysregulation and BBB disorganization, leading to neocortical defects. To investigate mechanisms by which neurovasculature disruptions impair fetal brains, we prenatally challenged mice with immune activators. Maternal immune activation elicited cytokine responses in the maternal periphery, placentas, and fetal brains. Through further fetal brain expression analyses, we demonstrated downregulation of multiple target genes encoding tight junctions, adherens junctions, and metalloproteinases at the BBB. These modulating effects were also accompanied by suppression of the transcriptional factors of neural progenitors' self-renewal and mislocalization of neural subtypes. In prenatally exposed neocortex, the blood vessel formation was altered with aberrant neurovascular patterning. Our study identified novel molecular pathways which regulate BBB formation during neocortical development. This study also highlights that these networks are vulnerable to prenatal immune disturbances during the critical time points of development. These findings provide new evidence that modulation of the BBB integrity and homeostasis may serve as a new therapeutic strategy to mitigate neuroinflammation by restoring endothelial cell functions and regulating crosstalk between the brain and peripheral system.

Abstract: Birth is among the most complex biological mechanisms in mammals and epidemiological studies suggest that birth-related alterations could lead to a higher incidence of autism spectrum disorders and other developmental disorders. Astonishingly, we have little information on how the brain is prepared for and endures this critical step. Experimental observations suggest that labor and birth are critical periods playing an important role in the pathogenesis of brain disorders. Furthermore, several indirect lines of evidence obtained in humans suggest that brain growth velocity slows during the third trimester, possibly in an effort to avoid an exacerbated brain volume during vaginal delivery, and this is followed by a spurt of growth after birth that correlates with synapse density. To understand whether and how the brain is prepared to meet the challenge of labor and birth, we performed experimental studies in control and *in utero* VPA injected rats (VPA model of autism) comparing brain and neuronal parameters shortly before and after birth. We report that in control animals neuronal morphology shortly before and after birth was similar, suggesting a "growth stop signal" in preparation for labor and birth. However, this stop signal is alleviated in VPA animals as illustrated by the increase in the length of apical dendrites of CA3 hippocampal pyramidal neurons during this period. Using the iDISCO clearing method, we further show that hippocampal, especially the CA3 region, and neocortical volumes are increased during labor and birth and that the cerebral volume distribution shifts from normal to lognormal in VPA animals. Maternal administration during labor and birth of the NKCC1 chloride transporter antagonist bumetanide, which reduces [Cl−]i and attenuates the severity of autism, abolished the neocortical and hippocampal volume changes and reduced the whole-brain volume in VPA-treated animals. These results suggest that the abolition of the oxytocin-mediated excitatory-to-inhibitory shift of GABA actions during labor and birth contributes to the pathogenesis of autism spectrum disorders by stimulating growth during a vulnerable period.

Title: Effects of cannabinoid drugs in preclinical models of autism spectrum disorder

Authors: S. SCHIAVI, A. MANDUCA, *V. TREZZA;
Roma Tre Univ., Rome, Italy

Abstract: The terms “Autism spectrum disorder” (ASD) define a group of pervasive neurodevelopmental disorders characterized by altered sociability, compromised communication and stereotyped/repetitive behaviors. No effective and specific treatments are yet available for ASD, and none of the off-label medications currently prescribed to ASD patients selectively ameliorates their deficits in the core social and communicative domains. Different lines of evidence support a role for the endocannabinoid system in ASD: 1. altered endocannabinoid activity has been observed in autistic patients, and 2. endocannabinoids are known to modulate behavioral traits that are typically affected in ASD. On this basis, we tested the hypothesis that changes in the endocannabinoid tone contribute to the altered phenotype observed in genetic and environmental preclinical models of ASD, with focus on behavioral features that resemble core and associated autistic symptoms. We used two validated rat models which display most of the core autistic-like behavioral features and which reflect the critical role played by both environmental and genetic factors in the pathogenesis of ASD: the environmental model based on prenatal exposure to the antiepileptic valproic acid (VPA), and the genetic model based on FMR1 protein deletion. In the course of development, VPA-exposed rats and and FMR1 KO rats showed specific core and secondary autistic-like traits, confirming the face validity of these animal models of ASD. At the neurochemical level, VPA-exposed rats and FMR1 KO rats showed changes in different components of the endocannabinoid system in multiple brain regions, from infancy to adulthood. Interestingly, pharmacological manipulation of endocannabinoid neurotransmission rescued the behavioral deficits displayed by these animal models of ASD. Altogether, these findings reveal that abnormalities in brain endocannabinoid activity may underlie the deleterious impact of environmental and genetic risk factors on ASD-relevant behaviors, and that the endocannabinoid system may represent an interesting therapeutic target in ASD.

Title: Single-cell analysis of Foxp1-driven mechanisms essential for striatal development

Authors: *A. ANDERSON, A. KULKARNI, M. HARPER, G. KONOPKA;
UT Southwestern Med. Ctr., Dallas, TX

Abstract: The striatum is a critical forebrain structure for integrating cognitive, sensory, and motor information from diverse brain regions into meaningful behavioral output. However, the transcriptional mechanisms that underlie striatal development and organization at single-cell resolution remain largely unknown. Foxp1, a transcription factor strongly linked to autism and intellectual disability, is enriched in the striatum compared to the rest of the brain with high expression in spiny projection neurons (SPNs) of the direct (dSPNs) and indirect pathways (iSPNs). Here, we show that Foxp1 regulates organizational features of striatal circuitry in a cell-type-dependent fashion. Using single-cell RNA-sequencing (scRNA-seq), we examine the cellular diversity of the early postnatal striatum and find that deletion of *Foxp1* in distinct SPN populations alters both the cellular composition and neurochemical architecture of the striatum. We identify Foxp1-regulated target genes within distinct SPN populations and connect these molecular changes to functional and behavioral deficits relevant to phenotypes described in patients with *FOXP1* mutations. Additionally, we combined our early postnatal scRNA-seq dataset with other striatal single-cell datasets spanning embryonic to adult time points and built a developmental trajectory map of striatal cells. We then examined the global molecular changes that occur in glial and other striatal cell-types with deletion of *Foxp1* in SPNs. These data reveal cell-type-specific transcriptional mechanisms underlying distinct features of striatal circuitry and identify Foxp1 as an important regulator of striatal development.

Title: Sex differences in infant processing of social cues in the valproic acid-induced autism-like rat phenotype

Authors: *A. M. WHITE[1,2,3], X. AN[4,1,2], J. DEBIEC[1,2,3];
[1]The Mol. and Behavioral Neurosci. Inst., [2]Dept. of Psychiatry, [3]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI; [4]Yangzhou Univ., Yangzhou, China

Abstract: Disrupted processing of social cues and altered social behaviors are among the core symptoms of autism spectrum disorders (ASDs). Animal models are particularly useful tools for modeling aspects of ASDs, as they can help identify the neurobiological underpinnings of some of these symptoms. One such model is the prenatal valproic acid (VPA) exposure autism-like phenotype. Developing rat fetuses exposed to VPA at embryonic day (E) 12.5 show reduced play behavior, social exploration, and social interactions as juveniles and adults. However, less is known about how VPA-treated rats respond to social cues in infancy. Here, we examined the behavioral response to social odors in infant rats exposed to 500 mg/kg VPA or saline at E12.5. In early infancy, (postnatal day (P) 6-7), pups underwent an odor preference test (OPT) in an arena that contained clean bedding at one end and contained soiled bedding laden with social olfactory cues from the pup's homecage at the other end. VPA-treated pups spent significantly less time and made fewer entries into the section of the arena that contained soiled bedding than saline-treated pups (p's < 0.05). When examining these results by sex, we observed that female VPA-treated pups spent significantly less time in the section of the arena that contained soiled bedding than saline-treated pups ($p < 0.05$), but this effect was not present in male pups ($p > 0.05$). Both female and male VPA-treated pups made fewer entries into the section of the arena which contained soiled bedding than female and male saline pups. Regardless of sex, VPA and saline-treated pups did not differ in their total distance traveled during the test ($p > 0.05$), so the differences we observed are unlikely to be due to motor deficits in the VPA-treated pups. When we examined behavior in the OPT in older pups (P13), we did not observe any significant differences between VPA and saline-treated pups. We also did not observe any differences between treatment groups when we analyzed our pups by sex. In accordance with previously published data, our data suggest that in early infancy, VPA-treated pups may have impaired social recognition and/or may be less motivated to approach social odors. This is especially

important because early infancy is a period of intense attachment learning, which relies on social cues. Our results may inform about the underlying behavioral characteristics of ASDs, including sex differences reported by clinical studies, and could shed light on potential opportunities for intervention.

Title: Neuroanatomical consequences of prenatal exposure to ASD-specific maternal antibodies in rat's offspring

Authors: *M. WOLF-OCHOA[1], C. FALCONE[1], M. R. BRUCE[2], M. D. BAUMAN[3,4], J. VAN DE WATER[2,4], V. MARTÍNEZ CERDEÑO[1,4];
[1]Pathology and Lab. Med., Univ. of California - Davis, Sacramento, CA; [2]Immunol., [3]Psychiatry and Behavioral Sci., Univ. of California - Davis Sch. of Med., Sacramento, CA; [4]UC Davis Med. Ctr., Med. Investigation of Neurodevelopmental Disorders (MIND) Inst., Sacramento, CA

Abstract: Autism spectrum disorders (ASD) are a set of neurodevelopmental disorders classified by core impairments in social interactions and communication that are accompanied by the presence of repetitive and stereotyped behaviors. Despite increasing prevalence rates and awareness, the causes for idiopathic ASD are unknown. One potential non-genetic contributing factor to ASD is immune system dysregulation, which has been frequently described in individuals with ASD. Immunoglobulin G (IgG) antibodies transfer at high concentrations during mid-gestation in humans. Under normal conditions, antibodies are unable to cross the blood-brain barrier (BBB) to access the brain. However, the BBB is permissive during early brain development thus permitting maternal antibodies access to the fetal brain. A strong association between maternal AB reactivity towards fetal brain proteins and risk of ASD has been previously identified. Early studies identified patterns of reactivity to fetal brain proteins at approximately 37 and 73 kDa that were uniquely found among mothers of children with ASD. Several preclinical animal models have been conducted to determine pathogenic importance of these particular maternal AB, finding ASD-like behavioral alterations in offspring exposed to the AB from mothers of children with ASD. However, all of the animal models to date have utilized passive transfer techniques in which pregnant animals were injected during mid-gestation with human IgG isolated either from mothers of typically developing children or from mothers of

children with ASD. Herein, we propose to use our antigen-driven animal model of maternal AB related (MAR) autism. In this model, rat embryos are continuously exposed to the maternal AB throughout gestation, better representing the MAR ASD environment. We investigated the neuroanatomical and neuropathological consequences of prenatal exposure to the ASD-specific maternal AB in offspring. We quantified the number of the main neural cell populations in the cerebral cortex (neurons, astrocytes, oligodendrocytes) in the brain of adult MAR offspring (Ongoing). We analyzed the synaptic component by quantifying the number of pre- (V-glut+) and post-synaptic (PSD95+) structures in the cerebral cortex of the MAR ASD rat, and found a decrease in the number of pre- and post-synaptic structures. We evaluated the status of the immune cells of the brain, microglial cells, and did not find a change in their number. We are currently analyzing state of activation. Understanding the underlying etiology of ASD is crucial. The identification of risk factors and mechanisms would allow for earlier identification, treatment, and prevention.

Title: Therapeutic potential of granulocyte-colony stimulating factor for core autism behaviors

Authors: *G. G. GOULD[1], S. FEDORCHAK[1], L. F. FERREIRA[1], B. RICE[1], N. PATHAPATTI[1], B. SAYGIN[1], M. LEONARD[1], S. T. SCHULTZ[1], E. B. KRAIG[2], L. C. DAWS[1];
[1]Cell. & Integrative Physiol., U Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [2]Cell Systems and Anat., U Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: The need for more effective and comprehensive treatments for core autism symptoms remains critical. In about 20% of autism cases, excessive serotonin transporter (SERT) function is evident, and hyperactive SERT seems to underlie behavior deficits paralleling autism in rodents. Pro-inflammatory cytokines can impact SERT function and vice versa. Signs of altered immune response and inflammation are evident in many autism patients, so therapeutics that modulate inflammatory immune response can have therapeutic potential. Granulocyte-colony stimulating factor (G-CSF) is an endogenous cytokine that is a hematopoietic growth factor stimulating neutrophil production. G-CSF has neurotrophic, anti-inflammatory and anti-apoptotic

functions in the central nervous system that were unknown prior to its approval for human use as an adjuvant to chemotherapy for cancer patients. As such G-CSF is emerging as a potential therapeutic to protect or restore memory and cognitive flexibility. We hypothesized G-CSF might ameliorate autism-like behaviors in black and tan brachury (BTBR) mice, wherein other researchers found evidence of elevated neuro-inflammatory markers. The mean baseline serum G-CSF in BTBR is 85 ± 26 pg/ml lower than in C57BL/6J mice. To better understand G-CSF's role in shaping autism-relevant behaviors, we studied them in adult male BTBR after G-CSF (5 d, 125 µg/kg/day) or saline injections. Behavior tests started 3 days after final injection were social preference and marble burying. Two days later dominance was tested, and 3 days later water T-maze tests commenced for 5 days, followed by 3 days of reversal to assess cognitive flexibility. To ensure rigor and reproducibility, a priori power analysis was performed and treatment-blind observers collected behavior data**.** G-CSF treatment did not alter dominance, preference for social interaction or novelty or marble burying relative to saline controls. Yet interestingly G-CSF treatment reduced errors and time to locate the platform on reversal day 1 in the water T maze. Hence weeks after treatment subacute G-CSF enhanced BTBR cognitive flexibility, wherein initial serum G-CSF levels are relatively low. To reveal potential underlying mechanisms we examined SERT and dopamine transporter binding in brains from behavior-tested mice in terminal field areas using [^{125}I] RTI-55 with selective blockade. SERT density was increased in the hippocamus following G-CSF treatments. Future studies of G-CSF treatment effects on BTBR autism-relevant behaviors under different treatment regimens paired with cytokine panel measures will help to elucidate the mechanisms of action involved in the brain.

Title: Effects of prenatal stress and/or forebrain Atrx deficiency in C57BL/6 male mice on maternal care, brain development, and emotional, cognitive and social behaviors in the adult offspring

Authors: *G. J. RODRIGUES[1], K. LEE[2], H. MAILLET[2], D. GOGUEN[2], I. C. G. WEAVER[2]; [1]Psychology and Neurosci., Dalhousie, Halifax, NS, Canada; [2]Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Introduction: Early childhood experience and degree of parental-infant attachment influence the developing brain, notably in brain areas that support stress regulation, cognition and social behaviors. Animal models examining gestational stress suggest that sustained changes in gene expression in response to prenatal stress and/or natural variations in mother-pup interactions during the first week of postnatal life is mediated by changes in chromatin structure and DNA methylation. Although the exact mechanism is not completely understood, the chromatin remodeling factor ATRX is stably regulated by maternal care. We compared the affiliative behavior of mothers toward Atrx hemizyogous (Atrx+/-) and wild-type (Atrx+/+) offspring during the first week of life as a function of prenatal experience (gestational restraint stress verses no restraint stress).
Methods: Restraint-stress and behavioral phenotyping assays to measure the frequency of mother-pup interactions of C57BL/6 mice as well as open-field, Morris water maze and social investigation performance in the adult male and female Atrx+/+ and Atrx+/- offspring. RT-qPCR arrays for gene activity, western blotting for signaling proteins and immunohistochemistry for structure and function in transgenic mice and chromatin immunoprecipitation confirmed by sodium bisulfite-pyrosequencing to profile DNA methylation and chromatin modifications.
Results: Mothers provided less active maternal care and spent less time in contact with Atrx+/- offspring by comparison to Atrx+/+ offspring— similar to gestational-stressed mothers. Stress during pregnancy and maternal behaviour influenced Atrx expression, and Atrx genotype influenced maternal behaviour toward the whole litter. As adults, offspring prenatally stressed and/or reared with Atrx+/- males showed altered Atrx gene regulation, reduced forebrain growth and increased anxiety, social avoidance and cognitive deficits—including Atrx+/+ female mice.
Conclusion: Our findings demonstrate an unexpected role for ATRX in prenatal and early postnatal mouse development involving experiences of social and affiliative interactions, such as parenting, with a persistent effect on DNA methylation, hippocampus development, cognition, and anxiety-related and social behaviors in the adult offspring.

Title: The basolateral amygdala plays an integral role in modulating social memory deficits in neurofibromatosis type 1 mice

Authors: *H. P. DROZD[1], J. L. LUKKES[2], A. R. ABREU[2], E. T. DUSTRUDE[2], D. W. CLAPP[3], A. SHEKHAR[2], A. I. MOLOSH[4];
[1]Stark Neurosciences Res. Inst., [2]Dept. of Psychiatry, [3]Dept. of Pediatrics, Indiana Univ. Sch. of Med., Indianapolis, IN; [4]Dept. of Psychiatry, IU Sch. of Medicine,, Indianapolis, IN

Abstract: Neurofibromatosis type 1 (NF1) is an autosomal dominant disease affecting approximately 1 in 3000 people. NF1 results from a mutation in one copy of the neurofibromin gene (*NF1*), a negative regulator of the RAS-MAPK/ERK pathway. In addition to neurocutaneous lesions and tumors, individuals with NF1 show increased incidence of specific learning disabilities, attention deficit hyperactivity disorder, and autism spectrum disorder (ASD), with 20-30% meeting diagnostic criteria for ASD. ASDs represent a heterogeneous group of disorders characterized by deficits in social interaction and communication and restricted behaviors or interests. We have previously shown that male mice haploinsufficient for the neurofibromin gene ($Nf1^{+/-}$) demonstrate deficits in long-term social memory and hyperactivation of the RAS-MAPK/ERK pathway in the basolateral amygdala (BLA). Reduction of RAS-MAPK/ERK activity directly in the BLA of $Nf1^{+/-}$ male mice using p21 protein-activated kinase inhibitor rescued long-term social memory deficits. To further elucidate the role of the BLA in social learning, we injected a calmodulin-kinase II (CaMKIIα) adeno-associated virus (AAV) that expressed eYFP (control; AAV5-CaMKIIα-eYFP) or channelrhodopsin-2 expressing AAV (ChR2; AAV5-CaMKIIα-ChR2(H134R)-eYFP) into the BLA of adult C57/BL6J wild-type (WT) male mice. Additionally, we injected control and archaerhodopsin-3 AAVs (eArch; AAV5-CaMKIIα-eArch3.0-eYFP) in the BLA of adult $Nf1^{+/-}$ male mice. Four weeks later, mice were photostimulated in the BLA for forty-five minutes after acquisition of a social memory in the three-chamber social preference test. Twenty-four hours after BLA photostimulation, long-term social memory in the social preference test was assessed. During acquisition of short-term social memory, all mice displayed preference for the novel mouse. However, twenty-four hours after BLA photostimulation, BLA ChR2-expressing WT mice exhibited equal preference for a novel mouse compared to the familiar mouse in the social preference test. Dual immunofluorescence was used to map pERK, c-fos, and eYFP expression in the BLA of control-, ChR2-, and eArch-injected mice. Increased pERK activation immunoreactivity was observed in ChR2-expressing WT mice after BLA photostimulation compared to control WT mice. In contrast, long-term social learning deficits observed in $Nf1^{+/-}$ control mice were restored in BLA eARCH-expressing $Nf1^{+/-}$ mice when the BLA was inhibited with green light. These data provide evidence for the significant role of the BLA in regulating long-term social memory in an experimental model of NF1.

Title: Set shifting deficits in valproic acid model of autism in Long Evans rats

Authors: *Z. MCKINNELL[1], B. CHALLANS[2], T. MAZE[2], A. RAMOS[2], A. PRITCHARD[2], B. PLAKKE[3];
[1]Psychological Sci., Kansas State, Manhattan, KS; [2]Psychological Sci., [3]Psychological Sciences, Behavioral Neurosci., Kansas State Univ., Manhattan, KS

Abstract: According to the CDC approximately 1 in 59 children will be diagnosed with autism spectrum disorder (ASD), which is characterized by social deficits, impairments in communication, restrictive/repetitive behavior, and deficits in cognitive flexibility. Research focused on understanding the underlying neural network of this disorder is an important step in developing more efficient treatment strategies for individuals that struggle with this disorder. The Valproic acid (VPA) model of autism is a widely used model of autism in animals (Mabunga et al., 2015), where VPA treated offspring exhibit alterations in social and repetitive behavior. In tasks testing cognitive flexibility, people with ASD tend to exhibit a higher shift cost, which means it is more difficult to shift attention on trials where the rule changes (Van Eylen et al., 2011). In order to examine cognitive flexibility within the VPA model we ran offspring through the attentional set-shifting task, which is the rodent equivalent of the Wisconsin Card Sorting Task (Birrell et al., 2000). To control for order effects, a Latin square counterbalancing technique was used to ensure that each pair of exemplars would be experienced in each phase of the task across rats (Tait et al., 2018). All offspring from controls and VPA litters were kept for a total of 82 rats. Both males and females were run to investigate sex differences. Rats went through the set shifting task after reaching adulthood, after postnatal day 60. VPA rats made significantly more errors during the intra-dimensional shift (IDS) than control rats. Preliminary analyses also indicated there is a main effect of sex across multiple phases including on simple discrimination and IDS. Additionally, fewer VPA rats formed an attentional set, evidence that they had difficulty learning the rules of the task. One of the symptoms of ASD is cognitive/behavioral rigidity, such that individuals who struggle with the disorder have problems changing their pattern of behavior. This was reflected within this study by the large amount of VPA rats who did not form an attentional set. The sex difference results are supported

by studies in humans where ASD females perform worse in cognitive flexibility tasks when compared to males in the same task (Memari et al., 2013). Overall, these results provide further support that males and females may suffer from different symptoms and present a different profile that encompasses their experience with ASD.

Title: Behavioral characterization of mice deficient for the mammal-specific microRNA 379-410 cluster

Authors: *A. Ö. SUNGUR[1,2], M. LACKINGER[3], L. STEMMLER[1], R. GROSSE[1,3], R. K. W. SCHWARTING[1,2], G. SCHRATT[3,4], M. WÖHR[1,2];

Abstract: microRNAs (miRNAs) represent a group of small, noncoding RNA molecules that play a major role in the posttranscriptional regulation of gene expression. Members of a large placental mammal-specific miRNA cluster, namely miR379-410 encompassing 38 miRNAs, have been implicated in a variety of neurodevelopmental disorders. We have conducted comprehensive behavioral phenotyping on mice deficient for the miR379-410 cluster throughout development. Recently, we have shown that deletion of this cluster in mice leads to hypersocial behavior and increased emission of ultrasonic vocalizations (USV), which is accompanied by altered excitatory synaptic transmission, and exaggerated expression of ionotropic glutamate receptor complexes in the hippocampus. Mutant mice further displayed more pronounced anxiety-like behavior across the entire lifespan, in the absence of cognitive deficits. To further investigate the contribution of miR379-410 cluster to communication deficits present in neurodevelopmental disorders, here we have performed detailed analysis on acoustic features of isolation-induced pup USV. In addition to increased call rate, mice lacking miR379-410 cluster displayed increased peak amplitude and frequency modulation when isolated from the mother and littermates. In adulthood, mutant mice displayed increased self-grooming but reduced marble burying behavior. We also tested for mania-like elevated drive by studying effects of the psychostimulant d-amphetamine (AMPH) on locomotor activity. Mutant as well as wildtype mice reacted to AMPH treatment by a significant increase in locomotor activity, and no genotype

differences were evident, indicating lack of mania-like behavior in miR379-410 mutants. Taken together, the present study confirms and extends previous findings, showing that deletion of miR379-410 cluster leads to altered communication and repetitive behavior, without affecting psychostimulant-induced hyperactivity.

Title: Study of post-pubertal social vocalization in pre-adolescent males and females coming from maternal hypothyroidism: Link for neurodevelopmental aspects in autism-related conditions?

Authors: *D. M. SANTOS[1], J. D. SILVA[1], G. GIANNOCCO[2], M. RIBEIRO[3], C. A. PENATTI[4];
[1]Univ. Nove de Julho - UNINOVE, São Paulo, Brazil; [2]Dept. of Biol. Sci., Federal Univ. of São Paulo – UNIFESP, São Paulo, Brazil; [3]Developmental Disorders Program, Ctr. for Hlth. and Biol. Sci., Mackenzie Presbyterian Univ., São Paulo, Brazil; [4]UNINOVE - Univ. Nove De Julho, Sao Paulo, Brazil

Abstract: Subtle maternal thyroid dysfunction and its most common condition, subclinical maternal hypothyroidism (MH), may facilitate fetal neurodevelopmental disarrangements, which share similarities to some of the cognitive and behavior alterations manifested in the autism spectrum disorders (ASD). To date, however, there are few studies, which approach in detail oral communication of the new born and pre-adolescence individuals and regarding their sex differences subjected to MH during pregnancy. Using a C57black6 mouse model of discrete MH, we investigated the social interaction of both male and female matched-offspring before puberty across animal behavioral paradigms to look for differences in motor locomotion, anxiety, maternal care and preference, and vocalization based on innate social behavior display for that mouse strain and species. In addition, we checked the expression levels of three mRNA of genes related to verbal communication in models of ASD. Behavioral testing did not show overall differences in locomotor behavior based on open field paradigm when applicable to males and females. We show that first generation male but not first generation female offspring from

hypothyroid dams has increased anxiety levels tested at pre-pubertal age post-natal (PN) day 30, using *plus-maze* paradigm when compared with control offspring. Regarding oral communication, one group of males born from hypothyroid dams displayed increased total vocalizations only in early age (PN 6 and 7) when compared with age-matched control males. In later ages (PN 15 and 21), the difference of the vocalization patterning between the experimental groups was lost. In order to look for specific differences in the display of maternal behavior, we developed the paradigm of foster mother's place-preference. Despite the observational preference for the foster moms going more frequently towards the maternal hypothyroid-born offspring in males, there were no significant differences in overall choice among all male and female offspring. Our preliminary results on mRNA expression within prefrontal cortex of oral communication-related genes did not show differences. Therefore, our findings suggest that subtle or subclinical MH during early pregnancy may facilitate complex and variable social behavior disarrangements in maternal care, anxiety in infancy and childhood and verbal communication deficits in a sex-dependent manner. We thus speculate that the animal model in subtle or subclinical MH has much to mimic the highly variable neuropsychological manifestations in ASD and may favor the understanding in children's development among the ASD individuals.

Title: The role of maternal anti-CASPR2 antibody in autism spectrum disorder: A second hit model

Authors: *C. BAGNALL-MOREAU[1], R. BERLIN[2], P. T. HUERTA[2], B. T. VOLPE[3], B. DIAMOND[3], L. BRIMBERG[4];

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by core deficits in social interaction, impaired communication and stereotypic behavior. Numerous studies highlight the role of the maternal immune system in fetal neurodevelopment, and perturbations in the prenatal environment are associated with an increased risk of ASD. Maternal cytokines and autoantibodies have been demonstrated to disrupt fetal brain development and contribute to an ASD-like phenotype in primate and rodent offspring. Work from our lab have previously found that antibodies targeting Contactin Associated Protein-Like 2 (Caspr2) are frequently found in the serum of women with anti-brain antibodies and a child with ASD. Furthermore, mice exposed *in utero* at gestational day E13.5 to human anti- Caspr2 antibody (namely C6), cloned from a mother with anti-brain antibodies and an ASD child resulted in an ASD like phenotype in male, but not female offspring. In the current study, we have characterized a new model in which female mice are immunized with the extracellular domain of human Caspr2 and produce anti-Caspr2 antibody. Male offspring of these immunized females also present with a neurodevelopmental phenotype, similar to what has been seen following a single exposure *in utero* to C6. Since the affected offspring of women harboring anti-Caspr2 antibody can be male or female, and some mothers with anti-Caspr2 antibody and an ASD child also have a typically developing child, we propose to use this model to explore the additional immune factors that predispose to the development of an ASD-like phenotype in offspring of dams harboring anti-Caspr2 antibody. We hypothesize that immunological activation during pregnancy may serve as a 'second hit' and exhibit a synergistic effect with anti-Caspr2 antibody to promote ASD phenotype in female and male offspring. Caspr2 or adjuvant-only immunized dams are injected with recombinant IL-6 or saline on gestational day E12.5 to mimic maternal inflammation. We are assessing cortical laminar organization of fetal brains at E14.5 and E18.5. The expression and activation of cytokine signaling pathway proteins is also being assessed in the placenta and fetal brain by qPCR and western analysis. We expect that the gender bias observed in offspring will be altered when a combination of risk factors is present. Furthermore, these studies will explore the contribution of the placenta to fetal brain development during maternal infection and antibody exposure. These studies will increase our understanding of the triggers of neurodevelopmental impairment and possibly suggest novel approaches to protecting the fetal brain.

Title: Early-life developmental profile of ultrasonic vocalizations in the valproic acid model of autism

Authors: *R. S. BESSA, R. N. ROMCY-PEREIRA;
Brain Inst., Federal Univ. of Rio Grande do Norte, Natal, Brazil

Abstract: Autism is a heterogeneous developmental disorder in which neural circuits involved in social cognition and sensory processing are dysfunctional. In animal models of autism, ultrasonic vocalizations (USV) are thought to be a measure of communication skill related to social deficits. In rodents, prenatal exposure to valproic acid (VPA) produce autistic endophenotypes including social deficits, repetitive behaviors and reduced USV emissions. In the present study, we aimed to analyze the dynamic of USV production in VPA-treated rats from P7 to P21. Adult female Wistar rats received a single dose of VPA (500mg/kg, ip. in saline) at gestational day 12.5. At P7, P14 and P21 isolated pups had USV measured in an acoustic isolated box set with dim red light and an ultrasonic microphone (Dodotronics; Ultramic250K) positioned 45 cm above. For 5min, USVs were recorded with a sampling rate of 250 kHz. USVs were analyzed in MATLAB with an entropy-based method for USVs identification and clustered/classified using a deep learning-based algorithm DeepSqueak. Our results showed that all control animals at all ages vocalized when isolated. In contrast, 84%, 96% and 96% of VPA rats vocalized at P7, P14 and P21, respectively. In addition, VPA pups produced less USVs at P7 and P14 compared to controls, with no difference at P21. Total vocalization time was similar between VPA and control. However, the distribution of call durations changed across ages. At P7 and P14, 90% of the USVs consisted of <130ms and <170 ms-long USVs, respectively for control animals, whereas for VPA animals, 90% of USVs consisted of <200ms and 270ms-long emissions at P7 and P14. At P21 both groups showed shorter emissions - 90% of the USVs up <70ms. USVs at P7 had principal frequency around 45 kHz and at P14 and P21 were distributed around 45 kHz and 68 kHz. USV bout clusters were analyzed theough inter-USV interval (IUI). At P14, VPA animals had shorter intervals than controls, with three distribution peaks at 100ms, 200ms and 300ms whereas controls had peaks at 150ms, 270ms and 400ms. USVs were also classified in 11 pre-defined types using a supervised learning algorithm and the relative frequency of occurrence for each type were analyzed at all ages investigated. At P7, control animals emitted more ‘Complex Trill’ than VPA animals. No difference was found at P14 and P21. Transition probabilities between USV classes were also computed. P14 was the age that animals in both groups showed the most significant differences. In conclusion, our results confirm some of the previous findings of the literature and extends our understanding of development of isolation USV emissions in VPA-treated rats.

Title: Shank3b loss in the mouse results in deficits to motivation for social reward

Authors: *K. B. MCCULLOUGH, S. E. MALONEY, C. WEICHSELBAUM, J. DOUGHERTY;
Washington Univ., Saint Louis, MO

Abstract: Loss-of-function polymorphisms in the *SHANK3* gene cause Phelan-McDermid syndrome, a neurodevelopmental disorder characterized by global developmental delay, intellectual disability, speech delay, poor motor function, and Autism Spectrum Disorder (ASD). ASD is defined in part by deficits in social communication and social interaction, yet a long-standing hypothesis is that the root deficit may actually be in social motivation. Previous work in mice with genetic disruption of the *Shank3b* gene has shown subtle social approach deficits yet normal direct social interactions, with pathologically repetitive grooming behaviors. We recently developed a novel behavioral assay for assessing social motivation for social reward in the mouse, the social operant task. Here, we tested social motivation function in the *Shank3b* heterozygous (*Shank3b*$^{+/-}$) and homozygous (*Shank3b*$^{-/-}$) mutants. *Shank3b*$^{-/-}$ mutants failed to work for access to a social partner, whereas the *Shank3b*$^{+/-}$ mutants and wild type littermates demonstrated intact motivation for access to a social partner as well as increased effort under more constrained parameters. To understand if the deficits observed in the *Shank3b*$^{-/-}$ mutants were due to underlying deficits in the global reward circuitry or learning and memory function, we also conducted cocaine conditioned place preference and Barnes maze testing. We further examined these mice in the sucrose operant task to understand if the motivational impairments were specific to the social domain. Recent work has helped to define the role of oxytocin in social reward, and altered oxytocin function has been implicated in ASD. Therefore, were interested in understanding the role of oxytocin in this phenotype. Our study shows for the first-time deficits in social motivation in the *Shank3b* mutant mouse model. On the whole, our work allows us to better understand how motivation and reward are involved in the social deficits characteristic of ASD and other neurodevelopmental disorders.

Title: Shank3 is required for late-phase juvenile ocular dominance plasticity in mice

Authors: *C. GROVES KUHNLE, V. TATAVARTY, S. D. VAN HOOSER, G. TURRIGIANO;
Dept of Biol., Brandeis Univ., Waltham, MA

Abstract: In order to better understand how autism-associated genes impact the experience-dependent development of visual cortical circuits, we investigated the role of *Shank3* - an Autism Spectrum Disorder associate gene - in ocular dominance plasticity. Ocular dominance plasticity after monocular lid suture has been divided into two stages that consist of 1) an early-phase (1-3 day) decrease in responsiveness to the closed eye, and 2) a late-phase (3-7 day) homeostatic increase in overall responsiveness. The late phase of OD plasticity is thought to rely on synaptic scaling, and previous studies in our lab have shown that *in vitro* cultures in which Shank3 has been depleted by RNAi fail to exhibit homeostatic synaptic scaling either up or down. We thus hypothesized that that late-phase ocular dominance plasticity would be reduced in *Shank3*-knockout animals. Wildtype mice showed the expected decrease in response to drive from the closed eye at 3 days and the subsequent strengthening of response to both eyes at 6 days. In contrast, while Shank3 knockout animals exhibited the expected decrease in cortical responsiveness to the closed eye during short monocular deprivation (MD) of 3 days (similar to their wildtype colony mates), they lacked the normal homeostatic increase in responsiveness after 6 days MD. These data show that the homeostatic component of experience-dependent plasticity is absent in Shank3 knockout mice, and suggest that loss of homeostatic plasticity may contribute to circuit dysfunction in these mice.

Title: Development of a quantitative measure of social motivation in mice and its regulation by oxytocin

Authors: *S. E. MALONEY[1], K. B. MCCULLOUGH[2], C. T. WEICHSELBAUM[2], J. D. DOUGHERTY[3];
[1]Psychiatry, IDDRC, [2]Genet. and Psychiatry, Washington Univ. Sch. of Med., St. Louis, MO;
[3]Genetics, Psychiatry, IDDRC, Washington Univ. Sch. of Med., St Louis, MO

Abstract: Humans and other social species find social interaction inherently rewarding. Facets of social motivation are critical to the development and maintenance of healthy social functioning. Autism spectrum disorder (ASD) is defined in part by deficits in social communication and social interaction, yet a long standing hypothesis is that the root deficit may actually be in social motivation. Recent work has helped to define the role of oxytocin in social reward, and altered oxytocin function has been implicated in ASD. We seek to understand if abnormalities in social motivation for social reward underlie the core social phenotypes in ASD, and to what extent oxytocin is playing a role. While current behavior assays in mice can answer questions regarding direct social interactions or sociability, assays for assessing social motivation (how much work an animal is willing to do for social reward) are not well established. Thus we developed a task to directly examine motivation for social interaction. To do this, we modified standard mouse operant conditioning chambers to create an automated system in which social motivation is directly assessed by quantifying nose pokes performed for access to a social partner. Specifically, a correct nose poke opened a door to reveal a social partner separated by steel bars and allowed for a 12-sec interaction. Quantification of nose pokes allowed for examination of motivation to interact with a social partner compared to only the opening the door (control). Behavioral tracking also enabled quantification of social interactions including total time interacting, time spent per reward and latency to interact. We first demonstrated adult wild-type C57BL/6J female and male mice will work for access to a social interaction, increase that work under more constrained parameters, and exhibit an increased work breakpoint for access to a social interaction compared to only opening the door. We also observed sex differences: male mice exhibited increased motivation for access to a conspecific compared to females. We next investigated the role of the oxytocin system in this task. We administered an

oxytocin antagonist continuously through an IVC cannulation with subdermal pump during social operant testing and again quantified social motivation in male and female mice. Here, we have established a behavioral paradigm for social motivation that can be used to examine operant responses to social reward in mouse models of ASD. Further, we have tested the role of the oxytocin system in this paradigm that can be leveraged in the future to determine whether oxytocin can be used to modulate social motivation performance in ASD models.

Title: Assessment of somatossensory development after neonatal pain

Authors: *V. S. FAZAN[1], L. S. SANADA[2], E. C. CARMO[2], N. L. B. MACHADO[2];
[1]Surgery and Anat., [2]Sch. of Med. of Ribeirao Preto, Ribeirão Preto, Brazil

Abstract: Advances in medicine have increased the survival of preterm neonates that are constantly submitted to invasive procedures, causing repetitive painful experiences in the neonate period. However, morphological consequences of early painful experiences in the central and peripheral nervous system remain fairly explored. We aimed to evaluate the possible alterations in the sural nerves of male and female adult Wistar rats, after painful stimulation in the neonatal period. We also aimed to assess the glial activity in cortical areas related to pain processing (pre-frontal, anterior insular, anterior cingulated, primary and secondary somatossensorial area, primary and secundary motor area). Wistar rats were followed from birth to 180 days of life, separated in 8 groups: 1) Control-male neonate group; 2) Control-female neonate group; 3) Pain-male neonate group; 4) Pain-female neonate group; 5) Control-male adult group; 6) Control-female adult group;7) Pain-male adult group; 8) Pain-female adult group. Neonatal pain was induced by repetitive needle insertion in one heel twice per day for 15 days starting at birth. The control groups were stimulated with a cotton swab, twice per day for 15 days starting at birth. Both male and female Wistar rats (N=48) received either neonatal injury or control stimulation and they were tested behaviorally for mechanical withdrawal thresholds of the paw and muscle, and for gait alterations. The animals were then weighed, anesthetized, and

they had their right and left sural nerves dissected and fixed in glutaraldehyde. After that, the animals were perfused and their brains dissected. After preparation with conventional histological techniques with epoxy resin, cross-sections of the right and left sural nerves were obtained for analysis by light microscopy. The morphometry was performed with the aid of an image analysis software. The brains were used for immunohistochemistry of glial cells in the cortical areas (pre-frontal, anterior insular, anterior cingulated, primary and secondary somatossensorial area, primary and secundary motor area). The statistical analysis was performed using specific statistical tests. Differences were considered significant when $p<0.05$. It was observed that the nociceptive stimuli in the neonatal period were able to produce hyperalgesia and changes in gait pattern; additionally, pain in neonatal period increased glial cells in the cortical areas and it altered the morphology and morphometry of sural nerve, which persisted into adulthood. Therefore, pain in the neonatal period can cause persistent sensorymotor changes.

Title: Relation between movement and respiration in preterm infants

Authors: *I. ZUZARTE[1], D. PAYDARFAR[2], D. STERNAD[3];
[1]Dept. of Bioengineering, Northeastern Univ., Boston, MA; [2]Dept. of Neurol., The Univ. of Texas At Austin, Dell Med. Sch., Austin, TX; [3]Depts. of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ. Dept. of Biol., Boston, MA

Abstract: An estimated 15 million babies (>10% of all births) are born preterm (<37 week gestational age). Apnea resulting from prematurity and instability of the respiratory system is a common condition in preterm infants that is implicated in several acute and long-term complications. Few studies have investigated whether respiration is coupled to infants' movements. For clinical applications, prediction of apneas would be of high significance to counteract the onset of apneas or alarm clinical personnel. This study proposes the hypothesis that infant movements are a predictive marker for apneic episodes; specifically, we examine this relation in preterm infants' breathing cycle. Movements were estimated based on artifacts in

physiological signals with a custom-developed wavelet-based algorithm. Respiratory activity was measured in 13 infants using respiratory inductance plethysmography. In an additional 8 infants, respiration and partial pressure of carbon dioxide (PCO_2) were measured by a nasal cannula circuit with side-stream capnometry to avoid direct mechanical effects of movement on respiration. Respiratory and movement data of the 13 preterm infants were investigated and correlated with the frequency and characteristics of apneas during movement. Results of a previous study were validated, while also highlighting critical limitations due to restricted selectivity of the included data samples. To overcome these limitations, we analyzed the stability of respiration with respect to the onset and offset of movement in 8 preterm infants, using standard deviation of inter-breath intervals and Poincaré maps of the respiratory activity. A significant difference ($p < 0.05$) was observed in the stability of respiration following movement onset using both methods. Movement increased the variability of inter-breath intervals and PCO_2, while also causing a significant reduction in the end-tidal carbon dioxide ($ETCO_2$). Low $ETCO_2$ has been shown to be associated with decreased cerebral hypoxia, one of the primary causes of preterm apnea. Moreover, results showed that the degree of destabilization of respiration was dependent on the duration of movement. These findings support that bodily movements of the infants might serve as predictors of life-threatening events, useful for effective clinical management and for risk stratification of infants.

Title: Dynamic connectivity and changes in coordination during walking

Authors: *J. N. KERKMAN, A. BEKIUS, A. DAFFERTSHOFER, N. DOMINICI;
Human Movement Sci., Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: We studied the locking between the arms and legs displaying spontaneous switches from a 2:1 to 1:1 frequency ratio when walking speed increases. Is this transition induced by biomechanical factors or caused by active motor control processes? To answer this question, we studied dynamic connectivity within and between groups of muscles.
Sixteen healthy subjects (five males, eleven females, mean age 25.3 ± 2.4 years) walked on a treadmill with their arms swinging along their body while kinematics and surface

electromyography (EMG) was recorded. We grouped EMG signals in muscle synergies using non-negative matrix factorization (NMF). We also estimated intermuscular coherence between all muscle pairs to estimate connectivity between muscles at different frequency bands. Again, NMF was used to group the coherence spectra. Both outcome measures were combined into minimally-connected multiplex networks. We compared these networks within and between modules and examined their changes as a function of walking speed.
As expected, the coordination between arms and legs changed from 2:1 to 1:1 when treadmill speed increased. Muscle synergy analysis disclosed five relevant synergies. The corresponding temporal activation patterns differed between speeds in both temporal structure and amplitude. The muscle synergy network turned out to consist of two modules of which one was mainly located at the legs and the other at the pelvis and the upper body. However, the NMF of the coherence spectra yielded four networks enclosed distinct frequency bands: 1-3 Hz, 3-8 Hz, 8-18 Hz, and 18–60 Hz. The corresponding multiplex network contained four modules enclosing both arms, trunk, right leg, and left leg. The community structure of the muscle synergy and coherence networks differed primarily in the organisation of arms and legs. The coherence networks revealed an increased connectivity in the lower frequencies between trunk and legs and the arms appeared uncoupled from the rest of the body when looking at higher frequencies after the switch from a 2:1 to a 1:1 coupling between arms and legs.
Taken together, the change in coordination between arms and legs was accompanied by changes in muscle synergies. Both synergy and coherence networks underwent changes in their functional and structural community structure. In particular the latter may indicate the involvement of different neural pathways in the control of muscle synergies at different walking speeds. This seems to support the concept that the switch in coordination is not merely due to biomechanical factors.

Title: Assessing the impact of chewing on motor function in children and adolescents

Authors: *J. PREBOR[1], B. SAMULSKI[2], S. MORRISON[3];
[1]Kinesiology and Rehabil., Old Dominion Universtiy, Norfolk, VA; [2]Kinesiology and Rehabil., [3]Physical Therapy and Athletic Training, Old Dominion Univ., Norfolk, VA

Abstract: Previous research has shown that, for young and older adults, walking is constrained by a person's chewing rate with step frequency altering in line with the speed of chewing. However, it is unclear whether this coupling relation occurs in younger populations or if the gait-chewing relationship extends to other rhythmical motor tasks like finger tapping. Consequently, the aim of the study was to assess the impact chewing at different speeds (i.e. fast, slow, and preferred) on walking performance and finger tapping as a function of age from childhood to adolescence. The responses from 16 individuals, ranging from 10-17 years of age were assessed. To determine chewing rates, surface EMG recordings from the masseter muscle were used.. For the gait assessments, individuals walked at their preferred speed over a 20ft Protokinetics pressure sensitive walkway. For finger tapping, participants were asked to tap on a force sensor with their index finger at their preferred speed. Our results demonstrated that chewing was strongly related to the performance of both the finger tapping and walking tasks. For gait, cadence and step time changed as a function of the chewing rates while step length was relatively unaffected. Similarly, the speed of finger tapping altered in line with changes in the persons chewing rates. Interestingly, the robustness of the link between chewing and the other motor tasks appeared to be mediated by the participant's age, with older children exhibiting stronger coupling between tasks compared to the younger individuals. Taken together, these results illustrate that the oral motor task of chewing has a strong driving influence on other neuromotor functions. This influence appears to be more pronounced in adolescents indicating less synchronization in younger children. Younger children were also highly variable in their motor responses. These distinctions between younger and older children may be supported by previous research of motor development where younger children have less established motor patterns. These differences in motor patterns with age have been linked to increased activity in the frontal cortex and cerebellum in children as compared to adults. As a result, the movement responses of the younger persons appear to be less automatic, more variable and exhibit decreased synchronization between motor effectors. The findings from this study suggest rhythmical motor dual tasks are less established in early childhood and affected by increasing age.

Title: Motor drive to the paretic lower limb in children with hemiplegic cerebral palsy: A pilot study

Authors: *V. GOYAL[1,2], T. SUKAL-MOULTON[1,3], J. P. A. DEWALD[1,2];
[1]Physical Therapy and Human Movement Sci., [2]Biomed. Engin., [3]Pediatrics, Northwestern Univ., Chicago, IL

Abstract: Individuals with a unilateral brain injury experience a loss of corticofugal projections from the lesioned hemisphere to the contralateral side of the body. In adults with hemiparetic stroke, it is postulated that upregulation of corticobulbospinal pathways causes an abnormal coupling between the extensors in the lower limb (hip adduction with hip/knee extension and ankle plantarflexion), leading to a loss of independent joint control. However, previous work showing spontaneous mirror movements in the paretic upper extremity suggests that children with hemiplegic cerebral palsy (HCP) from an early-onset brain injury (a pre-natal injury before the early third trimester or a peri-natal injury during birth) may additionally rely on retained ipsilateral corticospinal pathways. To investigate potential differences in descending drive to the lower extremity, we use a novel device previously developed for adult stroke studies to quantify abnormal joint torque coupling at the hip. The device includes two load cells and is able to capture high-resolution and simultaneous isometric multi-joint torque measurements. We include three participants without HCP (three females aged 9.1, 13.2, and 13.9 yrs) and two participants with HCP (a 10.5 y/o male with a pre-natal injury and a 16.8 y/o male with a peri-natal injury) in our pilot study. Testing was done in the non-dominant/paretic lower limb. Participants were first instructed to generate maximum voluntary torques in hip extension and abduction. Participants were then instructed to combine submaximal hip extension efforts (20%, 40%, 60%) with maximal hip abduction torque generation, a grouping outside the stereotyped hip extension/adduction pattern. Hip abduction torque was normalized to the max for comparison. Participants without HCP were able to generate 81±4% hip abduction max during 20% hip extension, 76±5% hip abduction max during 40% hip extension, and 81±2% hip abduction max during 60% hip extension. Both participants with HCP demonstrated comparable values at 71-80% hip abduction max during 20% hip extension, 82-100% hip abduction max during 40% hip extension, and 79-96% hip abduction max during 60% hip extension. These results indicate no abnormal coupling between hip extension and adduction and support the hypothesis that children with HCP from early-onset brain injury do not employ corticobulbospinal pathways for motor control of the paretic lower limb. Future work will include children with HCP from late-onset brain injury to quantify possible coupling between hip extension and adduction to confirm the hypothesis that this cohort may instead rely on corticobulbospinal pathways for motor control.

Title: A novel two-body sensor system to study spontaneous movements in infants during caregiver physical contact

Authors: *P. PATEL[1], Y. SHI[2], F. HAJIAGHAJANI[2], S. BISWAS[2], M.-H. LEE[1];

Abstract: Spontaneous movements, which refer to repetitive stereotyped limb movements in the absence of any external stimulus, have been found to be reflective of neurodevelopmental status during infancy. These movements are modulated by both individual and environmental factors, including physical contact with the caregiver. However, it is a challenge to measure spontaneous movements during physical contact because infant-generated movements are coupled with caregiver-generated movements. Here, we propose the use of a novel two-body sensor system to distinguish infant-generated movements in the presence of physical contact with the caregiver. Data from seven typically developing infants and their caregivers were recorded during different simulated home activities, which involved different combinations of physical interaction, caregiver's movement and infant positions. The two-body sensor system consisted of two wearable accelerometers - one placed on the infant's arm and one on the caregiver's arm, and we developed a Kalman-filter based algorithm to isolate the infant-generated movements. In addition, video was recorded for qualitative analysis. Results indicated that spontaneous movement activity was higher when there was no physical contact with caregiver. When there was physical contact, spontaneous movements were also increased when the caregiver was still and when the infant was held horizontally. These results show that the novel two-body sensor system and the associated algorithms were able to isolate infant-generated movements during physical contact with the caregiver. This approach holds promise for the automated long-term tracking of spontaneous movements in infants that may provide critical insight into developmental disorders.

Title: Acetaminophen exposure during the juvenile period impairs motor coordination in C57Bl/6 mice

Authors: *J. V. GEORGE[1], G. GUNAWAN[1], A. A. WISLOTSKY[1], P. T. ORR[1,2];
[1]Neurosci. Program, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: Although acetaminophen (APAP) or paracetamol is a common over-the-counter analgesic and antipyretic, it is associated with an increased likelihood of hyperkinetic disorder following prenatal exposure in humans and is associated with hyperactivity and deficits in motor coordination after prenatal exposure in mice. Currently, it is not known if similar effects are found after APAP exposure during the juvenile period. This study investigated whether chronic APAP exposure affects locomotion and anxiety in juvenile mice. C57BL/6 mice were injected with 50 mg/kg APAP or vehicle every third day after weaning until sacrifice. At 6 (cohort 1) or 8 (cohort 2) weeks of age, mice were tested on open field, marble burying, Von Frey tactile sensitivity, and accelerated rotarod. There were no significant sex differences; thus, analyses were combined across sex. Regardless of age, acetaminophen impaired performance in the rotarod. Vehicle- and acetaminophen-treated mice improved across the ten rotarod trials at 20 rpm/min ($F(9, 234) = 8.463$, $p < .001$) on the first day. However, mice receiving acetaminophen spent significantly less time on the rod across all ten trials ($F(1, 26) = 4.308$, $p < .05$). There was no trial by condition interaction ($F(9, 234) = .649$, $p > .05$). Overall, these results suggest that recurrent acetaminophen exposure during the juvenile period impairs motor coordination, which is consistent with our previous results in prenatally exposed mice.

Title: Prenatal acetaminophen exposure alters FAAH expression in newborn C57Bl/6 mice

Authors: G. GUNAWAN[1], S. N. WIERBOWSKI[1], *P. T. ORR[1,2];
[1]Neurosci. Program, [2]Psychology Dept., Univ. of Scranton, Scranton, PA

Abstract: Previous work has demonstrated that prenatal acetaminophen (APAP) is associated with increased risk of hyperkinetic disorders in humans and hyperactivity in mice. There are multiple potential mechanisms which could mediate these effects, including conversion to AM404, a cannabinoid reuptake inhibitor, via fatty acid amide hydrolase (FAAH) and inhibition of cyclooxegenase-2 (COX-2). We administered 15 mg/kg/day of APAP or regular tap water to pregnant C57Bl/6 mice throughout once gestation was detected and collected brain tissue from pups within 48-72 hours of birth. Western blotting was used to detect changes in FAAH and Cox-2 in these samples. There was no significant difference in Cox-2 levels between groups ($t(27) = .322$, $p > .05$), but pups prenatally exposed to APAP showed a significant upregulation in FAAH ($t(24) = 1.987$, $p = .029$). These result suggest that FAAH may be an important mediator of the effects of long-term APAP exposure, although more mechanistically-focused work is still needed.

Abstract: Essential tremor (ET) is one of the most common movement disorders, the prototypical disease model for motor rhythm control and for clinical application of focused

ultrasound. However, the pathophysiology of ET remains poorly understood. Here we report that GluRδ2 protein deficiency in the cerebellar Purkinje cells can recapitulate key features of ET. We identified a reduction of GluRδ2 expression in the postmortem cerebellum of ET patients. *Grid2*^{dupE3} mice, a mouse model with GluRδ2 insufficiency, developed ET-like tremor that is adult-onset, chronic and progressive kinetic (action-only) tremor and responsive to ET medications including primidone, propranolol and ethanol. GluRδ2 rescue via intra-cerebellar viral transfection confirmed the necessity and specificity of GluRδ2 in tremor generation of *Grid2*^{dupE3} mouse model, while shRNA knockdown of GluRδ2 in adult, wild type mouse cerebellum sufficiently recapitulates ET-like tremor. Our findings identified that GluRδ2 insufficiency can be a molecular mechanism of tremor pathophysiology. An animal model of ET-like tremor with matched human-to-animal molecular mechanism may open a window for translational research in ET and motor rhythm control.

Title: Maternal care impact spontaneous and dopaminergic-induced yawning and penile erection frequencies in Sprague-Dawley rats

Authors: *J. EGUIBAR[1], C. CORTES[2], A. TRUJILLO[3], A. UGASTE[2], M. DORANTES-NIETO[2];
[1]Res. Office, VIEP, [2]Inst. of Physiol., [3]Biol. Sci. faculty, Benemerita Univ. Autonoma De Puebla, Puebla, Pue., Mexico

Abstract: We select an inbred a high-yawning (HY) subline from Sprague-Dawley (SD) with 20 yawns/h that is one order of magnitude higher with respect to SD with just of 2 yawns/h. HY male rats are more active in the open-field arena indicating are less emotional reactive and also less anxious in elevated plus maze with respect to SD rats. Importantly, HY dams showed a disorganized maternal care. In base of that the aim of this study was to analyze the influence of maternal care on yawning and penile erections through in- and cross- fostering in both rats. All subjects (Ss) were maintained under standard conditions. Saline (NaCl 0.9%) and (-)-quinpirole

were administered by s.c. injection in the dorsal neck region. Yawning and penile erection recorded 1h in a Plexiglass cage and video recorded and measured using The Observer XT (Noldus) by two trained observers.Spontaneous yawning and penile erection frequency were significantly higher in HY with respect to SD rats independently of the maternal care received ($P < 0.05$); as well as after s.c. injection of (-)-quinpirole ($P < 0.05$). Importantly, in-fostered male rats had highest responses, with a peak response at 50 and 100 μg/Kg of (-)-quinpirole, with respect to saline-treated rats ($P < 0.05$). In conclusion, males that are in-fostered increase the spontaneous and dopaminergic-induced yawning and penile erections. These results showed that maternal care has a strong impact in the expression maternal care has a strong impact in the expression of yawning a well know behavior related to emotion and empathy.

Title: TMEM35/NACHO recognizes α7 nicotinic receptor transmembrane domains but cannot rescue mixed chimeras

Authors: *R. H. LORING, S. K. IYER, K. ADHIKARI, Z. WANG, S. ORUGANTI, L. HANSEN, V. RAMESH;
Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: Alpha7 nicotinic receptor (α7 nAChR) subunits have four transmembrane domains (TMDs) and assemble in cells as pentamers, but require chaperone proteins to properly fold and assemble. The two best characterized α7 chaperones are Resistance to Inhibitors of Cholinesterase 3 (RIC3) and TMEM35 (Transmembrane protein 35, also known as Nicotinic Acetylcholine Regulator, or NACHO). Others established that chimeric receptor subunits consisting of α7 extracellular and intracellular domains, but with serotonin 5HT3 receptor TMDs do not require chaperones for folding and expression. Gee et al. (Br. J. Pharm. (2007) 152: 501) showed that chimeras consisting of rat α7 non-TMDs and mouse 5HT3 TMDs express well without RIC3 but that RIC3 could not rescue expression when the chimera TMDS were mixed. We investigated whether TMEM35 could rescue expression of mixed chimeras by producing receptor subunits consisting of human α7 non-TMDs and mixed amounts of mouse 5HT3 and human α7 TMDs. TMEM35 is not required for cell surface expression of 5HT3 TMD1-4 chimeras when transfected into HEK cells and measured by α-bungarotoxin binding, but native α7 (α7 TMD1-4) requires RIC3 or TMEM35, with optimum expression at a chaperone ratio of

1:3 respectively. However, TMEM35 did not significantly rescue expression when TMDs were mixed (α7 TMD1-3+5HT3 TMD4, or 5HT3 TMD1-3+ α7 TMD4). These data suggest that like RIC3, the site of action of TMEM35 is most likely in the α7 TMD regions, and that mixing TMDs from α7 and 5HT3 receptors results in chimeric subunits that do not properly fold or assemble.

Title: Expressing extracellular domain α4β2 nicotinic acetylcholine receptors depends on proximal proline of first transmembrane domain

Authors: A. M. PERSON, ***G. B. WELLS**;
Mol. and Cell. Med., Texas A&M Univ. Col. of Med., College Station, TX

Abstract: Background: The smaller size and reduced transmembrane sequence of extracellular domain (ECD) receptors from α7, α4, α3, β2, and β3 nicotinic receptor (nAChR) subunits might allow higher resolution structural studies and lead to better understanding of functional roles of the ECD and transmembrane domains. A long-term goal is to insert a protease site at the interface between the ECD and first transmembrane domain (M1), leading to *in vitro* liberation of water soluble ECD nAChRs. Characteristics of the interface that control expression of ECD nAChRs, however, are not well understood. Proximity of the conserved Cys-loop with proximal residues of M1 in crystallographic structures leads to the hypothesis that this interaction controls expression of ECD α4β2 nAChRs. We previously found that 1) substituting valine for the proximal proline of M1 blocks expression of ECD α4β2 nAChRs and 2) duplicating proximal M1 residues at the interface functionally unlinks the ECD from M1. We combined these findings to study the role of the interfacial proline with the upstream ECD and with the downstream M1 for expressing ECD α4β2 nAChRs.
Objective: Determine whether the interfacial proline needs to be adjacent to the ECD, to M1, or to both domains for expressing ECD α4β2 nAChRs.
Methods: Human α4 and β2 cDNAs were truncated after M1 (α4M1 and β2M1). Five residues of proximal M1 were inserted at the interface, producing an extended ECD with duplicated interfacial prolines separated by nine residues (α4PP and β2PP). Duplicated prolines were

mutated to valine or serine, leading to α4PV, α4VP, α4PS, α4SP, β2PV, β2VP, β2PS, β2SP. Subunits were expressed in *Xenopus laevis* oocytes. Immunoblotting and immunoisolated [^{3}H]epibatidine binding sites assessed expression of subunits and ECD α4β2 nAChRs. **Results**: Expression of α4PP/β2PP and α4M1/β2M1 nAChRs were comparable. Mutating the second proline (α4PV/β2PV and α4PS/β2PS) did not adversely affect expression. In contrast, mutating the first proline to valine (α4VP/β2VP) severely reduced expression. Unexpectedly, mutating the first proline to serine (α4SP/β2SP) did not adversely affect expression. **Conclusions:** These results support the hypothesis that interaction between the Cys-loop and proximal M1 is important for expressing ECD α4β2 nAChRs. Valine appears to be acting as a negative effector of ECD α4β2 nAChR expression when substituted for the interfacial proline. Serine can substitute for the interfacial proline, suggesting that proline is not required at the interface for expressing ECD α4β2 nAChRs. Functionally unlinking the ECD from M1 facilitates studying how the interfacial region contributes to the structure of ECD nAChRs.

Title: Effects of nicotine + morphine on reward-related behavior and nicotinic acetylcholine receptor regulation in mouse midbrain

Authors: *A. J. AVELAR, A. T. AKERS, S. Y. COOPER, B. J. HENDERSON;
Biomed. Sci., Marshall Univ., Huntington, WV

Abstract: In the United States about 480,000 deaths/year are caused by cigarette smoking. Nicotine is the addictive component of cigarettes. Also, in the United States about 50,000 overdose deaths/year occur due to opioid abuse. Morphine is an opioid drug that is prescribed to treat pain, but is often abused. Co-use of more than one drug is very common, therefore, it is vital that we study the effects of drug combinations to understand how co-use alters the brain. Especially given the fact that in America, > 90% of heroin and opioid dependents are heavy smokers. The objective for this study is to determine how combined nicotine + morphine alters reward-related behavior and nicotinic acetylcholine receptor (nAChR) expression in the midbrain. Our hypothesis is that co-use of nicotine + morphine leads to enhanced GABA neuron disinhibition of VTA dopamine neurons. Female and male (adults, 3-5 months old) C57BL/6J

background strain animals with or without α4-mCherryα6-GFP nAChRs were used in conditioned place (CPP) preference assays to examine reward-related behavior with 0.5 mg/kg nicotine + 10 mg/kg morphine (intraperitoneal injections). To examine changes in nAChR number in midbrain neurons we used a previously characterized α4-mCherryα6-GFP (nAChR) mouse line (C57BL/6J background). We used confocal microscopy to analyze the density of α4-containing (α4*), α6*, and α4α6* nAChRs in ventral tegmental area (VTA), substantia nigra pars compacta (SNc), and substantia nigra pars reticulata (SNr). In our CPP assays, a Two-way ANOVA (factors: treatment and sex) showed a significant effect of sex ($F(1, 42) = 5.75$; $p = 0.02$) on reward-related behavior, suggesting a sex-dependent dose effect with morphine. In our microscopy assays, nicotine + morphine treatment downregulated α4* nAChRs on SNr GABA cells. We observed little or no effect of nicotine + morphine on nAChRs expressed on VTA and SNc dopamine neurons. Although the drug treatments tested using CPP did not affect reward behavior, we will next test additional doses of morphine. However, our CPP data does support that sex is an important variable in the effects of drugs on reward-related behavior. This study is ongoing and will contribute new knowledge of how co-use of nicotine + morphine affects reward-related behavior and receptor regulation in the midbrain. We have no conflicts of interest.

Title: Identification of multiple accessory proteins for nAChR alpha6 containing receptors

Authors: *S. GU, J. A. MATTA, W. B. DAVINI, G. B. DAWE, B. LORD, D. S. BREDT; Janssen Pharmaceuticals of Johnson & Johnson, San Diego, CA

Abstract: Nicotinic acetylcholine receptors (nAChRs) are well-recognized therapeutic targets and play crucial roles in many physiological processes. These receptors are also regulated by interactions with diverse accessory proteins and the full repertoire of these accessory proteins remains uncertain. In the case of α6-containing nAChR, functional reconstitution in transfected cells is especially challenging. Therefore, neuronal accessory proteins are likely necessary for functional expression in vivo. To search for these unknown accessory proteins, we developed a genome-wide cDNA screening assay that scores accessory proteins candidates through agonist evoked functional response. Using this assay, we identified the accessory proteins, NACHO, BARP, LAMP5 and SULT2B1 for α6-containing nicotinic acetylcholine receptors. Co-expressing these proteins with α6 nAChR enables its functional reconstitution in a heterologous

expression system. Knockout of NACHO or BARP markedly decreases α6 mediated function in the striatum. The discovery of these accessory proteins will facilitate drug-targeting of the mesolimbic dopaminergic system and enable physiological studies of α6 containing nAChRs.

Title: A stably transfected, doxycycline inducible, HEK-293 model for the characterization and screening of alpha3 beta2 neuronal nicotinic acetylcholine receptors

Authors: A. SEGO, R. RICHTER, M. WRIGHT, R. WAGNER, C. MERRILL, M. KROPELNICKI, R. JOHNSON, ***S. N. SUDWEEKS**;
Neurosci. Ctr., Brigham Young Univ., Provo, UT

Abstract: Nicotinic acetylcholine receptors (nAChR) of various forms are found widely throughout the body (i.e., in skeletal muscle, central nervous system, and the peripheral nervous system). Like other members of the cys-loop family of receptors, nAChRs are composed of five protein subunits, each with four transmembrane domains. Neuronal nicotinic acetylcholine receptors, created from combinations of the α2-10 and β2-4 subunits, can form in many arrangements and stoichiometries. Each arrangement can have varying binding affinities and channel kinetics, resulting in great modulatory capacity for these receptors. mRNA for the α3 and β2 subunits is found in surprisingly high abundance in CA1 interneurons in the *stratum radiatum* and *stratum oriens* of the rat hippocampus. α3 and β2 subunit mRNA injected into *Xenopus laevis* ooctes at different ratios (1:5 and 5:1) demonstrates at least two α3β2 subtypes. In order to further study the α3β2 nAChR in a more physiologically relevant mammalian environment, with consistent control over subunit expression ratios, we created a stably-transfected doxycycline-inducible HEK-293 cell line. This line has been stably transfected with the human α3 and β2 nAChR subunits and NACHO, a chaperone protein which has been shown to mediate the assembly of several nAChRs. This new model is able to induce expression of α3 and β2 subunits in various ratios, which should prove to be valuable tool in the characterization and screening of the α3β2 nAChR subtypes.

Abstract: The α4β2 and α7 receptors are the most abundant nicotinic acetylcholine receptors (nAChRs) in the brain. Here, they contribute to a wide variety of behaviours, including cognition, reward and mood. They have also been implicated in a number of brain dysfunctions such as cognitive deficit, addiction to tobacco smoking and depression. Activation of these receptors by agonists, particularly partial agonists is a valid strategy to intervene therapeutically in the aforementioned dysfunctions. The design of an α7- or α4β2-specific agonist is however problematic, mainly because of the highly conserved nature of the aromatic box that binds agonists in both subtypes of receptors. Using docking and molecular dynamics simulations combined with single point mutations, two-electrode voltage clamping and single channel recordings, we have interrogated the structural determinants that may contribute to the differences in the functional potency of cytisine at the α4β2 (logEC50 = -5.27 ± 0.09 at the $(\alpha4\beta2)_2\alpha4$ stoichiometry) and α7 (logEC50 = -4.61 ± 0.15) nAChRs. Comparison of the crystal structure of the α4β2 nAChR with a homology model of the α7 nAChR indicated that non-aromatic residues in loop B differ in the α4 and α7 subunits: α4-KFGSWTYDK *vs.* α7-KFGSWSYGG. Because these differences may affect how agonists interact with the conserved tryptophan (W) residue of loop B, we made α7 loop B α4-like and tested the functional consequences of this modification at the whole- and single-channel level. α7 receptors with an α4-like loop B have higher sensitivity to activation by cytisine (logEC50 = -5.07 ± 0.19, n = 11), compared to wild type (two-tailed Student's *t*-test). Single-channel analysis showed that in loop B mutant α7 receptors, cytisine induced longer activation episodes, named as bursts (τ_{burst} (ms) =

1.25 ± 0.30, n = 4), whereas those were brief and infrequent in α7 WT (τ_{burst} (ms) = 0.72 ± 0.12, n = 6, two-tailed Student's *t*-test). Together, our findings highlight the importance of the environment surrounding the tryptophan conserved aromatic residue of loop B impacts on the interaction of agonists with this residue.

Title: Effects of MMB4 and 2-PAM on alpha1-, alpha7-, and alpha3-type nicotinic acetylcholine receptors

Authors: *S. E. WOLFE, P. M. BODNER, M. G. KRICHTON, J. B. MACHAMER, P. M. MCNUTT;
USAMRICD, Gunpowder, MD

Abstract: Organophosphate (OP) nerve agents, such as soman and sarin, act by deactivating acetylcholinesterase (AChE) via phosphorylation, causing acetylcholine (ACh) to accumulate in the synaptic cleft and overstimulate cholinergic receptors. The resulting cholinergic toxidrome includes vomiting, confusion, seizures, neurotoxicity and respiratory failure. Current treatment for OP poisoning includes the use of oximes to reactivate AChE, such as pyridine-2-aldoximechloride (2-PAM). However, 2-PAM works against a comparatively narrow range of OP nerve agents and has dose-limiting toxicities. Oximes that antagonize a broader range of OP nerve agents, such as MMB4, HI-6 and HLo7, are currently under consideration as next-generation oxime replacements for 2-PAM. However, preclinical animal trials have found that each oxime exhibits toxicities that include respiratory depression. Hypothesizing that respiratory depression results from antagonism of nicotinic acetylcholine receptors (nAChRs), we used patch-clamp electrophysiology of dissociated mouse flexor digitorum brevis (FDB) muscle fibers to characterize agonist-induced α1 nAChR currents in the presence of oximes. To further evaluate whether each oxime antagonizes multiple peripheral nicotinic receptors, human embryotic kidney (HEK) cells were transfected with cDNA for human and mouse α1-, α7-, and α3-type nAChRs, and agonist-evoked currents were evaluated in the presence of increasing concentrations of each oxime. Preliminary data suggest that (1) nAChR antagonism is a class effect of quaternary ammonium oximes, (2) each oxime has differing potencies against various nAChRs, and (3) 2-PAM is the most toxic oxime among the oximes tested.

Title: An investigation into the effects of two epilepsy-implicated point mutations within human nicotinic acetylcholine receptors containing accessory subunits

Authors: *J. MCKAY, T. J. SMITH, M. M. WELTZIN;
Chem. and Biochem., Univ. of Alaska Fairbanks, Fairbanks, AK

Abstract: Nocturnal frontal lobe epilepsy (NFLE) is a group of familial and sporadic seizure disorders associated with mutations in nicotinic acetylcholine receptor (nAChR) subunits. NFLE is characterized by nighttime seizures that are frequently uncontrollable with available antiepileptic therapies. More effective therapies may be those that selectively target NFLE-associated nAChRs, such as the α3α4β2 and α4α5β2 subtypes, which are enriched in the epilepsy-implicated thalamocortical pathway compared to other brain regions. NFLE-associated intracellular cytoplasmic loop point mutations in the α4 or β2 subunits enhance the function of the pentameric α4β2 nAChRs. An accessory subunit can replace an α4 or β2 subunit, resulting in dramatic effects on receptor properties. We determined the outcomes of incorporating an accessory subunit in NFLE-containing nAChRs by substituting in an α3 or α5 accessory subunit in wildtype or NFLE-containing α4β2 nAChRs. To control receptor stoichiometry, we used wildtype or NFLE-containing concatenated β2 and α4 subunits that are linked with six alanine-glycine-serine repeats. Wildtype and NFLE-containing α4α5β2 and α3α4β2 nAChRs were expressed by co-injecting the concatenated β2-α4 dimer with the accessory subunit in 2:1, 1:5, and 1:50 ratios into *Xenopus laevis* oocytes. Agonist-induced currents were measured using nAChR-expressing oocytes and two-electrode voltage-clamp electrophysiology to determine differences in receptor peak function, efficacy, and potency for physiologically relevant ligands. Preliminary results show no variations in acetylcholine potency between wildtype and NFLE-containing receptors. Initial tests indicate that the α4α5β2 subtype has a decreased functional response to the partial agonist Sazetidine-A compared to the high agonist sensitivity α4β2

isoform. Notably, we observed a 2.4-fold increase in receptor function for the NFLE-mutated α4α5β2 nAChR versus wildtype receptors. This increase in function is similar for the low agonist sensitivity α4β2 isoform, identifying that the NFLE gain-of-function effect is still present despite containing fewer mutated α4 subunits. Characterizing receptors with restricted expression patterns may identify novel therapeutic targets.

Abstract: Pentameric ligand-gated ion channels (pLGICs) or Cys-loop receptors belong to a class of ion channels involved in fast synaptic signaling in the central and peripheral nervous systems. Molecules acting as allosteric modulators target binding sites which are remote from the neurotransmitter binding site, but functionally affect the coupling of ligand binding to channel opening. Allosteric modulators hold therapeutic potential as they finely tune channel function while preserving the normal fluctuations of neurotransmitter release at the synapse. In this study, we focus our attention to an allosteric binding site in the ion channel vestibule, which has converged from a series of studies on prokaryote and eukaryote channel homologs. We developed antibody fragments, called nanobodies, which are functionally active as allosteric modulators and solved co-crystal structures of the prokaryote channel ELIC bound either to a positive (PAM) or a negative (NAM) allosteric modulator. In combination with cysteine-scanning mutagenesis, we extrapolate the functional importance of the vestibule binding site to eukaryote ion channels, suggesting an evolutionarily conserved mechanism of allosteric modulation. Together, our work contributes to a better understanding of strategies to target new allosteric binding sites in pLGICs.

Title: Structural foundations for ionic current stability and gating efficiency in cys-loop receptors

Authors: *J. R. STRIKWERDA, S. M. SINE;
Mayo Clin., Rochester, MN

Abstract: Cys-loop receptors mediate rapid synaptic excitation and inhibition throughout the central and peripheral nervous systems. They are pentamers comprised of five homologous subunits that assemble in a ring to form a central ion pore. Their principal functions are to rapidly open in response to bound agonist, select either cations or anions, and promote their rapid flow across the cell membrane. Here, for the acetylcholine receptor (AChR) from the neuromuscular junction, we investigate the structural bases for its efficient gating and high and uniform ion throughput. In particular, the ion pore is formed by five alpha-helices, one from each subunit. Near its cytoplasmic end, the pore constricts to its narrowest point and subtype specific residues select the ions for translocation. In this region, there is a highly conserved and yet uninvestigated intra-subunit salt bridge between the pore-lining alpha-helix and the most peripheral alpha-helix, which may stabilize the pore architecture in this critical region. Using site-directed mutagenesis we neutralize the charge on one member of the salt bridge in the human muscle AChR, and study the mutant receptors heterologously expressed in human embryonic kidney cells. Receptors with disrupted salt bridges exhibit decreased channel open times and increased closed times compared to wild type receptors. Furthermore, open channel currents show a marked increase in fluctuations and a decrease in amplitude. These open channel current fluctuations increase as the number of mutant subunits is increased. These results suggest that the inter-domain salt bridge is a universal stabilizer of the ion pore, enabling rapid and uniform ion flow, and that it serves to enhance the gating efficiency of the receptor. Future work will develop a residue-level mechanism behind the inter-domain salt bridge’s contribution to gating efficiency and open channel current stabilization.

Title: A study of a dog-variant rabies virus glycoprotein derived peptide interactions with nicotinic receptors subtypes

Authors: *S. THAO, C. SPAIN, K. HUEFFER, M. WELTZIN;
UAF, Fairbanks, AK

Abstract: The zoonotic virus, rabies (genus *Lyssavirus*, family *Rhabdoviridae*), kills approximately 60,000 people each year. Animals infected with rabies show changes in locomotor, breathing, and aggression behaviors. These behaviors are controlled by brain regions that express unique nicotinic acetylcholine receptors (nAChRs) subtypes and isoforms. nAChRs are cholinergic receptors that bind to exogenous and endogenous proteins and ligands, including the neurotransmitter acetylcholine (ACh). The rabies virus glycoprotein (RVG) is predicted to bind to nAChRs in a similar manner to snake toxins, but detailed analysis has not been performed.
The purpose of this study is to determine the activity of RVG using a derived peptide on various nAChR subtypes and isoforms involved in the modified behavior of animals infected with rabies.

We used a RVG-derived peptide of the putative glycoprotein region that interacts with nAChRs. nAChR subtypes and isoforms were expressed using biased cRNA subunit injection ratios. The electrophysiology technique, two-electrode voltage clamp, was used to collect concentration-response data to measure the potency of RVG peptide inhibition on acetylcholine activated nAChRs. Results show that there are differences in RVG peptide inhibition potencies between each nAChR subtype tested. Interestingly, this study shows that the RVG peptide has higher inhibition potency for the α7 nAChR subtype. Results will likely identify new molecular targets (nAChR subtypes or isoforms) for the RVG, and will expand our understanding of basic mechanisms in host-pathogen interactions that result in neurological disorders. Identification of specific nAChR subtype interactions with the RVG peptide could lead to the development of new antiviral pharmacological approaches to improve survival of this severe infectious disease, which so far has evaded successful therapy once rabies infection symptoms occur.

Abstract: Homomeric α7 nicotinic acetylcholine receptors (nAChR) have an intrinsically low probability of opening that can be overcome by α7-selective positive allosteric modulators (PAMs), which bind at a site involving the second transmembrane domain. Mutation of a methionine that is unique to the sequence of α7 at the 15' position of this domain to leucine, the

residue in most other nAChR subunits, largely eliminates the activity of such PAMs. We tested the effect of the reverse mutation (L15'M) in heteromeric nAChR receptors containing α4 and β2, the nAChR subunits that are most abundant in brain. Receptors containing these mutations were found to be strongly potentiated by the α7 PAM TQS but insensitive to the alternative PAM PNU-120596. The presence of the mutation in the β2 subunit was necessary and sufficient for TQS sensitivity. The primary effect of the mutation in the α4 subunit was to reduce responses to ACh applied alone. Sensitivity to TQS required only a single mutant β subunit, regardless of the position of the mutant β subunit within the pentameric complex. Similar results were obtained when β2L15'M was co-expressed with the alternative α subunits α2 or α3 and when the L15'M mutation was placed in β4, co-expressed with α2, α3, or α4. Interestingly, the ACh responses of muscle-type receptors with the L15'M mutation in γ, ε, or δ subunits were decreased by co-application of TQS, and functional receptors were not observed when β1L15'M subunits were co-expressed with other muscle nAChR subunits. GAT107, the active isomer of the ago-PAM 4BP-TQS, did not produce allosteric activation of heteromeric β2L15'M containing receptors, and was less effective as a PAM than it is on α7 nAChR. An alternative PAM, GAT927, which like TQS has a bulky aromatic base group, was extremely efficacious on α4β2L15'M receptors and produced activation when applied without ACh. The unique structure-activity relationship of PAMs and the α4β2L15'M receptor compared to α7 and the availability of high resolution α4β2 structures may provide new insights into the fundamental mechanisms of nAChR allosteric potentiation.

Abstract: Positive allosteric modulators (PAMs) of α7 nicotinic acetylcholine receptors (nAChR) bind to a site in the transmembrane domains of α7 and diminish desensitizing effects of agonists to produce strong activation when co-applied. GAT107 ((+)-4BP-TQS) has been identified as an ago-PAM, that, unlike the PAMs PNU-120596 and TQS, produces strong activation without the co-application of an agonist. Data indicate that GAT107 produces direct allosteric activation by binding to both the transmembrane site shared by PNU-120596 and TQS and a unique extracellular allosteric activation site with unique activation profiles. GAT107 strongly activates mutant forms of the α7 receptor such as C190A that are incapable of orthosteric activation by ACh, even when ACh is co-applied with a PAM. TMP-TQS (*cis-trans*-4-(2,3,5,6-tetramethylphenyl)-3a,4,5,9b-tetrahydro-3H-cyclopenta[c]quinoline-8-sulfonamide) functions as an allosteric antagonist that blocks GAT107 allosteric activation of both wild-type α7 and α7C190A. In silico modeling predicted the binding of 2NDEP (1,1-diethyl-4(naphthalene-2-yl)piperazin-1-ium) to the putative allosteric activation site in the extracellular domain of the receptor, and we confirmed 2NDEP to be an allosteric agonist, able to activate both wild-type α7 and α7C190A in a TMP-TQS-sensitive manner (Gulsevin et al., 2019). A family of tri-substituted 2-aminopyrimidines, first identified as high affinity ligands of the AChBP, produce PNU-120596-dependent calcium signals in α7-transfected HEK cells (Kaczanowska et al., 2019). We evaluated the orthosteric and allosteric activities of these structurally complex heterocyclic compounds on both wild-type α7 and α7C190A. To varying degrees, theses agents activated currents when applied alone to *Xenopus* oocytes expressing α7 but not other nAChR subtypes. Following activation, we observed an associated persistent PAM-sensitive desensitization of α7 receptors. Compounds also effectively activated C190A mutants in a PNU-120596-dependent and TMP-TQS-sensitive manner. Taken together, these data indicate that these tri-substituted 2-aminopyrimidines function at both the orthosteric and allosteric activation sites of α7 nAChR.

Abstract: Postsynaptic nicotinic acetylcholine receptors (nAChRs) expressed by chromaffin cells of the adrenal medulla are directly involved in the stimulus-secretion coupling response and the release of catecholamines into the bloodstream. However, despite decades of use as a model for studying exocytosis, few studies have been conducted using subtype-selective ligands to pharmacologically identify the nAChRs expressed by these cells. Quantitative polymerase chain-reaction analysis of rat adrenal medulla revealed a relative abundance of mRNAs for α3, α7, β2 and β4 subunits and a lower abundance of mRNAs for α4 and α5 subunits. A novel conopeptide antagonist, PeIA-5469, that targets α3β2, and the α3β4-selective α-conotoxin TxID were used in combination with whole-cell patch-clamp electrophysiology to probe for the presence of receptors formed from the identified subunit mRNAs. Our results demonstrate that rat adrenal medulla contain two populations of chromaffin cells that express either α3β4* alone (~60%), or α3β4* together with the α3β2β4* subtype (~40%) (asterisk denotes the potential presence of other subunits). Conclusions were derived from results demonstrating that acetylcholine-gated currents could be inhibited by 97 ± 1 % (n=18) using TxID. In a subset of these cell, PeIA-5469 inhibited the acetylcholine-gated currents by 28 ± 8 % (n=7). In the remaining 11 cells, the acetylcholine-gated currents in the presence of PeIA-5469 were 102 ± 4 % of control amplitudes. Additional experiments using the α4β2 positive allosteric modulator NS206 were conducted to probe for the presence of receptors formed from α4 and β2 subunits. In the presence of TxID, there was no increase in acetylcholine-gated current amplitudes when the cells were exposed to NS206 (-48 ± -25 pA vs -18 ± -8 pA, respectively, n=17). The results of these studies demonstrate that rat adrenal chromaffin cells express two main populations of nAChRs, namely α3β4* and α3β2β4*.

Title: Lead α-conotoxins for development of novel, highly selective, α3β2*-nicotinic acetylcholine receptor antagonists

Authors: *B. EATON[1], E. JAISWAL[1], R. J. LUKAS[1], T. GORDON[2], A. J. HONE[3], J. MCINTOSH[3,5,4], P. WHITEAKER[1];

Abstract: The medial habenula-interpeduncular (MH-IPN) tract nuclei play an important role in nicotine reward, withdrawal, and satiety. The MH and IPN express significant levels of α3β4*-, α3β2*-, and α6β2*-nAChR. Investigations of nicotine's effects within the MH and IPN have predominantly focused on α3β4*-nAChR. However, the highest densities of α3β2*-nAChR within the CNS are found in the MH-IPN tract. Therefore, it seems likely that α3β2*-nAChR play an important role in nicotine addiction phenotypes and may be effective targets for novel smoking cessation aides. Preliminary experiments have shown that infusion of the IPN with the α-conotoxin, α-CtxMII, disrupts aspects of nicotine withdrawal. Unfortunately, α-CtxMII inhibits both α3β2*- and α6β2*-nAChR, and there is currently no ligand that can be used to selectively target α3β2*-nAChR. Using directed mutagenesis of α-Ctxs MII and PeIA, we have previously demonstrated that affinity for α3β2*-nAChR can be reduced without significantly decreasing affinity for α6β2*-nAChR. Here we report our results after screening a library of >400 α-conotoxins and analogs to identify leads with selectivity for human α3β2*- over α6β2*-nAChR. Functional antagonism by each candidate was assessed in turn with $^{86}Rb^{+}$ efflux in SH-EP1 cells engineered to express α6/3β2β3-nAChR and then TEVC electrophysiology in *Xenopus laevis* oocytes made to express α3β2-nAChR. We have identified seven leads that have EC_{50} values in the low to mid nM range at α3β2*-nAChR, while exhibiting little or no activity at α6/3β2β3-nAChR at a concentration of 100 nM. These peptides also show little activity at the common α3β4- and α4β2-nAChR subtypes. No discrimination was seen between $(\alpha3\beta2)_2\beta2$- and $(\alpha3\beta2)_2\alpha3$-nAChR isoforms for any of the seven α3β2*-nAChR selective leads. We are now applying a positional scanning mutagenesis approach to these lead peptides with the aim of developing a panel of highly α3β2-nAChR selective derivatives, including ones bearing fluorescent or radioactive labels. These will be used to characterize the distinct contributions of α3β2*-nAChR function, with particular focus on the MH-IPN tract in which prominent α3β2*-nAChR expression overlaps with that of multiple other nAChR subtypes, including closely-related α3β4*- and α6β2*-nAChR.

Abstract: Smoking is the leading and preventable cause of death in the United States, driven by dependence on nicotine, the major addictive compound found in all tobacco products. The medial habenula (MH)-interpeduncular nucleus (IPN) tract is an important contributor to nicotine addiction phenotypes, and expresses the highest density of nicotinic acetylcholine receptors (nAChR) containing α3 and β2 subunits (α3β2*-nAChR; *denotes the possible presence of further subunits) in the central nervous system. However, the closely-related α3β4*- and α6β2*-nAChR subtypes are also prominently expressed in the same pathway. In order to determine the particular roles of α3β2*-nAChR in nicotine addiction phenotypes, highly selective compounds are required. We have developed a panel of 14 lead derivatives of α-Ctx PeIA that are potent (high-pM to low-nM) and selective (up to ≈1000x) for α3β2*-nAChR over other subtypes (including α6β2*-nAChR) heterologously expressed using rat subunits. However it has been observed that, at least in some cases, the exceptional selectivity of refined α-Ctx derivatives can be lost when they are applied to nAChR assembled from subunits of a different vertebrate species. Using two-electrode voltage-clamp recordings of nAChR expressed in *X. laevis* oocytes, we determined that absolute potencies at human α3β2*- and α6/α3β2β3*- nAChR were similar to those in rat and human. However, a modest trend towards reduced potency for human nAChR relative to rat α3β2*-nAChR was seen, especially in the cases of PeIA-5469 and PeIA -5460 (for which human α3β2*- over α6/3β2β3*- selectivity was reduced by 16- and 17-fold, respectively). However, the most-selective derivatives still retain ≈100-fold selectivity and low-nM affinity for human α3β2-nAChR. This will be sufficient to probe the properties and roles of α3β2*-nAChR in both human and rodent models.

Title: Importance of fluidic control in high-throughput studies of acetylcholine and GABA receptors

Authors: *A. YEHIA, C. IONESCU-ZANETTI;
Fluxion Biosci., Alameda, CA

Abstract: Extensive understanding of agonist/modulator/receptor interactions in ligand-gated ion channel assays is dependent upon advanced abilities in solution control and precise fluidic manipulation. These capabilities have traditionally resided in the domain of slow but reliable single cell patch clamp techniques due to technologically limiting factors plaguing most automated patch clamp (APC) systems. Even with the implementation of microfluidics, precise timing in fluidic exchange while consistently applying continuous solution flow has been elusive to most high throughput APC systems, limiting the scope of most drug research in that domain. By eliminating the need for external liquid handlers for in-assay solution exchange, we utilize a unique APC capable of in-plate continuous perfusion and precise parallel application of compounds while clamping and recording from ensembles of cells in whole-cell patch clamp formation. Here we demonstrate the effects of precise fluidics on high throughput research in nACh receptor agonist response and desensitization. We also show the effects on consistency of GABA receptor current responses. While imperfect agonist washout presents a challenge for traditional APC systems, this data set shows the superior performance of this microfluidic approach, forming a great foundation for serial application of modulators in high throughput APC environments.

Title: The underlying mechanism of propofol-induced intracellular calcium elevation

Authors: *N. SAKAI[1], **T. URABE**[2], S. MOTOIKE[3], K. HARADA[1], I. HIDE[1], S. TANAKA[1]; [1]Grad Sch. of Biomed & Hlth. Sci, Hiroshima Univ., HIroshima-shi, Japan; [2]Dept. of Anesthesiol. and Critical Care, Grad. Sch. of Biomed. and Hlth. Sciences, Hiroshima Univ., Hiroshima-shi, Japan; [3]Dept. of Dent. Anesthesiology, Grad. Sch. of Biomed. & Hlth. Sciences, Hiroshima Univ., Hiroshima-shi, Japan

Abstract: Propofol, most frequently used as general anesthetic, is thought to exert its anesthetic actions via $GABA_A$ receptors. Propofol also has additional beneficial actions such as myocardial and neuronal protection, whereas adverse actions such as angialgia and propofol infusion syndrome (PRIS). However, the precise mechanisms of these propofol actions remain unclear.In this study, we examined the propofol-induced elevation of intracellular calcium using SHSY-5Y neuroblastoma cells, COS-7 cells, HEK293 cells, and HUVEC loaded by calcium indicator Fluo-4 in order to identify the underlying mechanism. Propofol (higher than 50μM) induced intracellular calcium elevation in a dose-dependent manner in SHSY-5Y cells as well as COS-7 cells, HEK293 cells, and HUVEC. These phenomena were not influenced by the elimination of extracellular calcium. And, the calcium elevation was abolished when intracellular or intra-endoplasmic reticulum (ER) calcium was depleted by BAPTA-AM or thapsigargin, respectively, suggesting that the calcium was mobilized from ER. Studies using various inhibitors including U-73122, Xestospongin C, and dantrolene revealed that the propofol-induced calcium elevation was not mediated through G-protein coupled receptors, IP3 receptors, or ryanodine receptors.We captured the live imaging of ER, Mitochondria, and Golgi apparatus after the propofol application using ER-tracker, Mito Tracker™ResCMXRos, and CellLight™Golgi-GFP BacMam2.0, respectively. Accompanying the calcium elevation, the structures of these intracellular organelles were altered. Especially, ER and Mitochondria was fragmented and aggregated, which might not be restored as long as we observed. This morphological change of ER structure could be observed even after intracellular calcium was depleted by BAPTA-AM. These results suggest that propofol directly act on these organelles, thereby mobilizing calcium.In case of clinical usage, the maximum plasma concentration of propofol is approximately 30-40μM. Although the concentration of propofol used in this experiment was larger than that of clinical use, it is possible that the concentration could reach more than 40μM at the site where propofol was injected into the blood vessel or in case of high-dosed and prolonged usage of propofol. Therefore, these propofol-induced phenomena might be involved in its various adverse effects including angialgia and PRIS.

Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD; [6]Neurosci., USAMRICD, Aberdeen Proving Ground, MD

Abstract: All currently used intravenous anesthetic agents are associated with an entire spectrum of undesirable side effects, most notably cardiovascular instabilities. These side effects are poorly tolerated in many patients without our intervention, but especially in very young children who possess immature physiologic compensatory mechanisms, as well as in the elderly with confounding comorbidities and otherwise exhausted compensatory mechanisms. In light of this, we have pursued the development of new lead compounds to produce the next generation of safer anesthetic agents. Our methodologies of *in silico* screening and prediction of compounds which bind to our validated model of the gamma amino butyric acid receptor ($GABA_AR$) have now identified a novel class of lead compounds which demonstrate overt anesthetic activity. The most potent of the series is KSEB 14-01 which anesthetizes both tadpoles (EC_{50}= 0.28 μM; n=5) and male Sprague Dawley rats (ED_{50} = 0.78 μM, n=5) with a potency greater than that of propofol, the current intravenous anesthetic standard. KSEB 14-01 increases Cl ion flux in CHO cells transfected with α1β2γ2 receptor subunits (EC_{50} = 1.7 μM) (FLIPR Tetrus, Eurofins San Diego CA). These structures are devoid of the chemical moieties known to produce adrenal suppression, the dreaded side of effect of the other commonly used anesthetic, etomidate. *Of even greater importance is the fact that our new class of compounds shows minimal to no suppression of blood pressure and respiration or changes in blood gas concentration of CO_2, O_2, and O_2 saturation or in blood pH at anesthetic concentrations, in stark contrast to the deleterious effects of propofol on these parameters.* These compounds are derived from novel chemical structures not previously associated with or known to produce significant anesthetic effect. We have now refined our lead to enhance its solubility while maintaining the desirable characteristics of anesthesia without significant hemodynamic or respiratory suppression. This

class of compound will have ready application as an anesthetic in any patient with the potential for such physiologic instabilities and, through its $GABA_AR$ mechanism, provide a stable means of acute and possibly chronic seizure suppression.

Title: Alcohol enhances hops modulation of $GABA_A$ receptors

Authors: *A. Y. BENKHEROUF, S. L. SOINI, M. UUSI-OUKARI;
Integrative Physiol. and Pharmacol., Univ. of Turku - Inst. of Biomedicine, Turku, Finland

Abstract: Hops are major component of beer that is added during brewing. In addition to its wide range of bioactivity, it exhibits neuroactive properties as a sedative and sleeping aid. These effects are mediated by an increase in the function of γ-aminobutyric acid type A ($GABA_A$) receptors, the major sites of fast synaptic inhibition in the central nervous system (CNS). Recent evidence revealed prenylflavonoids in hops acting as potent positive modulators on native and recombinant $GABA_A$ receptors. These findings raised the question whether ethanol brings further potentiation in the GABAergic modulation of hops compounds in beer.
In radioligand binding assays, we assessed the synergy of selected hops compounds with respect to their pharmacological activity in the absence and presence of ethanol. [^{3}H]ethynylbicycloorthobenzoate (EBOB), a potent radiolabelled noncompetitive blocker, was used on native $GABA_A$ receptors expressed in male Sprague-Dawley rat brain membranes. Combinations of 6-prenylnaringenin (6PN) and/or humulone with isoxanthohumol (IXN) or 8-prenylnaringenin (8PN) led to an additive potentiation in GABA-induced [^{3}H]EBOB

displacement that was equal to the sum of the displacement by individual compounds. Despite the fact that ethanol alone showed no effect on GABA-induced [^{3}H]EBOB displacement, it induced a significant reduction in the residual radioligand binding in the presence of 1 µM hops prenylflavonoid or humulone. Furthermore, the inclusion of ethanol produced a leftward shift in the IXN-induced [^{3}H]EBOB displacement curve. Ethanol reduced the IC_{50} of IXN modulation from 16.7 µM to 13.2 µM in forebrain and from 18.0 µM to 15.9 µM in cerebellum. Similarly, in the presence of low IXN (1 µM), ethanol decreased the IC_{50} of GABA-induced displacement of [^{3}H]EBOB binding from 3.2 µM to 2.9 µM in forebrain and from 2.3 µM to 1.8 µM in cerebellum.
Our results displayed an evident additive effect in the allosteric modulation of $GABA_A$ receptors by hops compounds and demonstrated ethanol synergy as a second-order modulator in [^{3}H]EBOB assay suggesting a probable enhancement in the intoxicating effects of ethanol in hops enriched beer.

Abstract: GABA-A receptors (GABAR) are the major mediators of inhibitory neurotransmission and targets for many therapeutic agents for seizures, anxiety, sleep, learning, cognition, and drug use disorders. Recent technological advances in single-particle electron cryomicroscopy (cryoEM) data collection and processing have produced high resolution protein structures including recombinant GABAR. This powerful technique can test hypotheses about direct ethanol (EtOH) enhancement of extrasynaptic δ subunit-containing GABAR. We purified δ-GABAR from pig cerebellum using an antibody to δ subunit (gift of W Sieghart and P Scholze, Vienna), and synaptic γ2-GABAR from cortex using a benzodiazepine Ro7-1986 (Roche, Basel) affinity column (Stauber et al.,1987), obtaining sufficient purity for cryoEM. We described binding sites for EtOH antagonist Ro15-4513 (~10 nM) on δ-GABAR, likely at the

extracellular domain α+/β- interface, competitively inhibited by EtOH (IC_{50}~20 mM) and defined by the α6(R100Q) polymorphism found in EtOH-hypersensitive rats (Wallner et al.,2014). These EtOH sites differ from GABAR anesthetic sites in the transmembrane domain (Mihic et al.,1997, EtOH IC_{50}~100 mM). Using pig cerebellum membranes (2.5 pmol/mg protein of α1-GABAR, 1.0 pmol/mg of α6-GABAR, including 50%=0.5 pmol/mg of δ-GABAR), 50% of the detergent-solubilized [^{3}H]Ro15-4513 binding was bound to anti-δ immunobeads, eluted by pH 3.6, followed (as in Liu et al.,2018) by size-exclusion chromatography and electron microscopy (2D for negative staining to identify single particles with receptor size and shape, 3D reconstruction and refinement for cryoEM images, and modeling. Analyzing *native brain* GABAR proteins minimizes problems associated with recombinantly expressed GABAR, which may lack endogenous assembly, trafficking, and clustering proteins, auxiliary subunits, lipids, and post-translational modifications, and may assemble into non-native architecture and subunit arrangements. CryoEM structures have confirmed ligand binding sites, agonist gating of ion channel, modulation by PAMs, and the Monod-Wyman-Changeux allosteric model. The importance of cryoEM to explain complex cellular and brain functions, diseases, and structure-based drug design cannot be overstated.

Title: Modulation of recombinant and cortical $GABA_A$ receptors by the alkaloid gelsemine

Authors: *A. M. MARILEO, J. A. GAVILAN, C. O. LARA, C. F. BURGOS, V. P. SAN MARTIN, A. SAZO, J. FUENTEALBA, L. GUZMÁN, P. A. CASTRO, L. G. AGUAYO, G. MORAGA-CID, G. E. YÉVENES.;
Physiol., Univ. De Concepción, Concepcion, Chile

Abstract: Gelsemine is one of the main alkaloids produced by the *Gelsemium genus* of plants. Behavioral studies have shown that gelsemine exerts analgesic and anxiolytic effects in rodents. Despite these evidences, the pharmacological targets underlying the behavioral effects of gelsemine are still unclear. Several evidences have suggested that the analgesic and anxiolytic actions of gelsemine are related with the functional modulation of inhibitory glycine receptors.

However, it is currently unknown whether gelsemine is able to modulate the activity of inhibitory $GABA_A$ receptors. The present work aims to characterize the functional modulation of $GABA_A$ receptors by gelsemine using electrophysiology, calcium imaging and bioinformatics. Using whole-cell recordings of $GABA_A$ receptors expressed in HEK293 cells, we determined that benzodiazepine-sensitive $GABA_A$ receptors (i.e. $\alpha1\beta2\gamma2$, $\alpha2\beta3\gamma2$, $\alpha3\beta3\gamma2$ and $\alpha5\beta2\gamma2$) were inhibited by gelsemine. On the other hand, benzodiazepine-resistant $GABA_A$ receptors (i.e. $\alpha1\beta2\gamma2$ H101R mutant and $\alpha1\beta2$ receptors) were also inhibited by gelsemine. Further electrophysiological studies performed on cultured mouse cortical neurons showed that whole-cell current through native $GABA_A$ receptors were inhibited by the alkaloid. The acute application of gelsemine to these neurons produced a significant reduction of the frequency, but not of the amplitude, of the GABAergic mIPSCs. Similar experiments showed that the frequency of glutamatergic mEPSCs was also decreased by the alkaloid. Coincidentally, calcium imaging studies indicated that gelsemine decreased the frequency of spontaneous cytosolic calcium transients. Our results show that gelsemine modulate the activity of recombinant and native $GABA_A$ receptors, possibly through a direct interaction of the alkaloid with the ion channel. In addition, our results showed that gelsemine negatively modulates excitatory and inhibitory synaptic activity of cultured cortical neurons. Altogether, these results suggest that the analgesic and anxiolytic actions of gelsemine, at least in part, appears to be not related with the potentiation of benzodiazepine-sensitive $GABA_A$ receptors.

Title: Functional modulation of the glycine receptor alpha3 subunit by tropeines

Authors: *V. P. SAN MARTÍN, C. F. BURGOS, A. M. MARILEO, C. O. LARA, A. E. SAZO, J. FUENTEALBA, L. GUZMÁN, P. A. CASTRO, L. AGUAYO, G. MORAGA-CID, G. YÉVENES;

Abstract: Glycine receptors (GlyRs) are chloride-permeable pentameric ligand-gated ion channels. The inhibitory activity of GlyRs is fundamental for physiological processes, such as motor control and respiration. In addition, several pathological states, such as hyperekplexia, epilepsy, and chronic pain, are associated with abnormal glycinergic inhibition. Several studies have shown than positive allosteric modulators targeting the GlyR α3 subunit (α3GlyR) displayed beneficial effects in chronic pain models. Interestingly, previous electrophysiological studies have shown that tropeines, a family of synthetic antagonists of 5-HT3Rs, potentiate the activity of other GlyR isoforms in the nanomolar range. However, despite its importance as a pharmacological target in chronic pain, it is currently unknown whether the α3GlyR function is modulated by tropeines. The present work intends to initiate the characterization of the potential modulation of α3GlyR by tropeines using electrophysiological techniques and molecular docking simulations. Our electrophysiological experiments show that tropisetron, a prototypical tropeine, exerted concentration-dependent inhibitory effects on α3GlyRs at the low micromolar range. In addition, three other tropeines (granisetron, ondansetron, and dolasetron) showed similar effects. Single-channel recordings show that tropisetron inhibition is associated with a decrease in the open probability of the ion channel. Using the α3GlyR crystal structure as template, molecular docking assays suggest that tropeines preferentially bind to an agonist-free, closed state of the ion channel. The tropeine binding occurs in a discrete pocket around the vicinity of the orthosteric site within the extracellular domain of α3GlyR. Our results describe the pharmacological modulation of tropeines on α3GlyRs. These findings may contribute to the development of GlyR-selective tropeine derivatives for basic and/or clinical applications.

Title: A novel highly alpha5-subunit selective benzodiazepine

Authors: *P. SCHOLZE, X. SIMEONE, F. KONIUSZEWSKI, M. MÜLLEGGER, A. SMETKA, F. STEUDLE, R. PUTHENKALAM, M. ERNST;
Ctr. for Brain Res., Med. Univ. of Vienna, Vienna, Austria

Abstract: The most frequent $GABA_A$-receptor subtype is composed of two alpha two beta and one gamma2-subunit. Benzodiazepine, which are commonly used in the treatment of sleep disorders, anxiety, epileptic seizures and many other conditions, bind selectively at the alpha-

gamma-interface of those receptors. Nearly all of the clinically relevant drugs target all $GABA_A$receptor subtypes with equal affinity. The nature of the alpha subunit seems to be critical for the clinical effect elicited by the compound. Therefore drug development research is focusing on identifying subtype selective drugs such as, among others, drugs selective for alpha5-containing $GABA_A$receptors. Although those receptors are rare (<5% of total) and their distribution is limited to few brain areas like hippocampus, they are believed to be promising future drug targets to potentially treat cognitive and/or mood disorders. One of the compounds already identified is SH-053-2′F-R-CH3, which is moderately selective for alpha5-subunit containing $GABA_A$ receptors. Here we present data on a novel imidazobenzodiazepine-compound. Using radioligand displacement assays on transfected HEK 293 cells and two-electrode voltage clamp electrophysiology in *Xenopus laevis* oocytes, we demonstrated that an acid group as substituent leads to large improvements of functional and binding selectivity for alpha5beta3gamma2 over other $GABA_A$receptors (e.g. >60fold compared to alpha1beta3gamma2). In order to provide a structural hypothesis for the extraordinary potency preference of the novel ligand we performed a computational study utilizing homology models and computational docking. Based on these results, point mutated subunits were generated and analyzed. Both atom level structural studies and mutational analysis confirm that loop C of the GABAA-receptor alpha-subunit is the dominant molecular determinant of drug selectivity. With this novel alpha5-subunit-selective drug we propose to have discovered a future promising drug candidate.

Title: Human and dog $\alpha_4\beta_3\delta$ $GABA_A$ receptors display differential sensitivity to GABA and positive allosteric modulators

Authors: *A. L. ALTHAUS[1], K. KAMBARA[2], S. BERTRAND[2], D. C. BERTRAND[2], M. A. ACKLEY[1];
[1]SAGE Therapeut., Cambridge, MA; [2]Hiqscreen, Vesenaz - GE, Switzerland

Abstract: The type A γ-aminobutyric acid ($GABA_A$) receptors are a large heterogeneous class of pentameric chloride channels comprised of two α, two β, and one γ, δ, ρ, θ, or ε subunits (Sigel E and Steinmann ME 2012). Thought to be the most important inhibitory receptors in the brain, $GABA_A$ receptors are targets for clinically active drugs used to treat a variety of psychiatric and

neurological disorders. To date, 19 genes encoding for $GABA_A$ receptors have been identified in vertebrates and these receptors are very well conserved throughout the animal kingdom, with some precursors already present in bacteria (Thompson 2012).
Xenopus oocytes are a powerful in vitro system in which to study specific $GABA_A$ receptor configurations. To examine potential species differences between human and dog $GABA_A$ receptors, we utilized *Xenopus* oocytes recombinantly expressing species-specific $GABA_A$ receptors representative of either the synaptic ($\alpha1\beta2\gamma2$) or exytrasynaptic ($\alpha4\beta3\delta$) type. Both dog and human $\alpha1\beta2\gamma2$ receptors exhibited similar sensitivity to GABA, while dog $\alpha4\beta3\delta$ receptors exhibited a 10-fold reduction in GABA sensitivity relative to human. In addition, dog $\alpha4\beta3\delta$ receptors were less sensitive to the δ specific allosteric modulator DS2 compared to human $\alpha4\beta3\delta$ receptors.
Sequence alignment between the human and dog subunits reveal a high degree of conservation for the $\beta3$ subunit, small but interesting differences in the $\alpha4$ subunit, and relatively more variation in the δ subunit. Ongoing work is aimed at identifying which parts of the receptor underlie the observed species differences in pharmacological sensitivity. Understanding species differences in $GABA_A$ receptor activity, particularly with respect to pharmacological sensitivity of novel therapeutics, is critical for interpreting the translational validity of preclinical data.

Title: Characterizing negative allosteric modulators of α5GABA$_A$ receptors in primary hippocampal neurons

Authors: *M. A. MANZO[1], W. W. LI[1], D.-S. WANG[1], B. A. ORSER[1,2,3];
[2]Anesthesia, [1]Univ. of Toronto, Toronto, ON, Canada; [3]Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada

Abstract: Excess function of α5 subunit-containing GABA$_A$ receptors (α5GABA$_A$Rs) has been implicated in several neurological disorders including Alzheimer's Disease, perioperative neurocognitive disorder, depression and motor deficits after stroke. Negative allosteric modulators that preferentially inhibit α5GABA$_A$Rs (α5-NAMs) have been developed to treat these disorders. α5-NAMs lack many of the adverse neurological effects associated with non-selective GABA$_A$R antagonists; indeed, several α5-NAMs have already been investigated in clinical trials. To date, α5-NAMs have primarily been studied in GABA$_A$Rs recombinantly expressed in non-neuronal cells. The data show that α5-NAMs also act on other GABA$_A$R subtypes with lower efficacy and selectivity. Surprisingly, no studies have directly compared the effects of α5-NAMs on native GABA$_A$Rs. This information would assist in the development and selection of more effective compounds for clinical trials. Thus, the goal of the current study is to characterize and compare the effects of α5-NAMs on the amplitude of a tonic current primarily generated by α5GABA$_A$Rs in primary neurons. Five α5-NAMs including α5IA, MRK-016, L-655,708, Ono and basmisanil, were each studied at 3 concentrations. Tonic current was recorded using whole-cell voltage clamp technique in cultured hippocampal neurons isolated from fetal mice. Results showed that α5IA inhibited the tonic current by 30 ± 7% at 1 nM, 47 ± 5% at 10 nM, and 56 ± 8% at 100 nM (mean ± SEM, $n = 9$, $p < 0.05$ compared with 1 nM). MRK-016 (1, 10, 100 nM), L-655,708 (2, 20, 200 nM) and Ono (1, 10, 100 nM) showed similar levels of inhibition at all concentrations ($n = 8$-10, $p > 0.05$ for each drug). In contrast, basmisanil enhanced the tonic current by 9 ± 11% (10 nM) and 6 ± 22% (100 nM); and inhibited the current at 1 μM (56 ± 9%, $n = 8$, $p < 0.01$ compared with lower concentrations). Next, a comparison of all α5-NAMs at concentrations with the highest efficacy demonstrated that they all similarly inhibited tonic current (40 ± 6% to 56 ± 9%, $p = 0.3$). In conclusion, all α5-NAMs at the most efficacious concentrations are equally effective. Only α5IA inhibits the tonic current in a concentration-dependent manner. Uniquely, basmisanil enhances the tonic current at low concentrations, and inhibits it at the highest concentration. These results suggest that factors other than efficacy, such as toxicity, should be considered when selecting an α5-NAM for clinical trials.

Title: Comparison of Z-drugs on the three gamma subunits of $GABA_A$ receptors

Authors: *G. A. RICHTER, P. K. AHRING, V. W. Y. LIAO, N. ABSALOM, P. VAN NIEUWENHUIJZEN, M. CHEBIB;
The Univ. of Sydney, Camperdown, Australia

Abstract: Background and Aim: It is well established that benzodiazepines bind to $GABA_A$ receptors at the interface between α_x-γ_2 subunits. While the majority of $GABA_A$ receptors contain γ_2 subunits, a small portion in distinct brain regions contain a γ_1 or γ_3. Little is known about the physiological importance of these subunits, and no drug has been found which selectively modulates them over γ_2. To investigate this, we are using a mutant mouse knock-in γ_2F77I model which has drastically attenuated zolpidem, but not diazepam binding in the α_x-γ_2 pocket. We are testing the nonbenzodiazepine 'z-drugs' zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata). In this model, 'classic benzodiazepine' binding is largely unaffected, so we use diazepam as a control. Methods: 1. Using c-Fos immunohistochemistry we investigated the response to zolpidem (10 mg/kg), diazepam (5 mg/kg), zaleplon (3 mg/kg), and vehicle in male γ_2F77I mice and wildtype littermate controls (n=8). Locomotor activity over 90 minutes was tracked in an open field test. 2. To determine if benzodiazepine binding-site affinity changes after damage to the brain, 12-13-week-old male mice were given a photothrombotic lesion targeting the M1 motor cortex. Three weeks later, an *in-vitro* autoradiography competition experiment against [^{3}H]-flumazenil was run in mutant and wildtype mice three weeks post-stroke with (n=5). 3. To determine receptor response to these drugs, $GABA_A$ receptors containing one of the three types of γ subunits, or the γ_2F77I mutant, were expressed in *Xenopus laevis* oocytes and two electrode voltage clamp recordings were taken. Results: We found that in γ_2F77I mice zolpidem did not significantly reduce locomotor activity and overall c-Fos expression was lower in these mice compared to wildtype. No differences were found with diazepam. Autoradiography revealed that in mutant mice, zaleplon was more effective than zolpidem at competing off [^{3}H]-flumazenil suggesting that zaleplon could be binding to non γ_2 $GABA_A$ receptors. Electrophysiology data demonstrates that zaleplon also has modulatory effects on γ_3 vs. γ_2F77I or γ_1. Conclusions: These results suggest that zaleplon may be exhibiting some of its effects via γ_3 $GABA_A$ receptors.

Title: A role for entropic forces in tuning a ligand gated ion receptor function

Authors: *K. KAMBARA[1], P. M. SELZER[2], S. NOACK[2], Y. MORENO[3], J. HARRINGTON[3], D. BERTRAND[1];
[1]Hiqscreen Sarl, Geneva, Switzerland; [2]Boehringer Ingelheim Vetmedica GmbH, Ingelheim am Rhein, Germany; [3]Boehringer Ingelheim Animal Hlth. USA Inc, Duluth, GA

Abstract: Entropic forces play an important role in the conformational changes occurring in proteins and can modulate the allosteric transitions. A good example was recently provided by the role of the carboxy terminus at the human UDP-α-d-glucose-6-dehydrogenase (UGDH) in which the entropic force produced by an intrinsically disordered sequence causes a shift towards high affinity for an allosteric inhibitor (1). These observations raised an important question that may be broadly applicable to even more complex proteins such as ligand gated ion channels (LGIC).
To examine the putative role of entropic forces on the function of LGIC's the use of homomeric receptors, such as that formed by the γ-aminobutyric acid (GABA) chloride permeable channel, represents an ideal model. Recombinant receptors from the tick *Ixodes scapularis* were expressed in *Xenopus* oocytes and recordings were performed using two electrode voltage clamp. Extension of the carboxy terminus by adding fourteen amino acids that are predicted to adopt an intrinsically disordered state caused no detectable alteration of the receptor expression. However, a hundred-fold decrease in the effective concentration of GABA was observed. This suggests that increasing the length of the carboxy terminus reduced the energy barrier for receptor activation. In agreement with the hypothesis of the role of the entropic forces on allosteric transitions, reversing the sequence of the carboxy terminal end also caused an increase in the apparent affinity of the receptors for GABA. Further increase of the length of the carboxy terminal by duplication of the initial fourteen amino acid caused the same increase in apparent affinity for GABA without altering the response time course.
These observations confirm the relevance of the entropic forces and suggest that binding of a peptide or a molecule on a receptor can alter the energy landscape of receptors. Such modification by, for example associated proteins, could play a determinant role in normal physiological conditions as well as in pathologies such as Alzheimer's disease with the example of the beta amyloid Aβ interaction with the α7 neuronal nicotinic acetylcholine receptors (2,3).

Title: Photomodulation of alpha1beta3gamma2 $GABA_A$ receptors expressed in Xenopus laevis oocytes using a tethered propofol photoswitch

Authors: *C. M. BORGHESE[1], E. J. BERTACCINI[2], J. R. TRUDELL[2], R. A. HARRIS[1]; [1]Univ. of Texas at Austin, Austin, TX; [2]Dept. of Anesthesia, Stanford Univ., Stanford, CA

Abstract: Photoswitches are freely diffusible molecules with two photo-dependent isomeric forms, each with different actions on their biological targets. Tethered photoswitches, in addition, have chemical groups that can be covalently bound to a biological target, either to a native or engineered residue. This tethering leads to high local concentration (the residue cannot diffuse away) and spatial restriction within the biological target. Either kind of photoswitches can be agonists, inverse agonists, antagonists, blockers or modulators.
Previous studies have used a diffusible propofol photoswitch (Stein 2012) and a tethered propofol photoswitch with a very long spacer between the tethering cysteine (located in the extracellular domain) and the propofol moiety (Yue 2012). Our aim was to identify and characterize the propofol binding sites in $GABA_A$ α1β3γ2 using a tethered photoswitch (MAP4), with short spacers between the tether (methane thiosulfonate), the azobenzene, and the ligand (propofol) groups, which would allow a more precise identification of the residues involved in the propofol binding. We focused on the β+α- interface of the transmembrane domains (TMs). First, we replaced all cysteines present in the TMs, and one in the b extracellular domain, with alanines (Cys-to-Ala receptor), without affecting the basic function or modulation of the receptor when expressed in *Xenopus laevis* oocytes. Then we used molecular modeling to identify

possible tethering sites in β3TM3 and α1TM1, and introduced cysteines in the candidate positions.
Most of the cysteine mutants, after incubation with MAP4, showed little to no modulation, similar to the Cys-to-Ala receptor. But after incubating α1β3(M283C)γ2 with MAP4 and upon illumination with lights of specific wavelengths, we observed modulation of GABA responses, which decreased as GABA concentration increased. This indicated that MAP4 covalently bound to β3(M283C) and the propofol moiety docked into and out of the binding site, depending on the light-induced isomerization of the azobenzene group. The location of the mutations that produced photomodulation suggested that the propofol binding site is located near the extracellular side of the β+ α- interface.

Abstract: Inhibitory neurotransmission in the brain is mediated mainly by two ligand gated receptors - $GABA_A$Rs and GlyRs. Disequilibrium in their function leads to many sever neurological disorders, such as epilepsy, hyperekplexia, anxiety, depression, schizophrenia and sleep disorders. Thus, development of effective modulators that would regulate the activity of these receptors with minimized side effects is of great importance. Photopharmacology is a unique tool for these purposes allowing precise spatial and temporal light-driven control of pharmacophores´ activity, and consequently of their target proteins. Here we present a series of azobenzene-based derivatives of benzodiazepine that successfully photocontrol activity of GABA and GlyRs. Compounds obtained by azologization of 7-aminonitrazepam with nitrosobenzenesulfonamide and nitrosopyridine (UR-DW285 and UR-DW290 respectively) demonstrated reversible photochromism and were selected for *in vitro* testing at inhibitory receptors. GABA and GlyRs were heterologously expressed in cultured CHO cells, their activity was monitored using whole-cell configuration of patch-clamp technique. At visible light UR-DW285 inhibited activity of $GABA_A$, GABA-rho2 and alpha2 GlyRs, while upon UV (365nm) irradiation their activity was restored. Using series of point mutations and molecular modelling approach we were able to demonstrate that UR-DW285 is a photo-switchable blocker of the ion channel pore of GABA and GlyRs. UR-DW290 displayed minor activity at GABARs, but it allowed photosensitive modulation of GlyRs of various subunit composition. In *trans* configuration UR-DW290 slightly inhibited glycine-induced currents, while in *cis*, generated by UV illumination, inhibitory effect was significantly strengthened. Zebrafish testing demonstrated high efficiency of UR-DW290 for the photo-control of their inhibitory system *in vivo*. In summary, we have developed a group of azobenzene/nitrazepam based compounds that modulate activity of two main inhibitory brain receptors in light-dependent manner. In contrast to nitrazepam, they did not potentiate GABAR currents but induced subunit-specific inhibition of both $GABA_A$Rs and GlyRs.

Abstract: The α6 subunit-containing $GABA_A$ receptors (α6$GABA_A$Rs) are expressed in cerebellar granule cells centrally and in trigeminal ganglia (TG) peripherally. Due to the lack of selective ligands for α6$GABA_A$Rs, their pathophysiological role(s) were largely unknown. We have identified a series of pyrazoloquinolinones to be α6$GABA_A$R-selective positive allosteric modulators (PAM),[1] and demonstrated the efficacy of Compound 6 in suppressing migraine via TG α6$GABA_A$Rs peripherally,[2] trigeminal neuropathy[3] and sensorimotor-gating deficit centrally via cerebellar α6$GABA_A$Rs[4] in rodents. DK-I-56-I is a deuterated derivative of Compound 6 with enhanced pharmacokinetic profiles.[1] Here, we compared central and peripheral effects of DK-I-56-I and Compound 6 in various rodent models of neuropsychiatric disorders. The central effects evaluated include the attenuation on methamphetamine and phencyclidine (PCP)-induced deficit in prepulse inhibition (PPI), as well as on chronic PCP-induced social withdrawal and impairment of novel object recognition. DK-I-56-I (3-10 mg/kg, *i.p.*) rescued PPI disruptions induced by methamphetamine and PCP. Furthermore, *i.p.* DK-I-56-I at 3 mg/kg also reversed the social withdrawal and memory impairment in mice receiving 14-day PCP treatment. The central effect of DK-I-56-1 is comparable with Compound 6. The antimigraine activity of DK-I-56-I was examined histopathologically in intracisteral (*ic.*) capsaicin-induced trigeminovascular system (TGVS) activation in rats and behaviorally in repeated nitroglycerin (NTG)-induced grimaces in mice. DK-I-56-I (3-10 mg/kg, *i.v.*), similar to Compound 6, significantly inhibited the brain stem activation, TG CGRP elevation, and dural CGRP depletion in *ic.* capsaicin-treated rats. Mice treated with NTG once every two days for 5 times displayed significant headache-like behaviors, including orbital tightening, nose & cheek bulge, and ear & whisker position changes, which were measured as the mouse grimace scale (MGS). We evaluated preventative and abortive effects of DK-I-56-I on the MGS on day 9 (the 5th session). In contrast to Compound 6 that only showed abortive effect in the NTG-induced migraine model, DK-I-56-I (3 mg/kg, *i.p.*) displayed both preventative and abortive effects, probably due to its enhanced bioavailability. These results suggest that both central and peripheral α6$GABA_A$Rs are novel therapeutic targets

for schizophrenia and migraine, respectively, and α6GABA$_A$R-selective PAMs are a potential therapy. [1]Knutson et al (2018) J Med Chem 61:2422. [2]Fan et al (2018) Neuropharmacology 140:1. [3]Vasović et al (2019) Eur J Pain 23:973. [4]Chiou et al (2018) Br J Pharmacol 175:2414.

Title: Preclinical and clinical studies with GT-002, a novel GABA$_A$ receptor ligand with putative antipsychotic and pro-cognitive effects

Authors: *M. R. WITT, C. RYAN, S. REHNMARK, M. NIELSEN;
Gabather AB, Malmoe, Sweden

Abstract: GT-002 is a novel compound of the triazoloquinazoline class which binds with high affinity to the benzodiazepine site of the gammma-aminobutyric acid (GABA$_A$) receptor complex in the mammalian brain. The compound shows potent antipsychotic effects in rodent *in-vivo* models comparable to those of clozapine. Furthermore, GT-002 shows pro-cognitive effects in the Novel Object Recognition (NOR) test and increases social interaction in rat models. GT-002 has been tested in 28-day GLP tox study in dogs without adverse effects. In summary, GT-002 has a profile that is distinct from other GABA$_A$ receptor modulators such as Diazepam.

Title: Development and characterisation of a panel of 19 $GABA_A$ receptor cell lines to facilitate the identification of subtype specific GABA compounds

Authors: *L. HUTCHISON, P. MADAU, L. MCCRACKEN, A. DICKSON, C. KADI, H. J. TRACEY, D. E. SMITH, C. BROWN, L. GERRARD, P. CONWAY, D. DALRYMPLE, I. MCPHEE, D. PAU;
SB Drug Discovery, Glasgow, United Kingdom

Abstract: The majority of inhibitory neurotransmission in the brain is mediated by the binding of γ-aminobutyric acid (GABA) to the $GABA_A$ receptor subtype. These pentameric receptors are assembled from a variety of subunit combinations, the majority of which are composed of two α subunits, two β subunits, and either a γ or δ subunit. The varying subunit combinations determine the biophysical and pharmacological properties of the receptor such as the GABA affinity and modulatory compound sensitivity. Dysregulation of GABAergic neurotransmission is associated with a number of diseases and psychiatric disorders which make these receptors attractive targets for drug discovery programs, especially as there is a need for greater subtype selectivity in order to improve drug efficacy, safety and tolerability. Developments in HTS technologies have allowed for rapid testing of large numbers of compounds against ion channel targets, however until now, the lack of an expansive panel of $GABA_A$ cell lines has limited the identification and characterisation of subtype-specific $GABA_A$ compounds.
Using the inducible HEK parental cell line, we have developed 19 $GABA_A$ recombinant cell lines consisting of α1–6 in combination with β1-3+γ2L, as well as the α4β3δ receptor. Automated patch-clamp validation of the cell lines allowed testing of at least of 6 subtypes in a single experiment, resulting in rapid accumulation of pharmacological data. Responses to the agonist, GABA were reproducible over several applications, with the α6 containing subunits conferring the highest sensitivity to GABA. Further validation with known positive allosteric modulators Diazepam, which displayed modulation (EC_{50} of 10-60nM) of α1, α2, α3 and α5 containing subtypes only, and Allopregnanolone, which displayed activity at all 19 $GABA_A$ subtypes (EC_{50} of 10-50nM) was in line with literature data.
Using one of these robust cell lines ($GABA_A$ α3β2γ2) we screened 2000 compounds in a fluorescence assay which generated 11 positive allosteric modulator hits. These hits were confirmed by automated patch-clamp, with EC_{50} values ranging from 0.6-4μM. A number of these hit compounds also produced a leftward shift in GABA sensitivity. Selectivity studies against 9 recombinant $GABA_A$ cell lines revealed one compound with higher selectivity for α2

and α3 subtypes in comparison to α1 subtypes and minimal or no activity against the α4-6 containing subtypes. We have shown that screening hit compounds against a panel of GABA cell lines can be accomplished quickly and efficiently. The selectivity assay will allow for determination of improved subtype specificity in lead compounds obtained from GABA drug discovery programs.

Title: Mapping the binding site mediating carisoprodol's direct activation of $GABA_A$ receptors

Authors: *M. C. CLAUDIO[1], H. HAYATSHAHI[2], N. M. MISHRA[2], G. H. DILLON[3], K. A. EMMITTE[2], J. LIU[2], R. HUANG[3];

Abstract: Carisoprodol (CSP) is a centrally-acting prescription muscle relaxant that can directly activate and allosterically modulate the $GABA_A$ receptor. $GABA_A$ receptors are the target of many different clinically prescribed compounds because of the role they play in regulating the central nervous system. Our previous studies have shown that CSP differentially potentiates $GABA_A$ receptor subtypes via allosteric modulation and direct activation. It has been reported that a single amino acid residue, L415, located at the top of the fourth transmembrane domain (TM4) in the α1- subunit of the $GABA_A$ receptor is critical to CSP's direct gating effect. Whether the residue is involved in CSP binding remains unsolved. The purpose of the present study is to explore the binding site mediating CSP's direct action with *in-silico* docking, site-directed mutagenesis and whole-cell electrophysiology. Initial *in-silico* docking of CSP at the $GABA_A$ receptor suggested that the CSP binding pocket may be formed by residues from the TM4, pre-TM1 and cys-loop regions of the α-subunits. In whole-cell electrophysiology studies performed on HEK-293 cells either stably or transiently expressing different $GABA_A$ receptor subtypes, specific modifications of CSP's molecular structure produced greater direct action on

$GABA_A$ receptors. Furthermore, the ability of CSP and its analogs to open the channels aligned with *in-silico* docking at the interest region in the $GABA_A$ receptors. The role of the residues predicted as a CSP binding site in *in-silico* docking analysis are being verified with mutagenesis and patch clamp studies. It is expected that the results will not only enhance our understanding of CSP pharmacology but also the structure-function relationship at $GABA_A$ receptors.

Title: Effects of the diazepam binding inhibitor on GABA-mediated currents

Authors: *J. S. BORCHARDT[1], N. GIEZENDANNER[2], R. A. PEARCE[3], C. M. CZAJKOWSKI[2];
[1]Univ. of Wisconsin-Madison, Madison, WI; [2]Dept Neurosci., Univ. Wisconsin-Madison, Madison, WI; [3]Anesthesiol., Univ. of Wisconsin, Madison, WI

Abstract: Benzodiazepines (BZDs) are a major class of drugs used to modulate GABA-mediated signaling in the brain. Since their synthesis in the 1950s, these drugs have been widely used for their sedative, anxiolytic and anticonvulsant effects, which are elicited by binding to the extracellular domain of the GABA-A receptor (GABAR). A competitive binding experiment in 1983 using rat brain homogenate to displace radiolabeled BZD binding to GABARs identified a putative endogenous BZD, the diazepam binding inhibitor (DBI) (Guidotti et al., PNAS 1983). Recent work suggests that DBI is able to alter GABA-mediated signaling in mouse brain (Alfonso et al., Cell Stem Cell 2012; Dumitru et al., Neuron 2017; Christian et al., Neuron 2013; Courtney and Christian, Neuroscience 2018), yet our understanding of exactly how DBI interacts with GABARs is limited.
In order to evaluate the direct effects of DBI on GABARs, we purified human DBI and expressed $\alpha_5\beta_3\gamma_{2L}$ GABARs in human embryonic kidney (HEK) 293-T cells. We performed both whole-cell and outside-out patch clamp electrophysiology using rapid ligand exchange. We measured GABA-elicited current responses in the presence and absence of DBI, and monitored changes in peak current amplitude and the rate of deactivation. Preliminary results indicate that outside-out patches exposed to DBI have a moderate slowing in their rate of deactivation,

indicating DBI is acting as a mild positive modulator. However, initial experiments using whole-cell recording show DBI causes an almost complete suppression of GABA-elicited current. We are performing additional experiments to understand whether these differences in DBI effects on outside-out patches versus whole cells are due to differences in receptor composition, subunit inclusion or other factors associated with whole-cell biology.
Additionally, we have performed preliminary radioligand binding experiments which show purified DBI is able to displace radio-labelled flunitrazepam from binding $\alpha_1\beta_2\gamma_{2L}$ GABARs expressed in membranes purified from HEK cells. This suggests that DBI able to bind GABARs at the BZD site. Taken together, the electrophysiology and binding data provide evidence that DBI is able to directly interact with the GABAR and modulate its function.

Title: Allopregnanolone potentiates and prolongs phasic inhibition of dorsal vagal motor neurons via the protein kinase C pathway

Authors: *E. LITTLEJOHN, L. ESPINOZA, C. BOYCHUK;
UT Hlth. San Antonio, San Antonio, TX

Abstract: Neurons in the dorsal motor nucleus of the vagus (DMV) comprise the preganglionic parasympathetic motor output to much of the subdiaphragmatic viscera and critically contribute to autonomic regulation of homeostasis. DMV neuron function is tightly regulated by gamma-aminobutyric (GABA) type A receptors. However, GABAA receptors have another endogenous ligand allopregnanolone (Allo). Allo is a centrally and peripherally produced neuroactive steroid metabolite which readily crosses the blood brain barrier is a potent allosteric modulator of $GABA_A$ receptor inhibition. Although no studies to date have investigated the potential for Allo to induce changes in GABAergic signaling to DMV neurons, Allo signaling may represent a novel pathway to augment the gut-brain axis signaling. **We hypothesize that acute Allo exposure will increase inhibition of DMV neurons**. To test this hypothesis we isolated brain stem slices from adult male mice and used whole-cell patch-clamp electrophysiology to examine

the effects of Allo (100nM) or vehicle on $GABA_A$ receptor mediated postsynaptic inhibition. To test our hypothesis, we incubated brainstem slices in Allo or vehicle containing artificial cerebral spinal fluid (ACSF) for 30min. We then analyzed GABAergic currents (phasic and tonic) in DMV neurons during drug washout at 30, 60, and 120 minutes (min) following the secession of Allo incubation. IPSC frequency and decay time were increased within 60 min of Allo washout. There was no significant modification of tonic GABAergic currents at any time point. Since IPSC modulation was present long after Allo removal, we examined non-allosteric effects of Allo on DMV inhibition. We applied PKC inhibitor (Bisindolylmaleimide II, 500nM) during Allo and Veh incubation as well as during washout to elucidate the role of posttranslational modification by protein kinase C (PKC) in mediating the inhibitory effects of Allo. In the presence of PKC inhibitor, the effects of Allo on PSC frequency were abolished and the effects on decay time were reduced by 70%. Additionally, we found that Allo begins augmenting GABAergic inhibition in DMV neurons immediately after exposure. Using a within-subject design, we recorded IPSCs before (control condition) and after a 10min Allo superfusion. Our data suggests that both frequency and decay time of IPSCs are increased within 10min of Allo application. It further suggests that this brief exposure to Allo potentiates $GABA_A$ receptor mediated inhibition in DMV neurons long (>120 min) after Allo exposure. Allo may play an important role in dynamically modulating vagal inhibition in models of disease.

Title: Comparison of the pharmacological signatures of arginine vasopressin and oxytocin analogs at marmoset, macaque, and human vasopressin 1a and oxytocin receptors

Authors: *M. L. PIERCE[1], J. A. FRENCH[2], T. F. MURRAY[1];
[1]Dept. of Pharmacol., Creighton Univ., Omaha, NE; [2]Dept. of Phychology, Univ. of Nebraska Omaha, Omaha, NE

Abstract: Arginine vasopressin (AVP) and oxytocin (OT) are neuropeptides that bind to G-protein coupled receptors and influence social behavior. Consensus mammalian AVP and OT (Leu^8-OT) sequences are highly conserved. However, in New World monkeys (NWM), six distinct OT ligand variants have been discovered. Notably, in marmosets, an amino acid change in the 8th position of the peptide (Pro^8-OT) exhibits unique structural and functional properties.

In addition to sequence homology between AVP and OT, there is ~85% structural homology between the OT receptor (OTR) and vasopressin 1a receptor (V1aR) resulting in significant cross-reactivity between the ligands and receptors. Chinese hamster ovary (CHO) cells expressing marmoset, macaque, or human OTR (mOTR, qOTR, and hOTR) or V1aR (mV1aR, qV1aR, and hV1aR) were used to assess AVP, Leu^8-OT and Pro^8-OT pharmacological signatures. To assess activation of Gq, functional assays were performed using Fluo-3 to measure ligand-induced Ca^{2+} mobilization. At qOTR and hOTR (endogenous ligand Leu^8-OT), AVP was much less potent than Leu^8- or Pro^8-OT at elevating intracellular calcium; whereas at mOTR (endogenous ligand Pro^8-OT), there was no significant difference in AVP and OT potency. In all three V1aR-expressing cell lines, AVP was more potent than the OT ligands. To assess ligand-induced hyperpolarization, FLIPR Membrane Potential (FMP) assays were performed. At mOTR and hOTR, Leu^8-OT was more potent than Pro^8-OT or AVP. In qOTR, AVP was less potent than both OT analogs. In all three V1aR lines, AVP was more potent than the OT analogs. The distinctive U-shaped concentration-response curve displayed by AVP may reflect enhanced desensitization of the mV1aR and hV1aR, which is not observed with qV1aR. Evaluation of Ca^{2+}-activated K^+ channels using the inhibitors apamin, paxilline, and TRAM-34 demonstrated that both intermediate and large conductance Ca^{2+}-activated K^+ channels contributed to membrane hyperpolarization, with different pharmacological profiles identified for distinct ligand-receptor combinations. Integrative studies of behavior, genetics and ligand-receptor interaction are crucial for translating signaling activation at the cellular level to effects of AVP and OT ligands on social behavior.

Title: Somatostatin receptors on inhibitory SST, VIP and PV interneurons in the barrel cortex

Authors: *A. LUKOMSKA, G. DOBRZANSKI, M. LIGUZ-LECZNAR, M. KOSSUT; Lab. of Neuroplasticity, Nencki Inst. of Exptl. Biol. PAS, Warsaw, Poland

Abstract: A considerable diversity of inhibitory interneurons is a distinct characteristic of the mammalian neocortex. A unique form of inhibition is provided by inhibitory neurons that specifically suppress the firing of other inhibitory neurons leading to disinhibition, which can support plasticity, learning, memory. In the neocortex disinhibition is performed primarily by

interneurons containing somatostatin (SST-INs) and vasoactive intestinal peptide (VIP-INs), targeting parvalbumin-containing (PV-INs) interneurons. Our data for learning-dependent plasticity of the mice barrel cortex showed involvement of SST-Ins in the development of learning induced plastic change of vibrissae representation. In the brain SST is not only a marker of interneuron subtype but also an important neuropeptide that participates in numerous biochemical and signaling pathways *via* somatostatin receptors (SSTRs1-5). SST acts as a neuromodulator and neurotransmitter possibly by co-release with GABA, targeting not only principal cells, but also interneurons. However, the SSTRs distribution among cortical layers and their localization on particular types of interneurons has not been investigated in detail.We examined localization of different SSTR subtypes on the barrel cortex inhibitory interneurons containing PV, SST and VIP. Immunofluorescent staining using antibodies against SSTR1-5 was performed on brain sections from transgenic mice whose specific interneuron subtypes showed red fluorescence (PV-Ai14, SST-Ai14, VIP-Ai14).We found that SSTRs expression on PV, SST and VIP interneurons varies depending on the cortical layer. According to the specific pattern of the localization of the SSTRs in the barrel cortex, we classified them into two types. The first type was characterized by a high receptor (SSRT1 and SSTR2) concentration in the barrel walls, while the second type was characterized by a homogeneous receptor (SSTR3, SSTR4 and SSTR5) distribution in the barrel hollows. We demonstrated that PV cells do not express SSTR2, in contrast to other SSTRs. Other interneurons expressed all SSTRs. SST-INs, which were not found to make chemical synapses among themselves, expressed all five SSTR subtypes, suggesting their extrasynaptic localization.

Title: A2A adenosine receptors blockade reverts synaptic and memory in aged rats

Authors: *R. A. CUNHA[1], C. SOUZA[2], J. GUTIERREZ[3], H. B. SILVA[2], P. M. CANAS[2]; [1]CNC -Center For Neurosci. and Cell Biol., Coimbra, Portugal; [2]CNC-Center for Neurosci. and Cell Biol., Coimbra, Portugal; [3]CNC-Center for Neurosci. and Cell Biol., CNC-Center for Neuroscience and Cell Biology, Portugal

Abstract: Adenosine is a signaling molecule released in an activity-dependent manner directly or upon catabolism of ATP by ecto-nucleotidases. The extracellular levels of adenosine and ATP, both danger signals in the brain, rise even more in noxious brain condition and the over-activation of adenosine A_{2A}receptors (A_{2A}R) is paramount to trigger neuronal damage (J Neurochem 2016; 139:1019-55). Since neurodegenerative diseases are prevalent upon aging, we now posted that A_{2A}R over-activation might be a critical factor responsible the age-associated increase risk of brain disorders. Objective: We now tested if A_{2A}R blockade reverts synaptic and memory impairment in aged rats. Methods: We first compared memory performance in young adult (3 months-old) and aged (20-22 months-old) rats. Most of the aged rats displayed a poorer memory performance compared to young adult rats. Half of the aged impaired and half of the young rats were treated for 3 weeks with the selective A_{2A}R antagonist SCH58261 (0.1 mg/kg/daily, ip). Results: SCH58261-treated aged rats recovered performance in memory tests to the level of young rats, in which SCH58261 had no effects. Memory-impaired aged rats also displayed lower hippocampal synaptic plasticity together with a lower density of vesicular glutamate transporter type 1 (vGluT1), an increased density of A_{2A}R and of ecto-5'-nucleotidase and increased ATP release from hippocampal synaptosomes. All these changes were reverted by treatment with SCH58261 in aged rats. Conclusions: These findings show that A_{2A}R over-function is critically required for the development of age-associated memory deficits, likely involving synaptic dysfunction. This prompts considering A_{2A}R as a biomarker of poorer quality brain ageing. Supported by Fundacion LaCaixa, FCT (POCI-01-0145-FEDER-031274) and Centro 2020 (CENTRO-01-0246-FEDER-000010).

Abstract: RFamide-relatide peptide 3 (RFRP3) and Neuropeptide FF (NPFF), belong to the family of so-called RFamide peptides. In mammals, they are involved in the modulation of several functions including metabolism, reproduction and nociception. They target two different G protein-coupled receptor subtypes called Neuropeptide FF1 receptor (NPFF1R alias GPR147 or GnIH receptor) and Neuropeptide FF2 receptor (NPFF2R or GPR74), respectively. However, the respective role of these two receptors is unclear, and the study of their function *in vivo* is severely limited by the lack of highly selective antagonists. In this work, we describe the identification of small compounds that display high affinity and selectivity for NPFF1R as well as potent antagonist activity *in vitro*. We then showed that one of them, RF3286, efficiently and selectively blocks RFRP3-induced hyperalgesia in mouse and luteinizing hormone release in hamster, indicating that this compound is a useful pharmacological tool to study the *in vivo* functions of NPFF1R and its endogenous ligand RFRP3. Pharmacological blockade of NPFF1R with RF3286 prevented the development of pain hypersensitivity and analgesic tolerance induced by chronic administration of morphine revealing that NPFF1R/RFRP3 system is critically involved in neuroadaptation associated with administration of opiates. These results were further confirmed in NPFF1R knockout animals. Moreover, we observed the expression of NPFF1R and RFRP3 transcripts by fluorescent *in situ* hybridization in the dorsal horn of spinal cord, indicating that this receptor/peptide system can modulate nociception in part by spinal mechanism. We further observed that cells expressing NPFF1R transcripts were also MOP positives (50%) and DOP positives (20%), suggesting a direct modulatory role of NPFF1R on the action of opioid. Finally, we observed an increase of NPFF1R positive cells in dorsal horn of spinal cord of CFA-treated animals compared to saline controls suggesting a potential role of this system in inflammatory pain. In agreement with these data, we further showed that pharmacological blockade of NPFF1R with RF3286 can efficiently reverse hyperalgesia induced by CFA injection. Altogether, our data allowed us to identify NPFF1R/RFRP3 as a pronociceptive anti-opioid system and further suggest that antagonists of this receptor might represent interesting therapeutic tools to limit the development of opioid-induced hyperalgesia and analgesic tolerance associated with chronic opioid administration as well as hyperalgesia induced by inflammatory pain.

Title: Identification of the key molecules involved in GPCR-mediated primary cilium shortening

Authors: Y. KOBAYASHI[1], S. TOMOSHIGE[1], D. MIKI[1], T. MIYAMOTO[2], ***Y. SAITO**[1]; [1]Hiroshima Univ., Higashi-Hiroshima, Japan; [2]Res. Inst. for Radiation Biol. and Med., Hiroshima Univ., Hiroshima, Japan

Abstract: The primary cilium is a protrusion supported by a microtubule axoneme that extends from the basal body. It is a sensory organelle that responds to environmental stimuli and communicates the signal to the cell's interior function. Primary cilium coordinates multiple cellular signaling pathways through ion channels and conventional G-protein-coupled receptors (GPCRs) harbored in the cilium membrane. During postnatal development, the neuronal cilium membrane becomes equipped with a limited set of GPCR such as melanin-concentrating hormone (MCH) receptor 1 (MCHR1), which has the important connection with fundamental systems influencing feeding, mood and sleep. Cilium length has been predicted to be a critical parameter that has implications for cilia function in most neuron. Recently, we have found a new biological phenomenon, that is the MCH-induced cilia length shortening via ciliary MCHR1 in rat hippocampal slice culture, human induced pluripotent stem cells, and human telomerase-immortalized retinal pigmented epithelial (RPE1) cells. By using RPE1 cells, we further showed the MCH-MCHR1-Gi/o-Akt pathway causes a series of signal cascade connecting dynamics to cytoplasmic tubulin depolymerization and actin polymerization. However, the major downstream targets from Akt activation toward cilia shortening remain unclear. In this study, we investigated changes in the transcriptome profile in MCHR1-expressing RPE1 cells with RNA-seq technology. There were more than 500 genes, which were significantly changed more than two-fold in response to MCH treatment. After performing qPCR to validate the results of RNA-seq, several candidates in the list showed great potential for further study as reflected by the fold change in mRNA expression along time-course. Finally, functional analysis by using siRNA knockdown and CRISPR-ObLiGaRe knockout revealed several molecules as the significant regulator for MCHR1-mediated cilia shortening. One of these molecules has been reported to be associated with schizophrenia, bipolar depression, and major depressive disorder. Thus, our

findings will offer the new insights into the relationship between GPCR-mediated neuronal cilia length control and pathophysiology of mental illness.

Abstract: Lysophosphatidic acid (LPA) is a bioactive lipid acting on G-Protein coupled receptors (LPAR1-6), leading to calcium influx. LPA has been identified as a powerful pruritogen; in rodent models, it induces scratching behavior upon intradermal injection. Autotaxin, the main extracellular enzyme that catalyzes LPA synthesis is found elevated in patients suffering from cholestatic itch and can serve as a marker for intrahepatic cholestasis of pregnancy. Here we show that LPA activates satellite glial cells as opposed to having direct action on neurons. In addition, we record similar effects in Schwann cells, which are of glial lineage like the satellite glial cells, and characterize these effects from a functional standpoint. Cell activation was assessed using calcium microfluorimetry in dorsal root ganglia and Schwann cell primary cultures and immunohistochemistry served to validate the receptor distribution on the different cell types. In a dorsal root ganglia primary cell culture, acute exposure to LPA was followed by calcium influx in satellite glial cells, yet only few neurons exhibited this phenomenon. Moreover, responses to LPA were inversely correlated with those for agonists of transient receptor potential channels, including TRPV1. Direct TRPV1 activation by LPA was marginal and no differences were observed in the respective TRPV1 knockout mice. LPA induces calcium transients in Schwann cells, mainly from intracellular stores, which can be abolished by selective inhibition for the LPA1 receptor. Upon repeated LPA application in continuous superfusion conditions, desensitization can be observed. Antibody staining for LPA1 receptors revealed a highly localized distribution, hypothesized to fit growth areas of the cell. Schwann cells and satellite glial cells respond to lysophosphatidic acid, pointing to signaling pathways with importance for neuronal responsiveness and sensory responses such as itch and pain.

Title: G-protein-coupled estrogen receptor 1 (GPER1)-mediated enhancement of excitatory synaptic transmission in layer II of the entorhinal cortex

Authors: ***A. A. BATALLÁN BURROWES**, A. SUNDARAKRISHAN, C. A. CHAPMAN; Concordia Univ., Montreal, QC, Canada

Abstract: Estrogens are thought to contribute to cognitive function via rapid synaptic changes associated with activation of α, β, and GPER1 estrogen receptor (ER) sub-types. GPER1 is the predominantly expressed ER in the hippocampal formation, followed by β, and α receptors. Hippocampal application of 17-β estradiol (E2) enhances excitatory synaptic transmission and improves working memory performance. Activation of ERs can inhibit GABAergic neurons, modulate excitatory NMDA and AMPA currents, and reversibly increases CA1 pyramidal neuron dendritic spine density. The entorhinal cortex is the major source of cortical sensory and associational input to the hippocampal formation. However, it is unclear how estrogen may impact synaptic transmission in the entorhinal cortex. The present study assessed the effects of the acute application of E2 on excitatory glutamatergic synaptic transmission in layer II of the rat entorhinal cortex in vitro. On PD63, rats were ovariectomized and implanted with a subdermal E2 capsule to maintain constant low levels of circulating E2. Electrophysiological recordings were collected between PD70 and PD91. Acute horizontal brain slices were obtained and evoked field excitatory postsynaptic potentials (fEPSP) were recorded in layer II following stimulation of layer I afferents. After baseline recordings, 20 min application of E2 (100 nM) yielded an approximately 10% increase in fEPSP amplitude that reversed during the 30 min washout period. Application of the ERα agonist PPT (100 nM) did not significantly change synaptic responses compared to baseline. Conversely, application of the GPER1 agonist G1 (100 nM) induced a reversible increase in fEPSP amplitudes similar to that induced by E2. This indicates that the rapid enhancement of excitatory synaptic transmission induced by estrogen in the entorhinal cortex is likely mediated by activation of GPER1 receptors. This enhancement may support estrogen's contribution to cognitive function in the hippocampal region.

Title: Interaction between dopamine and type 2 corticotropin releasing factor receptors modulates the basolateral amygdalar transmission to the medial prefrontal cortex

Authors: H. E. YARUR, J. A. ZEGERS, I. VEGA-QUIROGA, *K. GYSLING;
Dept. of Cell. and Mol. Biol., Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: The prefrontal cortex (PFC) is a brain area involved in working memory, attention and goal directed behavior. Stressful events could modify the animal behavior, affecting the performance of working and/or emotional memories. One of the brain areas which projects heavily to the ventral region of the PFC and that have been implicated in the emotional information of the stimuli is the basolateral amygdala (BLA) (LeDoux, 2000). Acute stressful stimuli can block the induction of plasticity between the BLA and the PFC (Maroun and Richter-Levin, 2003). Corticotrophin releasing factor (CRF) is a central regulator of endocrine and behavioral responses to stressors. The evidence shows that dopamine (DA) receptors (D1R and D2R) modulate transmission between BLA-PFC (Floresco and Tse, 2007). Furthermore, CRF and DA act synergistically to regulate the transmission of the BLA to PFC (Orozco-Cabal et al, 2008). Thus, we decided to further study whether type-2 CRF (CRF2) and DA receptors regulate synaptic transmission between BLA and PFC. To this end, we performed *in vivo* microdialysis experiments in the presence or absence of pharmacological antagonists for CRF and DA receptors. Our results show that antisauvagine 30, CRF2 antagonist, increased PFC glutamate extracellular levels and decreased DA extracellular levels induced by BLA stimulation. The combination of D1R and CRF2 antagonists blunted the increase of PFC glutamate levels induced by BLA stimulation. However, the combination of D2R and CRF2 antagonists disrupted the effect of the CRF2 antagonist alone over PFC glutamate levels induced by BLA stimulation. Synaptic expression of CRF2 and dopamine receptors was analyzed in PFC synaptosomes devoid of post-synaptic elements. CRF2 was mainly colocalized with D1R in PFC synaptosomes. Furthermore, agonist dependent-ERK signaling of CRF2 and D1R in was suppressed by the co-incubation of PFC synaptosomes with both agonists. Our results suggest that CRF2 exerts control over PFC glutamate and dopamine extracellular levels induced by BLA

stimulation. In addition, our results suggest a complex interaction between dopamine receptors and CRF2 modulating the BLA-PFC synapsis.

Title: Loss of trace amine-associated receptor 2 function results in impairments in hippocampus-dependent behavior and hippocampal synaptic function

Authors: *A. G. ALMONTE[1], A. DEAL[2], J. K. KONSTANTOPOULOS[2], J. L. WEINER[1], E. A. BUDYGIN[2];
[1]Physiol. and Pharmacol., [2]Neurobio. and Anat., Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Trace amine-associated receptor 2 (TAAR2) is a member of a family of G-protein coupled receptors that are activated by a class of biogenic amines called trace amines, which are present at nanomolar concentrations in the brain and periphery. While previous work suggests that TAAR2 is expressed in the olfactory system and may function as a chemosensory receptor, little is known about TAAR2 expression and function in other brain areas. Here, we have begun a behavioral and neurophysiological characterization of a TAAR2 knockout mouse line in which the TAAR2 gene is deleted and replaced with a lacZ reporter. We show reporter expression in various brain regions, in particular the hippocampus. We find that TAAR2 KO mice have impaired performance in the novel object recognition and object location memory tasks, which are two hippocampus-dependent behavioral tests. Extracellular field potential recordings at hippocampal Schaffer collateral-CA1 synapses reveal differential effects of TAAR2 deletion along the dorsoventral axis. In the dorsal hippocampus, TAAR2 KO mice show normal baseline synaptic transmission, but impaired induction of long-term potentiation (LTP). In the ventral hippocampus, however, TAAR2 KO mice display decreased baseline synaptic transmission and

normal LTP induction. Notably, our observations of deficits in the novel object recognition and object location memory tasks and in LTP induction in dorsal hippocampal slices are consistent with the known roles of the dorsal hippocampus in encoding this type of declarative memory. Together, these behavioral and neurophysiological phenotypes suggest novel roles for TAAR2 function in modulating behavioral output, synaptic function, and the induction of synaptic plasticity.

Title: Role of type-2 corticotrophin-releasing factor receptors in nucleus accumbens neurotransmitter levels after basolateral amygdala stimulation

Authors: J. A. ZEGERS, *H. E. YARUR, C. P. BASTIAS, K. GYSLING;
Dept. of Cell. and Mol. Biol., Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: Basolateral amygdala (BLA) is a brain nucleus that innervates the nucleus accumbens (Nac) and prefrontal cortex (PFC) (McDonald, 1991). The relation between BLA and Nac has been implicated on the control of motivated behavior (Stuber et. al., 2011). Furthermore, BLA has been implicated in fear, anxiety and stress (Simon et. al., 2014; Janak and Tye, 2015). The stress response is centered in the corticotropin releasing factor (CRF) system (Bale and Vale, 2004). There are two major receptors for CRF in the brain, type-1 and type-2 corticotrophin-releasing factor receptors (CRF-R1 and CRF-R2). Several studies have shown a significant role of CRF-R1 in the stress response; however, the role of Nac CRF-R2 in the stress response is poorly understood. We studied the anatomy and role of CRF-R2 in the relation between BLA and Nac. First, to detect if CRF-R2 is localized in BLA synaptic terminals innervating Nac, we injected biotinylated dextran amine (BDA) in the BLA of adult male Sprague-Dawley rats. Then, we performed immunofluorescence on Nac synaptosomes, devoid of post-synaptic elements. Second, we studied the role of CRF-R2 in Nac neurotransmitter levels after BLA stimulation by double *in vivo* microdialysis in NAc and BLA of adult rats. We observed colocalization of CRF-R2 and BDA in Nac synaptosomes. In addition, using local infusion of antisauvaganine 30 (CRH-R2 antagonist) in the NAc, we observed an increase in Nac dopamine and glutamate

extracellular levels after BLA stimulation. Our results show that CRF-R2 is present in BLA nerve terminals innervating Nac. They also suggest that there is an inhibitory tone mediated by CRF-R2 that control Nac dopamine and glutamate extracellular levels depending on BLA stimulation.

Title: Structural and pharmacological characterization of the μ-opioid-galanin Gal_1 receptor heterodimer

Authors: *P. A. DE OLIVEIRA[1], N. CASAJUANA-MARTÍN[2], H. ZHU[3], C. NING-SHENG[1], E. MORENO[4], A. BONIFAZI[1], A. GONZÁLEZ[2], V. CASADÓ-ANGUERA[4], S. PITTENGER[3], A. NEWMAN[1], V. CASADÓ[4], M. HALL[3], L. PARDO[2], S. FERRE[1];

Abstract: We have recently shown that μ-opioid receptors (MOR) form functional heteromers with galanin Gal_1 receptors (Gal1R) in the ventral tegmental area (VTA) and that these MOR-Ga1R heteromers determine the dopaminergic effects of opioids.[1,2] Among the pharmacological properties of the MOR-Gal1R heteromers, we found that Gal1R ligands significantly counteract MOR signaling (negative crosstalk) and a specific insensitivity to methadone, as compared to other opioids, such as morphine and fentanyl.[2] This pharmacodynamic difference between methadone and the other opioids determined a weaker proficiency of methadone to activate the dopaminergic system and predicted a dissociation of the therapeutic versus euphoric effects of methadone.[2] We are now studying the molecular mechanisms responsible for these pharmacological properties of the MOR-Gal1R heteromer in mammalian transfected cells, using radioligand binding experiments, cell signaling assays, biophysical methods, including Bioluminescence Resonance Energy Transfer (BRET) and Bimolecular Complementation of BRET biosensors, and computational modeling. Results from co-transfection of MOR fused to complementary halves of a BRET biosensor and increasing amounts of Ga1R suggested the same intermolecular interface for MOR-MOR homomers and MOR-Gal1R heteromers. Experiments with synthetic peptides with the amino-acid sequence of the different

transmembrane (TM) domains of MOR and Gal1R confirmed the dimeric nature of the MOR-Gal1R heteromer and the specific TM domains involved in the heteromeric interface. This allowed the establishment of the quaternary structure of the MOR-Gal1R heteromer by computational modeling and its comparison with the MOR-MOR homomer. In silico experiments are now being performed to evaluate the molecular mechanisms responsible for the negative crosstalk of Gal1R and MOR ligands and the unique behavior of methadone within the MOR-Gal1R heteromer. The dimeric quaternary structure of the MOR-Gal1R heteromer implies the coupling with only one (heterotrimeric) molecule of G protein. Experiments with MOR and Gal1R fused to complementary halves of a BRET biosensor and the α subunit of different G protein subtypes fused to the other potentially interacting BRET biosensor are being performed to determine the preferred G protein and signaling of the MOR-Gal1R heteromer. This study should provide information that leads to new opioids with lower addictive liability or to compounds that can counteract the addictive effects of opioids, by targeting the MOR-Gal1R heteromer. Title: Possibility to recover from anorexia: A disorganized synaptic network in the prefrontal cortex did not block the ability to restore hypophagia in adult stressed 5-HT4 knockout

Authors: M. EL OUAHLI[1], M. NAJIMI[2], F. CHIGR[2], ***V. COMPAN**[1];
[1]Nimes Univ., Nimes, France; [2]Beni Mellal Univ., Beni Mellal, Morocco

Abstract: Adult restoration of serotonin 4 receptor (5-HT_4R) expression in the medial prefrontal cortex (mPFC, HSV5-HT_4R-transduced mice) rescues hypophagia and specific molecular changes related to depression resistance in the dorsal raphe nucleus (DR) of stressed 5-HT_4R knockout (KO) mice, involving the glutamatergic descending pathway from the mPFC to the DR (Cell Report 2017). These neural events are then not implemented during earlier developmental stages, but adapt rapidly, with high flexibility, in response to uncontrollable stress. Is it because synapses, known as the functional unit of learning and memory, are less required for this behavioral response to stress? Here, we set out to observe the number of dendritic spines of

pyramidal cells in the mPFC under basal conditions in mice of both genotypes at 3 and 7 months after birth in the presence or absence of 5-HT_4Rs (GFP-M 5-HT_4R KO). The number of dendritic spines of pyramidal cells in the mPFC is similar between WT mice aged of 3 and 7 months, but 5-HT_4R KO mice displayed a reduced density of dendritic spines when aged of 7 months compared with WT animals at identical age under basal conditions. Half reduced mRNA levels of BDNF were correlated with the possible disorganized synaptic network in the mPFC in 5-HT_4R KO mice compared with WT animals. Further considering localization of 5-HT_4Rs on 60% of pyramidal glutamatergic neurons in the mPFC, the mRNA levels of intercellular adhesion molecule-5 (ICAM-5) were analyzed, as ICAM-5 appears to contribute to spine maturation in glutamatergic neurons. The mRNA levels of ICAM-5 were reduced in the mPFC in 5-HT_4R KO mice compared with WT animals. The present findings suggest that restoring hypophagia following stress during adulthood did not depend on an implemented cortical synaptic network.

Title: Mechanisms for pituitary adenylate cyclase-activating polypeptide-induced increase in excitability in adrenal medullary chromaffin cells

Authors: *M. INOUE, H. MATSUOKA, K. HARADA;
Cell and Systems Physiol., UOEH Sch. of Med., Kitakyushu, Japan

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) acts on adrenal medullary chromaffin (AMC) cells as a neurotransmitter of the preganglionic sympathetic nerve. We have elucidated that in guinea-pig AMC cells PACAP facilitates catecholamine secretion evoked by muscarinic receptor stimulation, PACAP itself induces a depolarizing inward current, and muscarine-induced depolarization is at least in part due to insertion of TRPC1/4 heteromeric channels into the cell membrane. The present experiments aimed first to investigate the ion channels involved in the PACAP-sensitive current in guinea-pig and mouse AMC cells and second to explore how PACAP enhances muscarinic receptor-mediated secretion. The whole-cell current was recorded at -50 or -60 mV in isolated AMC cells with the perforated patch clamp technique. Bath application of 3 nM PACAP and 1 μM muscarine produced inward currents in 6

and 8 of 9 guinea-pigs AMC cells, respectively. In contrast to guinea pigs, almost all the mouse AMC cells (14/15) developed inward currents in response to 3 nM PACAP, whereas only 30% of the mouse cells exhibited inward currents in response to 30 μM muscarine. Exposure to PACAP consistently resulted in enhancement of the muscarinic inward current. This enhancement of the muscarinic current did not depend upon the amplitude of PACAP-induced currents, and PACAP enhanced membrane insertion of TRPC1/4 channels in response to muscarine. In guinea-pig and mouse AM cells, 1 μM mucarine-induced currents were suppressed by quinine in a dose-dependent manner with an IC_{50} of 20 μM, whereas PACAP-induced inward currents were not noticeably suppressed by 100 μM quinine. The PACAP current was completely suppressed by the replacement of external Na^+ with N-methyl D-glucamine. Addition of 30 μM 9-phenanthrol, a specific TRPM4 channel, to the external solution resulted in the inhibition of PACAP currents by about 90%, and TRPM4-like immunoreactivity was detected at the cell periphery in guinea-pig and mouse AMC cells. The present results reveal that PACAP activates Na^+-permeable cation channels, which are not affected by quinine and suppressed by 9-phenanthrol. These properties of the ion channels are reminiscent of those of TRPM4. We conclude that PACAP activates Na^+-permeable cation channels in guinea-pig and mouse AMC cells and facilitates the membrane insertion of TRPC1/4 channels in response to muscarinic receptor stimulation.

Title: NECAB2 is a major calcium-binding protein of GPR3-positive neurons in various regions of the mouse brain

Authors: *F. IKAWA, S. TANAKA, K. HARADA, I. HIDE, N. SAKAI;
Dept. of Mol. and Pharmacol. Neurosci., Hiroshima Univ. Grad. Sch. of Biomed. and Hlth. Sci., Hiroshima, Japan

Abstract: The G-protein coupled receptor 3 (GPR3) is a member of the class A rhodopsin-type GPR family that is highly expressed in the brain. GPR3 comprises a subfamily with GPR6 and GPR12 and shows >50% identity at the amino acid level and a very close relationship with the lysophosphatidic acid family receptors, sphingosine-1-phosphate family receptors, and cannabinoid family receptors. We have recently clarified that GPR3 promoter activity increased

in the medial habenular nucleus, CA2 region of the hippocampus, thalamus, and pontine nucleus and was rather weak in the striatum and cerebellum using GPR3−/−; LacZ+/+ mice. However, subpopulations of GPR3 in neurons have not been fully elucidated. It was recently reported that diphenyleneiodonium chloride has agonistic potential for GPR3 to release calcium from ER in an IP3-dependent manner. In addition, EF-hand Ca-binding proteins (CaBPs) were used as valuable anatomical markers for morphologically and functionally distinct neuronal subpopulations. Among CaBPs, neuronal Ca^{2+}−binding proteins (NECABs) are attractive as markers because NECAB2 is reported to be specifically expressed in the CA2 area of the hippocampus where GPR3 is specifically distributed. The NECABs subfamily comprises three members (NECAB1-NECAB3), of which NECAB1/ NECAB2 are restricted to the nervous system. We investigated whether GPR3 co-localizes with NECAB1/ NECAB2 using immunohistochemistry and analyzing by confocal microscopy. Of note, GPR3-expressing neurons were exclusively positive for NECAB2 in areas highly expressing GPR3, including the medial habenular nucleus, CA2 region of the hippocampus, and thalamus. However, NECAB1 partially co-localizes with GPR3-positive neurons. NECAB2 reportedly interacts with the adenosine A2A receptor or metabotropic glutamate receptor 5, thereby contributing to receptor functions. These results suggest that the neuronal expression of GPR3 may be associated with NECAB2 and could modulate calcium signaling in specific neurons.

Title: PI 4-kinase and PIP 5-kinase cooperate to replenish $PI(4,5)P_2$ after receptor-mediated depletion

Authors: *L. DE LA CRUZ[1], J. B. JENSEN[1], B. HILLE[2];
[1]Dept. of Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [2]Physiol. & Biophysics, Univ. of Washington Dept. of Physiol. and Biophysics, SEATTLE, WA

Abstract: $PI(4,5)P_2$ is a key cofactor for many cellular processes in neurons. This phospholipid is synthesized from PI sequentially by PI 4-kinases and PIP 5-kinases, and it is depleted in plasma membrane (PM) by activation of muscarinic M_1R receptors. After M_1R activation, both PI4P and $PI(4,5)P_2$ are depleted, and $PI(4,5)P_2$ recovery takes ~125 s. However, if only the 5-

phosphate is removed from $PI(4,5)P_2$ (by activation of a voltage-sensing lipid phosphatase), recovery from PI4P takes only ~10 s. Using tsA201 cells transiently transfected with the enzymes PI4KIIIα or PIP5KIγ, we explored whether $PI(4,5)P_2$ recovery after M_1R activation could be accelerated by PI4K overexpression, and tested for cooperativity between PI4K and PIP5K. We evaluated $PI(4,5)P_2$ recovery after M_1R stimulation using KCNQ2/3 current. These ion channels require $PI(4,5)P_2$ and are rapid real-time indicators specific for PM $PI(4,5)P_2$. KCNQ2/3-current recovery showed a delay of 20-30 s before recovery began either in control or in PIP5KIγ-overexpressing cells, whereas recovery started immediately in PI4KIIIα+complementary proteins (CP) TTC7 and EFR3-overexpressing cells. The half-time of recovery was 81 s (control), 50 s (PI4K), and 70 s (PIP5K). Acceleration of recovery by PIP5K may reflect changes in PI4K localization. PI4KIIIα localized as a diffuse label in cytosol when expressed alone. However, co-overexpression of the 4-kinase with CP gave a PM localization in ~30% of cells, and additional co-overexpression of PIP5KIγ increased that to 50%. We performed mass spectrometry comparing phosphoinositides PI, PIP and PIP_2 in PI4KIIIα- or PIP5KIγ-overexpressing cells to control. There was no change in total PI levels but a 15-20% decline in PIP with PI4KIIIα or PIP5KIγ. At the same time, total PIP_2 increased 25% for PI4KIIIα and 35% for PIP5KIγ. With overexpression of PIP5K the overall conversion of PIP to PIP_2 was expected. However, with PI4KIIIα alone, an increase of PIP was expected rather than a decrease. The direct augmentation of PIP_2 observed in mass spec experiments and the increased localization of PI4KIIIα to the PM with the co-expression of PIP5KIγ suggest that the two enzymes might form a functional complex that resynthesizes $PI(4,5)P_2$ directly from PI (Supported by NIH/NINDS R37NS008174).

Title: Characterizing distinct subsets of hippocampal CA2 neurons through afferent and efferent circuit mapping and electrophysiological recording in vasopressin 1b-Cre transgenic mice

Authors: *N. I. CILZ, S. WILLIAMS, A. J. HOWLEY, E. SHEPARD, S. YOUNG;
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The dorsal CA2 area is an important component for circuits underlying social memory and aggression. The CA2 area is molecularly defined by several different region-specific genes,

including the vasopressin (Avp) 1b receptor (Avpr1b) (Young et al., 2006). Previously, we have shown that the Avp-Avpr1b system is important for both social aggression (Pagani et al., 2015) and memory (Smith et al., 2016). The underlying Avp-Avpr1b circuitry and cellular mechanisms, however, remain to be fully understood. To address these matters, we utilized a combination of techniques including viral-mediated circuit-tracing and *in vitro* electrophysiology in transgenic mice. To visualize the distribution of Avpr1b-expressing cells throughout the hippocampus, we crossed Avpr1b-Cre mice with a reporter line and found robust CA2 Avpr1b expression along the hippocampal dorsoventral axis. We utilized injections of Cre-dependent retro AAV and AAV vectors to map inputs and downstream targets, respectively, of the CA2 region at different dorsoventral locations. To better understand the relationship between Avp and Avpr1b expression, we used immunohistochemistry to stain for neurophysin 2 (the Avp carrier protein) fibers in Avpr1b-Cre reporter mice. Neurophysin 2 fibers were seen near Avpr1b-enriched hippocampal areas, supporting a modulatory action of Avp. To complement these findings, we attempted to map Avp inputs to the CA2 region using a Cre-dependent retro AAV in Avp-Cre mice. Finally, we made whole-cell recordings from Avpr1b-expressing cells in Avpr1b-Cre reporter mice to probe the cellular level of this circuit. We first characterized the electrophysiological properties of Avpr1b-expressing cells at different dorsoventral levels. We next probed for Avpr1b modulatory effects using exogenous application of an Avpr1b-selective agonist. We found that Avpr1b activation increases the excitability of Avpr1b-expressing cells. These findings expand on our previous studies by providing a more detailed understanding of the hippocampal Avpr1b-expressing circuit and Avp-Avpr1b signaling in the CA2 area.

Title: Structure-activity relationships of psilocybin analogs at serotonin 5-HT_2 receptor subtypes

Authors: *A. K. KLEIN[1], J. D. MCCORVY[2], S. D. BRANDT[3], A. L. HALBERSTADT[1]; [1]Psychiatry, UCSD Med. Ctr., San Diego, CA; [2]Med. Col. of Wisconsin, Wauwatosa, WI; [3]Liverpool John Moores Univ., Liverpool, United Kingdom

Abstract: In recent years, there has been increasing scientific interest into the effects and pharmacology of serotonergic hallucinogens. In addition, many structural analogs of controlled

hallucinogens have appeared as new designer drugs. While a large amount of experimental work has been conducted to characterize the effects of the tryptamine hallucinogen psilocybin (4-phosphoryloxy-*N*,*N*-dimethyltryptamine), there has been little systematic investigation of the structure-activity relationships (SAR) of other 4-substituted tryptamine derivatives. The present investigation attempts to address the gap of information. SAR studies were conducted with 16 tryptamines containing a variety of *N*,*N*-dialkyl substituents (methyl, ethyl, propyl, isopropyl, or allyl) and either a 4-hydroxy or a 4-acetoxy group. The ability of these compounds to activate human 5-HT_2 subtypes (5-HT_{2A}, 5-HT_{2B} and 5-HT_{2C}) was assessed using calcium mobilization assays. Head twitch response (HTR) studies were conducted in C57BL/6J mice to assess activation of the 5-HT_{2A} receptor (the site primarily responsible for hallucinogenesis) *in vivo*. The HTR was detected using a head-mounted neodymium magnet and a magnetometor coil; compounds were injected IP and head twitch counts were assessed over 30 min. The tryptamines acted as full or partial agonists at 5-HT_2 subtypes. Although the compounds displayed approximately equal potency at 5-HT_{2A} and 5-HT_{2B} sites, they typically had >10-fold lower potency at 5-HT_{2C} sites. In addition, *O*-acetylation reduced the 5-HT_{2A} agonist potency of 4-hydroxylated tryptamines by about an order of magnitude. All of the compounds induced head twitches in mice, consistent with an LSD-like behavioral profile. Most of the compounds had about the same potency as psilocybin (ED_{50} = 1.40 µmol/kg IP) in the HTR assay, indicating that the specific *N*,*N*-dialkyl substitution pattern is not a major determinant of behavioral potency in mice. Furthermore, in contrast to the *in vitro* data, *O*-acetylation of the 4-hydroxy group had little effect on HTR potency. These findings shed light on the SAR of *N*,*N*-dialkyltryptamines containing a 4-oxygenated substituent. The tryptamine derivatives have psilocybin-like pharmacological properties, supporting their classification as serotonergic hallucinogens. Psilocybin is rapidly *O*-dephosphorylated to psilocin (4-hydroxy-*N*,*N*-dimethyltryptamine) *in vivo* and is thought to act as a pro-drug; comparison of the *in vivo* and *in vitro* potencies of the 4-acetoxy-*N*,*N*-dialkyltryptamines indicates that these compounds may also serve as pro-drugs for their *O*-deacetylated derivatives.

Title: EEG correlates of the head twitch response induced by 5-HT_{2A} receptor agonist 25I-NBOH

Authors: *A. CONTRERAS, M. KHUMNARK, R. M. HINES, D. J. HINES;
Psychology, Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Serotonin (5-HT) is an evolutionarily conserved neuromodulator known to regulate attention and perception, as well as stabilize mood. Of the 5-HT receptor types, the 5-HT2A receptor is highly enriched in the frontal cortex and thought to mediate attentional processes. The 5-HT2A receptor also appears to be central to the mechanism of action for classical hallucinogens, with behavior like the head twitch response (HTR) in rodents serving as an assay for 5-HT2A activation and potential hallucinogenic effects. While the HTR provides a behavioral profile of 5-HT2A activation, less is known about the circuit level changes induced by hallucinogenic compounds acting at the 5-HT2A receptor. To better understand these changes, we used a combination of behavioral assays and EEG to characterize the HTR response in mice after administration of the potent and highly selective 5-HT2A receptor agonist 25I-NBOH. In the open field, mice injected with 25I-NBOH exhibited a robust HTR and a disorganization of behavior which included frequent stops. Treated animals displayed the HTR as early as 3 minutes after drug administration, which confirms findings from previous studies characterizing the HTR using other 5-HT2A agonists. We also observed that as the 60-minute testing period progressed, the HTR became less frequent and animals had longer stops. We then performed a series of EEG studies to understand the patterns of activity that underlie the HTR. We found that a characteristic pattern composed of two distinctive waveforms (Phase I and Phase II) occurred after injection of 25I-NBOH. This pattern also correlates temporally with the HTR, with Phase I most commonly preceding the HTR and Phase II mapping directly onto the HTR. Data suggests that dual administration of nicotine and hallucinogenic compounds alters the HTR effects, and we found that mice given a pretreatment of nicotine before 25I-NBOH injection exhibit an attenuated HTR along with alterations in the waveform patterns observed in 25I-NBOH alone.
Our findings contribute to our understanding of 5-HT2A actions, with major implications for clarifying the role of serotonergic and cholinergic signaling in the cortex for novel therapies.

Title: The effects of cannabinoid-type 1 receptor biased agonism on cellular signaling

Authors: *H. K. ANDERSEN, K. B. WALSH;
Univ. of South Carolina - Sch. of Med., Columbia, SC

Abstract: Biased agonists stabilize receptor conformations that preferentially stimulate cell signaling pathways. Cannabinoids have been found to have biased effects on the cannabinoid-type 1 (CB1) receptor when stimulating the inhibitory G protein (G_i) and β-arrestin pathways. Binding of cannabinoids to the CB1 receptor causes a dissociation of G_i into $G\beta\gamma_i$ and $G\alpha_i$ subunits, which mediate neuronal activity. An intriguing question remains whether cannabinoids differentially induce $G\beta\gamma_i$ and $G\alpha_i$ effects. In this study we examined CB1 receptor activation of the G protein-gated inward rectifier potassium (GIRK) channel (a $G\beta\gamma_i$ mediated effect) using a fluorescent assay developed in our lab. Since $G\alpha_i$ inhibits adenylyl cyclase, we used a cAMP ELISA to quantify cannabinoid-induced cAMP suppression. Data from both assays were measured using a pituitary cell line (AtT20) that endogenously express GIRK channels and was transduced with the human CB1 receptor (AtT20/CB1). Six cannabinoids including, WIN 55,212, AM1248, Anandamide, BAY 59-3074, CP 55,940 and Δ9-tetrahydrocannabinol (THC) were tested in the assays. All of the cannabinoids caused a strong suppression of forskolin/IBMX-stimulated cAMP production (ranging from 70 ± 5 % for Anandamide to 79 ± 4 % with WIN 55,212). In contrast, when normalized to GIRK channel activation caused by WIN 55,212 (100 %), the cannabinoids showed striking differences in their abilities to activate the GIRK channel (ranging from 136 ± 4 % for Anandamide to 13 ± 6 % with BAY 59-3074). In conclusion, our data suggest that cannabinoids may differentially stimulate the $G\beta\gamma_i$ subunit.

Title: C-terminal phosphorylation of latrophilin-1 regulates the interaction between its fragments

Authors: *O. BENLAOUER[1], M. ATIQUR RAHMAN[2], C. MANSER[2], J. SILVA[3,2], Y. USHKARYOV[1,2];

Abstract: Latrophilin-1 (LPHN1), is a presynaptic adhesion G protein-coupled receptor (aGPCR), present mainly in the brain. It binds several ligands, including α-latrotoxin (α-LTX) from black widow spider venom, which causes a massive mobilisation of stored calcium and release of neurotransmitters from nerve terminals. As a typical aGPCR, LPHN1 undergoes autoproteolysis within the "GPCR autoproteolysis-inducing" (GAIN) domain, which produces two fragments: the extracellular N-terminal fragment (NTF) and the heptahelical C-terminal fragment (CTF). The NTF and CTF of LPHN1 can exist as independent proteins in the plasma membrane. However, the binding of α-LTX or another ligand to NTF induces its association with the CTF and triggers G protein-mediated signalling. The functions of most GPCR are usually critically controlled by their C-terminal phosphorylation. However, CTF phosphorylation in LPHN1 has not been described yet and what role CTF phosphorylation could play in LPHN1 functions remains to be seen.
Post-translational modifications of the CTF in native and recombinant LPHN1 were analysed using glycohydrolases, alkaline phosphatase and protein phosphatase inhibitors. The differentially phosphorylated species of CTF were resolved by SDS electrophoresis without sample boiling, followed by western blot analysis. The interaction between the NTF and CTF was tested by affinity chromatography on α-LTX or wheat germ agglutinin (WGA) columns and by centrifugation in sucrose density gradients.
Our results demonstrate that a large percent of LPHN1 CTF in central nerve terminals is phosphorylated at several sites. Phosphorylated CTF co-purifies with the NTF on affinity columns and on sucrose density gradients. On the other hand, dephosphorylated CTF largely behaves as an independent protein. This indicates that the NTF of LPHN1 has a much higher affinity for the phosphorylated form of CTF. The binding of α-LTX to the complex of NTF with phosphorylated CTF leads to CTF dephosphorylation by presynaptic protein phosphatases and release of CTF from the NTF-CTF complex. Taken together, our results suggest that phosphorylation and dephosphorylation of LPHN1 depends on ligand binding, which regulates the interaction between its fragments and its function as a G protein-coupled receptor.

Title: Clinical study of the expression of cannabinoid receptors in temporal lobe epilepsy: Role of cannabinoid receptors in the regulation of α-synuclein expression in neuronal cells

Authors: *G. A. CARRASCO, S. VIMAWALA, J. KUSUSKY, N. PARIPATI, T. N. FERRARO, R. J. BUONO;
Biomed. Sci., Cooper Med. Sch. of Rowan Univ., Camden, NJ

Abstract: Temporal lobe epilepsy (TLE) is the most common form of refractory focal epilepsy and is usually regarded as a multifactorial polygenic disorder. Data from clinical studies suggest that cannabidiol and Δ^9-tetrahydrocannabinol may be effective in the prevention of seizures in some TLE patients. Here we used Western blots to study the protein expression of CB_1 and CB_2 cannabinoid receptors in human temporal lobe (Broadman area 39) from TLE and control patients. As recent studies describe α-synuclein deposits in some forms of epilepsy, the expression of this protein in human temporal lobe was also studied by Western blots. Further, we used Western blots and qRT-PCR to assess the effect of cannabinoid agonists on the expression of α-synuclein in rat prefrontal cortex (PFCx), and the regulation of its expression by selective cannabinoid agonists in a neuronal cell model, CLU213 cells.
Preliminary results revealed a significant ($p<0.05$) increase in both CB_1 and CB_2 protein levels in TLE patients (n=20) compared to controls (n=3) (45% and 30% increase for CB_1 and CB_2 receptors, respectively). The expression of 5-HT_{2A} receptors and GRK5 proteins was not significantly ($p>0.05$) different between the two groups. An approximately 25% increase ($p<0.05$) in α-synuclein protein expression in temporal cortex was found in TLE patients compared to controls.
In our preclinical studies, rats were injected with a non-selective CB_1/CB_2 receptor agonist, CP55940 (50 μg/kg, 7 days, ip). We found a significant ($p<0.05$) 20% reduction in α-synuclein mRNA levels in CP55940 treated-animals (n=6) compared to controls (n=6). Further studies conducted in CLU213 cells (n=6) showed that α-synuclein expression was significantly ($p<0.05$) reduced by either 1um or 1nM CP55940 incubation (45% an 35% inhibition, respectively). Preliminary data (n=3) using selective CB_1 (ACEA) or CB_2 (GP1a) cannabinoid receptor agonists suggests that activation of CB_2 receptors produces a stronger inhibition of α-synuclein mRNA expression than CB_1 receptors.
Overall, these studies support a rationale for the use of selective cannabinoid agonists in the reduction of brain α-synuclein and in the possible treatment of some forms of TLE.

Title: Glutamate receptors interactions and Alzheimer's disease

Authors: *M. V. VASEFI[1], K. MEEUWSEN[1], P. WARWICK[1], A. HAMILTON[2], S. FERGUSON[3];
[1]Lamar Univ., Beaumont, TX; [2]Univ. of Ottawa, Ottawa, TX, Canada; [3]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Alzheimer's disease (AD) is the seventh leading cause of death in the United States, affecting 5.5 million Americans with the number expected to double by 2050. As such, AD is expected to be a major public health problem in the upcoming decades. AD exhibits a primary hallmark of early deposition of Amyloid-Beta (Aβ) oligomers, which play a major role in the neuropathology of the disease. Glutamate receptors function as cellular binding sights for Aβ oligomers, resulting in receptor clustering and synaptic dysfunction. Aβ oligomer has also been shown to interact with metabotropic glutamate receptor subtype 5 (mGluR5). The extracellular building of Aβ/mGluR5 changes the receptor signaling and trafficking in the cells. Interactions between mGluR5 and N-methyl-D-aspartate (NMDA) receptors have been described previously. mGluR5 is a positive modulator of NMDA receptors. Agonist manipulation of mGluR5 reverses several NMDA antagonist-induced responses. NMDA receptors are tetrameric channels composed of two NR1 and two NR2 or NR3 subunits. It is indicated that the NMDA receptor composition, specifically the NR2 subunit, that dictates whether NMDA receptor activation will promote cell death (NR2B) or cell survival (NR2A). This work focuses on the interaction of the Aβ/mGluR5 and NMDA receptor, with a focus on NR2B containing NMDA receptor, expanding the view beyond a single receptor or a signaling pathway in AD. The increased in surface expression of NR2B containing NMDA receptor was observed in the present of Aβ in the neurons however, mGluR5 antagonist, CTEP, blocked the effect. Upregulated NR2B containing NMDA receptor display changes in the trafficking which induced by the activity of the mGluR5 in the present of Aβ oligomers. The mechanisms by which the activity of the NMDA receptor is altered by the formation of Aβ/mGluR5 complex, result in an understanding of neuronal receptor trafficking and synaptic plasticity in AD.

Title: Molecular mechanisms of superagonism elicited by synthetic cannabinoid actions on CB1 receptors

Authors: *H. YANO[1], A. F. HOFFMAN[2], C. R. LUPICA[2], M. H. BAUMANN[3], L. SHI[4]; [2]Electrophysiology Res. Section, [3]Designer Drug Res. Unit, [4]Computat. Chem. and Mol. Biophysics Unit, [1]Natl. Inst. on Drug Abuse IRP, Baltimore, MD

Abstract: Misuse of synthetic cannabinoids (SCs) continues to increase worldwide and is often associated with serious adverse effects including hallucinations, cardiovascular abnormalities, coma, or death. Many SCs are aminoalkylindole molecules that are distinct from the naturally occurring psychoactive phytocannabinoid, Δ^9-tetrahydrocannabinol (Δ^9-THC), found in cannabis. It is established that Δ^9-THC is a partial agonist at cannabinoid CB1 receptors, whereas SCs demonstrate much higher efficacy and potency at this site, and this likely relates to a much higher incidence of medically adverse effects. Moreover, some SCs exhibit a maximal efficacy at CB1 receptors that exceeds that seen with typical full agonists, and this has been termed "superagonism". Additionally, superagonism is usually associated with increased potency at CB1 receptors. At present, it is unknown whether these unique pharmacological characteristics at CB1 receptors directly relate to the adverse effects of some SCs, or whether their actions at non-CB1 sites may also be involved. In the current study, we examined molecular mechanisms of superagonism of SCs at CB1 receptors.
We first tested a series of SCs in our bioluminescence resonance energy transfer (BRET) assay in a CB1-Gi protein engagement configuration. Unlike other receptor function assays, this approach avoids caveats associated with signal amplification that can lead to false-positives for superagonism. Based on the structure-activity relationship for superagonism established by this BRET assay, we then performed molecular dynamics simulations of the CB1 receptor complexed with selected SCs to identify the molecular determinants of SC binding efficacy, and to characterize superagonism conformational states of the CB1 receptor-SC complex. Finally, to evaluate superagonism of selected SCs at CB1 receptors, we will perform electrophysiological experiments in hippocampal brain slices from both wildtype and CB1 knockout mice to determine effects of these SCs on glutamate release inhibition mediated by CB1 receptors, and to evaluate potential off-site effects of these drugs. In summary, our findings delineate molecular

mechanisms of superagonism at CB1 receptors and further our understanding of the mechanisms through which SCs may cause serious adverse health effects.

Title: Distinct phosphorylation sites/clusters in the carboxyl terminus regulate alpha1D-adrenergic receptor subcellular localization and signaling

Authors: ***G. CARMONA ROSAS**[1], D. HERNANDEZ ESPINOSA[2], R. ALCANTARA HERNANDEZ[2], M. ALFONZO MENDEZ[3], J. GARCIA SAINZ[2];
[1]Univ. of Chicago, Chicago, IL; [2]UNAM, Mexico, Mexico; [3]NIH, Baltimore, MD

Abstract: The human α1D-adrenergic receptor is a seven transmembrane-domain protein that mediates many of the physiological actions of adrenaline and noradrenaline and participates in the development of hypertension and benign prostatic hyperplasia.
We recently reported that different phosphorylation patterns control α1D-adrenergic receptor desensitization. However, to our knowledge, there is no data regarding the role(s) of this receptor's specific phosphorylation residues in its subcellular localization and signaling. In order to address this issue, we mutated the identified phosphorylated residues located on the third intracellular loop and carboxyl tail. In this way, we experimentally confirmed α1D-AR phosphorylation sites and identified, in the carboxyl tail, two groups of residues in close proximity to each other, as well as two individual residues in the proximal (T442) and distal (S543) regions. Our results indicate that phosphorylation of the distal cluster (T507, S515, S516 and S518) favors α1D-AR localization at the plasma membrane, i. e., substitution of these residues for non-phosphorylatable amino acids results in the intracellular localization of the receptors, whereas phospho-mimetic substitution allows plasma
membrane localization. Moreover, we found that T442 phosphorylation is necessary.
for agonist- and phorbol ester-induced receptor colocalization with β-arrestins.
Additionally, we observed that substitution of intracellular loop 3 phosphorylation sites for non-phosphorylatable amino acids resulted in sustained ERK1/2 activation; additional mutations in the phosphorylated residues in the carboxyl tail did not alter this pattern. In contrast,

mobilization of intracellular calcium and receptor internalization appear to be controlled by the phosphorylation of both third-intracellular-loop and carboxyl terminus-domain residues. In summary, our data indicate that a) both the phosphorylation sites present in the third intracellular loop and in the carboxyl terminus participate in triggering calcium signaling and in turning-off α1D-AR-induced ERK activation; b) phosphorylation of the distal cluster appears to play a role in receptor's plasma membrane localization; and c) T442 appears to play a critical role in receptor phosphorylation and receptor-β-arrestin colocalization.

Title: Characterization of an intranuclear β1-adrenergic receptor signaling pathway in astrocytes

Authors: *K. C. BENTON, D. S. WHEELER, M. B. ANSARI, B. KURTOGLU, A. DOOHAN, S. KHURSHEED, R. KNORR, J. MAGLASANG, D. C. LOBNER, P. J. GASSER; Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: The classical model of adrenergic signaling involves activation of G-protein-coupled receptors localized to the plasma membrane. A growing body of evidence suggests that adrenergic receptor signaling can also be initiated at intracellular membranes. We have recently identified β1-adrenergic receptors (β1-AR) localized to the nuclear envelope in cultured cortical astrocytes and have obtained evidence that ligand-induced activation of these nuclear receptors initiates G-protein mediated signaling in the nuclear compartment. These data have led to the hypothesis that, in addition to its plasma membrane receptor-mediated actions, norepinephrine (NE) can exert actions directly at the nucleus. Access of NE to nuclear membrane-localized receptors would require transport of the ligand across both plasma and outer nuclear membranes. Previous studies demonstrated that organic cation transporter 3 (OCT3), a high-capacity transporter for NE and other monoamines, is localized to both plasma membranes and outer nuclear membranes in astrocytes and neurons. The present studies examine the expression and localization of other monoamine transporters in cultured cortical astrocytes to fully describe potential mechanisms by which NE may access nuclear β1-AR. Reverse transcriptase PCR revealed the expression of mRNA for the uptake$_1$ transporters for NE (NET), dopamine (DAT), and serotonin (SERT), as well as the uptake$_2$ transporters PMAT (plasma membrane monoamine

transporter), OCT1, OCT2, and OCT3 in cortical astrocytes. Subcellular fractionation followed by western blot analysis was used to examine nuclear and plasma membrane distribution of these transporters. Immunoreactivity for NET, OCT2, OCT3, and PMAT was observed in both plasma membrane and nuclear fractions in these studies. To examine the potential role of these transporters in gating activation of nuclear β1-AR, cultured astrocytes were transfected with cytoplasmic- or nuclear-localized FRET sensors for cAMP based upon Epac (Exchange protein activated by cAMP). Treatment of astrocytes with NE led to increases in cAMP in both cytosolic and nuclear compartments. Ongoing experiments will further investigate the role of plasma and nuclear localized monoamine transporters in cytosolic and nuclear NE-induced cAMP responses.

Title: Phosphorylation of STAT3 by human serotonin 2C receptor in IDI and INI isoforms

Authors: Z. MILETIC LANAGHAN, M. MAISHA, M. CURTIS, L. FEARS, M. IVY, *H. M. FENTRESS;
Tennessee State Univ., Nashville, TN

Abstract: Serotonin (5-HT) is an indolamine neurotransmitter involved in a variety of functions including regulation of mood, appetite, sleep, learning, memory, and neuronal excitability. 5-HT elicits its effects by binding to at least 14 different receptor subtypes. One of the receptors, the 5-HT_{2C} receptor, has been studied and used as a target for atypical antipsychotic medication. 5-HT_{2C} subtype receptor exists as a 7-transmembrane spanning G protein-coupled receptor (GPCR) found in the central nervous system, and is the only GPCR known to undergo RNA editing, creating at least14 known isoforms in the human brain which affect its ability to couple with G proteins and other signaling proteins. The structurally similar 5-HT_{2A} receptor has been shown to activate the G protein independent JAK/STAT pathway. The purpose of this study was to explore if and how the human 5-HT_{2C} receptor also activates the JAK/STAT pathway by studying different isoforms of the receptor and comparing acute versus chronic treatments. Human Embryonic Kidney (HEK) 293 cells were transfected with human 5-HT_{2C} receptors in both the IDI and INI isoforms to produce stable cell lines. 5-$HT_{2C\text{-}IDI}$ receptor transfected cells

were treated with vehicle (control), 5-HT, olanzapine (neutral antagonist), or SB206553 (inverse agonist) for 30 minutes (acute) and 1 hour (chronic). 5-$HT_{2C\text{-}INI}$ receptor transfected cells were treated with control, 5-HT, and olanzapine for 30 minutes. Treated cells were lysed, proteins were separated by SDS-PAGE, and levels of phosphorylated JAK2, phosphorylated STAT3, and unphosphorylated STAT3 were analyzed using western blots. In cells treated for 30 minutes with vehicle, phosphorylation of STAT3 was observed in cells transfected with the 5-HT_{2C} receptor but not in untransfected cells indicating constitutive phosphorylation of STAT3 by the 5-HT_{2C} receptor. Upon treatment with serotonin, phosphorylated levels of STAT3 were increased in cells expressing the 5-HT_{2C} receptor in both isoforms while STAT3 phosphorylation was completely blocked with cells treated with olanzapine or SB206553 for 30 minutes, suggesting that these two compounds were inverse agonists. However, in the 1 hour treatment, olanzapine did not block constitutive phosphorylation which is expected if it is a neutral antagonist. This suggests that olanzapine may have a delayed effect. Phosphorylated levels of JAK2 were unaffected across all treatments in 5-$HT_{2C\text{-}IDI}$ receptors. These findings indicate that 5-HT_{2C} receptors are activating STAT3 independently of JAK2 and olanzapine behaves differently depending on the length of treatment. Acting on STAT3 may be the mechanism for how antipsychotics work.

Title: Differential modulation of L-type channel activity by G-protein coupled receptors

Authors: *K. N. MAN[1], J. W. HELL[2];
[1]Pharmacol., Univ. of California, Davis, Davis, CA; [2]Dept. of Pharmacol., UC Davis, Davis, CA

Abstract: L-type calcium channels Cav1.2 and Cav1.3 play pivotal roles in neuronal functions, including control of neuronal excitability, vesicular neurotransmitter release and initiation of gene transcription. In particular, Cav1.2 is required for certain forms of long-term potentiation in the hippocampus and for an intact spatial memory. Mutations in Cav1.2 underlies Timothy syndrome, which presents with arrythmia and autism spectrum disorder. Studying regulation of L-type channel function by neuromodulators will provide insights into mechanisms for memory formation and inform the development of therapeutics on the restoration of channel function.

Here we show that dopamine D1-like receptor regulates L-type channel activity in hippocampal neurons in a local manner. The D1-like receptor agonist SKF81297 potentiates L-type activity when included in the patch pipette but not when in the external solution during cell-attached single-channel recording in rat and mouse hippocampal neurons isolated from the CA1 region. The effect is specifically mediated by D1-like D1 and/or D5 receptor, as it can be blocked by D1-like blocker SCH23390. In contrast, α_1-adrenergic receptor (α_1-AR) agonist phenylephrine potentiates L-type activity when included in the external solution, but not when included in the patch pipette. Stimulation by muscarinic receptor agonist muscarine and/or mGluR Group I receptor agonist DHPG by inclusion in the external solution had no effect. Inhibition of PKA activity abrogates the effect of D1-like receptor activation on the increase in L-type activity. Preliminary data show that D1-like receptor stimulation increases phosphorylation of serine at position 1928 on the α_1 subunit of Cav1.2. D1-like potentiation of L-type activity is abrogated in mice expressing a mutant Cav1.2 defective of S1928 phosphorylation (S1928A knockin mutant). These results show that D1-like receptors are localized in close proximity to L-type channels to the region delimited by the patch pipette. D1-like receptor potentiates L-type calcium channel activity in hippocampal neurons, possibly through a canonical PKA-dependent mechanism. Phosphorylation of Cav1.2 S1928 is required for L-type activity upregulation. How localized signaling to channels by D1-like receptor occurs and the physiological significance of the regulation remains to be established.

Title: The effect of Resveratrol on ocular regeneration on Dugesia dorotocephala

Authors: *N. FERRARO, A. CICCOTTO;
St. Joseph By the Sea HS, Staten Island, NY

Abstract: *Dugesia dorotocephala* are flat, soft-bodied worms with regenerative abilities. Planaria can regenerate any part of the body including the central nervous system and can reproduce sexually as well as asexually. They have a triploblastic body plan and an abundance of adult stem cells. Also known as Neoblasts, they are naturally occurring pluripotent adult stem cells. Resveratrol is a phytoalexin that is commonly found in grape skins and has been found to counteract the oxidation of low-density lipoproteins with ethanol (ETOH) which acts as an increase of circulating high-density lipoproteins that can help for cardiovascular protection. Resveratrol is also known to act as an antioxidant by preventing the oxidation of polyunsaturated

fatty acids which can reduce the risk of heart disease. **β**;;;-Arrestins 1 and 2 belong to a family of adapter proteins associated with rod and cone cells of the eye. Arrestin plays a role in desensitization of G-protein coupled receptors or 7TMR (7 transmembrane receptors) in the **β**;;;$_2$AR pathway and Rhodopsin photosensing pathway. Arrestin proteins function as adapter proteins as well as participate in desensitization of 7TMRs. Binding of β;;-arrestin to the phosphorylated receptor desensitizes the receptor by inhibiting the interaction between the 7TMR and G-protein marking the receptor for sequestration into an endosome. In the current study, planaria were decapitated and arrestin was used as a biomarker for ocular regeneration upon treatment with resveratrol.

Title: Using receptor kinetics to quantitatively measure agonist bias at G-protein coupled receptors

Authors: S. MARTINKA[1], S. HOARE[2], K. HARLEN[1], A. QUINN[1], P. TEWSON[1], ***T. E. HUGHES**[1];
[1]Montana Mol., Bozeman, MT; [2]Pharmechanics, Owego, NY

Abstract: Biased agonism is a crucial concept in the search for drugs that produce analgesia without addiction. G-protein coupled receptors can signal through two different pathways: the G-proteins for which they were named, and β-arrestin. These two different pathways can mediate very different cellular responses, and some agonists at a particular receptor can be biased towards the activation of one of the pathways, a phenomenon known as biased agonism. This bias is typically measured by comparing two different end-point assays for G-protein and β-arrestin signaling. Such a comparison is difficult, and different results can be produced by measuring at different time points [1]. We recently created a green fluorescent β-arrestin sensor that can be used to follow the signaling over time in living cells. This kinetic measurement can be compared to G-protein signaling measured with sensors to Ca^{2+}, cAMP, or DAG. To determine whether the kinetics of the responses of these pathways could be used to determine bias, we measured the responses of the Angiotensin II receptor over time (~ 15 min.) to a panel of known biased agonists (at saturating concentrations). Treating the receptor as an enzyme, and fitting the responses enabled us to extract the initial rate of the reaction (kTau) for the activation

of the β-arrestin or G-protein signaling [2]. The ratio of kTau produced a precise, reproducible measure of bias that was consistent with the literature. We are currently testing whether this approach will be useful in the search for biased agonists at receptors that are involved in pain and addiction.

Title: Engineered zinc binding in the orthosteric binding site of beta$_2$-adrenergic receptor and trace amine-associated receptor 1 (TAAR1)

Authors: T. RUEDLIN[1], A. ZEGLEN[2], C. KARL[2], *Y. NORIMATSU[1];
[1]Physiol., A.T. Still Univ., Kirksville, MO; [2]Truman State Univ., Kirksville, MO

Abstract: Trace amine-associated receptor 1 (TAAR1) is a G protein-coupled receptor and a promising drug target for schizophrenia, major depression, and drug addiction. TAAR1 is expressed in the major monoaminergic pathways, including the ventral tegmental area, substantia nigra, locus coeruleus, raphe nucleus, caudate nucleus, putamen, nucleus accumbens and amygdala, and activated by a wide range of trace amines and monoamines. G protein dependent

signaling (increased cyclic AMP and stimulation of G protein-gated inward rectifying potassium channels) and beta-arrestin 2-dependent signaling are observed with receptor activation. In order to understand the activation mechanism of TAAR1, we created homology models of the active and inactive states based on X-ray crystal structures of beta2-adrenergic receptor (b2AR) and ran molecular dynamics simulations. A group led by Thue W. Schwartz previously showed that a single amino acid substitution, N312C enables zinc to activate b2AR. We tested this engineered zinc binding site in b2AR and also a corresponding mutation in TAAR1 in the *Xenopus* oocyte heterologous expression system using the two-electrode voltage clamp technique.

Title: Pharmacological identification of cholinergic receptor subtypes in modulation of neural circuits in *Drosophila melanogaster*

Authors: *U. BHUTTO[1], E. SOMASUNDARAM[2], C. MALLOY[3], R. L. COOPER[4];
[1]Biol., [2]Univ. of Kentucky, Lexington, KY; [3]Mol. Neurophysiol. and Biophysics, Natl. Inst. of Hlth. Office of Intramural, Bethesda, MD; [4]Dept Biol, Univ. of Kentucky Dept. of Biol., Lexington, KY

Abstract: Acetylcholine (ACh) is an abundant neurotransmitter and neuromodulator in many species. In Drosophila melanogaster ACh is the neurotransmitter used in peripheral sensory neurons and is a primary excitatory neurotransmitter and neuromodulator within the central nervous system (CNS). The receptors that facilitate cholinergic transmission are divided into two broad subtypes: the ionotropic nicotinic acetylcholine receptors (nAChRs) and the metabotropic muscarinic acetylcholine receptors (mAChRs). This receptor classification is shared in both mammals and insects; however, both the pharmacological and functional characterization of these receptors within the Drosophila nervous system has lagged behind its mammalian model counterparts. In order to identify the impact of ACh receptor subtypes in regulating the performance of neural circuits within the larval CNS, we used a behavioral and electrophysiological approach to assess cholinergic modulation of locomotion sensory-CNS-motor circuit excitability. We exposed intact and semi-intact 3rd instar larvae to ACh receptor

agonists and antagonists to observe their roles in behavior and regulation of neural circuit excitability and to investigate AChR pharmacological properties in vivo. We combined this with targeted AChR RNAi-mediated knockdown to identify specific receptor subtypes facilitating ACh modulation of circuit efficacy. We identify a contribution by both mAChRs and nAChRs in regulation of locomotive speed and reveal that they play a role in modulation of the excitability of a sensory-CNS-motor circuit. We further reveal a conspicuous role for mAChR-A and mAChR-C in motor neurons, directly, in modulation of their input-output efficacy in response to evoked sensory-CNS input, which is also manifested in alterations in locomotive speed.

Title: Ziram, a pesticide associated with Parkinson's disease, increases excitability in aminergic and glutamatergic neurons through inhibition of the eag potassium channel

Authors: *J. HARRIGAN[1], D. F. BRAMBILA[4], F. E. SCHWEIZER[4,2], D. E. KRANTZ[5,3]; [1]Mol. Toxicology, UCLA, Los Angeles, CA; [2]Brain Res. Inst., UCLA, Los Angleles, CA; [3]Brain Res. Inst., UCLA, Los Angeles, CA; [4]Neurobio., [5]Psychiatry and Biobehavioral Sci., UCLA, David Geffen Sch. of Med., Los Angeles, CA

Abstract: Exposure to environmental toxins, including the fungicide ziram, has been linked to an increased risk of PD. We tested the neurophysiological effects of acute ziram exposure at the *Drosophila* larval neuromuscular junction (NMJ; see also poster by Brambila et al). Using calcium indicators, we find that ziram increases excitability in aminergic neuronal processes at the NMJ. Ziram also evokes calcium signals in cell bodies of the ventral nerve code, but only when the processes are intact, suggesting that ziram acts on aminergic process. Using electrophysiological recordings of post-synaptic activity at the NMJ we find that ziram enhances excitability of glutamatergic neurons. Potassium channels are one of the regulators of neuronal excitability, we tested whether potassium channel mutants would phenocopy the excitability increase of ziram. Mutant flies that lack the *ether-a-go-go* (*eag*) but not those that lack the Shaker potassium channel phenocopy ziram's excitability effects. We hypothesize that the

increase in neuronal excitability by ziram could represent an early pathological process that may contribute to the increased risk of developing PD.

Title: Molecular and circuit mechanisms underlying sustained anti-depression effects of subanesthetic ketamine

Authors: *X. QIAO[1], S. GRIECO[2], X. XU[3];
[1]Univ. of California Irvine, Irvine, CA; [2]Anat. and Neurobio., UCI, Newport Beach, CA; [3]Anat. and Neurobio., Univ. California, Irvine, Irvine, CA

Abstract: Subanesthetic-dose ketamine is shown to have sustained antidepressant effects, which offers a potential for developing effective antidepressants. However, it is crucial to better understand the mechanisms underlying ketamine's antidepressant action. Preclinical studies indicate that ketamine's antidepressant mechanisms involve mammalian target of rapamycin pathway activation and subsequent synaptogenesis in the prefrontal cortex. As neuregulin-1 (NRG1)/ErbB4 signaling in parvalbumin (PV) interneurons regulates cortical plasticity, we hypothesize that ketamine's antidepressant action depends on modulation of cortical plasticity through NRG1/ErbB4 signaling in PV interneurons. We find that NRG1 signaling is implicated in acute and sustained ketamine's antidepressant effects by using forced swim test (FST). Pretreating mice with exogenous NRG1 suppresses FST effects of ketamine treatment at 30 minutes or 24 hours post ketamine injection; PV ErbB4 KO mice do not show antidepressant-like FST behavior with ketamine treatment. We identify that in vivo single-dose ketamine treatment results in sustained down-regulation of NRG1 expression in PV interneurons in mouse prefrontal cortex at 24, 48 and 72 hours post treatment. Translating ribosome affinity purification was employed to measure cell-specific mRNAs under different conditions. In contrast, there is no significant change of NRG1 expression in excitatory neurons following ketamine treatment. To examine if subanesthetic ketamine increases cortical excitability by reducing synaptic inhibition to excitatory pyramidal neurons, we recorded electrically-evoked inhibitory postsynaptic currents (IPSCs) in pyramidal neurons in prefrontal cortical layer 2/3. Low-dose ketamine treatment induces sustained decrease in IPSCs in pyramidal neurons at 24, 48 and 72

hours after ketamine injection. Exogenous NRG1 application restores reduced inhibitory inputs onto pyramidal neurons. We further mapped excitatory inputs (EPSCs) onto PV interneurons in prefrontal cortical layer 2/3 using laser scanning photostimulation (LSPS) in brain slices. We find that excitatory inputs onto PV interneurons are reduced in ketamine-treated mice at 24 hours after injection and that exogenous NRG1 application restores the reduced excitatory inputs onto PV neurons. Our results demonstrate that subanesthetic ketamine treatment induces sustained cortical disinhibition by downregulating NRG1 signaling in PV interneurons. Our results reveal molecular and circuit mechanisms of sustained antidepressant action of ketamine and provide insights in developing new effective treatments for depression.

Title: Potential novel treatments for the nicotinic effects of nerve agent poisoning

Authors: C. L. WHITMORE, A. C. GREEN, *J. E. H. TATTERSALL;
Toxicology, Trauma and Med. Group, Dstl, Salisbury, United Kingdom

Abstract: Nerve agents inhibit the enzyme acetylcholinesterase (AChE), resulting in an accumulation of acetylcholine (ACh) at cholinergic synapses, including the neuromuscular junction. This ACh accumulation at both muscarinic (mAChR) and nicotinic (nAChR) receptors leads to the toxic effects of nerve agent poisoning, including increased secretions, miosis, changes in heart rate, muscular paralysis, seizures and respiratory depression. Current nerve agent treatments contain a muscarinic antagonist (usually atropine) to reduce the effect of excess ACh at mAChR, an oxime to restore AChE activity and a benzodiazepine to reduce or prevent seizures. In this combination, the oxime is the only component targeting overstimulation of the nAChR, albeit indirectly. The reliance on oxime enzyme reactivators is a fundamental weakness in this approach, since no single oxime demonstrates adequate reactivating activity against all the known nerve agents. Nicotinic antagonists have been largely neglected in nerve agent poisoning, mainly due to the difficulty of administering an effective dose which avoids toxic effects of the antagonist [1]. We have previously shown that administration of MB327, a non-competitive nAChR antagonist, restored function in nerve agent-poisoned muscle preparations *ex vivo* and protected guinea-pigs against nerve agent exposure as part of a therapeutic drug combination [1]. These results demonstrate the benefit of effective nAChR treatment, but the toxicity of MB327 is still a problem for practical use. Here, the results of two different approaches to reducing overstimulation at the neuromuscular junction are described, the use of nAChR modulators and

production, *in situ*, of the false transmitters acetylmonoethylcholine and acetyldiethylcholine by administration of monoethyl- and diethylcholine, respectively. Using an automated patch clamp system, we investigated the effect of neuronal nAChR modulators at human muscle type nAChRs ($\alpha_1\beta_1\delta\ \gamma/\varepsilon$) in CN21 cells *in vitro*. We also characterised the action of the false transmitters at human muscle type nAChRs and two mAChR subtypes. Finally, we have demonstrated that production of the false transmitters improved muscle function in the guinea-pig phrenic nerve/hemi-diaphragm preparation after nerve agent exposure. This work suggests that both nAChR modulators and production of false transmitters offer promising avenues towards new broad-spectrum therapeutics which can reduce the effects of excess ACh at the neuromuscular junction and provide the same benefit regardless of the nerve agent used.

Title: Acetylcholine activates NMethylDAspartate receptormediated currents in absence of glycine in medium spiny neurons of rat

Authors: *J. L. FLORES-HERNANDEZ, O. TORRES-RAMIREZ, L. ARROYO-RIOS, A. LUNA-LEAL, B. SORIA_PEREZ, D. VAZQUEZ-CANDANEDO, G. LOPEZ-LOPEZ, E. MANJARREZ-LOPEZ;

Abstract: The function of the striatal is critically involved in the movement, learning, habit formation, and reward-related behavior. The most of population striatal neurons are GABAergic and they are represented by medium spiny projection neurons. The striatum also contains a small percentage of interneurons which provide this area with one of the highest acetylcholine (ACh) levels in the brain. The main target of cholinergic inputs is represented by spiny neurons which also receive cortical glutamatergic fibers. Recent studies report a decrease in the NMDAR-mediated currents (INMDA) by ACh. This effect is independent of the mechanism classics (muscarinic and nicotinic receptors). Moreover, the d-tubocurarine (nicotinic antagonist) reduces INMDA. These data suggest us the possibility of direct interaction between neurotransmitter

acetylcholine and molecules related to the NMDA receptor (NMDAR). NMDAR are heterotetrameric assemblies of two GluN1 subunits and other GluN2 (A-D). The functional diversity and signaling properties of GluN1/GluN2 NMDARs have been extensively characterized during the last 40 years, providing a wealth of information on the molecular basis of excitatory neurotransmission. Thus, it´s assumed that glycine is a co-agonist of the NMDA receptor and plays an essential role in the activation of this. However, our studies show INMDA in absence of glycine in medium spiny neurons (MSN´s). In the present study, by using an acutely dissociated MSN´s preparation with patch clamp technique in whole cell configuration, we found that the application of ACh (picomolar concentrations) as well of other drugs acting on muscarinic or nicotinic receptors induces an acute and reversible potentiation of INMDA (81% of control) in absence of glycine. This effect was persistent to the presence of the muscarinic antagonist atropine (10μM) and nicotinic antagonist d-tubocurarine (1μM). Furthermore, when ACh and glycine were co-applicated, the INMDA is reduced compared to glycine applicated alone. A detailed analysis of the effects of ACh could suggest that this neurotransmitter interfered with glycine-dependent NMDAR-activity. The application of the 5,7 dichloro kynurenic acid (a potent and selective competitive antagonist of the glycine site on NMDA receptors) in presence of glycine reduced the INMDA but with co-application of ACh, this effect was minor (46 ± 2% and 31 ± 4%, respectively). We conclude that INMDA can be potentiated directly by cholinergic drugs, possibly by direct interaction within one or more subunits of the NMDAR.

Title: Regulation of membrane insertion of the AMPA-type glutamate receptor via β2 adrenergic receptor signaling

Authors: *B. LEE, E. A. HAMMES, J. W. HELL;
Pharmacol., Univ. of California, Davis, Davis, CA

Abstract: AMPAR-type glutamate receptors (AMPARs) mediate most of the fast excitatory synaptic transmission in the brain. AMPARs are composed of four subunits (GluA1-4) and GluA1/A2 and GluA2/A3 are prevalent in the brain (W. Lu et al., 2009). Their abundance at postsynaptic sites determines synaptic strength. Surface expression and phosphorylation of AMPARs increase during the long term potentiation (LTP) of synaptic transmission. AMPARs are inserted to the membrane in a retromer dependent manner. β2 Adrenergic Receptor (β2AR) forms supramolecular signaling complexes with AMPARs and regulates phosphorylation of AMPARs through Gs protein, adenylyl cyclase (AC), and PKA signaling, which are also associated with the AMPARs (Joiner et al., 2010). Phosphorylation of S845 by PKA augments AMPAR surface expression and postsynaptic targeting. Norepinephrine (NE) is the endogenous ligand of β2AR and is crucial for arousal and learning in novel and emotionally-charged situations inducing LTPs in hippocampus. The voltage-gated calcium channel (VGCC) $Ca_V1.2$ mediates calcium influx, which governs neuronal excitability, LTP, and learning. Importantly, it stabilizes surface insertion of AMPARs, which otherwise undergoes only short-lived insertions (10-30 sec) (Hiester et al., 2017). We investigated how trafficking of AMPARs to surface is mediated by stimulation of β2AR by NE. Hippocampal neuron culture from rats were treated with NE and stained with antibodies against surface GluA1 and total PSD95, which define postsynaptic sites. Colocalization of sGluA1 and PSD95 puncta was quantified. In parallel, mouse brain slices were incubated with NE to examine the change in phosphorylation of AMPAR GluA1 subunit at S845. After immunoprecipitation of GluA1 from brain slice lysates, phosphorylation of GluA1 was analyzed by immunoblotting. Interaction of AMPARs with their accessary proteins and retromer proteins was investigated by co-immunoprecipitation from brain slice lysates with or without NE treatment. The results of immunostaining with hippocampal neuron culture show that stimulation of β2AR by NE enhances insertion of AMPARs into the plasma membrane. The effect of NE on surface insertion of GluA1 is blocked by L-type calcium channel inhibitor. Also, phosphorylation of S845 was increased by NE. These results represent that stimulation of β2AR by NE promotes trafficking of AMPARs to the cell surface in an L-type channel dependent manner. Electrophysiological analysis suggests that this mechanism is important for certain forms of LTP.

Title: Developmental NMDA receptor dysregulation in the infantile neuronal ceroid lipofuscinosis mouse model

Authors: *K. P. KOSTER[1], W. FRANCESCONI[2], F. BERTON[2], A. YOSHII[1];
[1]Dept. of Anat. & Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [2]Dept. of Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Mechanisms driving adult-onset neurodegenerative diseases remain enigmatic. Studying monogenic disorders that share features with common neurodegenerative diseases may highlight chief pathogenic mechanisms to better inform therapeutic strategies. Infantile neuronal ceroid lipofuscinosis (CLN1) is a devastating pediatric neurodegenerative disorder sharing pathological characteristics with Alzheimer's and related diseases. CLN1 is caused by mutations in *CLN1*, which encodes the depalmitoylating enzyme palmitoyl-protein thioesterase 1 (PPT1). Palmitoylation entails the post-translational addition of lipid (palmitate) to proteins, which can be depalmitoylated by PPT1. Protein palmitoylation dynamically regulates the localization and function of many synaptic proteins, including the N-methyl-D-aspartate receptor (NMDAR) subunits GluN2B, GluN2A, and the synaptic scaffold PSD-95. However, how loss of depalmitoylation by PPT1 leads to synaptic dysfunction and neuronal death in CLN1 is not understood. Here, we used the *Ppt1*$^{-/-}$ mouse model to decipher how lack of protein depalmitoylation drives synaptic dysfunction in CLN1, with potential implications across diseases. Synaptosomes prepared from cortices of wild-type (WT) and *Ppt1*$^{-/-}$ mice demonstrated decreased levels of GluN2A and PSD-95, which comprise NMDAR complexes at mature synapses. Total levels of GluN2B, which constitutes extrasynaptic NMDARs with prolonged decay kinetics, were unchanged. Correspondingly, NMDAR-mediated currents recorded from *Ppt1*$^{-/-}$ cortical neurons show decreased and enhanced contributions from GluN2A and GluN2B, respectively. In *Ppt1*$^{-/-}$ primary cortical neurons, calcium transients were diffuse, extrasynaptic, and sensitive to GluN2B-blockade, whereas WT cells exhibited compartmentalized calcium influx confined to spine heads. Potentially underlying these disruptions, Fyn kinase, which stabilizes GluN2B at the synaptic surface, and GluN2B are hyperpalmitoylated in *Ppt1*$^{-/-}$ neurons. Indeed, *Ppt1*$^{-/-}$ neurons demonstrated increased vulnerability to NMDA-induced excitotoxicity that, together with the hyperpalmitoylation of GluN2B and Fyn, was reversed by treatment with palmitoylation inhibitors. Thus, loss of PPT1 causes disrupted NMDAR function and susceptibility to excitotoxicity partly via hyperpalmitoylation of GluN2B and Fyn kinase, revealing these as novel mechanistic targets in CLN1. Notably, these proteins are already implicated in Alzheimer's disease and other neurodegenerative disorders, suggesting this may be a common mechanism underlying neurodegeneration with broad therapeutic potential.

Title: Cannabinoid-induced swimming-induced paralysis in the nematode *Caenorhabditis elegans*

Authors: *S. H. SHRADER, Y. G. TONG, J. H. FREEDMAN, Z. H. SONG;
Dept. of Pharmacol. and Toxicology, Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: The neurotransmitter dopamine (DA) plays a central role in the regulation of learning, memory, emotion, cognition and locomotion. Aberrant dopaminergic signaling is associated with a variety of neurological and neuropsychiatric pathologies, including Parkinson's disease, schizophrenia, attention-deficit/hyperactivity disorder and bipolar disorder. Thus, pharmacological targeting of the DA system is considered to have numerous therapeutic potentials. Compounds able to alter the synthesis, uptake or signaling of DA may prove therapeutically useful. In the nematode *Caenorhabditis elegans*, extrasynaptic DA controls locomotion behavior. This study used loss of function mutants to test the hypothesis that phytocannabinoids in *C. elegans* may act as agonists at the D2-type DA receptor DOP-3, or inhibitors at dopamine transporter DAT-1, resulting in swimming-induced paralysis (SWIP). The SWIP behavioral assay was used to analyze the effects of two phytocannabinoids - cannabidiol (CBD) and cannabidivarin (CBDV), on the locomotion of wild-type nematodes and dopamine-signaling mutant strains. *C. elegans* strains were obtained from the Caenorhabditis Genetics Center and cultured on OP50-seeded NGM agar plates. SWIP behavioral assays were performed using the following strains: N2 Bristol wild-type, LX703 *dop-3(vs106)X*, RM2702 *dat-1(ok157)III* and CB1112 *cat-2(e1112)II*. Drugs were purchased from Cayman Chemicals and dissolved in ethanol to generate 0.1mM, 1mM and 10mM stock solutions. Ten to fifteen late L4 hermaphrodite larvae were placed in a well of 100microL distilled water containing 1microL of drug or vehicle. The numbers of nematodes swimming versus paralyzed were recorded after 10 minutes. For each treatment group per genotype, six wells were scored per experiment and experiments were repeated on five separate days (n=30). Both CBD and CBDV dose-dependently induced SWIP in N2 wild-type nematodes, but neither induced SWIP in *dop-3, dat-1 or* c*at-2* mutants. Our results suggest that these phytocannabinoids may act through the DOP-3 pathway to induce SWIP. Cannabinoids CBD and CBDV are able to induce the DA signaling in *C. elegans* and alter locomotor activity. These compounds may be potential drug candidates for the treatment of neurological and neuropsychiatric diseases characterized by dysregulation of dopamine signaling.

Title: Social isolation combined with nicotine exposure alters the dopaminergic response to cocaine

Authors: *N. B. PAIGE, J. F. COMSTOCK, R. A. PENNELLA, S. A. TOWERS, J. P. MANUS, L. A. ROBINSON, D. B. LESTER;
Univ. of Memphis, Memphis, TN

Abstract: Factors relating to social interaction have been shown to alter patterns of psychostimulant use in preclinical and clinical models. In rodents, social isolation during adolescence is considered a stressor, leading to increased drug seeking and sensitization. In humans, nicotine is often one of the first drugs experimented with. The present study aimed to determine the effects of social isolation on nicotine salience using conditioned place preference (CPP) and the effects of social isolation and nicotine exposure on dopamine release in the nucleus accumbens (NAc). At 3 weeks of age, male C57BL/6J mice were either group housed or isolated for 3 weeks prior to nicotine CPP testing, in which mice were subcutaneously administered either nicotine (.35 mg/kg) or saline. Then, fixed potential amperometry was used to quantify dopamine release in anesthetized mice before and after administration of a drug challenge, the dopamine agonist and psychostimulant cocaine (10 mg/kg, i.p.). A three-way mixed ANOVA was used to determine the effect of housing and nicotine pretreatment on percent change in dopamine release over time. Regarding CPP results, there was a significant housing (group or isolated) x drug (nicotine or saline) x trial interaction on time spent in drug-paired chamber. Specifically, the isolated mice significantly preferred the nicotine-paired chamber more than mice in the other groups. Regarding dopamine recordings, there was a significant housing x drug exposure (nicotine or saline) x time (60 min recording period) interaction on percent change in dopamine release. Specifically, the isolated nicotine-exposed mice exhibited a significantly increased dopaminergic response to cocaine relative to the other groups 10 min post injection. Overall, these findings conclude that social isolation during adolescence increases nicotine salience, and nicotine administration in these isolated mice alters dopamine functioning in a direction that may enhance the reinforcing properties of cocaine. Identifying risk factors for drug abuse and understanding the neurochemical mechanisms associated with these risk factors is critical for prevention and treatment programs.

Title: Alterations in addiction-related behaviors and dopamine functioning in C57BL/6J mice following social isolation and environmental enrichment

Authors: *J. F. COMSTOCK[1], S. A. TOWERS[1], N. B. PAIGE[1], A. M. BYRN[1], P. E. DICKSON[2], D. B. LESTER[1];
[1]Psychology, Univ. of Memphis, Memphis, TN; [2]The Jackson Lab., Bar Harbor, ME

Abstract: In rodents, environmental enrichment (EE) has been shown to provide a protective effect on addiction-related behaviors, such as novelty reactivity and drug-seeking. The current study examined the effect of EE on locomotor activity and mesolimbic dopamine functioning, with specific aims at distinguishing the effects of physical and social stimuli by including 3 housing conditions: EE (with physical objects such as running wheels and tunnels and cage mates), social enrichment (SE, with cage mates but no EE objects), and isolation (with no EE objects or cage mates). Mice were separated into these housing conditions at 3 weeks of age and remained for 10-12 weeks. In both males and females, isolated C57BL/6J mice displayed increased locomotor activity and rearing relative to EE mice, with SE mice falling in between. *In vivo* fixed potential amperometry was used to quantify dopamine release in the NAc elicited by electrical stimulation of the VTA in anesthetized mice before and after cocaine administration. The housing conditions did not alter baseline dopamine release or reuptake rates in either sex. However, the housing variable did alter dopaminergic responses to cocaine during the 1 hr recording session post injection. Dopamine release following cocaine peaked sooner (10 min instead of 20 min post injection) and escalated to a higher concentration in isolated mice relative to EE and SE mice. Given that no differences are observed between EE and SE mice, this protective effect may be driven by social stimuli rather than physical stimuli. However, a different pattern was observed in measurements of the synaptic half-life of dopamine following cocaine. Cocaine-induced increases in dopamine half-life peaked at 20 min in SE and isolated mice but not until 40-50 min in EE mice, when the responses of the other groups were declining back to baseline. This extended response to cocaine may then be attributed to the physical stimuli in the EE condition and could indicate a longer reinforced experience. But generally drugs have a higher abuse liability when dopamine efflux peaks and makes a rapid return to baseline, thereby promoting additional drug seeking. Thus, these data could provide neurochemical support for

behavioral studies showing EE mice are less likely to self-administer cocaine. Follow-up experiments are being done with DBA/2J mice, a strain that has been shown to be more affected by housing conditions relative to C57BL/6J mice in some behavioral assays.

Title: Effects of subchronic oxytocin treatment on social behavior following social isolation in juvenile mice

Authors: K. BERRY[1], M. K. ESTES[2], N. B. PAIGE[2], M. MEADOWS[1], D. B. LESTER[2], ***T. D. ROGERS**[1];

Abstract: Social isolation during adolescence has been shown to produce a variety of abnormal behaviors in mice. However, the neurochemical effects of social isolation during adolescence have not been fully described. Additionally, sex-specific changes in behavior following social isolation have yet to be fully explained. In the current study, male and female juvenile C57BL/6 mice were group-housed or housed in isolation for three weeks beginning at three weeks of age. Mice were then subchronically pretreated with either saline or oxytocin (1.0 mg/kg, i.p.). Subchronic pretreatment consisted of four i.p. injections separated by 48 hours which has been previously shown to effectively alter dopamine neurotransmission and prosocial behavior in mice. Mice were then tested in the three-chamber sociability test which is a commonly used method to test social approach behaviors and preference for social novelty. The test was conducted in a clear, plexiglass box with three chambers. The chambers are separated by clear dividers which have passages for the experimental mouse to move between the chambers. The center chamber remained empty while the side chambers each contained a wire pencil cup placed upside down. The test included three ten-minute phases. During the first phase, mice were allowed to habituate to the novel environment. In the second-phase, mice were presented with a social stimulus, a novel conspecific, in one of the pencil cups. The mouse was allowed to approach the novel social stimulus without the stimulus moving around in the chamber. During the third phase, a second mouse was introduced into the remaining pencil cup. The experimental mouse was allowed to choose to interact with either the now familiar social stimulus or the novel stimulus. Male mice displayed more social approach during phase two than females, and isolated mice displayed more social approach than group-housed mice. Isolation reduced social novelty

preference in males while increasing total social approach in both males and females during phase three. Oxytocin exaggerated social novelty preference in males and in group-housed females. The current research demonstrates the need to further investigate the behavioral, neurochemical, and sex-specific effects of early social isolation in mice.

Title: Systemic oxytocin treatment reverses the effect of social isolation on mesolimbic dopamine release

Authors: *M. K. ESTES[1], N. B. PAIGE[1], M. N. MILLS[1], T. D. ROGERS[2], D. B. LESTER[1]; [1]Psychology, Univ. of Memphis, Memphis, TN; [2]Psychology, Middle Tennessee State Univ., Murfreesboro, TN

Abstract: Oxytocin has been shown to reduce drug seeking in rodents and is being examined in clinical trials as a relapse-prevention treatment. The mesolimbic dopamine system, which consists of midbrain dopamine neurons that project to the nucleus accumbens (NAc), is known to play a vital role in drug abuse. We have recently shown that mice subchronically pretreated with oxytocin (1.0 mg/kg, i.p.) had a reduced dopaminergic response to a psychostimulant. The present study aimed to determine whether this oxytocin treatment could rescue abnormal dopamine functioning. Social isolation in rodents has been shown to increase psychostimulant self-administration and sensitization. In this study, male and female mice were either group-housed or isolated for 3 weeks following weaning, then subchronically pretreated with either oxytocin (1 mg/kg) or saline. Subchronic pretreatment consisted of 4 i.p. injections administered every 48 hours. Fixed potential amperometry was used to quantify VTA-stimulated dopamine release in the NAc of anesthetized mice before and after cocaine administration. Overall, females seemed to be more affected by social isolation than males on the variables measured. Specifically, saline-pretreated isolated females displayed increased baseline (pre-cocaine) dopamine release and an increased dopaminergic response to cocaine compared to other groups. Interestingly, these altered profiles of dopamine functioning were not observed in the isolated mice pretreated with oxytocin. These results demonstrate one aspect of the neurochemical impact of social isolation, particularly in females. The present findings further suggest that oxytocin pretreatment can reverse isolation-induced changes in the dopaminergic functioning, perhaps

providing insight on neurochemical mechanisms for behavioral studies showing oxytocin reduces drug seeking and other addiction-related behaviors.

Title: Effect of the levetiracetam on the synaptic plasticity in the dentate gyrus of the hippocampus of rats in the chronic phase of the temporal lobe epilepsy

Authors: *G. GONZÁLEZ-HERNÁNDEZ[1], I. J. CONTRERAS-GARCÍA[2], K. B. SÁNCHEZ-HUERTA[3], L. R. GALLARDO-GUDIÑO[4], J. G. MENDOZA-TORREBLANCA[3], C. M. QUEIROZ[5], S. R. ZAMUDIO-HERNÁNDEZ[1];

Federal de Rio Grande del Norte, Natal, Brazil

Abstract: Temporal Lobe Epilepsy (TLE) is a chronic-degenerative neurological pathology, characterized by the appearance of seizures that causes changes in synaptic plasticity of intra-hippocampal circuits, causing learning and memory deficits. Recently, it was observed that the treatment with levetiracetam (LEV) during the period of epileptogenesis attenuated the cognitive deficits in a TLE model, But, it is unknown whether LEV, in addition to its anticonvulsant and neuroprotective effects, has any beneficial effect on the deficit of synaptic plasticity when is administered during the chronic phase of TLE. Thus, in this study the effect of LEV on the alterations of the synaptic plasticity of the hippocampal dentate gyrus (DG) of rats with TLE induced with lithium-pilocarpine was evaluated. Male Wistar rats were allocated in 4 groups: Control, Control-LEV, Epileptic and Epileptic-LEV. LEV (300 mg/kg/day) was administered along 7 days in the chronic phase of TLE. 3 days after the end of treatment, the rats were anesthetized and subjected to stereotaxic surgery where a concentric bipolar electrical stimulation electrode was implanted in the perforating pathway, and a concentric monopolar recording electrode was implanted in the hilus of the DG. An I/O curve protocol was applied,

with intensities from 50 to 1500 µA. An electrical stimulation protocol was also used for synaptic depression and facilitation by paired pulses in the perforating pathway, at inter-pulse intervals of 10, 20, 30, 70 and 250 ms with three intensity levels of 20, 50 and 100%. Finally, Long-Term Potentiation (LTP) was induced by triggering trains of 400 Hz using a stimulation intensity of 1500 µA. The evoked local field potentials were recorded and measured as EPSP slope and population spike (PS) amplitude. In the I/O curve protocol, Epileptic animals presented an increase in the amplitude of the PS with respect to Control and Control-LEV groups, interestingly; LEV in the Epileptic-LEV group reduced such increase in PS amplitude, but without reached control levels. In the depression and facilitation by paired pulses, a decrease in the facilitation and an increase in the depression in the Epileptic group were observed with respect to the controls; though, the epileptic group treated with LEV did not present a difference with respect to the Epileptic group. In LTP, it was observed that the Epileptic animals had a reduction of LTP with respect to the controls; however, the epileptic group treated with LEV did not reverse such alteration. It was concluded that LEV only reduced the excitability of the neuronal circuit but did not reverse the alterations on synaptic plasticity caused by ELT in its chronic phase.

Title: Cholecystokinin released from GABAergic neurons enhances inhibition function in the auditory cortex

Authors: *H. LING;
Biomed. Sci. (BMS), Col. of Vet Med. &, Hongkong, Hong Kong

Abstract: The neocortex mainly comprises pyramidal cells and non-pyramidal cells. Inhibition process is mainly mediated by some interneurons via the release of γ-Aminobutyric acid (GABA) from their terminals.GABAergic cholecystokinin (CCK) neurons are one of the major populations of interneurons in the auditory cortex (ACx). We injected the AAV-DIO-ChR2 with promoter (EF1α, elongation factor 1α), into ACx of Vgat-ires-cre mice, which restrictedly expressed Cre recombinase into GABAergic neurons. In the auditory cortex, a laser stimulation of the GABAergic CCK neurons induced an inhibitory response to an auditory stimulus that follow the laser stimulus. We hypothesized that high-frequency stimulation (HFS) of the GABAergic neurons induce the CCK release, which leads to enhance the inhibition of their own outputs to other cortical neurons. Also, we injected the pAAV-mU6-CAG-ChR2 with Cre-dependent U6-shRNA (CCK specific) cassette into Vgat-ires-cre mice to specifically knock down the expression of CCK in GABAergic neurons. The response to an auditory stimulus increased after laser stimulation with a lower CCK expression in GABAergic CCK neurons. We further hypothesized that a third receptor, CCK-C receptor, may exist in brain functioning in the inhibitory circuits on top of CCK-A and B receptors. Thus, we first utilized CCK-A/B receptor knock-out (CCK-AB-KO) mice in electrophysiology experiments. Auditory response was inhibited by a proceeded laser-stimulation of GABAergic neurons. The inhibition on the auditory responses was enhanced after high-frequency stimulation (80Hz, 100 pulses X 10, HFS). The same enhanced effect of inhibition was induced by CCK application that was followed by LFS. Neuronal responses in field potential to auditory stimulus was suppressed after HFS or CCK application in the auditory cortex. This enhanced inhibition disappeared after application of CCK antagonist: L365,260 before the HFS. In CCK-KO mouse, no significant change was observed the neuronal responses to either electrical stimulation or auditory stimulus. The results in the present study indicated that the inhibitory neuronal circuit in the neocortex could be enhanced by the high-frequency firing of GABAergic CCK neurons, through a possible new receptor, CCK-C receptor.

Title: Allopregnanolone: A biomarker candidate for mood disorders

Authors: *G. PINNA;
The Psychiatric Institute, Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Major depressive disorder and posttraumatic stress disorder (PTSD) are complex, highly prevalent and debilitating psychiatric conditions characterized by poor life expectancy and destructive behaviors. Current diagnosis is based on subjective rather than objective measures leading to misdiagnose and ineffective treatments. Recent advances in the field using more reliable animal models, novel technologies and neurobiological methods have offered a number of promising biomarker candidates to diagnose depression and PTSD more accurately. These biomarkers also offer new means to treating patients more efficiently. During the past decade, several studies have consistently documented a downregulation of the GABAergic neurosteroid allopregnanolone and its equipotent isomer pregnanolone (PA) in serum, plasma, cerebrospinal fluid (CSF) and post-mortem brain from patients with major depression and PTSD. Remarkably, the FDA has recently approved allopregnanolone (i.e., brexanolone) as the first specific treatment for post-partum depression. This new treatment is characterized by a high response-rate, rapid-acting pharmacological effects and long-lasting behavioral improvements. Now, the question arises as to whether allopregnanolone can be developed as a reliable biomarker to predict susceptibility to mood disorders, reliably diagnose depression and PTSD, and whether neurosteroid-based therapeutics offer a reasonable advantage over commonly administered traditional antidepressants. While the potential role of neurosteroid biosynthesis and their function as biomarkers for mood disorders is fascinating, more work is still required to firmly establish their diagnostic role. Furthermore, the identification of a *biomarker axis* that takes into account the interplay and synergism of several biomarkers is suggested as a base of support to univocally identify and discriminate disorders with large comorbidity and symptoms overlap and to develop individualized treatments.

Title: Altered $GABA_A$ receptor subunit expression and neurosteroid biosynthesis in subjects with alcohol use disorder

Authors: *E. GATTA[1], A. GUIDOTTI[1], D. ASPESI[2], D. R. GRAYSON[1], S. C. PANDEY[1,3], G. PINNA[2];

[1]Ctr. for Alcohol Res. in Epigenetics, Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [2]The Psychiatric Insitute, Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [3]Jesse Brown Veterans Affairs Med. Ctr., Chicago, IL

Abstract: Alcohol use disorder (AUD) is a chronic relapsing disorder affecting 6% of the US adult population. Few studies have investigated the mechanisms whereby alcohol affects $GABA_A$ receptor ($GABA_AR$) subunit composition and alters GABAergic allosteric modulation elicited by neurosteroids. We recently showed reduced $GABA_AR$ δ subunit expression in the cerebellum of AUD subjects suggesting an impaired sensitivity of $GABA_AR$ to neurosteroids. The long-term effects of alcohol exposure on neurosteroid biosynthesis and its consequences on GABAergic neurotransmission in individuals with AUD remain underinvestigated. In a cohort of postmortem brains from 25 pairs of controls and AUD subjects (New South Wales Brain Tissue Resource Centre, University of Sydney, Australia), we determined the mRNA expression of several $GABA_AR$ subunits by RT-qPCR. Protein levels were determined by Western Blot and neurosteroids were quantified by gas chromatography-mass spectrometry (GC-MS). We observed reduced α_2 and δ subunit mRNA expression in prefrontal cortex, hippocampus, striatum and cerebellum of AUD subjects. Like the δ subunit, α_2 protein expression was decreased in the cerebellum of AUD subjects. These data suggest that both synaptic (α_2) and extrasynaptic (δ) $GABA_AR$ subtypes might be affected in AUD. Modulation of the extrasynaptic $GABA_AR$-mediated inhibition is enhanced by allopregnanolone (Allo) and its equipotent GABAergic isomer, pregnanolone (PA). Neurosteroid biosynthesis is initiated by cholesterol translocation into the inner mitochondrial membrane by the 18 kDa translocator protein (TSPO). Cholesterol is then converted by P450scc into pregnenolone, which is further metabolized into progesterone by 3β-hydroxysteroid dehydrogenase (3β-HSD). 5α-reductase Type 1 (5α-R1) and 3α-HSD then convert progesterone into Allo. Thus, we studied neurosteroid biosynthesis in the cerebellum and observed reduced TSPO, 5α-R1 and 3α-HSD mRNA expression in AUD, with no changes in 3β-HSD. As expected, this resulted in reduced levels of Allo and PA in the cerebellum. Whether changes in $GABA_AR$ subunit expression result from a direct effect of alcohol or whether this is secondary to alcohol affecting neurosteroid biosynthesis remains to be investigated. Given the role of Allo in regulating the fine-tuning of $GABA_AR$, our data suggest that alcohol-induced impairments in GABAergic neurotransmission might be profoundly impacted by reduced neurosteroidogenesis.

Title: Dynamical physical interaction between RCOR2 and SC35 in nuclear speckles. implications for regulating alternative splicing in neurons

Authors: F. A. GUZMÁN, C. RIVERA, D. ARANCIBIA, ***M. E. ANDRES**;
Cell. and Mol. Biol., Pontificia Univ. Catolica de Chile, Santiago, Chile

Abstract: RCOR2 (CoREST2) is a transcriptional corepressor that belongs to the CoREST family (RCOR1, RCOR2, and RCOR3), which interacts with the enzymes LSD1 (Lysine-specific demethylase-1) and HDAC1/2 (Histone deacetylase 1/2) to form complexes that determinate the neuronal phenotype. It has been shown that RCOR2 plays a key role in maintaining pluripotency in stem cells. RCOR2 knockout mice models have shown that this protein is essential for cortical development, balancing proliferation with differentiation process. Our lab has described that CoREST proteins have distinct biochemical properties that lead to different transcriptional repressive capacities. However, whether each CoREST protein has a specific function is unknown. In this work, we show that CoREST proteins occupy different compartments in cells including neurons. Surprisingly, we observed that RCOR2 forms nuclear protein cumulus resembling non-membranous organelles. Also, we present evidence that RCOR2 colocalizes with the typical nuclear speckle protein SC35, and deletion of the C-terminal end of RCOR2, which is a low complexity region rich in basic amino acids, abolished its localization in the nuclear speckles. RCOR2 interacts with SC35, and decreasing RCOR2 levels using siRNAs reduces SC35 levels too. Nuclear speckles are protein-RNA bodies specialized in splicing regulation and maturation of pre-mRNAs. Therefore, our data suggest that RCOR2 may have a role in controlling mRNA splicing and maturation.

Title: Self-cleaving CPEB3 ribozyme regulates pre-mRNA processing and modulates polyadenylation in the mouse hippocampus

Authors: *C. CHEN[1], L. TONG[1], M. NIKAN[4], C. W. COTMAN[1], E. SWAYZE[4], M. A. WOOD[2], A. LUPTAK[3];
[2]Neurobiol & Behavior, [3]Pharmaceut. Sci., [1]Univ. of California Irvine, Irvine, CA; [4]Neurosci. Drug Discovery, Ionis Pharmaceuticals, Carlsbad, CA

Abstract: Transcriptional regulation, *de novo* protein synthesis, and molecular and cellular cascades have been implicated in long-lasting forms of neuronal plasticity and memory processes. Cytoplasmic polyadenylation element binding protein 3 (CPEB3) is an RNA-binding protein that modulates dendritic polyadenylation-induced mRNA translation, which is essential for persistence of memory. Previous studies identified a human self-cleaving CPEB3 ribozyme through *in vitro* selection, and demonstrated the ribozyme contains a single nucleotide polymorphism (SNP) that has been correlated with the function of CPEB3 in episodic memory. However, very little is known about the role of CPEB3 ribozyme in the regulation of CPEB3 mRNA processing in neurons. In this study, we inhibited CPEB3 ribozyme *in vitro* and *in vivo* using novel antisense oligonucleotides (ASOs), which is a particularly effective tool to study the function of a ribozyme such as CPEB3. Using primary neuronal cultures, we demonstrated that CPEB3 ribozyme activity was inhibited in the presence of ASOs. Application of the lead ASO targeting the CPEB3 ribozyme resulted in an increase in CPEB3 mRNA and protein expression in neurons. The inhibition of the CPEB3 ribozyme followed by neuronal stimulation increased GluA1, PSD-95, and NMDAR2B protein expression, suggesting the role of CPEB3 ribozyme is activity-dependent. Furthermore, administration of ASOs into the mouse CA1 region of the hippocampus resulted in an inhibition of CPEB3 ribozyme activity, which in turn led to an increase in CPEB3 mRNA expression and GluA2 polyadenylation. Collectively, these results

suggested a possible mechanism by which the CPEB3 ribozyme regulates synaptic structure and function required for learning and memory.

Title: Isoform specific transcriptional regulation of lipophorin receptors generate functional diversity

Authors: J. YIN, ***E. SPILLMAN**, J. SHORT, C. SHENG, M. GIBBS, Q. YUAN; NINDS, NIH, Bethesda, MD

Abstract: Lipids are essential building blocks for cell membranes and organelles. They also have versatile roles in regulating cellular metabolism and signaling events. In the nervous system, lipid synthesis, uptake, and recycling involve complex neuron-glia interactions, which, although functionally important, remain poorly characterized. How do neurons acquire and utilize the lipid supply? And how are these processes monitored and regulated during development? These are outstanding questions we are trying to study using Drosophila as a model system. Ventral lateral neurons (LNvs) in the larval brain are projection neurons which receive synaptic inputs from the photoreceptors. Altering visual experience generates profound impacts on both structural and physiological properties of developing LNvs. Through a combination of cell-type-specific RNA-seq analyses and genetic studies, we identified isoform-specific expression of lipophorin receptors LpR1 and LpR2 in LNvs. Uncovering LpRs' roles in supporting dendrite morphogenesis and synaptic functions in the CNS. We also provided evidence for the activity-dependent transcriptional regulation of LpRs and offer a mechanism for augmenting the capacity of lipoprotein uptake in response to alterations of synaptic activity. To further understand the physiological significance of isoform-specific regulation of LpRs, we performed additional cell biological studies on short and long-isoforms of LpRs by examining their cellular distributions, involvement in the endocytic pathway and associations with lipoproteins. Our results show that isoform-specific transcriptional regulation generates LpRs with diverse structural and functional properties. In conjunction with previous studies, our findings provide in vivo evidence for neuronal lipoprotein receptors serving as targets of cell-type specific transcriptional regulation. This contributes to distinct modes of lipid uptake in different cell types, an important regulatory mechanism that serves unique functional requirements of neurons.

Title: Increased neuropeptide VGF expression through post-transcriptional auto-feedback mechanisms improves cognitive functions

Authors: *W.-J. LIN[1,2], C. JIANG[2], J. WU[1], Y. ZHAO[4], X. YE[4], S. R. SALTON[2,3];
[1]Med. Res. Ctr., Sun Yat-Sen Mem. Hospital, Sun Yat-Sen Univ., Guangzhou, China; [2]Fishberg Dept. of Neurosci., [3]Friedman Brain Institute,, Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Zhongshan Sch. of Med., Sun Yat-Sen Univ., Guangzhou, China

Abstract: The expression of VGF (nonacronymic), a secreted neuropeptide precursor, can be induced in the brain by hippocampus-dependent learning and physical exercise. TLQP-62, a 62 amino acid peptide derived from the C-terminal region of the VGF precursor, has been shown to enhance neuronal activity in both cultured hippocampal neurons and hippocampal slices, and its direct administration to the hippocampus *in vivo* additionally results in increased neurogenesis, antidepressant-like effects, and memory enhancement in rodent models. While *Vgf* gene expression can be robustly regulated via CREB-dependent transcriptional activation in response to neuronal depolarization or growth factor treatment, for example, little is known about post-transcriptional regulatory mechanisms of VGF expression. Here we show that TLQP-62 can rapidly increase VGF translation in the absence of measurable increases in VGF mRNA levels, via an mTOR-dependent signaling pathway. Luciferase reporter-based assays suggest that the mouse 3'-untranslated region (3'UTR) of VGF mRNA reduces protein expression compared to the 3'UTR of mouse Gapdh. Consistent with the translational repression of VGF mRNA that is conferred by its 3' UTR, truncation of the endogenous VGF mRNA 3'UTR, results in dramatic elevation of VGF protein levels both in cultured neurons and mouse brains. Phenotypic analysis of this *Vgf* 3'UTR-truncated mouse model reveals enhanced memory performance, and anxiolytic and antidepressant-like effects, consistent with increased VGF expression. Our results identified a rapid, transcription-independent induction of VGF protein levels that is triggered by TLQP-62 peptide treatment, *in vitro*, and contextual fear memory training, *in vivo*. Moreover, we noted similar rapid induction of several other related chromogranin and secretogranin proteins

following memory training, suggesting that the rapid, positive feedforward increase in the synthesis of dense core vesicle secreted proteins could be a general mechanism to replenish stores that have been released in response to neuronal activation.

Title: Differential role of presynaptic translation in evoked and spontaneous release

Authors: *H. H.-W. WONG, P. J. SJÖSTRÖM;
Dept. of Medicine, Dept. of Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada

Abstract: The roles of postsynaptic molecules in neurotransmission have been well characterized and constitute important neuroscience principles. However, due in part to low accessibility, less is known about the contribution of the presynaptic terminal to long-term changes in neurotransmission. Axonal local protein synthesis (PS) has emerged as a major mechanism to regulate localized growth responses during development. This efficient process allows proteins to be strategically synthesized at the right time and place to optimally carry out biological functions. Latest evidence is pointing to potential roles of local PS in mature neurons, raising the possibility that axonal local PS may contribute to neurotransmission.
Using quadruple patch clamp, we explored the acute effect of PS inhibition on spontaneous and evoked excitatory release onto layer-5 pyramidal cells in acute visual cortex slices from P11-16 C57BL/6 mice. Acute PS inhibition with cycloheximide (CHX) wash-in increased the rate of spontaneous release after 10-20 minutes (140% ± 16%, n = 9 vs. 96% ± 8% in control, n = 8, $p < 0.05$), consistent with rapid, local PS. Although the rate of spontaneous release was upregulated for as long as monitored (~7 hours; 1.7 ± 0.3 Hz, n = 33 vs. 1.1 ± 0.1 Hz in control, n = 91, $p < 0.01$), it was not correlated with CHX incubation time ($r = 0.13$, $p = 0.5$, n = 33), suggesting that basal PS serves as a constitutive regulatory mechanism to maintain spontaneous release. We eliminated a possible postsynaptic contribution by intracellular CHX loading, while additionally

showing that the rate was increased by CHX wash-in during postsynaptic CHX loading (139% ± 14%, n = 10 vs. 85% ± 7% in CHX-loading control, n = 9, $p < 0.01$).
Spontaneous release rate is commonly used as a metric of presynaptic release probability. We therefore speculated that PS inhibition would upregulate evoked release as well. Surprisingly, CHX wash-in reduced EPSP amplitude (59% ± 8%, n = 8 vs. 97% ± 2% in control, n = 12, $p < 0.001$) by reducing release, as evidenced by analysis of the change in paired-pulse ratio (ΔPPR: 0.18 ± 0.06, n = 8 vs. -0.0066 ± 0.02 in control, n = 12, $p < 0.01$) and coefficient of variation ($1/CV^2$ normalized: 37% ± 6% vs. 106% ± 28% in control, $p < 0.05$). PS inhibition thus differentially affected evoked and spontaneous release.
Taken together, our findings demonstrate specific roles of presynaptic translation in tuning neurotransmission. Moreover, presynaptic translation confers a dichotomy in activity-dependent and activity-independent neurotransmitter release mechanisms.

Title: Characterization of the mTORC1 effector PDCD4 in activity dependent translation and memory

Authors: *I. KATS[1], F. LONGO[2], E. KLANN[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: The formation of eukaryotic initiation 4F (eIF4F), a critical, rate limiting step in cap dependent translation initiation, is relevant to both normal memory function and disease. Increased expression of eukaryotic initiation factor 4E (eIF4E) or deletion of its repressor eukaryotic factor 4E binding protein 2 (4E-BP2) causes autistic endophenotypes in mice. Inhibitors of either the interaction of eIF4E with eukaryotic initiation factor 4G (eIF4G) or the eukaryotic initiation factor 4A (eIF4A) have also been shown to affect protein synthesis in brain slices and to disrupt long-term potentiation. Targeting eIF4A, the DEAD box helicase in eIF4F, in cancer cells decreases translation of specific targets and reduces cell growth, showing promising preclinical efficacy. In cells eIF4A1 is inhibited by programmed cell death 4 (PDCD4)

which can be phosphorylated by S6K1 and broken down by the proteasome pathway in cancer cells to permit protein synthesis and cell growth. Our data show that PDCD4 is also down regulated by neuronal stimulation and that the pathway responsible for this regulation is both S6K1- and proteasome-dependent in a similar manner as seen in cancer. Moreover, in contrast to non-neuronal cell types, PDCD4 is present in the cell body as well as dendrites and its overexpression in neurons causes a decrease in dendrite complexity. The localization and down-regulation of PDCD4 implicates the importance of PDCD4 and eIF4A1 as mTORC1 effectors in not only activity-dependent translation but also synaptic plasticity and memory function. To test this idea we have begun to examine synaptic function and behavior and memory processes in PDCD4 knockout mice. In summary, our findings indicate that PDCD4 acts as a downstream effector of mTORC1 and thus, is an important regulator of activity-dependent translation.

Abstract: Long-term potentiation (LTP) and depression (LTD) are mechanisms of inherent synaptic plasticity of neurons and support the storage and recovery of memories in the mammalian brain. The ability to potentiate a synapse long-term declines significantly in neurodegenerative disorders. In keeping with deficiencies in synaptic plasticity, degenerating neurons display acute and chronic mitochondrial dysfunction, suggesting that dysregulated mitochondria play a role in synaptic dysfunction, separately from their role in apoptotic cell

death. Our previous work has shown that the anti-apoptotic protein Bcl-xL not only prevents apoptosis, but also potentiates long-term synaptic responses. Here, we present that Bcl-xL is required for dramatic changes in ATP levels in hippocampal neurons during LTP stimulation and progression. Using fluorescence imaging with a FRET based ATP construct (ATeam) in live hippocampal neurons, we find that LTP induction causes a sharp decrease in ATP levels followed by a persistent long-term increase in ATP production, suggesting that intense synaptic stimulation requires neurons to be metabolically more efficient. In agreement with this, the late phase increase in ATP levels is associated with decreases in oxygen consumption by single neurons and with maturation of dendritic spines. The LTP-associated increase in ATP levels and maturation of dendritic spines is blocked by application of Bcl-xL specific inhibitors and also by inhibition of mitochondrial ATP synthase activity. Bcl-xL inhibition also prevents the LTP induced increase in surface glutamate receptor insertion. In hippocampal slice recordings, inhibition of Bcl-xL impairs early stage LTP and prevents late stage LTP. Our findings suggest that long-term changes in mitochondrial efficiency brought on by activity-dependent Bcl-xL translocation to mitochondria are required for LTP and shed light upon the role of mitochondrial metabolic plasticity in acute induction and long-term maintenance of learning and memory processing. If such mitochondria-dependent metabolic changes fail to occur, synaptic dysfunction and neurodegeneration may ensue.

Abstract: Sensory experiences exert long-term modifications of neuronal circuits by regulating activity-dependent transcription programs, which are vital for regulation of long-term plasticity and learning. However, it has not been possible to precisely determine the interplay between neuronal activity patterns and transcription factor activity. Here we present a technique to image *in vivo* signaling of CREB, an activity-dependent transcription factor important for synaptic plasticity, using 2-photon fluorescence lifetime imaging (2pFLIM) with new FRET biosensors. Combination of red-shifted CREB sensor and GCaMP imaging allowed simultaneous imaging of CREB and calcium dynamics at single cells. With this approach, we explored how experience shapes the interplay between CREB and neuronal activity in the visual cortex of awake mice. We found that dark rearing augmented the sensitivity and persistence of visually evoked CREB activity, thereby shifting the threshold for neuronal activity-transcription coupling. This technique will allow to unravel the transcriptional dynamics underlying experience-dependent plasticity in the brain.

Abstract: Acute pain serves as a protective mechanism, guiding the organism away from actual or potential tissue injury. In contrast, chronic pain is a debilitating condition without any obvious physiological advantage. This supports the notion that, the transition to, and the maintenance of chronic pain rely on different gene expression patterns to support biochemical and structural changes within the pain pathway. Gene expression can be regulated at various levels including transcription and translation. While transcriptomics in pain is widely studied, there have been only very few studies aimed at identifying translationally regulated genes. Regulation of mRNA

translation has emerged as an important step in the control of protein expression in the cell. However, mRNAs whose translation is altered in different stages of chronic pain remain largely unknown. In this study we perform genome-wide translational profiling using Ribosome profiling in parallel with transcription profiling using RNA-Seq of dorsal spinal cord in a mouse model of chronic neuropathic pain. We also performed proteomics to assess the relative contribution of transcription and translation regulation toward protein levels. We perform this multi-level gene expression profiling at early and late time points to investigate the difference in gene expression pattern, between the induction and the maintenance stages of chronic pain. Interestingly, preliminary analysis shows that, while both transcription and translation regulation are exerted in the early stage, transcriptional regulation subsides by the late stage, and a new pattern of translation regulation emerges.

Abstract: Environmental stimuli initiate a cascade of activity-dependent signaling events that alter gene expression in specific sets of neurons. This process of excitation-transcription coupling drives activity-dependent expression of immediate-early genes (IEGs) such as c-Fos, Arc and Egr1 (Zif268). Using *in situ* hybridization, immunostaining or transgenic reporter animals, these genes have been used as surrogate markers for neuronal activity driven by environmental stimuli. For instance, much recent work has exploited the activity-dependence of c-Fos to mark neuronal ensembles associated with memory traces. However, while traditional IEGs such as Fos have played an invaluable role in identifying activity-dependent circuitry, the expression of these genes may not be entirely tuned to neuronal activity alone. Traditional IEGs are transcribed in response to synaptic activity and Ca^{2+} entry, but also in response to growth

factor signaling, neurotrophins and neuromodulators. In contrast, the more recently identified IEG, Npas4, is selectively driven by neuronal activity, suggesting that it may be a purer marker of neuronal activation *in vivo*. We have developed a recombinant rabbit monoclonal antibody against Npas4 and demonstrated specific immunoreactivity in stimulated primary neurons and in tissue from WT and *npas4* KO mice. To increase the throughput of whole-brain histological imaging for IEGs, we are taking advantage of recent developments in tissue clearing, fluorescence light sheet imaging and computational alignment and cell detection. For tissue clearing, we optimized the iDISCO tissue clearing method for whole brain immunostaining. For imaging, we have developed the Mesoscale Imaging System used with the ZEISS Lightsheet Z.1 microscope, improving spatial resolution and imaging speed, allowing for visualization of an entire mouse brain in less than 3 hours. Further, we have developed machine learning-based methods that mediate the identification and quantification of individual immunostained cells across the entire intact mouse brain and the automated quantification of cell densities in >1,200 brain regions defined by the annotated Allen Brain Atlas. We are combining the use of our recombinant Npas4 Ab and our whole-brain imaging methodologies to provide a regional analysis activity-dependent gene induction in response to visual stimuli and contextual fear conditioning. We are also performing direct comparisons of neuronal activity pattern snapshots determined with Npas4 and c-Fos immunoreactivity. These studies will provide a powerful tool for measuring neuronal activity throughout the entire mouse brain.

Abstract: Activity Regulated Genes (ARGs), including *Bdnf, Arc, Fos* and *Egr1*, are expressed in a rapid, transient manner following a variety of stimuli. Increased expression of these genes results in the initiation of well-characterized gene expression programs that support neuronal activity. As such, expression of these genes is commonly used as a proxy for demarcating activated neurons following behavior or other stimulation. However, whether unique patterns of ARGs are recruited in a cellular- and stimulus-specific manner is not well understood. Moreover, limited evidence exists to explain how unique combinations of ARGs are recruited to mark ensembles of activated neurons. To address this question, we examined ARG expression patterns using multiplex single-molecule RNA fluorescent *in situ* hybridization (smFISH) in mouse cortex following induction of widespread neuronal activity with electroconvulsive seizures. We found that the ARGs *Arc* and *Bdnf* are sometimes expressed in non-overlapping neuronal populations and differentially regulated by neuronal activity. To evaluate whether ARGs tag different ensembles of activated neurons *in vitro*, we similarly examined the expression patterns of ARGs in mouse cortical neuron cultures using smFISH following potassium chloride-induced depolarization (PCID). ARG expression following PCID has been shown to be altered in iPSC-derived neurons from schizophrenic patients, suggesting that examination of ARG expression in patient-derived human models is important. By performing RNAseq on human iPSC-derived neurons through the neural progenitor cell stage and early neuronal development, we found that a specific activity-regulated *BDNF* isoform containing untranslated exon 1 increases over development. We then investigated the response of human iPSC-derived neurons to PCID using qPCR for various ARGs. Induction of *BDNF* from both the activity-dependent exon 1 and exon 4 transcripts in human iPSC derived neurons following PCID is low, but expression of other ARGs, including *ARC, FOS* and *EGR1,* is upregulated. Similar to experiments in mouse cultures, multiplex smFISH was used to investigate activity-induced regulation of ARGs at single cell resolution in hiPSC-derived neurons across time. Our data suggest that differential ARG patterns represent dynamic molecular signatures, marking recruitment of neurons to specific ensembles.

Title: Proteomic landscape of genetically targeted neural systems

Authors: *V. DUMRONGPRECHACHAN, L. BUTLER, Y. KOZOROVITSKIY;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Neuromodulation is an essential process that regulates neuronal excitability, synaptic processing, and circuit activity across the vertebrate brain. Neuromodulators trigger complex intracellular signalling cascades resulting in effects that span multiple timescales. We hypothesized that long-term effects of neuromodulation involve changes in the proteomic landscape in a cell-type specific manner. However, current genetically-targeted proteomic approaches are limited to a timescale of a few days and are not optimal to investigate initial changes in the proteome with a timescale of hours. Here, we created a new Cre-dependent peroxidase reporter mouse line using CRISPR/Cas9 approach. In conjunction with exogenous biotin tag, genetically-encoded peroxidase can rapidly take snapshots of the proteome at earlier time points (hours). We validated Cre-dependent expression and activity by crossing the reporter line to various Cre-driver lines including VGlut2-Cre and VGAT-Cre. We showed that the proteome of Cre-positive cells were selectively labelled and enriched for mass spectrometry identification and quantification. Finally, we plan to use this novel approach to investigate changes in the proteomic landscape of glutamatergic and GABAergic neurons in the medial prefrontal cortex in response to rapidly-acting antidepressant ketamine.

Title: Sex differences in estradiol regulation of local protein synthesis and synaptic proteome

Authors: *D. P. SRIVASTAVA[1], P. RAVAL[2], S. MOSS[3], N. BRANDON[4];
[1]Inst. of Psychiatry, Psychology and Neuroscien, London, United Kingdom; [2]Inst. of Psychiatry Psychology and Neuroscience, King's Col. London, London, United Kingdom; [3]Tufts Univ., Boston, MA; [4]AstraZeneca, Cambridge, MA

Abstract: Estrogens, particularly 17beta-estradiol (estradiol), have repeatedly been shown to have long-lasting influences over learning and memory. The mechanisms underlying estrogenic-facilitation of memory are driven partly through activation of signalling cascades, resulting in modulation of synaptic structure and function. However, growing evidence indicates that estradiol can also rapidly modulate local protein synthesis (translation); the ability to produce nascent proteins near or at synapses, independent of gene transcription. However, the molecular and cellular mechanisms that underlie estradiol's ability to regulate local protein synthesis and subsequently, the consequence of modulating local protein translation of synaptic function and whether male and female brains utilise the same signalling mechanism to regulate this process are unknown. Using a combination of Surface Sensing of Translation (SUnSET) and fluorescent non-canonical amino acid tagging (FUNCAT) assays, we demonstrate that estradiol increases protein synthesis in acute hippocampal slices prepared from 10-12 week old male and ovariectomized (OXV'ed) female mice. This increase in protein synthesis was found to be independent of gene transcription indicting a local protein synthesis mechanism. Consistent with this, treatment with estradiol increased the number of active ribosomal complexes along dendrites and at synapses. Concurrently, an increase in the amount of newly synthesised protein was detected at synapses following estradiol treatment. This was further reflected by an increase in select synaptic proteins and an increase of these proteins at dendritic spines. Critically, the signalling pathways required for estradiol-induced protein synthesis differed between males and OVX'ed females. Surprisingly, this was not always reflected when individual proteins were examined, suggesting that estradiol employs both distinct and common signalling pathways to regulate the local synthesis of specific synaptic proteins. Taken together, our study suggests that the rapid modulation of local protein synthesis by estradiol may result in an increase in synaptic function in male and females and thus, contribute to the facilitation of cognition offered by estrogens; this however, occurs via distinct signalling mechanisms between sexes.

Title: Expression of mitochondrial uncoupling protein 4 in association with ATP-dependent k^+channel opening in neuron

Authors: *Y. FUKUSHI, C. SUN, S. YAMAMOTO;
Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Objective: Our previous study had shown that electrical stimulation of cerebellar fastigial nucleus (FN) before middle cerebral artery occlusion (MCAO) induced ischemic tolerance in rats, and increased UCP4 expression in the cerebral cortex [1, 2]. UCP4 is an uncoupling protein localized in the inner mitochondrial membrane and principally expressed in the central nervous system. It is expected that the expression of UCP4 might have related to the acquisition of cerebral ischemic tolerance; however, the mechanism of the UCP4 expression is still under discussion. We hypothesized that the UCP4 expression is regulated through an ATP dependent K^+ (kATP) channel opening. The objective of this study is to determine whether kATP channel opening induce expression of UCP4 in the neuronal cells. **Method:** For primary cultured cortical neurons, 1-day-old Wistar rat was used. The cerebral cortex was dissected and minced, then dissociated by the pipetting and suspended the culture medium. After one-week incubation, UCP4-promotor tdTomato (red fluorescence protein) reporter vector plasmid (UCP4-tdTomato) was transfected in the neurons. Then, expression of UCP4 was observed with the incubation fluorescence microscope for 30 hours with or without 500 μM diazoxide administration. For SHR rat (12-week), UCP4-tdTomato plasmid was transfected by intraventricular injection. One day after the transfection, diazoxide (10 mg/kg) was injected intraperitoneally. Two days after the injection, the brain slices were prepared, and the expression of UCP4 was observed with the fluorescence microscope. **Results:** UCP4 was up-regulated 1.3 times higher 24h after the administration of 500 μM diazoxide as compared to that without the administration. On the other hand, UCP4 expression was suppressed by 1 μM glibenclamide of kATP channel blocker with 500 μM diazoxide. In SHR rat brain, UCP4 expression was also induced by 10 mg/kg diazoxide administration. **Conclusion:** kATP channel opening induced the UCP4 expression in the neuronal cells. This result supports the hypothesis that the FN stimulation activates kATP channel opening and induces UCP4 expression in the event of ischemic tolerance in rat brain. **References**: [1] D J. Snyder Dept. of Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Brain-derived neurotrophic factor (BDNF) is an activity-dependent protein in the neurotrophin family that plays a vital role in neuronal growth and survival, synaptic plasticity, and behavior. Bdnf has a complex gene structure, with nine unique promotors that drive transcription of at least 20 distinct transcripts with unique 5' non-coding exons that encode an identical BDNF protein. Previous data from our group and others have shown that expression of these transcripts is regulated by independent, stimulus-specific mechanisms. For example, promoters I and IV contribute significantly to activity-dependent transcription of exon I and exon IV-containing transcripts, respectively. This regulation of Bdnf transcription results in spatial and temporally specific translation of BDNF protein and is thought to underlie the varied roles of BDNF in neuronal development and plasticity. However, it remains unclear whether individual cells preferentially transcribe Bdnf from one promoter over another. While transcript-specific Bdnf expression has been well-studied in rodent models, less is known about how well conserved Bdnf transcriptional regulation remains in human model systems, such as induced pluripotent stem cell (iPSC)-derived neuron. Using RNAscope single-molecule fluorescent *in situ* hybridization, we demonstrate that Bdnf exon (ex) 1 and ex4-containing transcripts are dynamically regulated following induction of widespread neuronal activity in largely non-overlapping neuronal populations in mouse cortex. To extend these findings, we examined Bdnf ex1 and ex4-containing transcript expression at single cell resolution in mouse cortical neurons and human iPSC-derived neurons at baseline and following induction of neuronal activity. To explore how selective elevation of ex1 or ex4-containing Bdnf transcripts impacts neuronal structure and network activity, we employed a recently developed CRISPR activator system to drive transcript-specific expression of Bdnf in single cells to examine transcript-specific effects

on dendrite branching and network dynamics. Our findings provide further support that, in both rodent and human-derived models, BDNF produced from different activity-regulated promoters may have unique functions in neurodevelopment, plasticity, and behavior.

Title: Distinct roles of Bdnf 1 and Bdnf 4 transcript variant expression in hippocampal neurons

Authors: *S. V. BACH[1], D. HOSEIN[1], D. WILLIAMS[1], L. IANOV[1], N. CARULLO[1], C. G. DUKE[2], J. J. TUSCHER[1], B. W. HENDERSON[3], J. H. HERSKOWITZ[5], J. J. DAY[4]; [1]Univ. of Alabama at Birmingham, Birmingham, AL; [2]Sch. of Med., UAB, Birmingham, AL; [3]Neurol., [4]Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL; [5]Neurol., The Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: *Brain-derived neurotrophic factor* (*Bdnf*) plays a critical role in brain development, neuronal differentiation, dendritic growth, and synaptic plasticity. Aberrant *Bdnf* regulation is implicated in numerous psychiatric and neurocognitive disorders, such as depression, schizophrenia, drug addiction, Rett syndrome, and memory impairments. The rodent *Bdnf* gene contains nine 5' non-coding exons (I-IXa) and one 3' coding exon (IX). Transcription of different *Bdnf* variants (which all code for the same BDNF protein) is initiated at unique promoters upstream of each exon. However, the functional significance of each *Bdnf* transcript is still unknown. Here we show that *Bdnf* mRNAs *I* and *IV* are the most responsive transcripts to neuronal stimulation or inactivation. Using single-molecule RNA fluorescent *in situ* hybridization (FISH) we show that they spread to different cellular compartments upon neuronal depolarization with potassium chloride. To investigate functional roles of *Bdnf* variants *I* and *IV,* we use a CRISPR/dCas9 transcriptional modulation system in which dCas9 fused to either a transcriptional activator (VPR) or a repressor (KRAB-MeCP2) is targeted to distinct *Bdnf* promoters, resulting in selective transcript upregulation or repression, respectively. Using this bi-directional regulation of endogenous *Bdnf* transcription, we are investigating

electrophysiological and morphological changes of hippocampal neurons. Microelectrode Array (MEA) recordings indicate that simultaneous upregulation of *Bdnf I* and *IV* variants increases neuronal action potential frequency and burst frequency. Dendritic spine analyses indicate that upregulation of *Bdnf* variant *I*, but not *IV*, increases mushroom spine density and decreases thin spine density. Whole genome RNA-sequencing reveals that upregulation of *Bdnf I* or *IV* variants increases expression of immediate early genes and genes implicated in synaptic plasticity, but also results in distinct gene expression changes that are specific to each transcript variant. Taken together, our data suggest that *Bdnf I* and *IV* are highly responsive to pharmacological stimulation and may have diverse contributions to neuronal excitability, dendritic spine development, and gene expression profiles in cultured hippocampal neurons. In addition to addressing a poorly understood mechanism in *Bdnf* transcriptional regulation, our work illustrates functional feasibility for endogenous *Bdnf* manipulation for the development of potential gene therapies against psychiatric and neurocognitive disorders.

Title: Physiological stimuli-dependent BDNF promoter activity in cortical cells revealed by live imaging with luciferase assay

Authors: *Y. MIYASAKA, *N. YAMAMOTO;
Osaka Univ, Grad Sch. Frontier Biosci, Suita, Osaka, Japan

Abstract: In the developing cortex, firing and synaptic activity is known to remodel neuronal circuits via activity-dependent gene expression. However, what physiological neuronal activity efficiently regulates the gene expression is almost unknown. To address this issue, we studied the promoter activity of brain-derived neurotrophic factor (BDNF), which is a well characterized activity-dependent gene, in living individual cortical cells by applying various physiological stimulation. Cortical slices from neonatal mouse and rat brains were cultured for two weeks. To visualize the promoter activity, a luciferase (luc) vector containing a BDNF exon4 promoter was transfected sparsely into upper layer neurons. The luc signals were observed by an EMCCD camera every 30 minutes for up to 24 hr. For conventional electrophysiological stimulation, a

pair of platinum electrodes were penetrated into the cortical slices, and various stimuli (0.1-60 Hz) were applied. Optogenetic stimulation with channel rhodopsin 2 (ChR2) was also used for relatively low frequency stimulation (0.1-10 Hz). For this, a ChR2-YFP vector was transfected into upper layer cells by *in utero* electroporation prior to culturing. First, the promoter activity was confirmed to be stable for several hours before stimulation. After high frequency electrical stimulation (>2 Hz), the luc signals in a large fraction of cells began to increase within a few hours and peaked around 6 to 8 hr after stimulation (2-6 fold increase). In particular, theta burst and 20 Hz stimuli were effective. In contrast, low frequency stimulation (0.1 and 1 Hz) did not increase the luc signals in most observed cells. A similar frequency-dependent increase was also found in the luc signals by optogenetic stimulation, indicating that synaptic responses contribute to the increase in the promoter activity. Moreover, the luc signals did not change in the presence of glutamate receptor blockers even after high frequency stimulation. Taken together, the present live imaging study of the luc signals in individual cells demonstrates that synaptic inputs with preferential frequency efficiently induces BDNF promoter activity in developing cortical neurons.

Title: Gene expression levels of the BDNF pathway in glutamatergic neurons from animal models with social deficits

Authors: *M. FAIN[1], B. BEASLEY[2], R. ABENS[2], K. SCOTT[2], G. WESLEY[2], M. CHANDLEY[2];

Abstract: Autism spectrum disorder (ASD) is a neurological developmental disability affecting communication and other social behaviors. ASD currently affects 1 in 59 children with males affected more frequently at a rate of 1 in 42. It has been postulated that an imbalance between the excitatory and inhibitory systems may be at the core of neuronal dysfunction in ASD. Increased excitatory glutamatergic markers and reduced inhibitory markers have been observed in the neuropathology of the disorder. Brain derived neurotrophic factor (BDNF) and the receptor TrkB were evaluated to determine if markers of impaired synaptic health may be present in brain tissue from mouse models that display social behavior deficits. BDNF binding to the receptor TrkB is

responsible for downstream signaling that facilitates synaptic plasticity and maintenance. Previous studies in human ASD from our laboratory have found that *NTRK2* expression (encodes TrkB receptor) in glutamatergic neurons is reduced in anterior cingulate cortex from donors diagnosed with ASD when compared to typically developing control donors. In this study, laser capture microdissection was used to obtain enriched populations of glutamatergic neurons from the cingulate cortex using male mice (postnatal day 21). Gene expression levels for *BDNF* and *NTRK2* in these neurons were compared to wild type control mice (C57BL/6J) using tissue from three mouse models (maternal immune activation, BTBR, and valproic acid) of social behavior deficits. A secondary goal of this study was to determine if comparable gene expression levels could be obtained between nested QPCR and quantitative endpoint PCR. For the nested QPCR method, twenty cycles of PCR were performed using reverse transcribed cDNA with Prime5 HotStart Master Mix followed by a subsequent QPCR reaction using Powerup sybr-based enzyme on the BioRad CFX96 RT detection system. No significant gene expression differences were found in *NTRK2* expression levels between groups, but expression levels of *BDNF* in only the BTBR model was significantly decreased ($p < 0.05$). The second method used the same starting cDNA for PCR amplification but was quantified using the Agilent tape station 2200 and no significant differences between *BDNF* or *NTRK2* were determined in any model. Behavioral analysis of mouse littermates matured to adulthood used in the study demonstrated expected behavioral changes between wild type and models in marble burying and sociability measures. Further analysis of additional genes in the BDNF signaling cascade in the mouse models could help establish a parallel between human BDNF abnormalities in ASD and brain development linked to social behaviors.

Title: Neuronal activation can modulate enhancer activity through *de novo* DNA methylation

Authors: *T. KAMEDA[1], T. IMAMURA[1], T. TAKIZAWA[2], F. MIURA[1], T. ITO[1], K. NAKASHIMA[1];

Abstract: External stimuli cause gene expression changes in the brain, and such changes are important for memory formation and learning. Contrary to the notion that non-dividing cells

exhibit low epigenetic dynamics, recent studies have shown that neuronal activation can induce epigenetic changes, including DNA demethylation, for gene induction. Here we show that neuronal activity-dependent DNA methylation also impose a considerable effect on gene expression memory formation. In order to examine the degree to which DNA methylation changes upon neuronal stimulation, we conducted DNA methylome analysis using post-bisulfite adapter-tagging method for primary cultured neurons that were hyper-activated by the treatment with bicuculline/4-aminopyridine. We identified 531 and 669 regions where methylation and demethylation respectively occurred upon stimulation. Many of these regions were located relatively far from gene promoters. Using publicly available ChIP-seq data for H3K4me1, accumulation of H3K4me1 was observed at the differentially methylated regions, raising the possibility that not only DNA demethylation but also DNA methylation occur at a set of enhancer regions to regulate downstream gene expressions. To test this hypothesis, we examined the enhancer activity of selected differentially methylated regions using a reporter assay system with a CpG-free luciferase. We found that DNA methylation at the differentially methylated regions impaired enhancer activity, and supply of a DNMT inhibitor, RG108, or simultaneous knockdown of *Dnmt1* and *Dnmt3a,*reversed the DNA methylation status from hyper-methylated to hypo-methylated. Our results suggest that rapid *de novo* DNA methylation occurs depending on neuronal activity in a set of enhancer regions and modulate their transcriptional activity through DNA methylation machinery including DNMT1 and DNMT3a.

Title: Activity dependent regulation of CaMKII and local RNA translation machinery in the postsynaptic density

Authors: *Y. JOO, D. R. BENAVIDES;
Dept. of Neurol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The ser/thr kinase calcium/calmodulin-stimulated protein kinase II (CaMKII) is essential in signaling pathways important for synaptic plasticity that underlie learning and memory. RNA transport and local translation are crucial for neuronal signal transmission and synaptic plasticity. Dysfunction of CaMKII and RNA metabolism have been implicated in numerous neuronal disorders. Synaptic accumulation of CaMKII is triggered by neuronal

activity, and local Ca^{2+} signaling induces translation of CaMKII. However, the timecourse for activity-induced regulation of CaMKII in the postsynaptic density (PSD) remains to be fully elucidated. We used dissociated rat primary neuron culture, proteomics, pharmacology, and immunoblotting to investigate the translational mechanisms of CaMKII regulation in the PSD. We discovered changes in total protein and phosphorylation states in the PSD following brief NMDA or KCl treatment. These data suggest that activity-dependent regulation of local RNA translation is induced in the PSD. This study may contribute to understanding of the underlying pathophysiology of neurological disorders and pathways for novel therapeutics.

Title: Presynaptic protein synthesis supports structural and functional plasticity at excitatory hippocampal mossy fiber synapses

Authors: *H. R. MONDAY[1], Y. J. YOON[2], R. H. SINGER[2], P. E. CASTILLO[1];
[2]Anat. & Structural Biol., [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: Activity dependent changes at synapses critically underlie information storage in the brain. Protein synthesis is required for long-lasting plastic changes of the postsynaptic compartment, but whether and how local protein synthesis contributes to presynaptic structure and function remains unclear. We recently reported that presynaptic protein synthesis is required for functional plasticity of a subset of inhibitory interneuron terminals. In order to test the role of protein synthesis in excitatory presynaptic terminals, we examined the hippocampal mossy fiber (MF)-CA3 synapse which expresses robust presynaptic functional plasticity, has notably large and complex boutons, and is known to undergo structural plasticity upon experience. Using electrophysiology, we first confirmed that long-term potentiation (MF-LTP) requires protein synthesis and showed that transected MF axons are capable of MF-LTP, suggesting that protein synthesis in the soma is not required for plasticity. Using high-resolution microscopy, we found that MF-LTP is associated with an enhancement of bouton volume that was protein synthesis-dependent. Importantly, we demonstrate that MF boutons are capable of synthesizing protein

locally. By selectively labeling ribosomes in the presynaptic neuron, we also show that MF boutons and axons contain ribosomes. Lastly, given that the Fragile X mental retardation protein (FMRP), a critical regulator of translation, is highly expressed in mossy fiber boutons, we tested whether conditional presynaptic KO of FMRP results in changes at the MF synapse. Presynaptic KO of FMRP resulted in a loss of the activity-dependent structural and functional plasticity. Together, these results indicate that presynaptic protein synthesis critically regulates bouton structure and function at diverse synapse types in the mature brain. This capability could underlie input-specificity of presynaptic plasticity and may represent a novel mechanism that regulates memory formation.

Title: Real-time imaging of activity-regulated arc gene transcription in acute hippocampal slices

Authors: *S. DAS[1], P. J. LITUMA[2], P. E. CASTILLO[2], R. H. SINGER[1,3];
[1]Anat. and Structural Biol., [2]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY; [3]Janelia Res. Campus, Ashburn, VA

Abstract: Spatio-temporal control of gene expression in a neuronal network is an essential element of memory formation. For immediate early genes (IEGs) strongly linked to behavior, this regulation initiates at the level of transcription. Arc (activity-regulated cytoskeletal associated), or Arg3.1 is one such IEG playing crucial roles in synaptic plasticity and memory consolidation. Although the distribution of Arc mRNA is known, it has not been possible to follow the temporal behavior of these mRNAs in tissue. To this end, we generated a transgenic mouse, where the endogenous Arc gene is tagged in its 3′UTR with an array of bacteriophage-derived stem loops that bind to fluorescent coat proteins. This approach allows the visualization

of actively transcribing Arc loci and mRNAs in real time both in cultured neurons and in acute hippocampal slices. Using optogenetic stimulation with channelrhodopsins (ChR2 in cultures, and ChIEF in slices), we have developed an all-optical method of triggering and measuring Arc transcription in tissue. By modulating the frequency of opto-stimulation we identified the minimal threshold required for transcription induction to be 25Hz. In addition, pairing optogenetics with antagonists for synaptic transmission allowed us to delineate the contribution of synaptic versus somatic inputs to trigger transcription. Furthermore, following activity, long-term imaging of Arc transcription revealed novel features - the immediate early phase is followed by subsequent reactivation phases in a subset of neurons without any additional stimulation. Our results provide unprecedented temporal insights into activity-regulated IEG transcription and these transcriptional signatures have implications in long-term memory consolidation.

Title: Two functionally distinct signaling cascades are required to efficiently couple neuronal activity with immediate early gene transcription

Authors: *R. N. SAHA[1], B. GUTIERREZ[3], R. POSTON[2], C. DUNN[4];
[2]Mol. and Cell Biol., [1]Univ. of California Merced, Merced, CA; [3]Univ. of California, Merced, Merced, CA; [4]Quantitative Systems Biol., Univ. of California, Merced, CA

Abstract: We have recently provided evidence that neuronal activity patterns induce different subsets of activity-induced immediate early genes (IEGs) [Tyssowski et al. (2018)]. Brief activity selectively induces a small subset of the activity-regulated gene program - rapid IEGs - that are mechanistically distinct from the later IEGs (delayed IEGs) in their open chromatin state with preloaded TFs and RNA Polymerase II (Pol2) at the regulatory regions and their requirement of MAPK/ERK signaling. However, further work in our laboratory has shown that MAPK/ERK signaling is not sufficient for optimal expression of most rapid IEGs and minimal expression of many delayed IEGs. This suggests the involvement of additional signaling cascades in the process. We have identified that neuronal activity induces the Calcineurin/CRTC1/CREB signaling cascade in parallel to MAPK/ERK pathway and both these two pathways then function together to provide the complete IEG transcriptional response.

Blocking the Calcineurin/CRTC1 pathway pharmacologically or genetically impairs optimal transcription of most rapid IEGs (two exceptions) and several delayed IEGs. Functionally, these two pathways are non-redundant and have distinct functions. While the primary function of the MAPK pathway is to regulate Pol2 recruitment and activity during elongation, the Calcineurin/CRTC1 pathway regulates the epigenetic landscape of regulatory regions (promoters and enhancers) via CBP/p300 HAT activity. Together, these two signaling cascades efficiently relay the information from the membrane for a proficient transcriptional response in the nucleus.

Title: Contrasting effects of pathologic and experimentally induced dentate granule cell hyperactivity on spatial tuning specificity in hippocampal CA1 cells

Authors: *S. A. PARK[1], H. TAKANO[1], J. B. KAHN[2], D. A. COULTER[1,2];
[1]Pediatrics Div. of Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: The dentate gyrus (DG) plays a crucial role in cognition by regulating hippocampal network activity. In pathological conditions such as epilepsy, where the DG is hyper-excitable, a dysregulation of hippocampal activity could affect cognitive abilities. To better understand how altered DG function affects downstream processing we examined cellular activity in the CA1 hippocampal region when normal DG function is perturbed. For this purpose, we implemented an in vivo approach and performed two-photon calcium imaging in the CA1 of awake, behaving mice traversing a virtual reality (VR) environment. Our experimental setup allowed us to monitor the activity of CA1 pyramidal cells and assess their spatial tuning with regard to the animal's position within the virtual environment. Compared to controls, the CA1 region in epileptic mice that had experienced pilocarpine-induced status epilepticus (SE), which generates chronic hyperexcitability in dentate granule cells (DGCs), had fewer place cells and a lower spatial tuning specificity. Some SE mice exhibited synchronous network activity in the CA1 region, considered to be interictal burst events. No synchronous network activity was observed in any control mice (n=12). We also investigated how spatial tuning in the CA1 region is affected by experimentally enhancing DGC excitability using chemogenetic approaches. CaMKIIa.hM3D

was expressed in the dorsal DG of Thy1-GCaMP6 mice which were treated with clozapine-N-oxide (CNO) 30 min before VR navigation to induce DGC hyperexcitability. Counterintuitively, increasing DGC excitability by CNO enhanced the spatial coding. The number of place cells increased and spatial tuning specificity improved. Enhanced spatial coding was observed in both 2.5m (short) and 5m (long) VR tracks, but with a less profound change when animals navigated a short track compared to the long track. This might be attributed to ceiling effects, since at baseline, spatial coding was poorer in the long track compared to the short track. These contrasting effects on CA1 cells following the modulation of DG excitability experimentally vs. by epilepsy development suggest that distinct factors not under experimental control may disrupt CA1 spatial coding in epilepsy.

Title: Differential neural activities in multiple rats brain regions in Lithium-pilocarpine-induced state epilepsy model

Authors: *Q. WANG[1,2,3], W. SHAN[1], H. YANG[1], A. GUO[1], J. WU[1,4];
[1]Beijing Tiantan Hospital, Capital Med. Univ., Beijing City, China; [2]Natl. Ctr. for Clin. Med. of Neurolog. Dis., Beijing City, China; [3]Beijing Institute for Brain Disorders, Beijing City, China; [4]Advanced Innovation Ctr. for Human Brain Protection, Capital Med. Univ., Beijing City, China

Abstract: Purpose: To confirm different regional brain activities characterized in Lithium-pilocarpine-induced status epilepticus model
Methods: we induced seizures and status epilepticus in Lithium-pilocarpine model. Regional brain activities were evaluated by EEG and c-Fos immunolabeling. ZnT3 immunostaining was performed to observe hippocampal mossy fiber sprouting within 7 days after induction of status epilepticus.
Results: EEG recordings showed distinctive features of activation in different brain areas. With the aggravation of behavioral manifestations of seizures, the frequency and amplitude of the

discharges on EEG were increasing gradually. Status epilepticus was eventually induced and sustained. The labeling of c-Fos was enhanced in the medial prefrontal cortex, hippocampal CA1, CA3, and dentate gyrus, and in the striatum. For each brain region, prominent c-Fos labeling was observed at 2h and 4h after induction of status epilepticus and diminished at 24h. In the chronic phase after SE induction, mossy fiber sprouting was observed at 7 days after SE accompanied by the dynamic evolution of epileptic EEG activities.
Conclusions: These findings validated Lithium-pilocarpine-induced status epilepticus as a seizure model with a specific spatial-temporal profile of neural activation. Hippocampal mossy fiber spouting might be associated with spontaneous seizures in the chronic phase.

Title: Enhanced susceptibility to pentylenetetrazol-induced seizure in forebrain excitatory neuron-specific connective tissue growth factor knockout mice

Authors: *C.-Y. TSAO, C.-Y. CHEN, L.-J. LEE;
Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Connective tissue growth factor (CTGF) plays critical roles in the development and regeneration of various connective tissues. In fact, CTGF is also expressed in the nervous system, especially under pathological conditions such as epileptic insult. However, the role of CTGF in epileptogenesis has not yet been studied. In order to elucidate the function of CTGF in the nervous system, we generated forebrain excitatory neuron-specific *Ctgf* knockout (Fb*Ctgf* KO) mice, in which *Ctgf* gene is removed under the expression of *Emx1-Cre*. In the present study, pentylenetetrazol (PTZ) was administrated intraperitoneally in a single dose of 30, 50 or 60 mg/kg to both control and Fb*Ctgf* KO adult male mice. The responses following PTZ injection were classified into hypoactivity, partial clonus, general clonus and tonic-clonic seizures. The behaviors of mice after the PTZ treatment were recorded for 30 mins and the lethality, occurrence of each seizure response and latencies to the first responses were analyzed. No significant difference was noted between control and Fb*Ctgf* KO at the dosage of 30 mg/kg. Higher lethality rate was evident in Fb*Ctgf* KO mice at higher dosages. The latencies to the first sign of hypoactivity and general colonus were shorter in Fb*Ctgf* KO mice compared with controls. Our result indicated an enhanced susceptibility to PTZ-induced seizure in mice lacking *Ctgf*, indicating a role of CTGF involved in the neuronal mechanism of epileptogenesis.

Title: Global correlates of local epileptiform activity in a chemically-induced seizure model

Authors: ***P. J. STEFFAN**, D. A. MCCORMICK;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Localization-related epilepsies are a commonly diagnosed neurological disorder. Although focal-onset seizures can secondarily generalize throughout the brain, the mechanism behind this transition remains unclear. A preliminary question in addressing this mechanism is to ask if spatiotemporal patterns of localized epileptiform activity are reflected in global readouts of arousal and behavioral state. Here we demonstrate that focal epileptiform activity is highly coordinated with key external biomarkers of global arousal and behavioral state in animals treated with focal cortical application of the $GABA_A$ antagonist picrotoxin. Electrophysiology *in vivo* demonstrates that the emergence of chemically-induced focal seizures causes pupil diameter and whisking motion to become highly correlated to inter-ictal activity. Further, wide-field fluorescence imaging demonstrates that the extent of spread of epileptiform activity is related to the magnitude of pupil dilation. This is true of inter-ictal spikes as well as focal and secondarily generalized seizures (i.e. ictal activity). These results suggest that even before a focal-onset seizure spreads throughout the brain, local epileptiform activity is already being reflected in the animal's global arousal and behavioral state. How local information comes to be represented in such global signals is of interest for future study as a possible mechanism for secondary generalization. Further, the coordination of external biomarkers to epileptiform activity may prove useful for covert seizure detection and closed loop stimulation paradigms.

Title: Single seizure induced retrograde amnesia in mice: Mechanisms

Authors: *A. A. NAIK, J. KAPUR;
Neurol., Univ. of Virginia, Charlottesville, VA

Abstract: Seizures can cause retrograde amnesia but underlying mechanisms are poorly understood. It is proposed that engram cells and circuits are engaged in acquisition, consolidation and retrieval of memories. We tested whether, single seizure and spatial learning activate CA1 pyramidal neurons and if so, do the CA1 ensembles activated by seizure overlap with those of spatial memory. We developed a model of single seizure retrograde amnesia. C57bl/6 mice (6-8 week, n=12) were trained for delayed discrete trial rewarded alternation task on T-maze to engage working memory. Animals then received pentylenetetrazole (PTZ; 40mg/kg, i.p.) to induce seizure or saline; they were tested the following day. We used TRAP mice expressing tamoxifen-dependent CreERT2 under cfos-promoter for activity-dependent labelling of CA1 pyramidal neurons with tdTomato following either a seizure or working memory acquisition. Entire hippocampus was sectioned (40µm), imaged and TRAPed (tdT+ve) CA1 neurons were counted. Mice that experienced a seizure following training made fewer correct choices on probe day than saline treated controls supporting retrograde amnesia. Seizure induced activation in CA1 as significantly more tagged CA1 pyramidal neurons were present following a seizure compared to saline controls (PTZ; 293.4±22.53, saline; 124.6±16.05, $P<0.001$). Similarly, untrained home cage controls demonstrated sparse CA1 labelling, whereas, significantly more TRAPed CA1 neurons in T maze group demonstrate CA1 activity following spatial memory (untrained; 113.0 ± 6.90, trained; 231.4 ± 18.42, $P<0.001$). The activation pattern was not spatially restricted as tagged pyramidal neurons were present in dorsal as well as ventral hippocampus. Individual sections with CA1 region contained 4 to 5 tagged neurons following either training or seizure with 1 to 3 in respective controls. We hypothesized same set of pyramidal neurons may be activated as positions of these tagged CA1 neurons from seizure and trained mice appeared to be similar on visual examination. Ongoing experiments are aimed to test this potential overlap. This study may shed light on the mechanisms of retrograde amnesia.

Title: Losartan affects seizure threshold and progression by decreasing blood brain barrier disruption

Authors: *S. MCDERMOTT[1], G. LANGUREN[1], N. P. SABETFAKHRI[1], J. M. RAKOTOMAMONJY[2], A. D. GUEMEZ-GAMBOA[3];
[1]Northwestern Univ., Chicago, IL; [2]Physiol., Northwestern University, Feinberg Sch. of Medici, Chicago, IL; [3]Physiol., Nortwestern Univ., Chicago, IL

Abstract: Blood-brain barrier (BBB) disruption is a key element in the pathogenesis of epilepsy. Previous studies have shown that BBB disruption allows immune cells, inflammatory mediators, and albumin to infiltrate the brain parenchyma, lower the seizure threshold, and promote epileptogenesis. However, the mechanisms underlying the complex interplay between BBB disruption and brain inflammation, and subsequent effects on seizure susceptibility and progression, remain unclear. In this study, we use a GABAA inhibitor, flurothyl, to determine whether seizure-induced BBB permeability and inflammation affect the seizure threshold and seizure progression. Our results show that the BBB remains intact during flurothyl-induced myoclonic jerks (MJ), but is disrupted upon reaching generalized tonic-clonic seizures (GTCS). We observe an increase in neuronal activity, cell death, and astroglial activation following flurothyl-induced GTCS. In addition, increased BBB permeability contributes to seizure progression, but does not correlate with changes in seizure threshold. Treatment with an FDA-approved drug, Losartan, inhibits BBB disruption, leading to an increased latency to GTCS and slower seizure progression. Losartan-treated mice also show a decrease in neuronal activity, cell death, and reactive astrogliosis. Altogether, these results suggest that inflammation and neuronal excitability due to an increase in BBB disruption occurring between the first MJ and GTCS contribute to seizure progression.

Title: Effect of deep microelectrodes implantation surgery on physiological and pathological behaviors in rats: A temporal analysis

Authors: *G. A. CHIPRES-TINAJERO, M. A. NUNEZ-OCHOA, L. H. SAT-DÁVILA, G. M. CAMBEROS-CAMARENA, L. G. MEDINA-CEJA;
Dept. of Cell. and Mol. Biol., Univ. De Guadalajara, Guadalajara, Mexico

Abstract: Wake-sleep cycle and exploratory are considered important behaviors to intact or sham animals that are usually not affected by experimental protocols in which several neurosurgeries are carried out, as well as in animal's model of neural diseases in which the impact of surgeries in the pathological phenomena that is studied is reduced; in epilepsy models some electrophysiological parameters such as Fast Ripples (FR) oscillations are associated with the disease and are studied without regard to surgery effect, even in specific brain areas in which circuits are associated with these behaviors. We analyzed the effects of microelectrodes implantation surgeries in the hippocampus of rats on physiological and pathological behaviors, in this last behavior considering: a) relationship between latency of first spontaneous and recurrent seizure and time on seizures over 3-5 Racine scale per day before and after surgeries, and b) correlation between the number of fast ripples (FR) recorded and the number and severity of seizures events in the same day. Male Wistar rats (210-300 g) were grouped in Sham and epileptic (n = 7, each group); to induce epilepsy, rats were injected with a single dose of pilocarpine hydrochloride (2.4 mg/2µl; i.c.v.). Sham and epileptic rats were implanted with deep microelectrodes in the CA1, CA3 and dentate gyrus; both groups were EEG recorded during 5 days; the behaviors were analyzed by video monitoring (24hours/7days), 15 days before and 15 days after the surgery. Quiet wakefulness, sleep and exploratory activity as physiological behaviors and convulsive behaviors according the Racine scale as pathological behaviors were analyzed. Epileptic animals showed a significant decrease in sleep time and exploratory activity compared with Sham group after surgery, while a reduction in quiet wakefulness period and an increase in the sleep and exploratory behavior time was observed in animals of Sham group after surgery; the rats with short latency to the first spontaneous and recurrent seizure (≤60 days) showed high variability in terms of total mean seizure time per day in contrast with epileptic animals with long latencies. Surgery increased the average time of seizures in scale 4 per day and the number of seizure events in 4 and 5 scales. No significant correlations between the

occurrence of FR and scales in epileptic animals were observed. In conclusion, surgery affects physiological as pathological behaviors in both Sham and epileptic groups; however a correlation between the severity of seizures and FR activity was not found in the present study. Title: Profiling of neuronal and microglial argonaute-2 bound microrna during epileptogenesis and in chronic epilepsy reveals cell-type specific contribution to disease

Authors: *G. P. BRENNAN[1], N. NGUYEN[2], T. HILL[2], E. BRINDLEY[2], M. DIVINEY[2], M. HEILAND[2], A. BATOOL[2], D. C. HENSHALL[2];
[1]Physiol. and Med. Physics, [2]Royal Col. of Surgeons Ireland, Dublin, Ireland

Abstract: *Introduction:* Epilepsy is a chronic neurological disorder characterized by spontaneous recurrent seizures and affects between 50-60 million people worldwide. Acquired temporal lobe epilepsy, induced by brain insult such as TBI, stroke or status epilepticus is the culmination of altered molecular and cellular function regulated by global changes in gene networks in numerous cell types. Recently it has emerged that microRNAs (small non-coding RNAs) are involved in the development of acquired temporal lobe epilepsy. How they shape the neuronal and microglial response to an epilepsy-inciting event however is unclear. Here we generate an inducible transgenic reporter mouse which allows genome-wide profiling of the miRnome from both neurons and microglia in healthy, epileptogenic and epileptic mice. *Methods:* A transgenic mouse line homozygous for a FLAG-tagged-Ago2 gene (Rosa-Stop$^{fl/fl}$-Flag-Ago2 were crossed with two different inducible cre-recombinase mouse lines, one with a Cx3cr1 microglial specific promoter and one with a Thy1 neuronal promoter producing two specific genotypes *Cx3cr1-cre$^{tg/tg}$;Rosa-Stop$^{fl/fl}$-Flag-Ago2, Thy1-cre$^{tg/+}$;Rosa-Stop$^{fl/fl}$-Flag-Ago2* respectively. Upon the administration of tamoxifen these mice then express Flag-tagged Ago2 in either microglia or neurons. Epilepsy was induced by injecting kainic acid directly to the amygdala of adult mice, a sham injection of PBS was administered to control animals. Hippocampus was harvested from epileptogenic animals (24h post KA) and chronically epileptic animals (2 weeks post KA) and from time matched control animals. Immunoprecipitation for

Flag followed by RNA isolation was performed to isolate Ago2-bound miRNAs from neurons or microglia. Sequencing libraries were generated from immunoprecipitated miRNAs and from total cellular miRNA and sequenced on an Illumina miSeq. *Approach for statistical analysis:* Count based miRNA expression data was generated by mapping to mouse miRBase. Principal component analysis (PCA) was used to reveal simplified dynamics within the data and identify clustering of samples. Differential miRNA expression between groups employed by using Bayesian moderations and an adjusted p-value set at 5%. *Results and Conclusions:* Initial characterisation of Flag-Ago2 mice revealed accurate identification of neuronal and microglial enriched miRNAs providing proof of concept for our sequencing studies. Neuronal and microglial miRNA profiles differed in both healthy brain and in epilepsy. Differential miRNA expression was a prominent feature and distinguishable between epileptogenic and epileptic tissue compared to control mice.

Title: Comparison of the effects of three antiepileptic substances in a genetic animal model of absence seizure

Authors: *E. ESNEAULT, A. SOYER, G. PEYON, V. CASTAGNE;
Porsolt, Le Genest Saint Isle, France

Abstract: Absence-type generalized seizures are particularly prevalent in children and often have a genetic origin. The WAG/Rij rat is a well-characterized genetic model of absence seizure. These animals develop non-convulsive seizures accompanied by neuropsychological and neurocognitive symptoms, with age. The aim of this study was to compare the efficacy of three antiepileptic substances: Ethosuximide (ETX), the standard treatment; levetiracetam (LEV); and valproate (VPA). We also evaluated comorbidities including neuropsychological and cognitive performances in WAG/Rij rats. Six month old rats were implanted with epidural electrodes placed over the fronto-parietal cortex. After a two-week period of recovery, video-EEG recordings were performed over periods of 4 hours, the first hour was used as a baseline session, and the following 3 hours of recording after administration of the antiepileptic drugs. In order to evaluate comorbidities, the rats were assessed in the Y-maze and social recognition tests for cognitive performances, and in the elevated plus maze (EPM) and forced swim (FST) tests for neuropsychological evaluation. ETX (50 and 100 mg/kg) and VPA (100 and 200 mg/kg) dose-

dependently decreased the number and the duration of spike and wave discharges (SWD). ETX and VPA fully suppressed SWD at high doses (200 and 300 mg/kg, respectively). The effects of LEV were of lower magnitude as compared with ETH for the same doses. With LEV, the number of SWD was decreased down to approximately 50 percent as compared with vehicle-treated control rats, and this corresponded to a ceiling effect observed at 100 and 200 mg/kg. Moderate spatial memory deficits were noted in the Y-maze test whereas no abnormal behaviour was observed in the EPM or the FST in eight-month old rats. These results confirm the efficacy of ETX and VPA to antagonize absence seizure in WAG/Rij rats. In humans, ETX remains the gold standard treatment for this type of seizure, while VPA is used more when absence seizure is accompanied of tonico-clonic convulsions. LEV showed a moderate efficacy against absence seizure. Slight cognitive dysfunction in WAG/Rij rats were observed in absence of clear evidence for an abnormal neuropsychological status. The results suggest that the strain of WAG/Rij rats may be particularly useful for evaluating absence seizure as well as comorbid cognitive deficits. This chronic genetic model is reliable and predictive to evaluate potential new treatments against absence seizure. Memory impairments observed in these animals reinforce the translational value of this model.

Title: Tracking neurometabolic markers during seizure activity in awake rodents

Authors: ***A. LEDO**[1,2], C. F. LOURENÇO[1,2], G. A. GERHARDT[3], J. LARANJINHA[1,2], R. M. BARBOSA[1,2];
[1]Fac. of Pharmacy, Univ. of Coimbra, Coimbra, Portugal; [2]Ctr. for Neurosci. and Cell Biol., Coimbra, Portugal; [3]Neurosci. Dept., Univ. of Kentucky Med. Ctr., Lexington, KY

Abstract: Synaptic communication is an energy demanding process, accounting for ca. 40% of energy consumption in the cerebral cortex. Under physiological conditions, glucose metabolism is highly compartmentalized between neurons and astrocytes. Although it is consensual that neural cells rely mainly on glucose/lactate to fuel neurotransmission, it is still a matter of debate how these substrates are used and supplied to each cell type. The pathways of bioenergetic dysfunction during disease are even more unclear, hindering therapeutic development.

Neurometabolic dysfunction is a critical pathophysiological aspect of the epileptic brain and appears to share many of the self-propagating features that are typical of epileptogenic processes. To understand the mechanisms of neurometabolic (de)coupling it is critical to monitor the fluxes of key metabolic markers (such as glucose, oxygen, lactate, pyruvate) in the living brain, under physiological stimulation and during aberrant synaptic firing (ex: seizures). One attractive strategy for in vivo monitor of such compounds consists in the use of micro(bio)sensors coupled to fast electrochemical techniques. Here we have used ceramic-based platinum microelectrode arrays (MEA) for direct recording of pO_2 and glucose/lactate oxidase based MEAs as biosensors to record changes in these substrates in the CNS of chronically implanted **freely-moving** rats during pilocarpine-evoked *status epilepticus*. Furthermore, by employing fast sampling amperometry (100Hz acquisition) we have concurrently recorded brain electrical activity in the form of LFP-related currents, a surrogate signal of LFP. We have found that Induction of *status epilepticus* by intrahippocampal injection of pilocarpine (1.2 mg in 1 microL) induces biphasic changes in pO_2 in the hippocampus. The initial dip at seizure onset (ΔO_2= -4.5 ± 0.7 µM) was followed by a prolonged hyperoxygenation phase (ΔO_2 = +10.4 ± 2.9 µM). Analysis of LFP-related currents at the site of pO_2 recording further revealed that the O_2 dip may precede observable change in high frequency power. This has high potential for translation into the clinical setting supported on intracranial grid or strip electrodes.

Title: Electric field orientation-dependence of evoked seizures and foci localisation using temporal interference and implantable electrodes

Authors: *E. RUSINA[1], S. SAFIEDDINE[1], R. POULKOURAS[1], F. MISSEY[1], B. BOTZANOWSKI[1], E. ACERBO[1], Y. ZILBERTER[1], M. DONAHUE[2], A. WILLIAMSON[1]; [1]Aix-Marseille Univ., Marseille, France; [2]Mines Saint-Etienne, Saint-Etienne, France

Abstract: Temporal lobe epilepsy (TLE) is the most common type of partial epilepsy among adults worldwide. Various animal models have been created in attempt to mimic the disease with

similar behavioural, electrophysiological, and morphological symptoms. In our study we used the kainic acid (KA) model of TLE to evoke seizures in male adult C57BL/6 mice. To evoke and to localise seizure foci we used a novel method of temporal interference (TI) electrical stimulation and electric field orientation-dependence, combined with *in vivo* EEG recording and post-mortem histological examination to confirm epileptic activity onset, originating from the CA3 field of the hippocampus. TI is based on the principle of interference between 2 electric fields, where 2 pairs of electrodes are placed on the skull or on the dura mater at precise coordinates and electrical stimulation is applied with a slight difference in frequency between each pair (2 kHz and 2.01 kHz), thus creating an oscillation within each electric field. By overlapping, these fields target accurately precise brain locations located far from the cortex surface without a penetrating electrode, and help to localise an epileptic focus. We used a computational model to calculate stereotaxic coordinates at the desired location for electrode placement, so that upon electrical stimulation, CA3 would be targeted. We have also modified an existing TI stimulation protocol, by placing the electrodes directly on the dura mater, via removal of the bone layer, which acts as a barrier for electric stimuli to penetrate the brain tissue. We have shown that TI can be successfully used in a virtual model of a mouse brain, and that, by altering the field orientation, significantly different results are achieved. For instance, we have found that if an electrode pair is oriented along the axons, the stimulation results in a greater depolarisation rate compared to the perpendicular orientation. Altogether, these findings may provide breakthrough in epilepsy research, allowing the targeting and stimulation of a seizure focus with an efficient, minimally invasive technique.

Title: Continuous *in-vivo* tissue oxygen recording for spontaneous seizure and spreading depolarization

Authors: *J. LIU, F. BAHARI, S. LÓPEZ, C. CURAY, B. J. GLUCKMAN;
The Pennsylvania State Univ., State College, PA

Abstract: Both brain slice (Ingram 2013) and in-vivo measurements (Farrell 2016) have demonstrated that tissue oxygenation (PO_2) varies with seizure dynamics. In recent work (Bahari bioRxiv) we have demonstrated in two very different chronic animal models of epilepsy, that spontaneous seizures are frequently accompanied by spreading depolarization (SD) events. Revealing the SD required the implementation of a recording system with near-DC sensitivity and sufficient dynamics range.

Theoretical modeling work at the single neuron level has unified a full range of neuronal dynamics that includes normal spiking, seizure, spreading depolarization, and even wave-of-death (Wei 2014) by including conservation constraints of ionic species, tracking extracellular concentrations of ionic analytes, cell swelling, and including tissue oxygenation, which is critical for fueling ionic pumps. Such modeling implicates tissue oxygenation as a critical parameter to understand the interactions between spontaneous seizures and SD. However, to date, there has not been simultaneous study In Vivo of chronic spontaneous seizures and PO_2 with sufficient sensitivity to observe SD.

We have now incorporated a floating 3-electrode potentiostat and accompanied waveform generation into our DC-sensitive recording system. The new system is capable of fulfilling chronic biopotential recording during seizure/SD and at the same time performing a range of different electrochemical measurements, and particularly for PO_2.

Here, we show the validation of both fast-scan cyclic voltammetry and constant voltage amperometry results and preliminary results for continuous In-Vivo oxygen concentration dynamics, and preliminary findings from chronic recordings from the tetanus toxin model of temporal lobe epilepsy.

This system provides a platform to study oxygen concentration dynamics, and predictions on evolution, and the ability to intervene with both seizure and spreading depression dynamics.

Title: Evaluation of modulation of cannabinoid receptor 1 (CB1R) for the alleviation of organophosphate-induced status epilepticus and mortality

Authors: *B. M. WINNER, S. W. O'BRIEN, P. B. DUBEE, S. E. WOLFE, K. E. KELLY, C. H. PHUNG, K. T. PAGARIGAN, M. R. EISEN, P. M. BODNER, M. R. NELSON, P. M. MCNUTT;
USAMRICD, Gunpowder, MD

Abstract: The acute toxicity of organophosphorus (OP) compounds is primarily a result of acetylcholinesterase inhibition in the central and peripheral nervous systems, which manifests as seizure, respiratory failure and neurotoxicity. Without aggressive and early treatment, OP-induced seizures rapidly transition to refractory status epilepticus (SE), characterized by sustained seizure activity that is resistant to anticonvulsant drugs. A high proportion of survivors of SE subsequently develop spontaneous recurrent seizures (SRS), which are also refractory to anti-epileptic drugs. Here we evaluated the potential for the endocannabinoid (eCB) system to act as an “on-demand” neuroprotective pathway by evaluating the effects of the CB1R positive allosteric modulator (PAM) ZCZ-011 on severity, latency and duration of SE and SRS in soman-exposed rats. In preliminary studies, we demonstrated that ZCZ-011 (20 mg/kg; i.p.) delayed latency to behavioral seizure versus vehicle. We also observed improved 10 d survival in the ZCZ-011 group versus vehicle (94% versus 60%, respectively). We are currently characterizing the functional effects of ZCZ-011 and other CB1R PAMs and agonists on local field potentials in telemeterized rats during and following soman exposure to more comprehensively assess whether agonism of the eCB pathway can reduce the severity of SE and/or recurrence of SRS. Taken together, these early results reveal a potential therapeutic target for acute and chronic OP-induced neurological effects.

Title: Diabetic hyperglycemia increases the severity of lithium-pilocarpine-induced SE in male Wistar rats

Authors: *C. V. MERIDA PORTILLA[1], F. CHENA BECERRA[2], K. P. RAMOS RIERA[1], C. MORGADO-VALLE[3], L. BELTRAN-PARRAZAL[4], L. LOPEZ-MERAZ[5];

Abstract: Diabetes Mellitus type II (DMII) is a metabolic disorder characterized by hyperglycemia and associated with beta-cell dysfunction and insulin resistance.
Clinical and experimental studies have shown comorbidity between DM and epilepsy, including a higher incidence of status epilepticus (SE). SE is a neurological emergency with high a mortality rate, characterized by continuous epileptic activity for along 30 minutes. However, the association between DMII and epilepsy is not fully understood. Therefore, the aim of this study was to analyze the severity of SE in male Wistar rats with DMII. To induce DMII, three-days-old (P3) rats were given a subcutaneous injection of streptozotocin (STZ) (100mg/kg) (n=6); control rats received an equal volume of citrate buffer (pH 4.5) (n=8). Glycemia was monitored at P30, P60, and P90 in both experimental groups. Rats were injected intraperitoneally with lithium chloride (3mEq/kg, i.p.) and 18 h later, at P90, SE was induced by injection of pilocarpine hydrochloride (30mg/kg, s.c.). Motor seizures were carefully monitored and evaluated using the Racine's scale: 0 = 1 abnormality; 1=Mouth and facial movements; 2=Head nodding; 3=Forelimb clonus; 4=Rearing; 5=Rearing and falling. Latency, duration, and frequency of seizures and SE were also evaluated. Time course of glycemia showed that control rats had normal glucose levels along with the study (114±3 mg/dL), whereas STZ-treated rats had hyperglycemia from P60 (198±20 mg/dL) to P90 (287±3 mg/dL). Diabetic rats had more stage V seizures (5.8±0.4) than control rats (2.8±0.3). However, STZ rats had increased latency to the first stage V seizure (44.3±1.6 min) and to SE (48.3±1.7 min) when compared to the control group (22.12±0.96 min and 27.6±0.31 min, respectively). The duration of stage V seizures didn't

show differences between STZ (1.2±0.1 min) and control (0.95±0.1 min) rats. These data suggest that the presence of DMII may increase SE severity.

Title: Optogenetic dissection of striatal outputs modulates absence-like spike and wave discharges

Authors: *S. HYDER, P. FORCELLI;
Pharmacol. & Physiol., Georgetown Univ., Washington, DC

Abstract: Absence epilepsy is a prevalent childhood epilepsy characterized by non-convulsive generalized seizures. These seizures are generated in corticothalamocortical loops. Nuclei of the basal ganglia (BG), while not sites necessary for generation of absence seizures, may be capable of modulating this seizure activity. Supporting this hypothesis, several basal ganglia nuclei can be either stimulated or inhibited to suppress seizures in a variety of preclinical seizure models. Here, we employed an optogenetic approach to determine the pathways by which the striatum modulates spike and wave discharges (SWDs) evoked by gamma-butyrolactone (GBL). Adult rats were stereotaxically injected bilaterally with activating (hChR2(H134R) or Chronos) or inhibitory (ArchT) opsins into the dorsal striatum and fiber optics were placed at the same sites. Epidural electrodes were placed over frontal and parietal cortices to monitor SWDs. Following post-operative recovery, seizures were evoked by systemic administration of GBL. We compared pan-striatal activation and inhibition to selective activation of DRD1-expressing direct pathway neurons and selective inhibition of DRD2-expressing indirect pathway neurons. We tested animals on a within-subject basis at baseline and with photostimulation. We also compared “open loop” stimulation to “closed loop” stimulation modes, in which stimulation was delivered only upon detection of a seizure. Pan-neuronal striatal activation suppressed SWDs in wild-type rats. Optogenetic activation of the direct pathway neurons was without effect on SWDs. Optogenetic silencing of indirect pathway neurons suppressed SWDs both in open-loop and closed-loop stimulation paradigms.

Title: Spectral correlates of loss of responsiveness during partial vs. secondarily generalized seizures

Authors: C. PAPANTONATOS[1], C. KOZMA[1], U. GORSKA[2], T. BUGNON[1], A. STRUCK[3], G. TONONI[1], M. BOLY[3], *E. JUAN[1];
[1]Univ. of Wisconsin-Madison, Madison, WI; [2]Donders Inst. of Neurosci., Nijmegen, Netherlands; [3]UW Hosp. and Clinics, Madison, WI

Abstract: Both complex partial (CPS) and generalized tonic-clonic (GTC) seizures lead to loss of responsiveness (LOR), causing serious risks of injury in patients with epilepsy. However, mechanisms of LOR during seizures are poorly understood. Here we aim to investigate in more details the spectral signatures characterizing the dynamics of LOR in CPS and GTC.
Intracranial recordings of 15 GTC and 13 CPS were obtained from 12 patients (7 male, median age 33 years, range 18-59). Two patients had both CPS and GTC. All CPS were from temporal origin; this was the case in 6/15 GTC (2 frontal and 7 parietal origin). Responsiveness was assessed through video review and scoring. The ictal period was split based on generalization onset in GTC (i.e. before/after behavioral tonic phase); CPS were split in two equal parts. We used a three-way ANOVA to contrast CPS vs. GTC in three brain regions (seizure onset zone [SOZ], parietal and frontal areas) during the two ictal periods, focusing on high-gamma and delta power. P values were corrected for multiple comparisons using false discovery rate.
GTC lasted on average 164 seconds, with generalization occurring ~38 sec after seizure onset. CPS lasted on average 110 sec. Both CPS and GTC were characterized by impairment in responsiveness but of different degrees: while 10/13 (77%) CPS showed preserved visual pursuit, all GTC followed a stereotypical sequence of events, with staring and severe LOR preceding head turn and screaming. Only 2/15 (13%) GTC showed a transient period of visual pursuit before this stereotypical sequence (10/13 CPS vs. 2/15 GTC; Fisher's exact test: $p = 0.002$). During the second ictal period, LOR remained partial in CPS, while it was complete in all GTC. Before generalization, both GTC and CPS showed increased high-gamma power in the SOZ, significantly stronger in GTC than CPS ($p < 0.001$), while delta power decreased to a similar extent. In parietal regions, GTC showed increased high-gamma and delta power as

compared to CPS ($p < 0.001$). In frontal regions, delta and high-gamma power changes did not differ between GTC and CPS. After generalization, GTC showed further high-gamma and delta power increase in all brain regions, unlike CPS ($p < 0.001$).
While both CPS and pre-generalization GTC show altered responsiveness, LOR was more severe in GTC. This behavioral difference was accompanied by stronger high-gamma increase in the SOZ, as well as stronger increase in high-gamma and delta power in parietal regions. Our results suggest a broader posterior cortical involvement accompanying more severe LOR in GTC as compared to CPS.

Title: Dissecting the role of temporal lobe epilepsy related parvalbumin+ and somatostatin+ interneuron loss in place cell dysfunction

Authors: ***C. YANG**[1], I. MOLLINEDO GAJATE[3], L. CHEN[4], L. PAGE-HARLEY[5], D. J. CAI[6], D. AHARONI[2], T. SHUMAN[7], P. GOLSHANI[8];

At Mount Sinai, New York, NY; [6]Neurosci., [7]Mount Sinai, New York, NY; [8]UCLA Dept. of Neurol., Los Angeles, CA

Abstract: Temporal lobe epilepsy (TLE) is associated with significant cognitive difficulties but the mechanisms underlying these deficits are not understood. We have previously shown that the number of CA1 place cells as well as the precision and stability of place-specific firing decreases in the pilocarpine model of TLE. As TLE has been previously associated with parvalbumin (PV+) and somatostatin (SOM+) interneuron loss, we asked whether decreased activation of these neurons contributed to the altered spatial coding in CA1. We expressed the inhibitory DREADD hM4Di in PV+ or SOM+ interneurons in CA1 using AAV5-Syn-DIO-hM4Di-mCherry injections into CA1 of PV-Cre or SOM-Cre animals, respectively. We performed patch clamp recordings from PV+ or SOM+ neurons in slices, and showed that CNO application significantly decreased the excitability of the hM4di expressing neurons. To determine whether decreased activation of PV+ or SOM+ neurons contributed to poor spatial coding of CA1

pyramidal neurons, we also virally expressed the calcium sensor GCAMP6f in CA1 neurons and used a miniaturized microscope (UCLA Miniscope) to follow the activity patterns of CA1 neurons as animals ran back and forth on a linear track with or without inhibition of PV+ or SOM+ neuronal firing. PV-Cre or SOM-Cre mice expressing FLEXed hM4di were injected with CNO or vehicle solution 45 minutes prior to running on the track while we performed calcium imaging of CA1 neurons. We found no differences in the information content (specificity of each neuron coding of spatial location), stability (reliability of neuron firing at the spatial location across trials), and in proportion of neurons that were place cells compared between animals that received CNO or Vehicle. These findings suggest that decreased activity of CA1 PV+ or SOM+ neurons likely does not significantly contribute to the place cell dysfunction recorded in TLE. Epilepsy-related changes to the activity patterns of CA1 inputs or desynchronization of activity arriving in CA1 may play a more important role than loss of PV+ or SOM+ interneurons.

Title: Deficits in place cell stability and precision have distinct time courses during the progression of pilocarpine-induced epilepsy

Authors: *L. PAGE-HARLEY[1], Y. FENG[1], L. M. VETERE[1], C. R. LEE[2], D. J. CAI[1], P. GOLSHANI[3], D. B. AHARONI[3], T. SHUMAN[1];

Abstract: Temporal lobe epilepsy (TLE) is associated with debilitating cognitive deficits in human patients and rodent models, but the underlying changes to circuit function that disrupt cognition remain poorly understood. Pilocarpine-treated epileptic mice have disrupted spatial coding in hippocampus, as place cells have less precise and less stable firing patterns compared to those from healthy controls. However, the time course of when spatial coding deficits emerge and how they relate to seizure onset has not been explored. In the pilocarpine-status epilepticus model, seizures take weeks to develop and progressively increase throughout the animal's life. Here we investigated spatial coding in dorsal CA1 of pilocarpine-treated epileptic mice in the

weeks after epileptogenesis in order to determine how stability and precision in spatial coding are altered during the progression of epilepsy. We used *in vivo* calcium imaging with open-source miniature microscopes (Miniscopes) paired with chronic EEG recordings to track spatial coding and seizure activity from 3-8 weeks after pilocarpine. All pilocarpine-treated mice had seizures throughout our recordings which progressively increased from 3 to 8 weeks after pilocarpine. Surprisingly, we found that the stability of spatial coding was initially normal 3-5 weeks after pilocarpine, despite the mice already having seizures throughout that time. Deficits in spatial stability did not emerge until 6-8 weeks after pilocarpine. In contrast, the precision of spatial coding (information content) was reduced in epileptic mice throughout the 3-8 weeks after pilocarpine. Thus, there was a clear dissociation between the precision and stability of the hippocampal place code deficits in epilepsy. In addition, neither of these measures correlated with seizure frequency, suggesting that independent circuit mechanisms lead to altered precision and stability of spatial coding in epilepsy.

Title: The ketogenic diet attenuates post-ictal hypoxia

Authors: *R. C. GOM[1], D. BHATT[1], R. M. MYCHASIUK[2], J. M. RHO[3], G. TESKEY[1]; [1]Cell Biol. & Anat., [2]Neurosci., Univ. of Calgary, Calgary, AB, Canada; [3]Alberta Children's Hospital, Univ. of Calgary, Calgary, AB, Canada

Abstract: Rationale: The ketogenic diet (KD) has shown efficacy as an anticonvulsant and results in numerous metabolic changes which influence physiological processes. More recently the KD has been shown to downregulate COX-2 expression and subsequent production of vasoactive prostanoids. Recent evidence has determined that postictal hypoxia, a stroke-like event that follows seizures, is COX-2 dependent. However, the effect of the ketogenic diet on postictal hypoxia is completely unknown. Here we tested the hypothesis that the KD can prevent severe postictal hypoxia using a repetitively induced seizure model (electrical kindling). **Methods:** Young adult Long-Evans rats weighing between 250-300 g at the start of experimentation were used in this study. We measured local tissue oxygenation in the hippocampus before, during and following electrically-induced seizures in awake, freely-moving rats. In the experimental group, the traditional ad libitum diet was replaced with a high fat/protein diet (6:1 fat to protein ratio consisting of lard, butter, corn oil, casein, and a vitamin

and mineral mix) that was maintained 14 days prior to seizure elicitation to ensure systemic ketosis (elevated blood ketone concentration >1.00mmol/L). Seizures were elicited at a suprathreshold (100 μA above previously determined threshold) current on a fixed schedule. In addition to observing changes in postictal hypoxia, measurements including weight change, seizure duration, seizure thresholds, and blood ketones were taken before and after the kindling protocol. **Results and Conclusions:** The KD attenuated postictal hypoxia by raising baseline oxygen levels. As expected, weight gain was reduced in diet exposed rats and a notable increase in blood ketones was measured. Regular chow and KD-treated rats had no significant difference in seizure duration however KD rats had a higher seizure threshold relative to rats receiving regular chow. These preliminary experiments illustrate that metabolic changes with the KD increased baseline oxygen levels rather than neurovascular responses to seizures and may provide another possible treatment to prevent severe postictal hypoxia.

Title: Dynamic changes in hippocampal oxygen levels following febrile seizures

Authors: *S. HARRIS[1], A. GEORGE[1], K. BARRETT[2], M. H. SCANTLEBURY[1], G. TESKEY[3];
[2]Pediatrics, Alberta Children's Hosp. Res. Inst., [3]Cell Biol. & Anat., [1]Univ. of Calgary, Calgary, AB, Canada

Abstract: *Rational:* Febrile seizures are the most common convulsive event, occur in childhood, and are preceded by inflammation and fever (above 38.3 ^{o}C). Febrile seizures can have long-term negative consequences such as memory deficits and an enhanced predisposition to develop temporal lobe epilepsy. Human adults with brief self-generated seizures and animals with induced brief seizures display a period of low brain oxygen levels after seizures terminate (postictal hypoxia) that can be prevented by administering either COX-2 blockers or L-type calcium channel antagonists. Animals with traumatic-induced seizures or seizures induced with chemical convulsants typically results in hyperoxia. It is currently unknown what the dynamic oxygen profiles are during and following febrile seizures. Here we examined oxygen dynamics in the hippocampus in two juvenile seizure models; hyperthermic seizures and febrile seizures. *Methods:* Eight-day old rat pups were implanted with an electrode to monitor electrographic activity and an optrode to measure local oxygen in the dorsal hippocampus. In the febrile model

pups received one injection of 400 µg/kg lipopolysaccharide (LPS) per day for 5 days. In the hyperthermic model no injections were given. At 12 days of age rat pups were subjected to exogenous heat in a heated dry air chamber, a common method to elicit seizures. Once a behavioural seizure occurred the pup was removed and allowed to recover while hippocampal oxygen levels and local field potentials were monitored.
Results and Conclusions: Infant rats typically display lower baseline oxygen levels in the hippocampus than their adult counterparts. However, in 12/20 pups we also observed a further drop in oxygen followed by a period of higher than baseline oxygen levels. 8/20 young rats did not show hippocampal hypoxia and only displayed higher than baseline oxygen levels following a hyperthermic convulsion. We have found that oxygen levels in the rat pup hippocampus following a hyperthermic convulsion were variable, with both increased and decreased levels observed. This research provides insight into the oxygen dynamics in the developing brain during common childhood convulsive events.

Title: Expression of Scn1a in brain regions related to sexual motivation

Authors: *A. CROCKETT[1], H. MARTIN[1], S. SANCHEZ[1], S. B. DUTTON[2];
[2]Biology/ Neurosci. Program, [1]Agnes Scott Col., Decatur, GA

Abstract: Individuals with epilepsy commonly report sexual dysfunctions, including an inability to orgasm, lack of sexual motivation, and erectile dysfunctions. These behaviors are reported at a higher percentage in patients with epilepsy compared to the general population. Currently, little information is available on the role that epilepsy plays on the specific brains regions that underlie these quality of life altering behaviors. The amygdala, nucleus accumbens, and medial preoptic area have been established as important brain regions for modulating sexual behaviors, particularly the motivational aspects. The present study examines the expression of the voltage-gated sodium channel $Na_v1.1$ in these regions of female R1648H (RH) GEFS+ mice. The RH mouse model of GEFS+ is an established line that recapitulates many of the symptoms patients with the condition present, including spontaneous seizures, increased susceptibility to febrile seizures, increased anxiety and altered cognition. In this current study, we determined the relative distribution of $Na_v1.1$ in inhibitory and excitatory cells in the amygdala, nucleus accumbens, and medial preoptic area and identified alterations in their expression. These results

suggests a potential mechanism for the altered sexual behavior seen in patients with epilepsy, and possibly other neurological disorders.

Title: Early postnatal cellular and network perturbations in the hippocampus of mice with a genetic $Na_v1.2$ channelopathy

Authors: *K. ULRICH[1], Y. LIU[2], M. BARBONI[3], M. SAMEHNI[1], S. MARGUET[1], R. M. NEVES[1], I. JAKOVCEVSKI[1], M. STOCKEBRAND[1], B. ENGELAND[1], H. BECK[3], H. LERCHE[2], T. KELLY[3], D. ISBRANDT[1];
[1]Exptl. Neurophysiol., German Ctr. For Neurodegenerative Dis., Bonn, Germany; [2]Exptl. Epileptology, Zentrum für Neurologie Hertie-Institut, Tübingen, Germany; [3]Life & Brain - Inst. for Exptl. Epileptology and Cognition Res., Bonn, Germany

Abstract: Neuronal network perturbations during early life such as those caused by ion channel dysfunctions can lead to neurodevelopmental disorders including epileptic encephalopathies (EE). Mutations in the *SCN2A* gene encoding the voltage-gated sodium channel alpha subunit $Na_v1.2$ are associated with a broad spectrum of epilepsies, ranging from benign phenotypes to severe EE including cognitive impairment. To investigate the mechanisms of epileptogenesis, we generated a knock-in mouse model harboring the missense mutation *Scn2a* (p.A263V), which was previously identified in a patient with neonatal onset, therapy-resistant seizures and resulted in a gain-of-function of heterologously expressed Nav1.2 channels. Homozygous and heterozygous A263V knock-in mice were viable but showed reduced body weight, increased mortality and behavioral deficits, which manifested as early as postnatal day P7. At this age, animals also exhibited increased cFos immunoreactivity in the hippocampus indicating increased neuronal activity. Furthermore, surviving mice showed spontaneous behavioral seizures. Hippocampal local field potential (LFP) silicone probe depth recordings from head-fixed awake neonatal mice revealed ictal network activity as early as P2, which evolved in frequency content, amplitude and duration during the first two postnatal weeks. Hippocampal CA1 pyramidal neurons exhibited an increased action potential firing frequency in in-vitro patch-clamp recordings from P21-28 mutant mice. We are characterizing the developmental and regional specificity of changes in neuronal excitability in CA3 and CA1 neurons from P10-14 and P21-28

mice. Characterization of somatic neuronal excitability in the hippocampal CA1 and CA3 regions in acute slices indicated increased somatic excitability in hetero- and homozygous mutants. Together, these results indicate a disease onset shortly after birth during early stages of hippocampal network maturation. Therefore, preventive therapeutic approaches would need to be targeted to the first postnatal weeks.

Title: Loss of I_h in forebrain during a critical period of striatal synaptogenesis results in somatomotor dysfunctions and antipsychotic-responsive hyperactivity

Authors: *A. MERSEBURG[1], S. SANDKE[2], I. JAKOVCEVSKI[1], A. NEU[3], Z. HUANG[4], M. SHAH[4], S. MARGUET[1], R. MELO NEVES[1], J. ROEPER[5], F. MORELLINI[2], D. ISBRANDT[1]; [1]Univ. of Cologne/ DZNE Bonn, Cologne, Germany; [2]Ctr. for Mol. Neurobio. Hamburg, Hamburg, Germany; [3]Univ. Clin. Hamburg Eppendorf, Hamburg, Germany; [4]UCL Sch. of Pharm., Univ. Col. London, London, United Kingdom; [5]Goethe Univ. Frankfurt, Frankfurt, Germany

Abstract: Hyperpolarization-activated, cyclic nucleotide-gated subunits (HCN) 1 to 4 mediate I(h), which is suggested to contribute to development-dependent network activity and maturation of the CNS. *De novo* mutations in *HCN1* are associated with early infantile epileptic encephalopathies (EIEE), and other neurodevelopmental disorders, including autism spectrum disorder. HCN channel-mediated currents are subject to developmental regulation over the course of pre- and postnatal development, including subunit composition, subcellular location and underlying current properties. Studies aimed at investigating I(h) function during brain development are limited when using knockout mouse models that target only specific subunits of the HCN1-4 family. Here, we present an approach that is designed to functionally and conditionally ablate I(h), independent of subunit composition, by controlling the expression of a dominant-negative HCN subunit (HCN-DN) with the Tet-off doxycycline (Dox) system and

CaMKIIα promoter-regulated expression in forebrain projection neurons in double transgenic mutant mice. This strategy allowed us to ablate I(h) independent of the underlying developmental expression pattern. We show that lifelong I(h) loss starting around birth is associated with impaired somatomotor development in neonatal mutants and psychomotor disturbances, including behavioral hyperactivity paired with stereotyped circling, and motor deficits in adult mutants. Notably, restricting I(h) loss to an early postnatal period, i.e., to the first three weeks of life, had more severe consequences than lifelong ablation of I(h) in that these mice also exhibited cognitive symptoms, indicating the presence of developmental changes that are not reversible by simple re-introduction of I(h). Of note, the locomotor hyperactivity could not be ameliorated by the administration of the psychostimulant methylphenidate which is a common treatment for ADHD hyperactivity. Instead, I(h)-deficient mutants responded to blocking D2-like dopamine receptors (D2R) with the typical antipsychotic haloperidol, or to the specific D2R blocker eticlopride. In addition, DREADD-mediated activation of indirect-pathway, D2R-expressing medium spiny neurons in the striatum of mutant animals strongly ameliorated the locomotor hyperactivity. Together, our results suggest that developmental I(h) loss in forebrain projection neurons caused persistent changes in cortico-striatal circuits and associated motor behaviors, resulting in a phenotype that is reminiscent of neurodevelopmental co-morbidities in disorders such as EIEE.

Authors: N. DRISCOLL[1], B. MURPHY[1], F. VITALE[2,3], ***H. TAKANO**[4,2];
[1]Bioengineering, [2]Neurol., [3]Ctr. for Neuroengineering and Therapeut., Univ. of Pennsylvania, Philadelphia, PA; [4]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: High-frequency oscillations (HFOs), when observed in electroencephalograms, have been proposed as a biomarker for epilepsy and, thus could potentially be used to identify the seizure onset zone. Understanding the cellular origin of HFO generation in animal models of

epilepsy is important for establishing HFOs as a biomarker for potentially improving both diagnostic and surgical precision. Multicellular calcium imaging allows characterizing the dynamic properties of multiple cells (>200 neurons) and provides information on functional connectivity and signal propagation through analysis of ordered temporal firing patterns. Because of the large number of cells that can be simultaneously probed with this technique, it can also provide the ability to isolate an unusual cellular population in pathological tissues. Unfortunately, because of the nature of calcium ion probing molecules, the temporal resolution is poor. To overcome this limitation, we demonstrated that a transparent electrode made of graphene can be used to record local field potentials (LFPs) and simultaneously image activities of multiple neurons via calcium imaging. We recorded 4AP-induced seizure activity simultaneously on the graphene electrodes and through calcium epifluorescence imaging in anesthetized GCaMP6-expressing mice (Jax #025776, Jackson Laboratory). More recently, we developed a transparent graphene electrode array/cannula assembly and implanted it *in vivo* to conduct imaging/recording of hippocampal CA1 pyramidal neurons. We implanted the electrode/cannula assembly consisting of 3 mm (O.D.) stainless steel tube with microelectrode arrays with a 4x4 grid of 50x50 µm2 graphene contacts in Thy-1 GCaMP6 mice. We recorded hippocampal CA1 activity simultaneously on the graphene electrodes and through calcium imaging by two-photon microscopy at cellular resolution. We apply this innovative multimodal, multiscale technology to kainate-induced cortical injury model to elucidate the dynamics of seizure generation and propagation at the cellular level.

Abstract: Temporal lobe epilepsy (TLE) is characterized by spontaneous recurrent seizures, and is the most common form of adult epilepsy. In light of efforts spent characterizing this disease, effective treatments and a cure have remained elusive. TLE develops over a latent period that comprises structural and functional changes to the hippocampus (HPC) including neuronal loss,

reactive gliosis, inflammation and neurogenesis. Epileptic seizures result in aberrant HPC neurogenesis, characterized by an increase in neural progenitor proliferation, production of ectopic granule cells, mossy fibre sprouting, neuronal hypertrophy and persistence of hilar basal dendrites on adult-born granule cells (abGCs). The intrinsically low excitability of the dentate gyrus (DG) acts to gate pathological activity from propagating through the HPC, and the breakdown of the DG gate is hypothesized to contribute to TLE. Evidence for the role of adult born neurons in the pathogenesis of TLE is lacking, though recent evidence suggests development of recurrent microcircuits possibly driven by aberrant abGC connectivity within the DG and CA3 abGC-GC-mossy cell (MC) populations. To assess the role of abGCs in TLE related electrographic activity, we used genetic cell-type specific labeling of newborn cells and MCs, and monitored DG neural activity in a unilateral HPC kainic acid mouse model of TLE. Using *in vivo* 2-photon calcium multi-plane imaging with concurrent local field potential (LFP) recording while mice explored a linear treadmill environment, we were able to visualize DG network dynamics during seizure events characterized by electromyography. abGC activity levels tend to increase at seizure initiation, followed by mature GCs, MCs and interneurons. MC and interneuron activity persists beyond that of all GCs as seizures terminate and the DG enters a period of general quiescence. These observations suggest that abGCs may play a leading role in seizure genesis. This possibility is supported by recent evidence linking pharmacological inhibition of abGCs with a general decrease in epilepsy related pathological LFP activity.

Title: Ca^{2+} imaging in seizured brain of novel zebrafish model

Authors: *L. SHIGEMITSU, K. OGINO, H. HIRATA;
Dept. of Chem. and Biol. Sci., Aoyama Gakuin Univ., Sagamihara, Japan

Abstract: A chronic brain disorder, epilepsy, is pathologically characterized by sudden spasm and/or loss of consciousness and is caused by hyperexcitability of the brain. The excess excitability can be induced by the efflux of chloride ion from neurons in the brain. One of the causes of epilepsy is the increase of chloride reversal potential induced by the loss of KCC2, which is known as a potassium-chloride cotransporter, consequently resulting in the excess activation of neural networks. Zebrafish have two paralogs of KCC2 gene (KCC2a and KCC2b), which were generated by ancestral gene duplication and both are expressed by the CNS. Here,

we found that KCC2a-KCC2b double knockout mutant (DKO) zebrafish exhibits the epileptic phenotype when exposed to LED flash light. However, how this epilepsy is triggered by external optical stimuli remain unclear. Therefore, we aimed to elucidate the location of focal area of the seizured brain in larval zebrafish. First, we established a motor assay to induce epilepsy following exposure to red flash light. Second, to visualize neural activity in seizured brain, we prepared KCC2a-KCC2b DKO zebrafish larvae (5 dpf) by genome editing crossed with a GCaMP transgenic for visualization of brain activity in the CNS. Finally, we performed *in vivo* calcium imaging and analyzed the increase of fluorescence intensity in five regions of the brain; cerebellum, diencephalon, telencephalon, optic tectum and hindbrain. Surprisingly, we found that all of the brain regions in KCC2a-KCC2b DKO larvae showed higher and persistent activity compared to that in wild-type larvae. Our spatial and temporal analysis also revealed that functionally reversed inhibitory transduction generates excess neural activity, which is different from a simple enhancement of neuronal excitability induced by PTZ. Taken together, we established a new pathologically relevant epilepsy model in zebrafish.

Title: Using zebrafish as a tool to study SLC7A5, a gene implicated in autism spectrum disorder and epilepsy

Authors: *A. COLON-RODRIGUEZ[1], J. M. URIBE SALAZAR[1], A. SRIRAM[1], P. LEIN[2], L.-E. JAO[3], M. Y. DENNIS[4];

Abstract: Autism spectrum disorder (ASD) affects 1 in 59 children according to the Center for Disease Control with many cases caused by often-unknown genetic alterations. Mutations of ion channels and/or transporters are commonly found to be an underlying factor. For example, mutations in *SLC7A5*, a gene encoding the large amino acid transporter LAT1, have recently been identified in patients with ASD, motor impairment, developmental delay, microcephaly and intractable seizures. Recent studies using conditional knockout *Slc7a5* mice showed that mutants exhibit decreased neuronal inhibition, microcephaly, decreased exploratory behavior, and motor delay compared to wildtype animals. We hypothesize that loss-of-function mutations of *slc7a5* in

zebrafish will recapitulate neurological phenotypes observed in patients and mouse models. Using zebrafish allows us to conduct experiments in higher throughput due to their high fecundity and rapid embryonic development. To generate mosaic F_0 mutants at high efficiency, we used a pooled CRISPR gene editing approach. Subsequent morphological and behavioral analyses were performed of 5 days post fertilization (dpf) mutant- and mock-injected zebrafish. Our results show a significant decrease in head size ($p=0.0002$) and increase in locomotor activity ($p=0.004$) in the presence of a $GABA_A$ antagonist (PTZ) between our mosaic mutant *slc7a5* zebrafish compared to our control fish. These phenotypes recapitulate the results observed in the conditional knockout rodent model and patients. Ongoing studies include validation of identified defects in stable lines carrying null mutations of *slc7a* as well as characterization of additional phenotypes, including seizures via electroencephalograms and neurodevelopmental defects. The results of this study will lay the groundwork to (1) identify neurodevelopmental alterations caused by *slc7a5* mutations in zebrafish and (2) develop tools that we will continue to use as we move forward to characterize unknown disease-related mutations in a higher-throughput manner.

Title: Anatomical staging of a rat pretangle model of sporadic Alzheimer’s disease

Authors: *S. G. WALLING[1], M. WASEF[2], A. GHOSH[3], G. MARTIN[4], C. W. HARLEY[2], Q. YUAN[5], D. M. SKINNER[6];
[1]Behavioural Neuroscience; Psychology, Mem. Univ. Newfoundland, St. John's, NL, Canada; [3]BMS-Neuroscience, Fac. of Med., [2]Mem. Univ. of Newfoundland, St John's, NL, Canada; [4]Mem. Univ. of Newfoundland, St. John's, NL, Canada; [5]Biomed. Sciences, Fac. of Med., [6]Psychol, Mem. Univ. of Newfoundland, St John's, NL, Canada

Abstract: Persistently phosphorylated tau (pPhtau), is associated with neurofibrillary tangles, a hallmark of Alzheimer’s disease (AD). pPhtau is first localized to the locus coeruleus (LC) in young adults, and progresses to insoluble tau and tangles in later stages of AD tauopathy (Braak et al., 2011). We have modelled the LC pretangle stages of sporadic AD in male and female TH-Cre rats by infusing an adenoassociated virus (AAV) with a pseudophosphorylated human tau

gene, htauE14 (Karen Ashe plasmid, Addgene) into the LC. To examine the expression and transfer of LC-htauE14 to modulatory regions and cortical structures, as predicted by Braak, rats were infused with 1μL of AAV9-hEF1a-DIO-eGFP-htauE14-WPRE (Virovek, CA) into the LC bilaterally, or controls (sham/vehicle). Brain tissue was examined for GFP and human tau at 1-mo (T1) post-infusion (p.i.) and at 3-mo intervals (T2-5). GFP antibody (ThermoFisher, rabbit, 1:5000) and an antibody against human tau (HT7, ThermoFisher, mouse, 1:5000) was used to detect eGFP-htauE14 in free floating coronal (LC) and horizontal forebrain sections using a DAB-metal kit (ThermoFisher). Images were collected using a Zeiss BX-2 microscope and converted to grayscale for densitometry measurement (MCID, UK). Relative optical density measurements (ROD) were collected from htauE14 LC infused male and female rats and compared to ROD measurements of control rats (sham, vehicle infused). Results: At T1 (1-1.5 mo p.i.) GFP- ROD measurements were increased in the LC, dorsal raphe, and lateral entorhinal cortex in htauE14 infused rats over control rats. Positive transneuronal transfer of GFP was observed in pyramidal and non-pyramidal cells of the hippocampal complex (specifically, parasubiculum). HT7-ROD measurement mirrored the GFP increases whereby HT7-ROD was also higher in the LC, dorsal raphe, and lateral entorhinal cortex compared to control rats. These results demonstrate the successful uptake and expression of AAV-eGFP-htauE14 in LC neurons in the pretangle AD model, and further characterize transfer to modulatory (raphe) and cortical brain regions at the first period outlined (T1).

Abstract: Persistently phosphorylated tau (pPtau), the precursor to the neurofibrillary tangles (NFTs) found in Alzheimer's disease (AD), is first found in the locus coeruleus (LC) in young adulthood (Braak et al., 2011). Soluble pPtau (pretangle) progresses to insoluble pPtau and NFTs in more advanced stages of tauopathy in higher cortical regions in AD. Given that the LC is implicated in the earliest stages of tau dysfunction, we have modelled the pretangle stages of AD in TH-Cre rats by infusing an adenoassociated virus (AAV) with a pseudophosphorylated human tau gene (htauE14, Karen Ash, Addgene) into the LC. To examine the effects of htauE14 on LC function, we assess performance on two pattern separation tasks longitudinally. TH-Cre rats infused with 1μL AAV9-hEF1a-DIO-eGFP-htauE14-WPRE (Virovek, CA) bilaterally into the LC, and controls (sham, vehicle or AAV-eGFP) were tested on olfactory and spatial pattern separation tasks at 1-mo post-infusion (p.i.), and 3-mo intervals thereafter (to 13-mo p.i.). LC-piriform dependent olfactory discrimination (OD) tests were assessed at two levels of difficulty, using the methods of Tronel and Sara (2003): Simple OD (SOD; almond vs banana) and a Difficult OD (DOD; heptanol vs 50:50 heptanol:octanol). OD tests took place in an open field with 3 scent infused sponges (1-S^+, 2-S^-) for FrootLoop reinforcement. Rats were given 6 training trials with the S^+ location changed on each trial and tested 48-hr later. At T1 (1-mo p.i.) there were no differences in %correct or place errors (nosepoke in previously reinforced location) for sex or htau condition in the SOD. However, preliminary data suggest female htauE14 infused rats had a lower %correct compared to female control rats in the DOD. Male htauE14-infused and control rats did not differ in the %correct choice. In the spatial separation task, rats were trained for 10 trials/day to discriminate between reinforced (S+) and non-reinforced (S-) arms in adjacent locations on a radial arm maze (RAM). No differences in trials to criterion (9/10 correct) between sex or htau condition were found at T1. Data at this staging period suggests the effects of LC-htauE14 on pattern separation first produces deficits in olfactory DOD (female) rather than deficits in spatial separation (adj-RAM).

Abstract: The locus coeruleus (LC) is implicated in the earliest stages of tauopathy and Alzheimer's disease (AD). Persistently phosphorylated tau is first localized to the LC in young adulthood in pretangle stages and the progression to insoluble tau and neurofibrillary tangles in cortical structures is associated with the progression of sporadic AD (Braak et al., 2011). We modelled the pretangle stages of AD in TH-Cre rats by infusing an adenoassociated virus (AAV) with a pseudophosphorylated human tau gene (htauE14) into the LC. To examine the effects of LC-htauE14, we assessed cognitive performance longitudinally in rats to mimic the repeated testing to assess cognitive impairment used in humans. Rats infused with 1μL of AAV9-hEF1a-DIO-eGFP-htauE14-WPRE (Virovek, CA) into the LC bilaterally, or controls (sham/vehicle/AAV-GFP), were tested at 1-mo (T1) post-infusion (p.i.) and 3-mo intervals (T2-5), on 4 behavioural tests. Spontaneous alternation in a Y-maze was used as a test of spatial working memory and no differences between sex or condition were found at T1 in the % alternation, or number of arm entries in an 8-min exposure. Novel object recognition was assessed in the same Y-maze. All rats were more likely to spend time in the arm containing a novel object compared to the arm containing a familiar object, 24-hr after initial exposure. In the cued platform version of the Morris Water Maze no differences were observed in escape latencies. In the hidden platform version, male htauE14 rats had significantly longer escape latencies than male controls at T1. By the last day of testing, no differences were found between male groups. There were no differences between female htauE14 and control groups in the hidden platform task, and there were no sex or group differences in the no-platform probe. In the What-Where-When episodic memory task, 2 5-min exploration trials (ITI 5-min) each with 2 distinct objects in distinct locations were followed by a 5-min test in which all 4 previously explored objects were presented, 2 in the same (static) locations and 2 in novel (switched) locations. No differences were found across sex or htau condition. These results detail subtle changes in the LC-htauE14 AD phenotype at the earliest behavioural staging interval (T1).

Title: Study of spatial memory impairment and hippocampal neurodegeneration in okadaic acid induced rat model of Alzheimer's disease

Authors: *M. CHIGHLADZE[1], G. BESELIA[2], M. DASHNIANI[1], M. BURJANADZE[1], N. CHKHIKVISHVILI[1], L. KRUASHVILI[1], T. NANEISHVILI[3];
[1]I.Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia; [2]Lab. of Behavior and Cognitive Functions, I. Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia; [3]Georgian Natl. Acad. of Sci., Tbilisi, Georgia

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease that causes progressive cognitive and behavior impairment in the elderly. It is widely believed that changes in the cerebral activity of protein phosphatases have been implicated in the pathogenesis of AD. Okadaic acid (OA) is a potent and selective inhibitor of protein phosphatases. Because of its property to inhibit phosphatase activity, OA is associated with protein phosphorylation and has been proved to be a powerful probe for studying the various regulatory mechanisms and neurotoxicity (intracerebral injection of OA, would provide a useful model of Alzheimer's disease). In the present study, we evaluated and compared effect of intracerebroventricular (ICV) and intrahippocampal bilateral microinjection of okadaic acid (OA) on spatial memory function assessed in one day water maze paradigm and hippocampal structure in rats. Rats were divided in following groups: Control(icv) - rats injected ICV with artificial cerebrospinal fluid (aCSF); Control(hipp) - rats injected intrahippocampally with aCSF; OA(icv) - rats injected ICV with OA; OA(hipp) - rats injected intrahippocampally with OA. At the end of the behavioral experiments OA treated and control rats were deeply anesthetized with pentobarbital and perfused through the ascending aorta with 300 ml saline followed by 600 ml 4% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4)). The surviving pyramidal cells in the hippocampus of rats were visualized by Nissl staining. The number of the hippocampal pyramidal cells in Nissl staining sections was counted at X 400 magnification. Nissl staining of hippocampal sections showed that the pyramidal cell loss in OAhipp group is significantly higher than that in the OAicv . The results of our behavioral experiments showed that all rats exhibited a decreased latency to find the hidden platform across the eight training trials and OA treatment did not affects probe-test performance 30m after training. In marked contrast, the present experiments indicate that OA treatment affects probe-test performance 24 h after training. These findings suggest that OA treatment did not affect learning process and short-term spatial memory but induced impairment in spatial long-term memory. OA-induced spatial memory impairment may be attributed to the hippocampal cell death. Based on these results OA induced memory deficit and hippocampal cell loss in rat may be considered as a potential animal model for preclinical evaluation of antidementic drug activity.

Hosp., Seoul, Korea, Republic of

Abstract: Alzheimer's disease(AD) is a devastating neurodegenerative disorder which leads to cognitive impairment and consequent behavioral abnormalities in patients. As in many diseases that afflict the central nervous system, progress in AD research has been largely hampered by difficulty in acquiring adequate human samples and inevitable limitations of animal models. Utilization of brain organoids could possibly surpass these hurdles by providing *in vitro* models of human origin that reliably represent pathological conditions of an AD brain.
Participants of the study were classified into Alzheimer’s disease(AD)/mild cognitive impairment(MCI)/cognitively normal(CN) groups by pre-established standards based on PiB/Tau/FDG PET & MRI imaging data. From patients’ blood samples we extracted peripheral blood mononuclear cells(PBMCs) and solely activated T cells for efficient introduction of transcription factors. Sendai viruses encoding four Yamanaka factors were infected to these cells to generate induced pluripotent stem cells(iPSCs). Then we aggregated iPSCs to form embryoid bodies and cultured them in suspension. Addition of defined growth factors at specific time points led to the differentiation of distinct cell types in organoids. Prolonged culture in suspension ultimately resulted in the maturation of cerebral organoids. We performed immunohistochemistry experiment with these organoids and observed major hallmarks of AD: amyloid beta plaques and neurofibrillary tau tangles. Secreted proteins such as amyloid beta 40, amyloid beta 42, total tau, and phospho-tau from organoids were detected by ELISA which showed a marked difference between AD and control group. These findings suggest that organoids are capable of recapitulating pathophysiology observed *in vivo*. Employing the system, we further aim to investigate how AD/control organoids differ in reacting to various environmental stimuli.

Title: Characterization of the molecular interplay between amyloid, nuclear splicing proteins and tau isoforms in Down syndrome hiPSC cortical neurons

Authors: *S. E. PEREZ, I. LORENZINI, J. LEVY, C. BURCIU, R. SATTLER, E. J. MUFSON;
Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Despite the presence of neurofibrillary tangle (NFT) and beta amyloid (Aβ) pathologies in the brain of adults with Down syndrome (DS), only two-thirds develop dementia (DSD+). Recently, we demonstrated a greater number of NFTs compared to amyloid plaques in the frontal cortex (FC) of DSD+ compared to non-demented DS (DSD-) individuals (Perez et al., 2019). However, the cellular and molecular mechanisms that underlie the increase in tau pathology between these two groups remain unknown. Recent studies suggest that alteration in nuclear splicing proteins play a role in NFTs in DS (Hales et al., 2014). Preliminary studies by our group found a reduction in the nuclear splicing factors SR splicing factor 2 (SRSF2 or SC35), SR repetitive matrix protein 2 (SRRM2) and heterogeneous nuclear (hn) RNP A2B1 in FC neurons in DS. Furthermore, we found an increase in extranuclear U1-70k small nuclear ribonucleoproteins (snRNP), which was associated with NFTs in FC neurons in DSD+ compared to DSD-. Functionally, dysregulation of splicing proteins has been associated with changes in the ratio of three (3R) and four (4R) microtubule-repeat tau isoforms, which is linked to NFT formation in various tauopathies. To examine the role of amyloid in tauopathies and dysregulation of splicing proteins we used trysomic and dysomic human induced pluripotent stem cells (hiPSCs) obtained from a one month-old mosaic DS case, which were differentiated into cortical neurons (CN). At day 65 of differentiation, hiPSCs-CNs were treated with 0.1 µM $A\beta_{25-35}$ for three days. Cells were then fixed and processed for the visualization of SRSF2, SRRM2, U1-70k, hnRNP A2B1, the early tau phosphorylation marker AT8 ($pSer^{202}/Thr^{205}$), 3R tau and MAP 2 using standard immunofluorescence techniques. Preliminary observations derived from non-$A\beta_{25-35}$ treated disomic and trysomic hiPSCs-CNs revealed that MAP 2-

positive neurons displayed immunoreactivity for the splicing proteins U1-70k, hnRNP A2B1, SRRM2, SRSF2 and tau markers AT8 and 3R. In addition, we found a reduction in hnRNP A2B1 and 3R immunofluorescence in $A\beta_{25-35}$ treated disomic and trysomic hiPSC-CNs. AT8 fluorescence was reduced in trysomic compared to disomic hiPSC-CNs independent of $A\beta_{25-35}$ treatment. No changes were observed for U1-70k across treatments and cell lines. These preliminary data suggest that Aβ affects select splicing proteins and tau markers in both disomic and trysomic hiPSCs-CNs, suggesting that DS-derived hiPSC-CNs provide a robust human *in vitro* model to study the molecular mechanisms behind the interactions of amyloid, tau and RNA splicing.

Abstract: Alzheimer's disease (AD) is the most common type of dementia. Pathologies of Alzheimer's disease are represented by amyloid plaque, neuro-fibrillary tangle (NFT) and gliosis. NFT, majorly consist of pathological tau protein, is highly correlated with cognitive impairment in AD. Recently, sleep deprivation and circadian rhythm disruption show high correlation with AD pathology. Previously, molecular mechanism of circadian rhythm disruption by amyloid beta (Aβ) was revealed. Focus of this study is molecular mechanism of circadian rhythm disruption in AD especially with tauopathy. AD pathology model mice ($ADLP^{Tau}$) were used in this study. $ADLP^{Tau}$ has hTau P301L and showing tauopathy, not amyloid pathology. $ADLP^{Tau}$ shows tauopathy and circadian rhythm disruption. Specifically, phase delay and body temperature of $ADLP^{Tau}$ mice was altered from wild type. In mRNA level, several clock gene oscillation was disrupted. In protein level, Per2 core clock protein was decreased in entire time point. From this results, degradation of Per2 induced by tauopathy was investigated and we

suggest this for major underlying mechanism of circadian rhythm disruption in AD and tauopathy.

Abstract: In Alzheimer’s disease (AD), pathological tau protein propagates along the neuronal circuit in highly conserved pattern. As accumulation of Aβ precedes the formation and propagation of tau, pre-existing Aβ may affect the propagation of tau. However, clear relationship between Aβ and tau propagation is poorly understood. To confirm the effect of Aβ on tau propagation, we constructed a novel mouse model for AD, ADLP^{APT} mice, which expresses both Aβ and human tau. We observed the accelerated tauopathy affected by Aβ in ADLP^{APT} mice. However, Aβ pathology is not affected by the presence of pathological tau, indicating that Aβ can work as an accelerant for the propagation of tau but not vice versa. Using neuronal cell line, we found that secretion of tau is not accelerated in presence of Aβ, while uptake of extracellular tau is accelerated in Aβ dependent manner. Extracellular tau is internalized via endocytic pathway. Taken together, we show that Aβ facilitates the propagation of tau by increasing neuronal uptake of extracellular tau, and the internalized tau induces formation of neurofibrillary tangles and cytotoxicity in receptor neurons, thereby promoting neuronal cell death.

Abstract: Cerebral amyloidosis and severe tauopathy in the brain are key pathological features of Alzheimer’s disease (AD). Despite a strong influence of the intestinal microbiota on AD, the causal relationship between the gut microbiota and AD pathophysiology is still elusive. Using a developed ADLP^{APT} transgenic mouse model of AD showing both amyloid plaques and neurofibrillary tangles, we found that the composition of the gut microbiota in ADLP^{APT} mice differed from that of healthy wild-type (WT) mice. Interestingly, suppression of gut microbial activity in antibiotics (ABX)-treated ADLP^{APT} mice did not attenuate Aβ deposition, tau pathology, reactive gliosis and cognitive impairment, however, frequent transfer of the fecal microbiota from WT mice into ADLP^{APT} mice or ABX-treated ADLP^{APT} mice ameliorated their pathogenic features. These results implicated that gut microbial community and gut microbiota-derived factors might contribute to the pathogenesis of AD. It suggested that the restoration of intestinal microbiota and the maintenance of healthy microbiota is one of factors to consider clinical treatment for AD patients.

Abstract: Alzheimer’s disease (AD) is an incurable neurodegenerative disease in which the risk of development increases with age (Alzheimer’s Association, 2019). People with the disease are plagued with deficits in their short-term memory and a chronic reduction in basic social skills such as speech (Faith, 2014). Histologically, many of these deficits are caused by the formation of amyloid-β plaques and phosphorylated tau tangles in regions of the brain associated with memory, such as the hippocampus (Choi et al., 2014). However, one of the earliest clinical symptoms of AD is the loss of olfactory detection and discrimination, which is possibly due to dysfunction of the olfactory bulb, through the degeneration of the neurons located there (Zou et al., 2016). To determine if mice expressed the same olfactory dysfunction seen in human AD, 3xTg-AD mice were run in a buried food test and were then compared to their background and parental strains. Results showed that over 52 weeks, the 3xTg-AD mice took significantly longer to find the buried food than the control strains. The olfactory bulbs of the 52-week-old mice were removed, sliced and stained using Congo red for further histological analysis. The slices were observed with a confocal microscope’s polarized lens to observe both birefringence and non-birefringence to look for amyloid deposits. Significantly more amyloid deposits were observed in the 52-week-old 3xTg-AD mice when compared to the other strains of mice. Continued observation of the olfactory bulbs also revealed that a greater number of 3xTg-AD females than males developed the amyloid deposits showing sex differences in the phenotype of the trans Alzheimer’s genes.

Abstract: The entorhinal cortex (EC) is one of the most vulnerable brain region that is attacked during the early stage of Alzheimer's disease. Accumulation of abnormally hyperphosphorylated tau in the EC is the earliest pathological hallmarks in AD patients and neurofibrillary tangles are known to spread in a hierarchical pattern during disease progression. However, the neuronal function of tau is still unknown despite its probable influence on specific neural circuits in the early Alzheimer's disease. We found that accumulation of pathological tau begins in the lateral entorhinal cortex (LEC), followed by the hippocampal CA1 region of 2- to 3-month-old tau mice. In early tauopathy (<3 months), CA1 pyramidal neurons had reduced the neuronal excitability and decreased c-fos immunoreactivity was observed in both LEC and CA1 area. In the present study, we report that the release probability (Pr) of inhibitory synapse at temporoammonic pathway (EC-CA1) is increased and GAD2, VGAT and $GABA_A$ Receptor β3 levels were increased in 3-month-old tau model mice. All these results suggest that the possibility that tau alters temporoammonic pathway by modulating GABAergic synaptic transmission in the early tauopathy.

Title: Tau uptake is mediated by muscarinic receptors

Authors: V. MOROZOVA[1], L. S. COHEN[2], A. E.-H. MAKKI[2], ***A. SHUR**[3], G. R. PILAR[4], A. EL IDRISSI[2], A. ALONSO[5];

Abstract: Alzheimer's disease and associated tauopathies are characterized by the presence of neurofibrillary tangles composed of hyperphosphorylated tau proteins. Tau is a microtubule-associated protein located in neuronal axons. This protein has recently been found in the extracellular space, but the role of extracellular tau is not yet known. Avila et al. (2008) has shown that tau has a high binding affinity for M1- and M3- type muscarinic receptors. Based on this finding, we hypothesize that tau uptake is mediated by muscarinic receptors. We demonstrate that normal and pathological tau can be taken up by HEK293 cells and neurons. Uptake of normal tau in neurons enhances neuronal process formation, but pathological human tau (PH-Tau) uptake results in the disruption process formation and accumulation of aggregates in the somatodendritic compartment. Hyperphosphorylated tau (AD P-Tau) had similar effects to PH-Tau on the cultured neurons. To explore whether specific subtypes of muscarinic receptors are implicated in tau uptake, HEK293 cells and cerebellar neuronal cultures were pre-incubated with broad muscarinic receptor antagonist atropine and selective M1 receptor antagonist pirenzepine prior to the addition of tau. Uptake was blocked by up to 80%. Pre-incubation with M2 and M4 receptor antagonists AF DX116 and PTX failed to block tau uptake. Furthermore, we showed that CHO cells do not express muscarinic receptors, and therefore cannot uptake either form of tau unless transfected with M1- and/or M3-type receptors. Interestingly, we found that our transgenic mouse model that conditionally expresses PH-Tau showed increased M1 muscarinic receptors compared to control. Similar results were observed in primary cerebellar cultures treated with PH-Tau. Based on our results, tau uptake is mediated by muscarinic receptors and induces different morphological consequences in neurons based on the phosphorylation state of the protein.

Title: The effect of synaptic adhesion molecules on *in vitro* tau propagation model

Authors: *Y. NEMOTO, Y. HORI, T. TOMITA;
The Univ. of Tokyo, Tokyo, Japan

Abstract: One of the distinct hallmarks of Alzheimer disease (AD) is neurofibrillary tangles, which is consisted of the aggregated tau protein. Because the spreading of tau pathology through brain correlates with the cognitive decline, understanding the mechanism of tau spreading has been highlighted. Recently, several studies proposed the tau propagation theory as a model of spreading tau pathology. In this model, tau propagation occurs between anatomically connected neurons, suggesting that neuronal synapses play an important role in the tau propagation. One of the synapse organizers is neuroligin (NL), which is the postsynaptic adhesion molecule. Human NL family is comprised of NL1, 2, 3, 4X and 4Y. NL1 specifically localizes at excitatory synapses, whereas NL2 and 4 at inhibitory synapses. Overexpression of NLs induces the formation of functional synapse with specific properties depending on the NL isoform *in vitro*. Moreover, previous report revealed that the synapse formation by overexpression of NL1 facilitated the tau propagation. However, the effects of synapse formation by other NLs on tau propagation remain unclear. To examine the roles of induced synapses by NLs on tau propagation, we developed the *in vitro* tau propagation model using co-culture system using murine primary neurons overexpressing full-length tau and HEK293 cells harboring tau aggregates. Immunocytochemical analysis revealed that the co-culture with HEK293 cells with tau aggregates induced the accumulation of tau in the primary neuron. In addition, tau in the primary neurons acquired the insolubility in the co-culture system, indicating that the aggregated tau seed was propagated from HEK293 cells to the neurons to induce the tau aggregation. Next, we overexpressed each NL isoform in HEK293 cells with tau aggregates to elucidate the effects of synaptic properties on tau propagation. We found that the levels of insoluble tau in the neurons was selectively increased by NL2-mediated inhibitory synapse formation. These results suggested that the tau propagation is modulated by the synaptic properties induced by different NL isoforms. Further molecular and cellular studies would clarify the mechanistic role of NLs in the tau propagation and the etiology of AD.

Title: Blood transfusion from young wildtype mice alters behavior in old Alzheimer's disease mice with hTau

Authors: *C. M. HERNANDEZ, K. A. PEDEMONTE, R. E. BARKEY, J. O. SANCHEZ, B. JOHNSON, J. M. FLINN;
George Mason Univ., Fairfax, VA

Abstract: Aging is characterized by a decline in synaptic plasticity and cognitive functions. This is intensified in Alzheimer’s disease (AD) by the buildup of amyloid plaques and tau tangles in the brain. There are limited treatments for AD, therefore the exploration of new alternatives is warranted. In a recent study, plasma was transfused from young wildtype (WT) mice to older mice containing human APP, which lead to improvement in spatial learning and memory tasks and an increase in synaptic plasticity (Middeldorp et al. 2016). Since mice with h-tau were not included in this design, we have transfused plasma from young WT mice to older transgenic mice with h-Tau (P301L/CaMKII). Previous studies in our lab have shown that these mice have learning and memory impairments in mice (Craven et al. 2018). Nesting and burrowing are innate behaviors in mice that have been shown to be impaired in AD, and they parallel activities of daily living in AD patients. Circadian rhythm is disrupted in AD mice, which are less active during the last four hours of dark cycle (Boggs et al. 2017). This study examined burrowing, nesting, circadian rhythm, based on 24-hour activity, in four groups: old WT mice injected with a) young plasma or b) saline, and old h-tau mice injected with c) young plasma or d) saline. Preliminary results show that plasma transfusions rescued the deficits in activities of daily living seen in older h-tau mice. Old h-tau mice with plasma built significantly better nests ($p<.05$), and burrowed more ($p<.05$) than those with saline; no effects were seen in old WT mice. Old h-tau mice had impaired circadian rhythms which were corrected with plasma transfusion, demonstrated by an increase of wheel-running activity during the last four hours of the dark cycle. Further examination will include tau staining in the brain, and protein expression of phosphorylated tau and total tau using western blotting. This study expands our understand of the behavioral and biochemical effects of young blood transfusion of AD.

Abstract: Introduction: Lifestyle choices contribute to nearly all of the 10 leading causes of death in the United States, and Alzheimer’s disease (AD) is no exception. Links from AD to metabolic and inflammatory diseases give dietary and lifestyle contributions to the disease further traction. Using established AD mouse lines we hypothesized that dietary insults would have a deleterious effect on the cognitive ability of our experimental mice. This effect would be caused by oxidative damage and iron dysregulation which we would visualize using experimental Ultra-short Echo Time MRI scanning techniques. Methods: We bred 74 total mice into cohorts of PSEN1 and Tau transgenes, with C57BL6 wild-types as controls. Mice received Methionine enriched or Western diets as insults, and rescue cohorts received diets enriched with Metformin. At time-points of 2 months (baseline), 3 months and 6 months, behavioral data was collected using a radial arm maze for 10, 5 minute trials each day for 2 weeks. The baited arm was changed after each testing period. Trials were recorded using a GoPro HERO4 and analyzed using ANYMaze software. Mice were scanned using a 3T Siemens MRI scanner to acquire 2D T2 weighted turbo-spin echo scans, 3D Gradient Echo scans, and Ultra Short Echo 3D Cone

images. ROI's were set on bilateral hippocampi and normalized to a water standard included in the scan. All statistics were analyzed using SPSS. Results: There was a statistically significant difference in mean time ($F(15, 8.683) = 15.183$, $p < 0.0005$), mean distance ($F(15, 8.683) = 7.309$, $p = 0.0003$), and mean errors ($F(15, 8.683) = 6.613$, $p = 0.0004$) in the maze, between the control and western diets. There was also a significant difference in mean failed (the subject failed to complete the task in 5 minutes) trials ($F(15, 8.683) = 13.333$, $p < 0.0005$) between controls and western diets. Significant interaction effects were also seen between genotype and treatment administered with each of the measures (time [$p = 0.003$], distance [$p = 0.037$], errors [$p = 0.033$], and failed trials [$p < 0.0005$]). Metformin rescue cohorts showed some improved cognitive ability, predominantly with co-administration of methionine. It did, however, have deleterious effects when administered alone. The MRI sequences showed some sensitivity to differences in brain tissue between control and western diets when measured using 3D CONE echo times of 1.2ms, but this requires further investigation and analysis. Conclusion: Western diet exacerbates the cognitive decline seen in AD transgenic mouse models, and metformin shows potential as a treatment, but not in healthy individuals. New MRI techniques also show promise as improved diagnostic tools.

Title: Effect of treadmill exercise training on anxious-depressive-like behavior in transgenic Alzheimer rat

Authors: ***L. YANG**, C. WU, Y. LI, Y. DONG, L. DONOVAN TUCKER, Q. ZHANG; Dept. of Neurosci. and Regenerative Med., Augusta Univ., Augusta, GA

Abstract: **PURPOSE:** This study aimed to examine the effects of treadmill training on anxious-depressive-like behaviors of transgenic Alzheimer rats in the early stage of Alzheimer's disease (AD) and provided the evidence of exercise in alleviating fear memory deficits. **METHODS:** Male 2-month-old TgF344-AD and wild-type (WT) rats were divided into WT, AD and AD + treadmill exercise (Exe) groups. After 8 months of exercise, the Passive Avoidance test (fear memory), Barnes Maze task, Novel Object Recognition test and Objection Location test

(hippocampus-dependent spatial learning/recognition memory) were used to measure learning and memory function. The Open Field test and Elevated Plus maze were performed to measure anxiety-like behavior. The sucrose preference test and forced swim test were conducted to determine the depression-like behavior of transgenic Alzheimer rats. **RESULTS:** The results of Passive Avoidance test revealed that treadmill exercise significantly alleviated the defective fear memory in AD rats ($p < 0.01$). The Barnes Maze, Novel Object Recognition test, and Object Location test revealed that the 12-month TgF344-AD rats did not develop significant hippocampus-dependent spatial learning and recognition memory deficits compared with WT animals ($p \geq 0.05$). Intriguingly, TgF344-AD animals displayed significant anxiety-like behavior compared with WT animals ($p < 0.05$), which was reversed by treadmill exercise ($p < 0.05$). TgF344-AD animals also displayed depression-like behavior compared with WT animals as measured by sucrose preference test and forced swim test, which could be effectively improved following exercise training ($p < 0.05$). **CONCLUSION:** Long-term exercise training alleviated anxious-depressive-like behavior and improved fear memory in transgenic AD rats, supporting exercise is an effective approach to prevent anxiety, depression and fear-related memory deficits in the early stages of AD pathogenesis. **Key Words**: Treadmill exercise; Anxiety; Depression; Learning and memory; TgF344-AD rat

Abstract: The aggregation of Aβ-proteins in senile plaques is a critical event during the development of Alzheimer's disease, and the postmortem detection of Aβ-rich proteinaceous deposits via fluorescent staining remains one of the most robust diagnostic tools. In animal models, fluorescence imaging can be employed to follow the progression of the disease and among imaging methods two-photon microscopy (TPM) has emerged as one of the most powerful. To date, several near-infrared-emissive two-photon dyes with a high affinity for Aβ-fibrils have been developed, but there has often been a tradeoff between excellent two-photon cross sections and large fluorescence signal to background ratios. In the current work, we introduced a TICT-based de-excitation pathway, resulting in a remarkable fluorescence increase of ~167-fold in the presence of Aβ-fibrils, while maintaining an excellent two-photon cross section, allowing high contrast *ex vivo* and *in vivo* TPM imaging. Overall, the results suggest that adopting TICT de-excitation in two-photon fluorophores may represent a general method to overcome the probe brightness vs. probe signal to background tradeoff.

Title: The dog as a preclinical species for the evaluation of Tau antibodies

Authors: *H. BORGHYS[1], D. DHUYVETTER[2], C. THEUNIS[3], K. VAN KOLEN[4], M. H. MERCKEN[1];
[1]Janssen Res. & Develop., Beerse, Belgium; [2]Janssen Res. @ Develop., Beerse, Belgium; [3]Neurosci., Janssen Pharmaceutica, Beerse, Belgium; [4]Janssen PRD, Beerse, Belgium

Abstract: Hyperphosphorylated and aggregated tau are among the main characteristics of Alzheimer's disease (AD) pathology and it is known that pathological tau can spread from cell to cell, continuously progressing the disease. Immunotherapy with anti-tau antibodies is currently investigated as treatment approach acting on this tau spreading hypothesis.
We evaluated the dog as a preclinical species for the pharmacokinetic/pharmacodynamic (PK/PD) properties of tau antibodies. Phosphorylated tau (pTau) was measured as PD biomarker in cerebrospinal fluid (CSF) sampled from the lateral ventricle (LV) in conscious dogs and from

the cisterna magna (CM) in anesthetized dogs. In addition, levels of antibodies were measured in serum and CSF. Baseline pTau levels at the 2 sample sites were compared in a separate study. The results show a decrease in pTau for both tested antibodies. It was also noted that the variability was lower in the samples from the CM making this sample site more suitable then the LV.
It is concluded that the dog is a suitable preclinical species to evaluate and compare PK/PD properties of Tau antibodies.

Title: Allopregnanolone potentiates bioenergetic capacity and restructures mitochondrial reticulum in neurons and astrocytes

Authors: *T. WANG, S. CHEN, Z. MAO, R. D. BRINTON;
Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tucson, AZ

Abstract: We previously demonstrated that the neurosteroid allopregnanolone (Allo) promotes neural stem cell regeneration, reverses neurogenic, metabolic and cognitive deficits and reduces Alzheimer’s disease (AD) pathology in a mouse model of AD. To determine the cell-type specific mechanisms of Allo in regulating brain energy metabolism, we assessed the effect of Allo on mitochondrial bioenergetic profile and their morphological changes in rat E18 hippocampal neurons and astrocytes.
In E18 hippocampal neurons, Allo treatment significantly reversed supplement depletion-induced (2%B27/NBM) decrease in mitochondrial maximal- and spare respiratory capacity and axonal and dendritic length and count. In parallel, in E18 hippocampal astrocytes, Allo rescued serum depletion-induced (10% Charcoal stripped-FBS/DMEM : F12) decline in mitochondrial spare respiratory capacity through increasing MT-encoded OXPHOS gene expression. Allo

treatment reduced the population of less efficient swollen globule mitochondria in both neurons and astrocytes. Specifically in astrocytes, Allo decreased the number of hyperfused tubule mitochondria and increased small globule mitochondria. The effect of Allo on re-structuring supplement depletion-induced mitochondrial reticulum in both neurons and astrocytes was further supported by the restoration of the balance between Drp1 and Opa1 expression, which are key regulators for mitochondrial fission and fusion, respectively.
Outcomes of our findings further support therapeutic development of Allo to reverse bioenergetic deficits and mitochondrial inefficiency that can emerge in early phases of AD, with mitochondrial dynamics being a potentially key targeted mechanism.

Title: Nobiletin effect on brain mitochondria as a neuroprotective mechanism

Authors: *N. SHARIKADZE[1,2], N. JOJUA[2], M. SEPASHVILI[2], E. ZHURAVLIOVA[2,3], D. MIKELADZE[2,3];
[1]Natl. Inst. of Drug Abuse, Baltimore, MD; [2]Inst. of Chem. Biol., Ilia State Univ., Tbilisi, Georgia; [3]I.Beritashvili Ctr. of Exptl. Biomedicine, Tbilisi, Georgia

Abstract: Citrus flavonoid nobiletin has anticancer, antiviral, neuroprotective, anti-inflammatory activities and depending on the cell types exhibits both pro- or anti-apoptotic properties that suggest the effect of this compound on the central metabolic systems, such as mitochondrial bioenergetics. The aim of our study was to investigate the influence of nobiletin on brain mitochondrial bioenergetics and determine the target molecules, involving in nobiletin-induced alterations. Here we analyzed mitochondrial enzymes activities and estimated of respiration rate, mitochondrial membrane potential, ROS production were performed in bovine brain mitochondria to evaluate the direct effect of nobiletin on the mitochondrial bioenergetics. Additionally, were made isolation and characterization of nobiletin-bound mitochondrial protein to identify the main target molecule.We have found that nobiletin decreases oxygen consumption in the presence of glutamate and malate and increases in the presence of succinate. In parallel, nobiletin increases NADH oxidation, alpha-ketoglutarate dehydrogenase activities and alpha-ketoglutarate-dependent production of ATP. Additionally, nobiletin reduces the production of peroxides in the presence of complex I substrates and does not change succinate-driven peroxide formation. Besides, nobiletin induces transient elevation of membrane potential followed by mild depolarization. Affinity purified nobiletin binding proteins revealed one major anti-NDUFV1

positive protein with 52 kD and NADH: ubiquinone oxidoreductase activity. We propose that nobiletin may act as a mild uncoupler, which through activation of a-KGDH-complex and acceleration of matrix substrate-level phosphorylation maintain membrane potential at a normal level. This switch in mitochondrial metabolism could elevate succinate-driven oxygen consumptionthat may underlay both pro-and anti-apoptotic effects of nobiletin.

Title: The role of synaptic vesicle protein 2a on mitochondrial morphology and autophagy

Authors: *J. REICHERT[1], M. CHRIST[2], M. JÖRG[1], A. KERN[2], C. W. BEHL[2], K. FRIEDLAND[1];
[1]Johannes Gutenberg Univ., Mainz, Germany; [2]Inst. For Pathobiochemistry, Mainz, Germany

Abstract: Synaptic Vesicle Protein 2a (SV2a) is a transmembrane protein mainly located on synaptic vesicles and involved in transmitter release via its calcium dependent interaction with SNARE complex proteins especially Synaptotagmin-1. SV2a is the postulated target of the anticonvulsant drug Levetiracetam (LEV), which was found to enhance the cognition of Alzheimer’s disease patients and slow down progression of Alzheimer’s disease (AD). These effects are discussed to be mediated due to LEVs efficient silencing of excitotoxic neuronal hyperexcitability which occurs in early stages of AD and is likely to contribute to neurodegeneration. Additionally, our group found LEV to affect mitochondrial morphology, increase ATP levels and mitochondrial membrane potential (MMP), which is surprising as in literature SV2a is claimed to neither be a mitochondrial protein nor to bind to mitochondria or to regulate mitochondrial function. Therefore, to this day the underlying mode of action on mitochondria remains elusive and needs further investigation. It is also interesting that in an epilepsy model of *c. elegans* LEV was found to reduce paralysis although *c. elegans* as an invertebrate does not possess SV2a but its evolutionary precursor Synaptic Vesicle 2-Related Protein (SVOP-1). To shape light on the mode of action of LEV on mitochondria our group first analyzed proteomics of isolated mitochondria and detected SV2a which gave rise to our idea that SV2a must either be a mitochondrial protein or an interactor. To further investigate whether SV2a is a mitochondrial protein or interactor we perform confocal microscopy and Super-Resolution GSDIM microscopy on SH-SY5Y cells to check for colocalization of SV2a with mitochondria. Luciferase-based cytotoxicity assays are used to compare ATP levels of control

cells and SH-SY5Y APP wt (APPwt) cells, which serve as a mild model of Alzheimer's disease. Using Western Blot we examine autophagic flux in control cells and APPwt. For *in vivo* investigation if knockdown of SVOP-1 alters mitochondrial morphology we created a genetically modified *C. elegans* strain expressing CFP tagged neuronal mitochondria. In conclusion clarifying the interaction of LEV and mitochondria via SV2a or via a different mode of action might represent an important step towards developing new therapeutic strategies to improve symptoms of Alzheimer's disease patients.

Title: Apoe isoforms differentially regulate neuronal- and astrocytic mitochondrial bioenergetic capacity and fuel dependency

Authors: *G. QI[1], Y. MI[1], S. CHEN[1], R. D. BRINTON[1,2,3], F. YIN[1,2];
[1]Ctr. for Innovation in Brain Sci., [2]Dept. of Pharmacol., [3]Dept. of Neurol., Univ. of Arizona, Tucson, AZ

Abstract: Late-onset Alzheimer's disease (LOAD) has a multifactorial nature and is associated with an early decline in brain glucose metabolism and mitochondrion dysfunction. As the greatest genetic risk factor for LOAD, APOE4 allele has been found to not only impair amyloid-β (Aβ) clearance and promote its aggregation, but also affect energy metabolism and mitochondrial function. While the exaggeration of age-related brain hypometabolism and mitochondrial inefficiency by APOE4 is well established in both AD patients and animal models of late stage AD, mixed results have thus far been reported regarding APOE4 effect on brain

bioenergetics in young animals or *in vitro* models. We propose that such a discrepancy is partially due to the heterogeneous cellular composition of the brain and the distinct capacity of these cells to metabolize various energy substrates. To distinguish the effect of APOE4 on regulating neuronal- and astrocytic mitochondrial function and their preference to fuels, primary neurons and astrocytes were isolated from the forebrain of humanized APOE4 and APOE3 mice (Jackson Laboratory). Mitochondrial bioenergetic profile and their dependency and capacity of metabolizing different substrates were characterized. As expected, both APOE3 and APOE4 embryonic neurons relied primarily on glucose than other fuels in terms of both dependency and capacity, whereas astrocytes could metabolize more fatty acids than neurons. Our results further revealed that APOE4 neurons and adult astrocytes exhibited lower spare respiration capacity ratio compared to APOE3 cells, although the basal respiration of APOE4 astrocytes was higher than that of APOE3 astrocytes. Across energy fuels, APOE4 astrocytes had higher maximum capacity metabolizing glucose than fatty acids while such a fuel preference was much less significant in APOE3 astrocytes. Consistently, the maximal capacity in metabolizing fatty acids was significantly lower in APOE4 astrocytes when compared to that of APOE3 astrocytes. Our findings indicated that the impact of APOE genotype on brain bioenergetics is not only cell type dependent but could also be age- and AD stage-dependent. It was suggested that the development of strategies to restore brain energy metabolism against AD should consider APOE genotype, age- and disease-stage, and the fuel preference of different cell types in the brain.

Title: APOE and chromosomal sex shows significant effect on the lipid pathways from multiple scale analysis of aged mice

Authors: *Y. SHANG[1], A. MISHRA[1], M. K. DESAI[2], T. WANG[1], R. D. BRINTON[1];
[1]Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tucson, AZ; [2]USC, Los Angeles, CA

Abstract: Late onset Alzheimer's disease (LOAD) is a complex neurodegenerative disease with four well-established risk factors: age, APOE*4 genotype, female sex, and maternal history of AD. Each risk factor impacts multiple systems biology pathways, making LOAD a complex systems challenge. To investigate interactions between LOAD risk factors, we utilized aged humanized hAPOE3 and hAPOE4 female and male mice. Multiple scale date sets including hippocampal bulk-RNAseq transcriptomics, AbsoluteIDQ-p180 metabolomics of cortical brain and plasma, brain diffusion-weighted magnetic resonance imaging (dMRI), and behavioral cognitive performance were derived from 16 months old female and male mice with targeted replacement of mouse Apoe with human APOE3 or APOE4 genes. Regression analysis indicated a significant positive correlation between cognitive test scores and brain structure changes indicated by the optic tract fractional anisotropy (FA) from dMRI imaging. hAPOE4 female and male mice exhibited significant cognitive deficits ($p<0.05$). Interestingly, in most brain regions, hAPOE4/4 females and males exhibited lower FA than their hAPOE3/3 counterparts, suggesting a lower level of white matter integrity in hAPOE4/4 mice. Because mitochondrial dysfunction and shifts in metabolic profile are among the earliest symptoms of AD, we analyzed metabolomic profiles of both cerebral cortex and plasma. Principal component analysis (PCA) of the plasma metabolites indicated that the clustering patterns were well separated by sex and by hAPOE isoform in females, suggesting a strong sex effect on peripheral metabolic profile and an APOE isoform effect primarily in females. Detailed analysis of metabolic changes in these mice indicated that amino acid concentrations were higher in hAPOE4/4 males while acylcarnitine concentrations were higher in females hAPOE4 carriers (hAPOE3/4 and hAPOE4/4). The AD signature accumulation of phospholipids, such as sphingomyelins and glycerophospholipids, was most prominent in hAPOE3/4 and hAPOE4/4 female mice. Consistently, the gene and pathway based RNAseq analysis indicated increased expression of fatty acid/lipid metabolism related genes and pathways in both hAPOE4 females and males, which was most apparent in the females. Collectively, these data provide therapeutic targets for sex-based precision medicine interventions during the prodromal phase of LOAD, when the potential to reverse, prevent and delay LOAD progression is greatest.

Title: ApoE2-mediated neuroprotective mechanism through regulation of glycolysis

Authors: *X. ZHANG[1], L. WU[1], L. ZHAO[1,2];
[1]Pharmacol. and Toxicology, [2]Neurosci. Grad. Program, Univ. of Kansas, Lawrence, KS

Abstract: Continued clinical failures in the search for a successful treatment of Alzheimer's disease (AD) raise questions about the validity of currently-focused therapeutic targets, underscoring the importance of a novel concept that emphasizes less on the pathological manifestation of the disease but more on the neuroprotective mechanism that promotes brain resilience against the onset of AD. We have recently demonstrated that human ApoE genetic isoforms (ApoE2, ApoE3, ApoE4) differentially modulate brain energy metabolism with the ApoE2 brain exhibiting the most robust while the ApoE4 brain displays the most deficient profile. Using neuro-2a (N2a) cells stably expressing human ApoE isoforms (N2a-hApoE), all-trans-retinoic acid (RA)-induced differentiated N2a-hApoE cells (dN2a-hApoE) and dN2a cells transfected with hApoE, this follow-up study was sought to investigate in-depth the interrelationship between ApoE isoforms, glycolytic status and overall cellular health. Our data demonstrated that ApoE isoforms exerted a significant impact on both the expression and activity of hexokinase as well as glycolytic function. Specifically, ApoE2-expressing cells remained robust on glycolytic outcomes within the passages studied; in contrast, ApoE4-expressing cells exhibited gradual reduction with increasing passages indicating a chronic toxic effect. These ApoE-mediated glycolytic differences directly correlated to cellular overall health status, as indicated by both metabolic activity and morphological phenotype of the cells. Furthermore, our investigation of ApoE impact on other major enzymes involved in glycolysis revealed that, opposite to its regulation of HK, ApoE4 appeared to upregulate phosphofructokinase (PFKP), providing further evidence for the deficit energy state of the cells. Taken together, these data indicate that human ApoE isoforms differentially modulate neuronal glycolysis, in large part via regulation of hexokinase, which markedly influences neuronal metabolic activity and overall health. The ApoE2-mediated glycolytic robustness may serve as a mechanistic rationale for its neuroprotective role and consequently provides a novel therapeutic approach in the prevention and early intervention of AD.

Title: Beta-amyloid monomers promote glucose uptake and aerobic glycolysis in neurons

Authors: R. SANTANGELO[1], M. GIUFFRIDA[3], C. SATRIANO[2], F. NICOLETTI[4], ***A. G. COPANI**[1];
[1]Dept. Drug Sci., [2]Dept. Chem. Sci., Univ. of Catania, Catania, Italy; [3]CNR, Catania, Italy; [4]Univ. Sapienza, Roma, Italy

Abstract: We have previously demonstrated that monomers of β-amyloid protein (Aβ) selectively activate type-1 insulin-like growth factor receptors (IGF-IRs) both in recombinant and native cells. In neurons, Aβ monomers enhance glucose uptake by promoting the translocation of the Glut3 glucose transporter from the cytosol to the plasma membrane. Consistent with the evidence that Aβ is released from neurons in response to synaptic activity (Cirrito et al., Neuron 48, 2005), depolarization-induced glucose uptake is blunted after blocking endogenous Aβ production with gamma-secretase inhibitors, and re-established by exogenous Aβ monomers. Similarly, APP-null neurons fail to enhance depolarization-stimulated glucose uptake unless exogenous monomeric Aβ is added (Giuffrida et al., Front Cell Neurosci 9, 2015). Noteworthy, it is aerobic glycolysis rather than oxidative phosphorylation that covers neuronal demands during synaptic activation (Ivanov et al., J Cereb Blood Flow Metab 34, 2014), while increasing neuronal resilience to stressors (Newington et al., J Biol Chem 287, 2012). We wondered whether Aβ monomers are physiologically required to sustain brain aerobic glycolysis *via* IGF-IR activation. We found that pure neurons in culture relied on aerobic glycolysis (measured as lactate release in the bathing medium) when oxidative phosphorylation was blocked by the ATP synthase inhibitor, oligomycin. Interestingly, the endogenous release of Aβ was required for the occurrence of aerobic glycolysis with ensuing neuronal survival. Hexokinase-1 (HK-1) is the driving force for aerobic glycolysis when it is bound to the outer mitochondria membrane (OMM) of cells (Bustamante and Pedersen, Proc Natl Acad Sci USA 74, 1977). Accordingly, confocal microscopy showed an increased HK-1 signal at the mitochondria of neurons activated by Aβ monomers, which was prevented by the IGF-IR antagonist, picropodophyllin. Overall, our data suggest that Aβ monomers may promote aerobic glycolysis to face energy demand during synaptic activity or incoming stressors.

Title: Wnt induced activation of glucose metabolism mediates the *in vivo* neuroprotective roles of Wnt signaling

Authors: *P. CISTERNAS[1], J. GUTIERREZ[1], C. GHERARDELLI[1], N. C. INESTROSA[2]; [1]Ctr. de Envejecimiento y Regeneración (CARE-UC), Dept. de Biología Celular y Molecular, Facultad de Ciencias Biológicas, Pontificia Univ. Católica de Chile, Santiago, Chile, Santiago, Chile; [2]Ctr. de Envejecimiento y Regeneración (CARE-UC), Dept. de Biología Celular y Molecular, Facultad de Ciencias Biológicas, Pontificia Univ. Católica de Chile, Santiago, Chile, Ñuñoa, Chile

Abstract: Dysregulated Wnt signaling is linked to major neurodegenerative diseases, including Alzheimer´s disease (AD). In mouse models of AD, activation of the canonical Wnt signaling pathway improves learning and memory, but the mechanism for this remains unclear. The decline in brain function in AD patients correlates with reduced glucose utilization by neurons. Here, we test whether improvements in glucose metabolism mediate the neuroprotective effects of Wnt in AD mouse model. APPswe/PS1dE9 transgenic mice were used to model AD, andrographolide or lithium was used to activate Wnt signaling, and cytochalasin B was used to block glucose uptake. Cognitive function was assessed by novel object recognition and memory flexibility tests. Glucose uptake and the glycolytic rate were determined using radiotracer glucose. The activities of key enzymes of glycolysis such as hexokinase (HK) and phosphofructokinase (PFK), ATP/ADP levels and the pentose phosphate pathway (glucose-6 phosphate dehydrogenase) were measured. Wnt activators significantly improved brain glucose utilization and cognitive performance in APPswe/PS1E9 transgenic mice. Wnt signaling enhanced glucose metabolism by increasing the expression and/or activity of HK, PFK and AMP-activated protein kinase (AMPK). Inhibiting glucose uptake partially abolished the beneficial effects of Wnt signaling on learning and memory. Wnt activation also enhanced glucose uptake and the glycolytic rate of cultured cortical and hippocampal neurons, as well as brain slices derived from APPswe/PS1E9 transgenic mice. In hippocampal neurons treated with amyloid-β, Wnt activation significantly reduced cell death; this protective effect was abrogated by inhibitors of glucose uptake or Wnt signaling. Combined, these data provide evidence that the neuroprotective effects of Wnt signaling in AD mouse models result, at least in part, from Wnt-mediated improvements in neuronal glucose metabolism.

Title: Alzheimer-related pathology impairs peripheral glucose tolerance by disrupting glucose transporter 1 localization and cerebral glucose delivery

Authors: *S. W. BARGER[1], R. D. HENDRIX[5], Y. OU[1], J. E. DAVIS[2], A. R. ALLEN[3], G. V. CHILDS[4];
[1]Geriatrics, [3]Pharmaceut. Sci., [4]Neurobio. and Developmental Sci., [2]Univ. of Arkansas for Med. Sci., Little Rock, AR; [5]Dept of Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Alzheimer's disease (AD) is associated with disturbances in blood glucose regulation, and Type-2 diabetes elevates the risk for dementia. A role for amyloid β-peptide (Aβ) in linking these age-related conditions has been proposed, tested primarily in transgenic mouse lines that over-express mutated amyloid precursor protein. Because APP has its own impacts on glucose regulation, we examined the BRI-Aβ42 line ("$A\beta_{42}$-tg"), which secretes $A\beta_{1\text{-}42}$ in the CNS without elevation of APP. We also looked for interactions with diet-induced obesity (DIO) resulting from a high-fat, high-sucrose ("western") diet. While female $A\beta_{42}$-tg mice were unaffected, males were impaired in both spatial memory and glucose tolerance. The latter was only additive with that caused by DIO, and though the DIO induced insulin resistance, $A\beta_{1\text{-}42}$ accumulation did not. $A\beta_{42}$-tg mice exhibited no significant differences from wild-type in insulin production, body weight, lipidemia, appetite, physical activity, respiratory quotient, an-/orexigenic factors, or inflammatory factors. Similar to AD patients, $A\beta_{42}$-tg mice did have a reduced cerebral metabolic rate for glucose (CMR_{glc}), and this was associated with insufficient trafficking of glucose transporter 1 (GLUT1) to the plasma membrane in parenchymal brain cells; this effect on GLUT1 was also documented in cortical specimens from humans with AD. Together, the lower CMR_{glc} and diminished function of parenchymal GLUT1 indicate that aberrant regulation of blood glucose in AD likely reflects a central phenomenon, resulting from the effects of Aβ on cerebral parenchyma, rather than a generalized disruption of hypothalamic or peripheral endocrinology.

Title: Allopregnanolone prevent the loss of neuronal differentiative capacity in 3xTgAD mice

Authors: *S. CHEN, T. WANG, R. D. BRINTON;
Ctr. for Innovation in Brain Sci., Univ. of Arizona, Tucson, AZ

Abstract: Previous studies demonstrated that the endogenous steroid Allopregnanolone promotes proliferation of rodent and human neural progenitor/neural stem cells (NSCs) *in vitro*, reverses neurogenic and cognitive deficits in the triple transgenic mouse model of Alzheimer's disease (3xTgAD). In this study, we investigated the impact of Allopregnanoloneon neural differentiation. We first assessed the effect of aging and Alzheimer's-associated genotype on the differentiation capacity of adult NSCs in 3xTgAD mice. NSCs from 3-, 6- and 15-month 3xTgAD and non-transgenic mice were cultured and differentiation capacity was analyzed. We found an age- and Alzheimer's gene-dependent decrease in overall NSCs differentiation with a shift from neuronal to glial differentiation. Consistently, the number of immature doublecortin (DCX) positive neurons declined more significantly with aging in 3xTgAD mice compared to age-matched non-TG mice. To further determine the *in vivo* efficacy of Allopregnanolone to prevent or reverse the loss of neuronal differentiative capacity, we investigated the impact of neuronal differentiation in 5-month-old male 3xTgAD mice. Flow cytometry-based analysis indicated that Allopregnanolone treatment increased the number of newly generated neurons as indicated by the increase in the number of BrdU positive cells and BrdU/NeuN double positive cells. Immunostaining on brain sections confirmed that the number of DCX positive neurons was significantly increased following Allopregnanolone treatment *in vivo*, which was further supported by the enhanced level of DCX expression in hippocampal samples. Allopregnanolone treatment also increased the expression of Olig2, an oligodendrocyte precursor cell marker. Immunohistochemistry analyses showed that more Olig2 positive cells were distributed in corpus callosum area in the Allopregnanolone-treated brain. The increase of differentiation in neuronal cell and oligodendrocyte precursors was paralleled with an increase of expression in insulin-like growth factor-1 (IGF-1) and IGF-1 receptor (IGF-1R). To determine mechanisms of neural differentiation induced by Allopregnanolone, we are currently investigating expression of AKT and IGF-1/IGF-1R signaling pathway. Collectively these findings suggest that Allopregnanolone

is a regenerative therapeutic candidate to prevent or delay neurogenic deficits associated with age and Alzheimer's disease.

Title: The role of diet and exosomes in the pathophysiology of Alzheimer's disease

Authors: *L. M. WISE[1], J. YANG[1], R. LALONDE[2], K.-I. FUKUCHI[1];
[1]Univ. of Illinois Col. of Med. at Peor, Peoria, IL; [2]Univ. of Rouen Normandy, Mont-Saint-Aignan, France

Abstract: Obesity has become a worldwide epidemic with over 30% of the world's population being classified as obese. Obesity increases the risk of many adverse health conditions, including diabetes. Chronic consumption of energy dense foods, high in fats, is associated with obesity, insulin resistance, and diabetes. Obesity and diabetes are both high risk factors of cognitive decline, dementia, and Alzheimer's disease (AD). To investigate shared mechanisms, C57BL/6 mice were fed either a normal chow diet or a high-fat diet (60% kcal from fat) from 9-11 months of age. Starting at 11 months, blood exosomes were extracted twice a week from the serum from 11-15 months. The exosomes were injected into transgenic APP/PS1 AD mouse models from age 3 -7 months. Additionally, two separate groups of AD mouse models were either fed a normal chow diet or a high-fat diet from age 3-7 months. At 7 months, the AD mouse models completed behavioral tasks and glucose tolerance tests. Histological analyses of the hippocampus and cortex will be presented.

Abstract: People with type-2-diabetes mellitus (T2DM) have an increased risk for developing Alzheimer’s disease (AD). However, the exact mechanisms for why this happens are currently unknown. Although iron is essential for many biological processes, it is also a potential contributing factor to disease since excess iron increases oxidative stress and cellular damage causing beta cell dysfunction and neurodegeneration. High fat diets (HFD) alter tissue iron levels and influence the regional distribution of iron in the brain; a pattern that could negatively impact cognition. Therefore, we investigated the relationship between T2DM, AD, and high iron using models of dietary and genetic iron overload in both wild type mice (WT) and mice overexpressing amyloid-beta (Aβ) and AD-related pathology (APP/PS1). Overall, a high fat diet is sufficient to drive the development of T2DM independent of iron levels. Mice on the control diet with normal dietary iron gained less weight and had lower blood glucose levels than the HFD groups. Although all experimental groups had comparable fasted blood glucose levels at baseline, HFD/normal iron and HFD/high iron groups had elevated fasted blood glucose levels after 3 months. The 1) APP/PS1/HFD/normal iron and 2) WT/HFD/high iron groups displayed the greatest glucose intolerance at 3 months post-intervention. HFE knockout mice, a genetic model of hereditary hemochromatosis and iron overload, bred to the APP/PS1 mice died prematurely, with a median survival of 105 days. Ongoing studies are characterizing the changes in pathology within the CNS and periphery, including the effects on iron distribution in the brain, plaque pathology, and neuroinflammation, as a result of T2DM, AD, and iron overload.

Title: Determination of low density lipoprotein receptor-related protein 1 (LRP1) and receptor for advanced glycation end products (RAGE) in the hypocamp of rats subjected to the consumption of hypercaloric diets

Authors: *F. HERNANDEZ-LANDERO[1], E. MARTINEZ-ABUNDIS[2], E. N. DE LA CRUZ-HERNANDEZ[1], N. P. GOMEZ-CRISOSTOMO[2];
[1]Univ. Juarez Autonoma De Tabasco, tabasco, Mexico; [2]Univ. Juarez Autonoma De Tabasco, Tabasco, Mexico

Abstract: The consumption of hypercaloric diets is the main factor associated with the development of metabolic syndrome (MS), this pathology is a public health problem worldwide that is associated with cognitive impairment. Several investigations have shown that patients with MS develop lesions in the cerebral microvasculature promoting alterations in the permeability and transport through of the blood-brain barrier (BBB). The BBB is responsible for eliminating the B-amyloid peptide (AB) by binding to the advanced glycosylation end products receptor (RAGE) and the receptor related to low density lipoprotein 1 (LRP1). The decrease in AB clearance is associated with cognitive impairment. The objective of this study is to evaluate the effect of consumption of hypercaloric diets (high in sucrose -HSD- or high in fat -HFD-) on the expression of RAGE and LRP1 in hippocampus of rats. Newly weaned male Wistar rats exposed to the consumption of HSD or HFD diets were feed for 2, 4 and 6 months with the two diets. Body weight, plasma levels of glucose, cholesterol and triglycerides were determined. The hippocampus was obtained to determine the expression of RAGE, LRP1 and AB by western blot. The results show that rats did not develop SM at anytimes of consumption of the hypercaloric diets, however, it was noted an increase in body weight in the rats feed with both diets, as well as an increase in the plasma levels of triglycerides, but not in glucose and cholesterol. The expression of RAGE showed an increase after 2 months of diet consumption been more evident in the HSD group, while at 4 months a decrease was observed with both diets and after 6 months the expression was increased again with both diets. LRP1 showed a decreased expression at 2 months of diets with respect to the control, although it was not significant, whereas in the 6 months group shown an decrease in both diets, been more evident in the HFD. Although our

experimental groups did not develop SM, the results suggest that high levels of plasma triglycerides could alter the expression of RAGE and LRP1 receptors and therefore affect the clearance of AB through the BBB.

Sch. of Med., Little Rock, AR

Abstract: Calcium-mediated signaling is critical to neuronal function and survival. Calcium homeostasis is dysregulated in neuropathies such as Alzheimer’s disease (AD), Parkinson’s disease (PD) and Huntington’s disease (HD). We here show that mice fed a diet rich in fat and sugar (diet-induced obesity, DIO) had half the levels of free SERCA2 (sarcoplasmic/endoplasmic reticulum calcium ATPase 2) found in control mice, associated with sequestration of the protein into detergent-insoluble aggregates. Similar sequestration of SERCA2 occurred in BRI-Aβ (AD-model) mice. SERCA2 was also enriched in aggregates from affected tissue of AD patients relative to age-matched controls. In mice fed either normal or DIO diets, >99% of the unaggregated fraction of cerebral SERCA2 is associated with membranes versus 86% in BRI-Aβ cerebra. In wild-type mice fed normal diet, ~20% of the membrane SERCA2 was bound to phosphatidylinositol (3,4,5)-triphosphate (PIP_3); this declined to ~5% in DIO mice and <1% in BRI-Aβ mice. Based on molecular-dynamic modeling of SERCA2, its PIP_3-binding region coincides with the binding site for thapsigargin, a non-competitive SERCA inhibitor. Threonine-230 is phosphorylated in DIO mice, which is predicted *in silico* to block

SERCA binding to PIP_3. In *C. elegans* models of neuropathic protein aggregation, SERCA knockdown led to an increase in total cellular protein aggregation. This was replicated after addition of palmitic acid, glucose, or both to the nematode diet; no further increase was seen in combinations with SERCA knockdown, whereas SERCA activation blocked the increase. *C. elegans* models of neurodegeneration implicated ER stress and depletion of ER calcium stores. These data show for the first time that SERCA2 binds to PIP_3 and that this is impaired by DIO and AD-like amyloidopathy, either of which disrupts calcium homeostasis and induces ER stress.

Title: Midlife obesity and metabolic dysfunction in the AD-BXD mouse model of Alzheimer's disease

Authors: K. O'CONNELL, A. DUNN, N. HADAD, ***C. C. KACZOROWSKI**;
The Jackson Lab., Bar Harbor, ME

Abstract: Age and genetic background are the greatest risk factors for Alzheimer’s disease, but it is increasing evident that mid-life obesity and metabolic syndrome further increase the risk of developing AD, as increased BMI is associated with an earlier age at onset. Furthermore, many AD patients also present with non-cognitive symptoms associated with metabolic dysfunction, such as weight loss, changes in appetite, and low circulating levels of the adipose-derived hormone leptin, suggesting that systemic metabolic function is an important factor in the etiology of AD in humans. However, the mechanisms underlying this dysfunction and their relationship to disease onset, progression, and severity are poorly understood. To address this gap, we assessed metabolic function in mice from our recently developed model of genetic variation in AD, the AD-BXD genetic reference panel (Neuner, et al 2019). A subset of AD-BXD and non-transgenic controls were fed a high-fat/high-sugar diet (HFD) starting at ~4 months of age to model mid-life obesity. Systemic metabolic function was measured using indirect calorimetry to

measure energy expenditure, V_{O2} and V_{CO2}, respiratory exchange rate (RER), locomotor activity, and food and water intake. A subset of mice were fed a high-fat/high-sugar diet (HFD) to model mid-life obesity. As previously reported, AD-BXD mice weigh less than their non-transgenic counterparts; assessment of body composition indicates this is due primarily to a loss of fat mass. AD-BXD strains also exhibited an increase in rearing behavior, which may indicate hypervigilance. Female AD-BXD strains exhibited increased energy expenditure and locomotor activity and failed to develop diet-induced obesity when fed HFD. Mice fed HFD generally displayed changes in RER consistent with a shift to fat metabolism; we further observed changes in patterns of food intake during the dark cycle, indicating possible circadian dysfunction in these mice. Taken together, these data indicate that AD-BXD mice exhibit some degree of metabolic dysfunction and that this is exacerbated by HFD. Ongoing work will quantify the impact of genetic background, diet, and complex geneXdiet interactions on these traits and determine causal relationships between metabolic and cognitive phenotypes using computational models.

Title: Dynamic metabolic aging of the female brain during endocrinological and chronological aging

Authors: *Y. WANG[1], Y. SHANG[1], A. MISHRA[1], E. BACON[2], F. YIN[1], R. BRINTON[1]; [1]Univ. of Arizona, Tucson, AZ; [2]Sch. of Pharm., USC, Los Angeles, CA

Abstract: Natural aging and the perimenopausal transition are associated with brain glucose hypometabolism and mitochondrial dysfunction in females. The bioenergetic crisis is also a hallmark of late-onset Alzheimer’s disease (LOAD). Comprehensive understanding of the dynamic metabolic aging process in the female brain can shed light on potential prevention and interventions windows of opportunities to promote healthy aging. Using a rat model recapitulating fundamental characteristics of human menopausal transition, we observed systematic bioenergetic dysregulation in the aging female brain, as well as alternations in key metabolic regulators. Using an unbiased, discovery-based metabolomic and lipidomic approach, we characterized the dynamic adaptation of aging female brain from glucose centric to utilization

alternative fuel sources including amino acids, fatty acids, lipids, and ketone bodies, and finally to anaerobic glycolysis, during endocrinological and chronological aging. Transcriptomic profiling of bioenergetic gene networks were consistent with the metabolomic profiles. These data provide the first detailed metabolic profile of the female brain across both endocrinological and chronological aging transitions.

Abstract: Alzheimer’s disease (AD) is characterized by a long latent prodromal stage with recent discoveries pointing to the perimenopausal transition in women as a “tipping point” in the development of the AD phenotype (Brinton et al., 2015). The hallmark chronic low-grade inflammation in both aging and menopause has been implicated as a unifying factor that bridges across AD risk factors (Mishra and Brinton, 2018). Yet, the endocrine state specific effect of neuroinflammation on female aging has not been characterized. In this study, we characterize the neuroinflammatory profile across chronological and endocrine aging transitions. Relevance to AD and neurodegenerative inflammatory mechanisms.
Preliminary findings from the perimenopausal rat model, in which we can experimentally segregate the effects of chronological aging from endocrine aging, indicate that the inflammatory phenotype is quite dynamic throughout the endocrine transition in menopause. Our results show that type I and type II interferon (IFN) response genes, recently implicated in age related neurodegeneration (Mathys et al., 2017) are upregulated in the hippocampus the perimenopausal transition. Co-incident with the upregulation of the IFN response genes in the hippocampus, was the overexpression of major histocompatibility complex (MHC) -II genes in white matter tracts – corpus callosum and fimbria. Reproductive irregularity also affected phagocytic response and

redox status of microglial cells. Endocrine aging was associated with shifts in mitochondrial function in astrocytes and microglia. Estradiol regulation of the upregulation of interferon response genes was validated by ovariectomy and estradiol prevention paradigm. Clinical microarray data from the hippocampus was also analyzed to accomplish translational validity of the findings and, establish if the upregulation of MHC-II was preferentially observed in females The characterization of inflammation in the female aging brain and its role in transition to AD vulnerability has, thus far, been scarce. This pioneering study elucidates the dynamic immune profile in brain that occurs during chronological and endocrine aging which is coincident with decline in steroid hormones and brain glucose metabolism . Molecular characterization of the neuroinflammatory mechanisms during this neuro-endocrine transition state can inform therapeutic strategies to mitigate the risk of onset of Alzheimer's disease in women.

Title: Emergence of an Alzheimer's disease bioenergetic endophenotype in mid-life: Preclinical model

Authors: *Z. MAO[1], Y. SHANG[2], J. BERGHOUT[3], Y. LUSSIER[3], F. YIN[1], R. D. BRINTON[1]; [1]Ctr. for Innovation in Brain Sci., [2]Ctr. for Innovation in Brain Science, Ctr. for Biomed. Informatics and Biostatistics, [3]Ctr. for Biomed. Informatics and Biostatistics, Univ. of Arizona, Tucson, AZ

Abstract: Perimenopause is a female aging transition that proceeds- and leads to reproductive senescence and is associated with multiple neurological symptoms, including those associated with increased Alzheimer's risk. We previously demonstrated decline in bioenergetic function and long-term potentiation coincident with perimenopausal endocrine aging in brain that were consistent with an early prodromal stage AD phenotype. Using a pathway-centric bioinformatic approach, the present study aimed to systematically determine the underlying biological processes that drive the transformation of perimenopausal brain and their contribution to AD vulnerability. Hippocampal RNAs from six groups of female rats undergoing chronological and endocrine aging were sequenced followed by bioinformatic analyses. Outcomes indicated that

rats undergoing perimenopause exhibit substantially higher variances in overall hippocampal gene expression relative to other groups, supporting the perimenopausal brain being in an unstable transition state. Gene Set Enrichment Analysis (GSEA) further revealed alterations in bioenergetic-, inflammatory-, and cell proliferation pathways during the transition and characterized by decline in bioenergetic gene expression and low-grade activation of immune pathways. Moreover, nuclear- (nDNA) and mitochondrial DNA (mtDNA)-encoded bioenergetic genes were differentially regulated by chronological- and endocrine aging: mtDNA genes correlated closely with chronological aging while nDNA-encoded counterparts were largely endocrine dependent. Notably, the differential regulation of mtDNA and nDNA was also observed in our analysis of a human brain transcriptome dataset including young, old and AD groups. Lastly, the strong correlation between bioenergetic pathways with genes associated with AD and other neurodegenerative disorders linked bioenergetic deficits to neurodegeneration and elevated AD vulnerability. Our findings suggest that hippocampal gene expression during perimenopause is a mid-life transition state characterized by perturbations to bioenergetic- and inflammatory pathways, which could contribute to increased AD risk in women. This study provides novel mechanistic insights into the impact of perimenopausal transition on brain function, which could have implications for identifying phenotypes of AD risk for earliest detection in aging females.

Title: Inhibition of adenylyl cyclase type 5, a novel model for protection against Alzheimer’s disease

Authors: D. BABICI[1], J. ZHANG[1], R. YAN[2], J. ZHANG[2], S. C. MADDILA[2], T. BERKMAN[1], D. E. VATNER[1], *M. M. MOURADIAN[2], S. V. VATNER[1];
[1]Rutgers - New Jersey Med. Sch., Newark, NJ; [2]Rutgers-Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: The Adenylyl Cyclase Type 5 (AC5) knockout (KO) mouse is a model of healthful aging, as these mice live a third longer than their wild type littermates (AC5 KO WTL) and are protected against diabetes, obesity, exercise intolerance, heart disease and cancer. In contrast,

Alzheimer's Disease is a model of unhealthful aging, and many features protected in the AC5 KO mouse are found to be more severe in Alzheimer's Disease. Accordingly, we hypothesized that inhibiting AC5 may be a novel model for protection against Alzheimer's Disease. Although a number of studies have shown a relationship between Alzheimer's Disease and adenylyl cyclase, the results are inconsistent. The goal of this investigation was to compare the AC5 KO mouse model (n=20) with J20 mice (n=12) at 10-18 months of age, at a time when J20 mice exhibit features of Alzheimer's Disease, as amyloid plaques develop in the hippocampus, and the animals exhibit abnormal responses in behavior tests. Rigor: 1) all experiments were conducted blinded and by two investigators; 2) ANOVA was used to compare the 3 groups statistically; 3) both males and females were studied. Results: Abnormal behavior was confirmed in the J20 mice. For example, the water maze test, used to assess spatial learning and memory, demonstrated the expected deficit, $p<0.05$; the rotorod test demonstrated impaired locomotor activity $p<0.05$; and the open field test showed anxiety behavior. In contrast, AC5 KO mice demonstrated opposite findings with significantly better performance, $p<0.05$, in all these tests, not only in comparison with J20 mice, but also in comparison with AC5 KO WTL (n=16). In addition, J20 mice exhibited reduced exercise performance and impaired glucose tolerance, in direct opposition to AC5 KO mice, which demonstrated enhanced exercise performance and glucose tolerance. Thus, AC5 KO mice are protected against behavioral changes, neuropsychiatric symptoms and locomotor impairment associated with Alzheimer's disease, as well as impaired exercise performance and glucose tolerance, also characteristic of Alzheimer's Disease. These findings suggest that inhibition of AC5 may be a novel therapeutic approach for Alzheimer's Disease.

Title: Increasing neuronal NAD(P)H pool protects Alzheimer's disease neurons from oxidative stress

Authors: *P. MARTIN-MAESTRO[1], Y. GANAT[2], A. SPROUL[3], D. PAQUET[4], S. NOGGLE[2], A. STARKOV[1];

[1]Weill Cornell Med., New York, NY; [2]New York Stem Cell Fndn., New York, NY; [3]Columbia Univ., New York, NY; [4]Inst. for Stroke and Dementia Res., Munich, Germany

Abstract: Background: The generation of reactive oxygen species (ROS) is a part of normal metabolism in a biological system. Oxidative stress is important in etiology of Alzheimer's disease (AD) and in age-related neurodegeneration and cognitive decline. The balance between the production and removal of ROS is essential to prevent adverse effects of oxidative stress. A failure of ROS scavenging can as well contribute to oxidative stress in brain cells. All cellular ROS scavenging systems are fueled by NADPH. Because of that, a decrease in glucose utilization, characteristic of AD brains, is expected to decrease the capacity of ROS scavenging systems and augment oxidative stress. Due to NADP is synthesized from NAD, controlling the cellular NAD pool by providing NAD precursors, or by inhibiting NAD degradation is essential for the cell.
Methods: In the present study, we have manipulated the level of NAD(P)H pool in a cellular AD model - human neurons derived from induced pluripotent stem cell (iPSC) harboring FAD-associated Presenilin 1 *M146L* mutation.
Results: We demonstrated that treating neurons with NAD precursors is a better way to increase the cellular NAD pool than preventing NAD degradation. This increase in the NAD pool clearly enhance tolerance of PSEN1-mutated AD neurons to oxidative stress.
Conclusions: Our findings indicate that increasing NAD(P) pool in AD-related cellular model (PSEN1-mutated neurons) is an efficient way to decrease the oxidative stress. Considering that our cellular model recapitulates many of the features previously described in other AD models, we think it is most suitable to evaluate AD-targeting pharmaceuticals. It also demonstrates that increasing NAD(P) pool alleviates neuronal oxidative stress, the effect which may be beneficial in other neurodegenerative diseases.

Title: Protein expression and activity levels of UCP2 in Alzheimer's disease brain tissue

Authors: *T. A. CLEMONS;
Chem. and Biochem., Spelman Col., Atlanta, GA

Abstract: The traditional role of uncoupling proteins is to allow protons back across the mitochondrial membrane during the electron transport process, which negatively impacts ATP production at complex V. There are five uncoupling proteins that have been identified and each uncoupling protein has a very distinct role. Recently, uncoupling protein 2 (UCP2) has been suggested to have a cell signaling role. Furthermore, the expression of certain UCP's have been shown to be diminished in Alzheimer's disease brains, which suggests that certain UCP's may have a protective role in preventing the disease. The question as to what proteins contributes to the diminished levels of UCP in Alzheimer's disease brains has yet to be elucidated. This study analyzes the protein expression and activity levels of UCP2 on Alzheimer's disease brains in comparison to SH-SY5Y cells. In addition, although plaque formation in Alzheimer's disease brains has already been established, the proteins that contribute to plaque formation are not understood. Amylin is a protein that is known to cross the blood-brain barrier and possibly contribute to plaque formation. Is there a possibility that UCP2 could be involved with preventing plaque formation? This study attempts to answer this question by analyzing amylin protein expression and activity levels to determine if there is a correlation between UCP2 and amylin protein and activity levels in Alzheimer's disease brain tissue and/or SH-SY5Y cells. The overall goal is to determine if UCP2 could possibly be a key protein in preventing plaque formation.

Title: Tissue plasminogen activator reduction mediates neurovascular dysfunction produced by amyloid-β peptides

Authors: *A. ANFRAY[1], J. ZHOU[1], P. ZHOU[2], J. SEO[3], J. ANRATHER[5], C. IADECOLA[3], L. PARK[4];
[1]BMRI, [2]Brain and Mind Res. Inst., [4]Feil Family Brain and Mind Res. Inst., [3]Weill Cornell Med., New York, NY; [5]Weill Med. Col. Cornell Univ., New York, NY

Abstract: The amyloid-β peptide (Aβ), a key pathogenic factor in Alzheimer's disease, markedly attenuates the increase in cerebral blood flow (CBF) evoked by neural activity

(functional hyperemia), a vital homeostatic response in which NMDA receptor plays a key role. The protease tissue plasminogen activator (tPA) regulates the NMDA receptor-dependent component of functional hyperemia (PNAS, 105:1073, 2008). Thus, we investigated whether tPA is involved in the deleterious neurovascular effects of Aβ. CBF was measured by laser-Doppler flowmetry in the somatosensory cortex of urethane-chloralose anesthetized male mice. In tg2576, the increase in CBF produced by neural activity (whisker stimulation; WS) or by topical application of the endothelium-dependent vasodilator acetylcholine (ACh) was attenuated compared to WT littermates (WS: -37%; ACh, -35%; $p<0.05$; mean±SE). Neocortical application of the NMDA receptor inhibitor MK-801 (10 μM) attenuated functional hyperemia in WT (-58%; $p<0.05$), but not tg2576 mice ($p>0.05$ from vehicle). Furthermore, the CBF increase elicited by neocortical application of NMDA (40 μM) was smaller in tg2576 mice (11±2%) than in WT littermates (36±3%; $p<0.05$), while responses to kainate (10 μM) or AMPA (10 μM) were comparable ($p>0.05$ from WT). The attenuation in the CBF increase produced by WS and NMDA in tg2576 mice was associated with reduced tPA activity, assessed by ELISA and *in situ* zymography (-47%; $p<0.05$ from WT mice), but not tPA mRNA and protein levels ($p>0.05$). Intranasal treatment of recombinant tPA (20 μg) in tg2576 mice rescued the attenuation in functional hyperemia ($p<0.05$ from vehicle-treated tg2576), but it has no effects on $A\beta_{1\text{-}40}$ or $A\beta_{1\text{-}42}$ level. Neocortical application of $A\beta_{1\text{-}40}$ (5 μM) failed to attenuate functional hyperemia in tPA-null mice and in mice lacking the tPA inhibitor PAI-1 ($p>0.05$). Furthermore, neocortical superfusion of the PAI-1 inhibitor PAI-039 (30 μM) prevented the Aβ-induced attenuation of functional hyperemia in WT mice and rescued neurovascular function in tg2576 mice, effects associated with increased PAI-1 activity ($p<0.05$), but not PAI-1 mRNA and protein levels ($p>0.05$). The data indicate that the neurovascular dysfunction produced by Aβ is mediated by a PAI-1-induced deficit in tPA activity, which, in turn, suppresses the NMDA-dependent component of functional hyperemia. Even though the mechanisms of PAI-1 upregulation require further investigation, targeted inhibition of PAI-1 activity may be a therapeutic strategy to counteract the detrimental effects of Aβ on cerebrovascular regulation.

Title: Aging and pathology cause sleep disruptions and altered metabolism in mouse models of Alzheimer's disease

Authors: *C. M. CARROLL[1], M. STANLEY[3], M. PAIT[1], D. A. RUBINOW[1], D. M. HOLTZMAN[4], S. L. MACAULEY[2];

Abstract: The development of Alzheimer's disease (AD), the most common form of dementia, is multifaceted and influenced by a variety of genetic, environmental, and lifestyle components. Both Type 2 diabetes (T2D), a metabolic condition associated with aging, and sleep disorders are implicated in the pathogenesis of AD, but the exact role sleep and metabolism play remains unclear. Further, individuals with T2D are 2-4-fold more likely to develop AD, suggesting a common mechanism underlying these diseases. The goal of this study, therefore, is to determine if AD pathology and glycemic fluctuations synergize to cause sleep loss and peripheral glucose intolerance, thereby increasing the risk of both T2D and AD. We implanted biosensors detecting ISF glucose and lactate, measures of cerebral metabolism and neuronal activity, respectively, bilaterally into the hippocampi of two mouse models of AD: APP/PS1 mice, a model of Aβ pathology, and P301S mice, a model of tauopathy and neurodegeneration. We delivered hyper- and hypo-glycemic challenges to determine the effect of peripheral metabolic fluctuations on the brain as a function of both aging and pathology. Simultaneous cortical EEG/EMG recordings were utilized for sleep/wake analysis. Glycemic fluctuations resulted in a decoupling of the typical relationships between cerebral metabolism and neuronal activity while also causing increased arousal in 3-month old, wildtype mice. However, in an aged, 18 month old APP/PS1 model mouse, the metabolic response to glycemic challenges was muted and there was seemingly no impact on arousal state, likely due to an age and pathology-dependent increase in the overall amount of time spent awake. Further, in the aged, 11-month-old P301S mice, the metabolic response was lost with a similar ceiling effect on arousal state. Moreover, the 18-month-old PSAPP mice demonstrate decreased glucose sensitivity in glucose tolerance testing (GTT) as compared 9-month-old PSAPP mice that show glucose intolerance and insulin resistance. These results indicate a bidirectional, pathology-dependent shift in metabolic responsivity as AD progresses. This study represents a novel approach to defining the dynamic interplay between risk factors for AD and T2D and suggests feedforward loop of disease progression where sleep disruptions can modulate AD and T2D risk by altering the relationship between glucose tolerance, cerebral metabolism, neuronal activity, and Aβ/tau levels. Understanding the timing of these relationships is critical for offering potential strategies to mitigate the increased risk of AD among individuals with T2D.

Abstract: Globally, neurological disorders rank as the leading cause of disability-adjusted life-years, and the second-leading cause of deaths. The high global prevalence and economic impact of Alzheimer’s disease presents a significant public health challenge while the identification of early biomarkers to diagnose Alzheimer’s disease (AD) remains a challenge. It has been shown that risk for late-onset AD is partially driven by genetics while studies using pathway analysis have implicated immunity, lipid metabolism, tau binding proteins, amyloid precursor protein (APP) metabolism and mitochondrial energetics as possible mechanisms of disease risk. Given the lack of successful mechanistic studies for AD biomarkers, the Center for Innovation in Brain Science (CIBS) at the University of Arizona has acquired and banked fibroblast lines from male and female patients with sporadic age-associated neurodegenerative diseases (n=12/disease) and age-matched healthy controls. Human dermal fibroblasts (hDF) from patients with Alzheimer’s disease (AD) were phenotypically profiled for both genetic (genetic sex, APOE genotype, mitochondrial haplotype) and molecular (transcriptomics, metabolomics, immunological profile, bioenergetic signature and mitochondrial respiration) characteristics to determine inherited, age- and sex-related mechanisms of neurodegeneration. To address morphological and cytochemical phenotypes, hDF lines were stained by IHC for known AD aggregation proteins amyloid-beta and hyperphosphorylated tau and profiled using live in-vivo imaging for mitochondrial tracking. Using this approach, we have begun to establish phenotypic profiles for neurodegeneration in Alzheimer’s disease using a patient-specific cell model. We will continue to generate and characterize reprogrammed patient-derived fibroblast and induced neural cells to determine the molecular pathways driving early age-associated AD vulnerability. Preliminary results of comprehensive phenotyping in the hDF show a variety of APOE genotypes present in the samples (APOE 2/3, 3/3, 3/4, 4/4) representing a roughly even distribution of genetic sex in each

genotype. Preliminary staining shows common markers of aggregations between CNS and peripheral fibroblast indicating opportunities novel biomarker development.

Title: TREM1 mRNA expression in leukocytes and cognitive function in patients with Alzheimer's disease

Authors: *J. IGA, T. SAO, Y. YOSHINO, K. YAMAZAKI, Y. OZAKI, Y. MORI, S. OCHI, T. YOSHIDA, T. MORI, S.-I. UENO;
Neuropsychiatry, Ehime Univ., Toon, Japan

Abstract: Background: Triggering receptor expressed on myeloid cells 2 (TREM2) activates the innate immune system, promotes phagocytosis by microglia, and is associated with Alzheimer's disease (AD). The possible role of a related molecule, TREM1, in AD remains unknown. Objective: We investigated a possible role for TREM1 in AD by determining the gene expression and methylation levels of TREM1 in leukocytes from AD patients. Methods: Fifty patients with AD and 50 age-matched healthy controls were enrolled. AD patients underwent a battery of neuropsychiatric tests. Peripheral blood samples were obtained from each participant, RNA and DNA were extracted, and samples were assessed for TREM1 mRNA expression and methylation rates at three CpG sites in the TREM1 promoter. Results: TREM1 mRNA expression levels in AD patients were significantly higher than those in controls ($p = 0.008$). TREM1 mRNA expression levels were not correlated with sex, age, duration of illness, APOE genotype, donepezil treatment, or scores of most neuropsychiatric tests. TREM1 mRNA expression levels in AD patients were correlated with the total score of the Montgomery-Åsberg Depression Rating Scale ($p = 0.047$, $r = -0.344$). Methylation rates at the three CpG sites were significantly lower in AD patients than in controls. We also found a significant correlation between TREM1 mRNA expression and TREM1 DNA methylation rates ($p < 0.001$). Conclusion: TREM1 may be associated with the immune responses in AD, and along with hypomethylation at CpG sites in the TREM1 promoter, may become part of a biomarker panel for AD pathogenesis.

Title: Reduced expression of antioxidant enzymes in postmortem tissues of subjects with Alzheimer's disease and prior depression

Authors: *W. LUO[1], E. H. BIGIO[2], S. WEINTRAUB[2], M. MESULAM[2], E. E. REDEI[1]; [1]Dept. of Psychiatry and Behavioral Sci., [2]Mesulam Ctr. for Cognitive Neurol. and Alzheimer's Dis., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Earlier-life depression, defined as major depressive disorder (MDD) or depressive symptoms occurring before age 60, has consistently been associated with a more than two-fold increase in dementia risk including Alzheimer's Disease (AD). In an animal study, we measured hippocampus-based memory in females of a genetic rat model of depression, the Wistar Kyoto More Immobile (WMI) strain. At a young age, there was no difference in memory between the WMI and their genetically close control, the Wistar Kyoto Less Immobile (WLI), that does not show depression-like behavior. However, by middle age, memory decline had occurred in the WMI females. Hippocampal transcript levels of catalase (*Cat*) showed a pattern that paralleled memory decline, with decreases solely in the middle-aged WMI hippocampus. Enhanced oxidative stress has been implicated in AD, both as an active continuing process and as an early indicator of the disease. Although an oxidant/antioxidant imbalance has been found in postmortem AD brain regions, none of the antioxidants produced the expected benefits in clinical trials with AD patients. We hypothesized that the oxidative imbalance in the subpopulation of AD subjects with MDD might be more pronounced, and that if blood-based biomarkers for this process could be identified, it could lead to development of treatment in specific subgroups. We examined the differences in transcript levels of *CAT* and superoxide dismutase 1 (*SOD1*) in post-mortem brain samples from individuals with AD dementia and neuropathologic changes of AD, with (n=15) and without (n=19) prior depression. Hippocampal (Hip) and anterior cingulate cortex (ACC) tissues were received from the Brain Bank of the Northwestern Cognitive Neurology and Alzheimer Disease Center. Transcript levels were determined by quantitative RT-PCR. Both hippocampal and ACC expression of *CAT* were significantly lower in subjects with AD+MDD compared to those of AD. Although *SOD1* expression was significantly different by comorbidity with MDD, this difference came from decreased *SOD1* expression in females with

AD+MDD, specifically. Since excess *Cat* enhances cognition in animal studies, if the levels of these transcripts are further reduced in the brain of AD+MDD subjects, exploring their regulatory pathways could provide focused targets for drug discovery.

Title: Identifying subsets of subjects with mild cognitive impairment and cardiovascular risk factors based on differential expression of angiogenic and inflammatory biomarkers

Authors: *Z. S. WINDER[1], T. L. SUDDUTH[2], D. FARDO[3], Q. CHENG[4], L. B. GOLDSTEIN[5], P. T. NELSON[2], F. A. SCHMITT[2], G. A. JICHA[2], D. M. WILCOCK[2]; [1]Physiol., [2]Sanders-Brown Ctr. on Aging, [3]Biostatistics, [4]Biomed. Informatics, [5]Neurol., Univ. of Kentucky, Lexington, KY

Abstract: Agglomerative hierarchical clustering analysis (HCA) is a commonly used unsupervised machine learning approach for identifying informative natural clusters of observations. HCA calculates a pairwise dissimilarity matrix, and then clusters similar observations until all observations are grouped within a cluster. We compared a novel HCA technique with one used in previous biomedical applications by applying both techniques to plasma angiogenic (FGF, FLT, PIGF, Tie-2, VEGF, VEGF-D) and inflammatory (MMP1, MMP3, MMP9, IL8, TNFα) protein data. Our HCA model is novel in two ways: 1, use of consensus clustering to combine multiple HCA algorithms to create a dissimilarity matrix between observations determined by the percentage of models in which two observations are found within the same cluster; 2, creation of each HCA algorithm using the Minkowski distance to calculate dissimilarity between observations. We varied the p value, necessary to compute the Minkowski distance, to obtain multiple HCA algorithms for the consensus clustering within our novel HCA model. Study subjects were clinically diagnosed with mild cognitive impairment (MCI) associated with cerebrovascular disease (CVD). By comparing the two HCA techniques using this dataset, we were able to identify subsets of individuals showing differences in VEGF ($p < 0.001$), MMP1 ($p < 0.001$), and IL8 ($p < 0.001$) expression. These profiles provide novel insights into angiogenic and inflammatory pathologies that may contribute to vascular cognitive impairment and dementia.

Title: Identification of cathepsin D as a plasma biomarker candidate for Alzheimer's disease

Authors: ***Y. KIM**[1], S.-Y. JUNG[1], S. LEE[2], J. CHANG[1,3];
[1]Dept. of Biomed. Sciences, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [2]Dept. of Anat. and Hypoxia-related Dis. Res. Center, Col. of Medicine, Inha Univ., Incheon, Korea, Republic of; [3]Dept. of Brain Science, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Alzheimer’s disease (AD) is the most common neurodegenerative disease, but there are still no drugs available to treat or prevent AD dramatically. However, efforts to develop early diagnostic ways should also be made along with the development of treatment of AD for appropriate medical intervention from the early stage of the disease. Here, we have examined the change in the level of selected proteins implicated in the pathogenesis of AD using the plasma of control subjects and patients with cognition impairment. To precisely categorize the diseases, all the patients were examined with amyloid PET scan and the white matter hyperintensity was scored by magnetic resonance imaging. By analyzing quantitative immunoblot and ELISA, we found the plasma level of cathepsin D which is a major lysosomal protease significantly decreased in the group with amyloid plaque deposition at the brain compared to the control group. These results suggest that the plasma cathepsin D level could be a candidate to be developed as a diagnostic biomarker of AD. This study also suggests that lysosomal degradation activity could be associated with the onset or the progression of AD.

Title: Phosphorylation of specific serine sites on hippocampal insulin receptor substrate 1 is associated with Alzheimer's disease-unrelated memory deficit and -related pathology

Authors: D. TANOKASHIRA[1], W. WANG[1], Y. FUKUI[1], M. MARUYAMA[1], C. KUROIWA[1], T. SAITO[2], T. C. SAIDO[2], ***A. TAGUCHI**[1];

Abstract: Modification of Insulin receptor substrate 1 (IRS1) through the phosphorylation of serine (Ser) residues occurs in an insulin-dependent and -independent manners. In the central nervous system, increased phosphorylation of specific Ser residues on IRS1 is observed in patients and transgenic animal models with Alzheimer's disease (AD). To investigate whether the activation of AD-related Ser sites on neural IRS is incidental to any type of memory decline, we employed various memory impairment animal models, such as high fat diet (HFD)-induced type2 diabetes (T2DM) model mice, streptozotocin (STZ)-induced type 1 diabetes (T1DM) model mice, aged mice, and amyloid precursor protein (APP) knock-in (APPKI $^{NL-G-F}$) mice, a novel AD mouse model. The substantial phosphorylation of Ser307 and Ser1097 on hippocampal IRS1 occurred in T2DM and aging-associated memory deficits in mice, regardless of the presence/absence of the activities in canonical downstream factors, such as Akt and GSK3ß. By contrast, memory impairment in T1DM mice arose independently of IRS1 activities. Despite exhibiting normal memory formation, the phosphorylation of hippocampal IRS1 at multiple Ser residues increased on condition that amyloid β (Aβ) accumulation was already evident in young APPKI $^{NL-G-F}$ mice, whereas the phosphorylation level of Ser307 was unchanged in middle-aged APPKI $^{NL-G-F}$ mice exhibiting memory decline compared to age-matched wild-type mice. These data suggest that the phosphorylation of hippocampal IRS1 at specific Ser sites may be potential markers for non-AD-related memory deterioration caused by T2DM and aging; however, AD-associated activation of IRS1Ser residues may be induced in response to AD pathology but not to memory decline.

Abstract: Down Syndrome (DS) is a genetic condition where there is an extra copy of chromosome 21 resulting in triplication of the amyloid precursor protein (APP) gene. Increased APP results in an increased incidence of Alzheimer’s disease (AD) pathology in individuals with DS. AD pathology in DS individuals is a superb platform to study the mechanisms of AD pathology due to the increased production of the Beta Amyloid (Aβ) peptide. AD is currently the most prevalent neurodegenerative disease affecting the human population. Many avenues have been explored to determine the mechanism of action or important biomarkers for AD with partial success. Some of these avenues suggest polyamines potentially underlying the mechanism leading to AD pathology. Polyamines are aliphatic amines at physiological pH associated with a positive charge. This positive charge allows polyamines to interact with negatively charged macromolecules such as DNA, RNA, and some amino acids. Polyamines have been found to modulate cell proliferation, gene expression, and immune response but little investigation into polyamines effects on AD has been performed. Increased polyamine concentrations have been found in AD brains. We have found the same pattern exists in DS related AD brains. We hypothesize that polyamine concentrations increase due to increased beta amyloid proteins which activate ornithine decarboxylase (ODC) to convert ornithine into polyamines. We found increased polyamine concentrations in mice DS cell lines, with simultaneously increased aggregation of amyloid beta (Aβ) proteins. Besides facilitating aggregation of Aβ we have shown the increased concentrations of polyamines decreased mitochondrial motility. This decrease in motility has been found in primary cultured rat neurons as well as in a DS mouse

neuron model. The production of polyamines can be blocked using an Difluoromethylornithine (DFMO). DFMO inhibits ODC preventing the production of polyamines. DFMO restores the mitochondrial motility and decreases Aβ aggregation in the DS mouse model. In the mouse neuron model a normosomic control cell line was used to establish a reference point for polyamines and Aβ aggregation. Mitochondrial motility in relation to polyamines has never been connected prior to these results indicating a novel mechanistic pathway for the underlying pathology of AD in DS brains. This could potentially set the grounds for targeting the polyamine pathway to halt the progression of AD pathology in DS individuals. Title: Developing a method for detection of mitochondrial oxidative stress in a mouse model of amyloidogenesis

Authors: *L. J. OUILLETTE[1], S. J. MOORE[2], T. STEVENSON[2], V. A. CAZARES[2], R. PARENT[2], G. G. MURPHY[2];
[2]Mol. & Behavioral Neurosci Inst., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Alzheimer’s disease (AD) is a neurodegenerative disease and is the most common form of dementia. It is characterized by hallmark neuropathological changes including intracellular neurofibrillary tangles (NFTs), which are composed primarily of aggregates of hyper-phosphorylated microtubule-associated tau proteins, and amyloid plaques which are aggregated extra-cellular amyloid beta (Aβ) protein. While the study of Aβ and Tau pathologies have provided crucial information about their role in AD, the exact mechanism regarding the onset of AD pathology remains unclear. Mitochondrial dysfunction has been thought to be a critical factor in AD because of its potential to produce oxidative stress in the form of superoxide (O_2-), which is a reactive oxygen species (ROS) and a byproduct of cellular respiration. Additionally, mitochondrial oxidative stress has been hypothesized to play a role in aging and AD onset, including the propagation of Aβ. Recent advancements have facilitated the detection

of global oxidative stress using in vivo imaging (Berkowitz, 2017), but this method lacks cellular and subcellular resolution. To interrogate the cell types and cellular compartments that may experience increased oxidative stress, we have developed a method that allows direct identification of oxidative stress markers. This method combines confocal imaging of brain slices acutely prepared from mice with a mitochondrial specific probe that when oxidized, emits a fluorescent signal. We are currently testing this method in a variety of mouse models including the 5XFAD model of amylogenesis. Development of this method has the potential to foster significant progress in determining cell specific interactions between the declining health of brain tissue and ROS in many disease models.

Title: Levels of newly generated soluble amyloid precursor proteins in human cerebrospinal fluid

Authors: *J. A. DOBROWOLSKA ZAKARIA[1], R. J. BATEMAN[2], B. W. PATTERSON[3], R. J. VASSAR[1];
[1]Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [2]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO; [3]Med., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: The amyloid hypothesis proposes that increased production and/or decreased clearance of amyloid-beta (Aβ) leads to higher order amyloid structures that initiate a cascade of events, culminating in neuronal death manifesting as Alzheimer's disease (AD). Sequential cleavage of Amyloid Precursor Protein (APP) generates Aβ. APP may be processed in one of at least two pathways, initially being cleaved by either α- or β-secretase (BACE1). BACE1 cleavage of APP releases soluble APP-β (sAPPβ) and subsequent cleavage by γ-secretase produces Aβ. Alternatively, α-secretase cleavage of APP precludes Aβ formation and produces soluble APP-α (sAPPα).
We hypothesize that a subgroup of the AD and non-demented Amyloid+ populations overproduce Aβ because of increased BACE1 activity. Our objective is to measure CSF sAPPβ and sAPPα kinetic rates, as surrogate markers of BACE1 activity, to determine if, and by how much, BACE1 activity is increased in these individuals.

Using stable isotope labeling kinetics/immunoprecipitation/liquid chromatography-tandem mass spectrometry methods, we quantified sAPPβ and sAPPα in CSF from human Amyloid+ (AD) and Amyloid- (control) subjects who had undergone [U-$^{13}C_6$]-leucine labeling and hourly CSF collection. The fraction of metabolite derived from *de novo* synthesis was measured by calculating normalized metabolites' hourly mole fraction labeled (MFL), over 36 hours. Normalized MFL was multiplied by the metabolites' absolute concentration to quantitate newly generated metabolites. Regression analyses were performed to determine extent of the relationship between these measures and brain amyloid load.
We have previously shown in a pilot study that both sAPPβ and sAPPα turnover rates were slower in Amyloid+ subjects than in Amyloid- subjects. Additionally, the rate of turnover of sAPPβ was marginally slower than the sAPPα turnover rate in both groups. This difference was more pronounced in the setting of amyloidosis. Newly generated sAPPβ, and the newly generated sAPPβ:sAPPα absolute ratio, were significantly elevated in Amyloid+. Newly generated sAPPα was not significantly different between groups. Brain amyloid load was positively correlated to sAPPβ:sAPPα. The pilot results strongly suggest increased APP processing by BACE1 in the subjects with brain amyloid deposition.
This study is ongoing and we will be presenting data from an increased sample size. The full study's results will allow for characterization of AD subpopulations most likely to benefit from BACE1 inhibitors.

Abstract: Background: The development of tau targeted PET tracers has opened the opportunity of using them to improve diagnostic accuracy in Alzheimer’s disease (AD) and related tauopathies. We and others have previously demonstrated that [F-18]-Flortaucipir (AV-1451, T807) and [F-18]-MK-6240 bind with strong affinity to tau aggregates in AD but have relatively low affinity for tau deposits in non-AD tauopathies and exhibit off-target to neuromelanin- and melanin-contaning cells and hemorrhages. In the present work we examined region and substrate specific autoradiographic binding patterns and potential off-target of novel second generation tau PET tracer PI-2620 and compared the binding properties of the three tau tracers in some of same tissue specimens. Methods: We applied [F-18]-PI-2620 phosphor screen autoradiography to postmortem brain samples with a pathological diagnosis of Alzheimer disease, frontotemporal lobar degeneration-tau (Pick’s disease, progressive supranuclear palsy and corticobasal degeneration), frontotemporal lobar degeneration-TDP-43, dementia with Lewy bodies, cerebral amyloid angiopathy and controls free of pathology. High resolution nuclear emulsion autoradiography and immunohistochemistry experiments are currently ongoing. We examined potential nonspecific binding of the three tracers to monoamine oxidases (MAO) by using autoradiography in the presence of selective MAO-A and MAO-B inhibitors. Results: [F-18]-PI-2620 strongly binds to neurofibrillary tangles in AD. There is no evidence of tracer’s binding to

lesions containing beta-amyloid, alpha-synuclein or TDP-43. Like Flortacucipir and MK-6240, PI-2620 seems to have a relatively low affinity for tau aggregates in non-AD tauopathies. Autoradiography experiments avoiding ethanol in the washing conditions are currently ongoing to rule out the possibility that ethanol may have displaced some weaker signal in non-AD tauopathies. The three tracers exhibit identical off-target to neuromelanin and melanin-containing cells, and areas of hemorrhage. [F-18]-Flortaucipir, [F-18]-MK-6240 and [F-18]-PI-2620 autoradiographic binding signals are only weakly displaced by competing concentrations of selective MAO-B inhibitor deprenyl suggesting that MAO enzymes are not a significant binding target of these tracers. Conclusion : These novel findings provide relevant insights for the correct interpretation of *in vivo* [F-18]-PI-2620 PET imaging.

Title: Blood-brain barrier breakdown predicts early cognitive dysfunction in APOE4 carriers independent of aβ and tau

Authors: ***M. D. SWEENEY**[1], A. MONTAGNE[1], D. A. NATION[1], A. CHAKHOYAN[1], A. P. SAGARE[1], M. PACHICANO[1], F. SEPEHRBAND[1], M. G. HARRINGTON[2], D. P. BUENNAGEL[2], J. M. RINGMAN[1], E. Abstract: Vascular dysfunction is increasingly recognized in the pathophysiology of Alzheimer’s disease (AD), and measures of vascular dysfunction can be evaluated using

cerebrospinal fluid (CSF) and imaging-based biomarker approaches. A clinical need exists to identify reliable biomarkers for early AD diagnosis, early intervention, and evaluating the efficacy of clinical trials. In this study, human participants were recruited from the University of Southern California (USC) Alzheimer's disease Research Center (ADRC) and the Washington University Knight ADRC. Here, we quantified novel CSF biomarkers of responses and injury to the neurovascular unit (NVU) - comprising vascular cells, glia, and neurons - using immunoassays, and evaluated regional K_{trans} measures of blood-brain barrier (BBB) permeability using dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI). CSF NVU biomarkers and DCE-MRI were analyzed in relation to participants' cognitive status (cognitively normal and early cognitive impairment) and the major genetic risk factor for sporadic AD, apolipoprotein E-ε4 (*APOE4*). We found that CSF measures of microvascular pericyte injury, namely soluble platelet-derived growth factor receptor-β (sPDGFRβ), was increased in *APOE4* carriers with cognitive impairment. Biomarkers of BBB breakdown including, for example, albumin quotient were similarly increased in *APOE4* carriers during cognitive impairment. Glial, inflammatory and neuronal injury markers were not altered with *APOE4* or cognitive impairment. The BBB and pericyte injury biomarkers increased independent of amyloid-β (Aβ) and tau. Consistently, we also found increased regional BBB permeability in the hippocampus and parahippocampal gyrus in *APOE4* carriers, independent of Aβ and tau. These suggest that CSF and MRI-based biomarkers of BBB and/or pericyte dysfunction are early detectable changes that are altered early in cognitive impairment and accelerated in *APOE4* carriers. Pilot data also indicate that high baseline levels of CSF sPDGFRβ predicts longitudinal decline in cognitive function in *APOE4* carriers, but not in *APOE4* noncarriers. Altogether, BBB breakdown is related to early cognitive dysfunction in *APOE4* carriers independent of Aβ and tau, and cerebrovascular biomarkers may be useful predictors of subtle cognitive dysfunction.

Title: Treatment GSK3-beta inhibitor Tideglusib improves memory performance, regulate tau phosphorylation and amyloid beta peptide in a type 2 diabetics rats

Authors: *T. PONCE-LOPEZ, M. ABASCAL-DÍAZ;
Anahuac Univ. Mexico, Mexico, Mexico

Abstract: Several studies have shown that patients with diabetes mellitus type 2 (DM2) are at increased risk of developing Alzheimer's disease (AD). Due to the profound socioeconomic impact of diabetes and AD, understanding the mechanisms that could link both diseases is essential. Oxidative stress, dysfunction of glucose and cholesterol metabolism, and mitochondrial activity, among others, have been shown to be associated with diabetes and AD. In fact, patients with diabetes have cognitive impairment, beta amyloid peptide deposits and hyperphosphorylated tau protein, neuropathological features of AD. It has been associated with disorders of signal transduction of the insulin receptor (IR), termed "cerebral insulin resistance". This is analogous to peripheral insulin resistance, represented by impaired neuronal insulin functions; such as glucose regulation, growth, neuronal survival and remodeling, and assembly of microtubules. Insulin is known to regulate tau phosphorylation through the PI3K-Akt-GSK3 pathway of insulin receptor (IR), disruption of this balance leads to abnormal phosphorylation of tau and amyloid deposits. As a consequence, GSK3 inhibitors have emerged as potential therapeutic tools for neural diseases dealing the tiadiazolidindione-derivative tideglusib ATP-noncompetitive GSK3 inhibitor has been shown to induce beneficial effects in some clinical trials for AD treatment with cognitive decline. This study aims to evaluate the effect intrahippocamcal admnsitration of tideglusib a memory impairments, disruption insulin receptor (IR), phosphatidylinositol-3-kinase/protein kinase B/GSK3 (PI3K-Akt/PKB-GSK3) signaling cascade, and abnormal phosphorylation of tau and beta amyloid peptide in a DM2 model. Wistar rats were given streptozotocin (STZ; 45 mg/kg) and a high-fat diet. The administration of tideglusib stereotactic surgery will be performed for the intrahippocampal administration of tideglusib (50 mg/kg). The spatial memory were assessed by Morris water maze. We are quantifying peripheral insulin and lipids by the ELISA test, the Akt, GSK3 and tau protein will be through western blot in hippocampus. Results showed that tideglusib improved spatial learning and memory. This evidence will provide insight about the role PI3K-Akt/PKB-GSK3 signaling cascade of IR and the therapeutic benefits of tideglusib on abnormal phosphorylation tau and memory dysfunction to prevent the development of the AD in patients with DM2.

Title: Olfactory impairment is associated with *in vivo* tau and amyloid-β accumulation in Alzheimer's disease spectrum

Authors: *M. BAEK, C. LYOO, H. CHO;
Dept. of Neurol., Gangnam Severance Hospital, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Objective: To examine whether impaired olfaction is related to imaging biomarkesr of tau and amyloid-β (Aβ) accumulation in Alzheimer's disease spectrum disease **Methods:** From January 2015 to August 2017, we prospectively recruited 208 participants [67 healthy control(HC), 83 mild cognitive impairment(MCI) and 58 dementia(DEM)] at the Memory Disorder Clinic of Gangnam Severance Hospital. Participants completed clinical interviews, a neuropsychological test battery, Cross-Cultural Smell Identification Test (CCSIT), magnetic resonance imaging(MRI), PET scan studies including ^{18}F-flortaucipir for tau and ^{18}F-florbetaben for Aβ. After correcting for partial volume effect, standardized uptake value ratio (SUVR) images were created. Regional SUVRs were measured between normosmia and hyposmia groups, and we also investigated a correlation between olfactory function and *in vivo* tau and Aβ accumulation in Alzheimer's disease spectrum. **Results:** Mean CCIST score in DEM was lower than in MCI and in HC (9.0±2.3 in DEM, 7.1 ± 2.8 in MCI 9.0 ± 2.3 in HC, P<0.001), and the proportion of hyposmia was higher in DEM (46/58(79%) in DEM, 40/83(48%) in MCI, and 15/67(22%) in HC). While there was no difference in tau and Aβ accumulation between normosmia and hyposmia groups in HC, tau accumulation in multiple temporo-parietal regions were increased in hyposmia group in MCI. Aβ accumulation in cerebral white matter and, tau accumulation in sensorymotor cortex, and precuneous region were shown in DEM. After adjustment for sex, age, ApoE ε4 positivity, and education duration, olfactory impairment was correlated with tau accumulation in multiple regions in MCI [superior/middle temporal/inferior temporal (P<0.05, respectively), inferior parietal (P<0.05) and insular(P<0.05)], and in DEM groups [prefrontal (P<0.01), sensorimotor (P<0.01), superior/inferior parietal (P<0.01, repectively), precuneus (P<0.01), and entorhinal(P<0.01)]. Correlation between olfactory impairment and Aβ was relatively weak. CCSIT score also showed correlation with language(BNT), visual memory(RCFT_DR) and frontal/executive functions(COWAT).**Conclusions:** Olfactory impairment is correlated with *In vivo* tau accumulation in multiple brain regions. Olfactory impairment may precede the tau accumulation and cognitive impairment, so left possibility for early biomarker for Alzheimer's disease spectrum disease

Title: Type 2 diabetes alters CSF but not plasma metabolomic and AD risk profiles in vervet monkeys

Authors: *S. M. DAY[1], M. PAIT[1], W. MORTIZ[4], C. NEWGARD[5], O. ILKAYEVA[5], D. MCCLAIN[2], K. KAVANAGH[3,6], S. L. MACAULEY[2];

Abstract: Epidemiological studies have shown that individuals with type 2 diabetes (T2D) have a 2-4 fold increased risk for developing Alzheimer's disease (AD), however the exact mechanisms linking the two conditions remains unknown. In T2D and AD the majority of pathological changes (such as elevated glucose, elevated insulin, and insulin resistance in T2D, and amyloid β (Aβ) and tau aggregation in AD) occurs many years before the onset of clinical symptoms and diagnosis. In this study we sampled CSF and plasma from healthy, insulin resistant (IR), and T2D age-matched female vervet monkeys (*Chlorocebus aethiops sabeus*) and compared Aβ and metabolic biomarkers by metabolic status. T2D and insulin resistance were diagnosed by veterinary staff according to repeated fasting glucose measurements and American Diabetes Association criteria. We found that T2D vervet monkeys have decreased CSF acylcarnitine, CSF amino acid, and plasma lactate levels, which suggests a metabolic perturbation in the brains. Furthermore T2D monkeys also have decreased CSF Aβ40 and Aβ42 levels, which is indicative of increased amyloid deposition within the brain. In agreement with our previous rodent studies CSF Aβ40 and Aβ42 were highly correlated with CSF glucose levels, suggesting glucose drives Aβ production and aggregation within the brain. CSF Aβ40 and Aβ42 levels were also highly correlated with plasma lactate, but not CSF lactate. We also found that CSF glucose and plasma lactate were significantly correlated with amino acid and acylcarnitine levels. Together these data indicate that the brain begins to consume more amino acids and acylcarnitines as fuel while simultaneously accumulating Aβ as T2D progresses. Based on these

findings we hypothesize that the progression of T2D drives a state of hypermetabolic overconsumption in the brain that promotes Aβ aggregation; a finding that may explain the relationship between T2D and AD. Thus, AD and T2D exacerbate one another and contribute to increased AD risk factors, including altered brain metabolism and oxidative stress.

Title: Multi site electrode recordings in an Alzheimer's disease mouse model based on presenilin 2

Authors: A. LEPARULO[1], ***M. MAHMUD**[2], E. SCREMIN[1], S. VASSANELLI[1], C. FASOLATO[1];
[1]Univ. of Padova, Padova, Italy; [2]Nottingham Trent Univ., Nottingham, United Kingdom

Abstract: Alzheimer's disease (AD) is one of the most devastating disease conditions in today's aging population worldwide. It is now imperative to detect any initial sign of the disease leading towards an early diagnosis which then might facilitate the long-term treatment plan (1). One such detection approach could be to identify early network dysfunctions occurring well before plaque deposition and inflammation. Since last decade, network activities measured as local field potentials (LFPs) have been utilised in investigating higher level cognitive functions in mammals including rodents, primates and humans (2). Apposite frequency bands extracted from the LFPs, such as slow and fast oscillations, using sophisticated time-frequency based analysis, have been found to be appropriate in studying network functions. Therefore, relevant biomarkers can be derived from these slow and fast oscillations in the network which is the basis for memory consolidation and information transfer between the cortex and the hippocampus (3,4).
Towards the detection of an early biomarker based on network dysfunction, we recorded LFPs *in vivo* with a multi-electrode linear probe spanning the posterior parietal cortex (PPC) and the dorsal hippocampal formation (HPF) to investigate the spontaneous brain oscillatory activities of AD mice under anaesthesia. Recordings were performed in two groups of PS2APP (B6.152H) mice, at 3 and 6 months of age, i.e. before and after plaque deposition, and in age-matched WT

(C57Bl6/J) mice (5,6). Seven distinct channels were selected for the frequency-based analyses: 3 in the PPC, 2 in the Cornu Ammonis (CA1) and 2 in the Dentate Gyrus (DG). Analysis of power distribution in the different frequency bands showed that, with respect to WT, at 3 months of age, i.e. at the very onset of amyloid-beta accumulation, B6.152H mice have altered power ratios between slow oscillations (SO) [0.1-1.7 Hz] and Delta waves [1.7-4.7 Hz] at CA1 close to the hippocampal fissure. The phase-amplitude coupling between SO and higher frequency bands also appears dramatically impaired in CA1 as early as 3 months of age. With plaque deposition these defects worsen and reach the PPC.

Abstract: The diagnostic accuracy and therapeutic efficacy for neurodegenerative diseases can be improved by the combined evaluation of multiple central and peripheral biomarkers to differentiate among patients with different clinical-neuropathological phenotypes. Low sensitivity and specificity of current diagnostic methodologies lead to frequent misdiagnosis. This raises the need of more efficient integration of biomarkers with multidimensional clinical data. Through an interdisciplinary approach, to extract new models for more accurate diagnosis, we aim to compare real-word data of Alzheimer's (AD), Parkinson's disease (PD) and progressive supranuclear palsy (PSP, atypical parkinsonism) with public databases, such as ANM (AddNeuroMed) for AD, PPMI (PD Progressive Markers Initiative) for PD and PRIAMO (PaRkinsondIseAse non-MOtor symptoms) for PSP, by Machine Learning methods (ML). The platform will integrate and analyze clinical and instrumental parameters with transcriptomics from patients with the most severe neurodegenerative diseases, including PSP, less common and usually more severe than PD, characterized by rapid progression and atypical features. Its correct diagnosis is critical, as prognosis and symptomatic treatment of PSP is different from PD. Transcriptomics from ANM (multi-center initiative for AD clinical, transcriptomic and proteomic data), analyzed by ML, allowed identification of 268 (AD-CTL), 361 (AD-MCI) and 272 (MCI-CTL) genes unique to each gene-based classifier: 104 highly ranked genes shared between AD-CTL & MCI-CTL, 15 genes between AD-CTL & AD-MCI and 11 genes between AD-MCI & MCI-CTL classifiers. These genes represent potential transcriptomic biomarkers, highlighting the cellular processes involved. For gene-based classification, models provide excellent discrimination between AD vs CTL (AUC=0.94) and MCI vs CTL (AUC=0.90); good between AD vs MCI (AUC=0.81). Regarding PSP, RNASeq was performed on blood of 18 PSP patients and 12 matched CTLs, after approval of Ethical Committee and in accordance with current regulation. By ML, hundreds of clinical variables were correlated with real-world data, collected by excellence Italian AD, PD and movement disorders Centers. The integration of Statistics and ML in MCI and AD subjects allowed an efficient and significant selection of new sets of pathways and variables with the highest predictive power. We intend to realize a technological platform to support more precocious and accurate diagnosis of neurodegenerative diseases, towards more targeted and effective therapeutic intervention in terms of patient wellbeing and optimization of health costs.

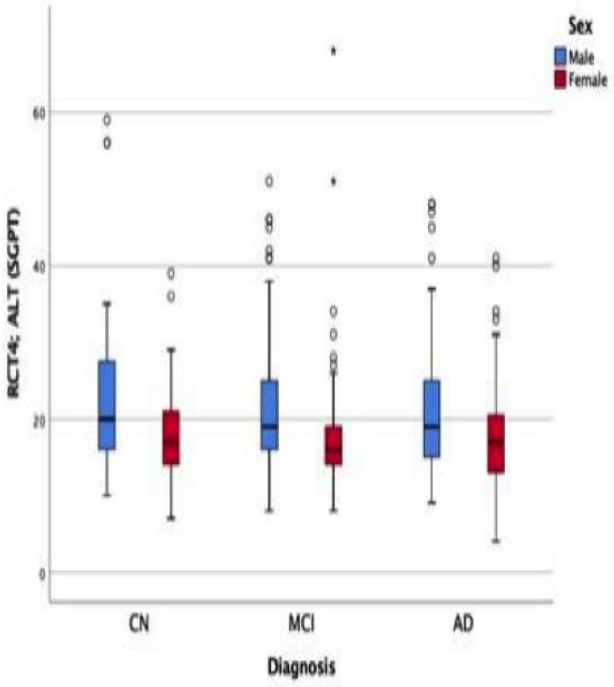
Title: Inflammatory markers related to liver function predict longitudinal brain atrophy

Authors: *C. P. BOYLE[1], C. CHING[2], S. THOMOPOULOS[3], A. ZAVALIANGOS-PETROPULU[4], A. MEZHER[4], P. M. THOMPSON[5];
[1]Imaging Genet. Ctr. @ Univ. of Southern C, Marina Del Rey, CA; [2]Keck Sch. of Med., [4]Imaging Genet. Center, Stevens Inst. for Neuroimaging & Informatics, [3]USC, Marina Del Rey, CA; [5]Stevens Inst. for Neuroimaging & Informatics, Univ. of Southern California (USC), Marina Del Rey, CA

Abstract: Objective and Rationale:
Dementia risk is associated with cardiovascular, metabolic, and inflammatory markers related to liver function. Here we analyzed the relationship between longitudinal brain atrophy and two markers of liver inflammation: aspartate aminotransferase (AST) and alanine aminotransferase (ALT).
Several processes in the brain and body have been linked to the risk of dementia, including cardiovascular, metabolic and inflammatory markers, which include enzymes related to liver function. Here we aimed to define the relationship between rates of brain atrophy in old age and two markers of liver inflammation: AST (aspartate aminotransferase) and ALT (alanine aminotransferase).
Methods:
We analyzed 1.5-Tesla T1-weighted brain MRI scans from 620 older adults from the Alzheimer's disease neuroimaging initiative (ADNI) [1] (142 with Alzheimer's disease (AD), 283 with mild cognitive impairment (MCI), 195 healthy elderly; mean age: 75.2 ± 6.7 years; 42.3% female). Baseline liver enzyme levels were measured from blood serum samples collected following an overnight fast. Both ALT and AST were generally within the normal range, i.e., 8 to 48 (U/L) for AST and 7 to 55 (U/L) for ALT [2].
We measured annualized rates of brain atrophy using unbiased tensor-based morphometry. Average expansion or contraction rates (Jacobian determinant) were derived for whole temporal lobe and statistically defined temporal ROIs [3].
Using multiple linear regression, we tested whether liver function markers differed by age, sex or diagnosis; we then tested associations of brain atrophy rates with ALT and AST (See Figure 1).
Results and Conclusion:

Higher baseline AST was associated with greater rates of brain atrophy and ALT and AST differed with respect to age and sex. AST and ALT measures are known to be related to atrophy in patients with alcohol dependence [7]. Continued analysis of ADNI phase 2/3 scans and the identification of additional markers will offer more insight into the effects of liver function and influencing factors (e.g., primary liver disease) on atrophy rates.

Figure 1: Both AST and ALT were negatively correlated with age and higher in men, in line with current literature suggesting that liver function measures decline with age and that men have, on average, higher measures than women [4,5,6]. After adjusting for age and sex, we examined the relationship between AST and ALT levels and diagnosis but found no detectable difference in average measures with varying diagnosis.



* These cases represent extreme outliers for ALT which we confirmed did not affect our results.

Along with covariates such as age, sex and diagnosis, AST (but not ALT) significantly predicted rates of brain atrophy, passing FDR correction at <.05 across the whole brain. People with higher AST levels had significantly higher brain atrophy rates measured using both ROI methods.

ROI	beta value	std. error	t-value	p-value

Title: Profiles of amyloid, tau and neurofilament light chain in plasma from Alzheimer's patients

Authors: M. CHEN[1], L. MOO[1], ***W. XIA**[2];
[1]Bedford VA Med. Ctr., Bedford, MA; [2]Bedford VA Hospital, Boston Univ., Bedford, MA

Abstract: Amyloid-containing neuritic plaques and hyper-phosphorylated tau-containing neurofibrillary tangles are pathological hallmarks in brains of Alzheimer's disease (AD) patients. Whether these pathological proteins are similarly increased in peripheral system remains to be an unresolved question. In addition, neurofilament light chain and neuroinflammation markers have been investigated in biofluid samples from patients with AD. Increased inflammatory profile in blood reflects vulnerabilities in AD patients caused by an aging immune system. Since the relatively invasive nature of cerebrospinal fluid (CSF) sampling limits the use of the current biomarkers of tau and amyloid β proteins (Aβ) for AD, we aim to use mass spectrometry (MS)- and ELISA-based analysis to study several classic pathological proteins and find the connection between the peripheral and central nervous system in AD pathogenesis. We collected blood from >100 AD patients and healthy controls, and at autopsy, post-mortem brain tissue (superior frontal cortex, inferior cortex and cerebellum area) from several subjects. Liquid chromatography/MS was used to analyze plasma proteins and proteins in brain tissues labelled with isobaric mass tags (TMT) for relative protein quantification. We examined protein-protein interaction networks through a bioinformatics approach and revealed a group of differentially expressed plasma proteins that are associated with AD. ELISA-based comparative analysis of the plasma proteins between the AD patients and healthy control subjects revealed increased pathological proteins in those from AD patients. While no significant difference in levels of plasma Aβ42 was observed, AD patients exhibited significantly higher levels of plasma tau and phosphorylated tau (ptau 181). Accordingly, levels of neurofilament light chain were also increased in the same group of AD patients, compared to those from control subjects. In conclusion, a group of pathological proteins associated with AD was found to be increased in blood, supporting our future effort to validate these proteins in peripheral compartment as valid biomarkers for AD.

Title: Classification of Alzheimer's disease patients using MRI-based cortical phenotyping 1 to 2 years before dementia onset

Authors: *F. PIZZAGALLI[1], S. P. GADEWAR[1], S. I. THOMOPOULOS[1], Q. YANG[1], P. KOCHUNOV[3], P. M. THOMPSON[4], N. JAHANSHAD[2];
[1]USC, Los Angeles, CA; [2]USC, Marina Del Rey, CA; [3]Maryland Psychiatric Res. Center, Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [4]Stevens Inst. for Neuroimaging & Informatics, Univ. of Southern California (USC), Marina Del Rey, CA

Abstract: MRI has a potential for early diagnosis of individuals at risk for developing Alzheimer's disease (AD). Cognitive performance in elderly patients with AD has been associated with measures of cortical gyrification (Cai et al. 2017) and thickness (CT) (Lee et al. 2018), yet the extent to which sulcal measures can help to predict AD conversion above and beyond CT measures is not known. Here, we analyzed 721 participants with MCI (mild cognitive impairment) from phases 1 and 2 of the Alzheimer's disease Neuroimaging Initiative. By their 24-month follow up, 188 individuals had converted from MCI to AD (76 females; mean age: 73.55 ± 7.29 years) and 533 remained MCI (214 females; mean age: 73.01 ± 7.51). Freesurfer 5.3 was used to extract 68 regional CT estimates; BrainVISA was used for identification and estimation of sulcal width (Pizzagalli et al. 2016) for 63 sulci. We used machine learning to classify individuals who converted from MCI to AD from the stable MCI group using the following features from their baseline assessments: sulcal width, CT, age, sex, Mini-Mental State Examination (MMSE) and the Clinical Dementia Rating Sum of Boxes (CDR-SB) scores. We compared classification performances of four classifiers (gradient boosting, extra trees, decision tree, random forests) when 1) using only clinical data, 2) with CT, 3) with sulcal-based width, and 4) all sets of measures. 75% of the dataset was selected as the training set (10 folds). We evaluated performance by assessing accuracy, ROC-AUC score, sensitivity and specificity. The width of the right inferior occipito-lateral sulci and the CT of the right inferior temporal gyrus were among the top 10 brain measures selected for classification. Classification performance was similar for classifiers that used only clinical/demographic data (accuracy=0.73 ± 0.05), sulcal width (accuracy=0.73 ± 0.05), or CT (accuracy=0.73 ± 0.02), although including all features

slightly improved accuracy (0.74 ± 0.01). In conclusion, sulcal width and CT may be useful as complementary features to help early detection of AD.

Title: Alzheimer’s disease biomarkers in exosomes isolated from the cerebrospinal fluid of rhesus monkeys injected with amyloid-β oligomers

Authors: *N. M. LYRA E SILVA[1], S. E. BOEHNKE[2], E. L. ROBERTSON[1], B. HYDUK[1], R. G. WITHER[2], A. WINTERBORN[1], V. BODART-SANTOS, SR[3], P. FRASER[4], F. G. DE FELICE[5], D. P. MUNOZ[6];

Studies, Queens Univ., Kingston, ON, Canada

Abstract: Alzheimer’s disease (AD) is the most prevalent type of dementia affecting the elderly population. Exosomes are small extracellular vesicles that can transport cargoes of nucleic acids and proteins, including amyloid-β (Aβ) and tau. Exosomes isolated from AD brains have elevated levels of Aβ oligomers and AD is proposed to be propagated by exosomes. Currently, there is no effective treatment for AD and the pursuit of novel disease-modifying therapeutics is the object of intense investigation. Drugs that showed promise in preclinical studies and early clinical trials, have failed to work in AD patients suggestive of problems translating from rodent model species to humans. To understand higher cognitive functions in the human brain, and how brain dysfunction develops in AD, experimental animals that are more similar to humans are essential. One way to overcome this critical hurdle is to generate viable models of AD in non-human primates (NHPs). Our lab has developed a NHP model of AD that consists of a series of injections of amyloid-β oligomers (AβOs) into the lateral ventricle of Rhesus macaque monkeys. This animal model develops cardinal pathological features similar to those observed in AD brains, and currently this model is being validated longitudinally across multiple platforms including cerebrospinal fluid (CSF) and blood biomarkers, functional and structural brain imaging, cognitive and behavioral testing, and pathophysiology. Here, we evaluated if

exogenous AβOs would trigger an alteration on AD biomarkers present in exosome preparations from the CSF of NHPs. CSF samples were collected before and after the injection sequence and exosomes were isolated with the Exosome Isolation kit from System Biosciences. Isolated exosomes were characterized by Light Scattering and Western Blot techniques. We used a multiplex panel from Millipore on a luminex platform to access the AD biomarkers **Aβ**1-40, **Aβ**1-42, total tau, and phosphorylated tau at threonine 181. We observed an increase in total tau level in the exosome fraction isolated from AβO-injected NHPs. **Aβ**1-42 level was also elevated in the exosomes of AβO-injected NHPs, but a similar effect was observed in the vehicle-injected NHP. This data indicates that AβOs promote tau propagation within CSF exosomes in Rhesus monkeys, which may contribute to disease progression.

Abstract: Alzheimer's disease (AD) is caused by nerve cell death, leading to progressive decrease in memory and changes in behavior. The 95% of dementia patients show late-onset of AD. The pathophysiology of AD appears to be multifactorial involving many intrinsic and extrinsic factors. Recently, type 2 diabetes (T2D) has been shown to linked with AD pathophysiology. T2D is caused by impaired insulin metabolism due to the lack of functional pancreatic β cells, which use it. T2D is generally attributed to the sedentary lifestyle and the consumption of higher amount of fat in the diet, which together result in obesity. Interestingly, T2D is usually accompanied by many pathophysiological conditions, including death of neuronal cells. Although Alzheimer and T2D diseases appear to be very different, they many shared phenotypes. Understanding the shared and unique mechanisms underlying these diseases would be helpful for the prevention and treatment strategies. We performed meta-analysis of available

gene expression datasets to determine the role of miRNAs/target genes regulating conserved pathways in both diseases, in specific populations with high prevalence of T2D, such as Hispanic Americans, a highly affected group. We observed that the miRNAs such as hsa-miR-206, hsa-miR-1-3p, and hsa-miR-511-3p, regulates conserved biological pathways in AD and T2D.

Title: The physiological activity and expression of neurotransmitters in the retinal ganglion cell of the 5xFAD Alzheimer’s disease mouse

Authors: *J. ARAYA[1,2], C. DURAN-ANIOTZ[3], M. ACOSTA[4], C. HETZ[3], M. CHACÓN[5], A. PALACIOS[2];
[1]Programa De Doctorado En Neurociencia, Universidad de Santiago de Chile, Chile; [2]Ctr. Interdisciplinario de Neurociencias de Valparaíso, Universidad de Valparaíso, Chile; [3]Biomed. Neurosci. Inst., Universidad de Chile, Chile; [4]Sch. of Optometry and Vision Science, Ctr. for Brain Research, Brain Res. New Zealand, The University of Auckland, New Zealand; [5]Dept. of Engin. Informatics, Universidad de Santiago de Chile, Chile

Abstract: Purpose: To determine whether the 5xFAD mouse, a model of Alzheimer’s disease (AD), shows changes in the expression of glutamate (Glu) and gamma-aminobutyric acid (GABA) neurotransmitters and in the physiology of the retinal ganglion cells (RGCs) during the temporal course of AD.
Methods: Retinas from youngs (2-3 months, n=20) and adults (6-7 months, n=20) 5xFAD and WT mice were employed. For each animal, one eye was collected and fixed for immunogold-silver staining to detect Glu and GABA in the retina. RGCs activity were recorded using a multielectrode array under scotopic and photopic conditions from the contralateral eye. All methods use here are in compliance with bioethical certification.
Results: Glu was predominantly visualized in the RGC layer in youngs and adults 5xFAD mice, but not in the youngs or adults WT. GABA was predominantly found in the inner retina in youngs and adults WT and the RGC layer of youngs 5xFAD but not in the adults 5xFAD. In scotopic conditions the firing rate of RGCs was higher in youngs 5xFAD compared to youngs WT (all numeric results are presented as 25% percentile, median, 75% percentile in Hz. 5xFAD

= 0.559, 3.025, 8.44. WT = 0.31, 1.819, 7.02. Significative difference (SD), Mann Whitney test (MW test), $p<0.05$), while adults 5xFAD shows lower firing rate compared to the adults WT (5xFAD= 0.223, 1.081, 3.82. WT= 0.415, 2.04, 5.85. SD, MW test, $p<0.05$). In photopic conditions was a high firing rate for the youngs 5xFAD compared to youngs WT (5xFAD= 0.5, 2.918, 9.96. WT= 0.30, 1.858, 6.83. SD, MW test, $p<0.05$). However, no difference was found between the adults 5xFAD and the adults WT.
Conclusions: We report sensitive changes in the levels of Glu and GABA in the RGC layer for 5xFAD mice retinas and a concomitant upregulation of the RGCs physiology for spontaneous scotopic and photopic activity in the youngs 5xFAD. In the scotopic conditions the spontaneous RGCs firing activity of the adults 5xFAD is downregulated, but not in photopic conditions. Our results supports the idea that the integrated homeostatic network, that enables functional stability of central circuits, it is disrupted too in the retina in the AD, depending on illuminated condition.

Title: Alzheimer's disease fluid biomarkers related gray matter covariance patterns in healthy older adults

Authors: *P. K. BHARADWAJ[1,7], J. R. ANDREWS-HANNA[1,2], P. H. KUO[3,8,9], G. E. ALEXANDER[1,4,5,6,10];

Ctr., Tucson, AZ; [10]Arizona Alzheimers Consortium, Phoenix, AZ

Abstract: Biomarkers of Alzheimer’s disease (AD) pathology in cerebrospinal fluid (CSF), including $A\beta_{42}$, $pTau_{181}$, and the ratio of $pTau_{181}/A\beta_{42}$, can help identify those with increased risk for dementia, before the onset of clinical symptoms. How these CSF biomarkers relate to

regional patterns of gray matter (GM) atrophy in cognitively unimpaired older adults has yet to be fully investigated. Here, we applied a multivariate network analysis technique, the scaled subprofile model (SSM; Alexander & Moeller, 1994) to identify gray matter covariance patterns related to CSF measures of $A\beta_{42}$, $pTau_{181}$, and the ratio of $pTau_{181}/A\beta_{42}$, in a sample of healthy older adults drawn from the Alzheimer's disease Neuroimaging Initiative (ADNI2; N=146; Age=73.5 ± 6.4 years, range=56-89 years; sex (F/M)=76/70; Education= 16.5 ± 2.5 years; MMSE=29.1 ± 1.2; CDR = 0; APOE-ε4 (N/Y)=108/38). GM maps were segmented from 3T T1-weighted volumetric magnetic resonance imaging (MRI) scans with SPM12, spatially normalized using diffeomorphic registration (DARTEL), and smoothed with a Gaussian kernel of 10mm. Regional SSM network analysis was performed on these GM maps using Akaike Information Criteria with 2000 Bootstrap iterations to identify linear combinations of GM patterns associated with each of the three fluid biomarker measures. The $pTau_{181}/A\beta_{42}$ - related GM SSM pattern (R^2=0.10, p≤ 4.4E-05) was characterized by bilateral reductions in the vicinity of the superior temporal gyrus (STG), and extensive bilateral GM reductions in cerebellar lobules. The $pTau_{181}$ related GM SSM pattern (R^2=0.06, p≤ 2.75E-03) showed extensive bilateral reductions in the cerebellum extending into the anterior cerebellar lobule. In contrast, CSF $A\beta_{42}$ did not exhibit an SSM pattern with robust regional GM contributions in this cohort. Additionally, the $pTau_{181}/A\beta_{42}$ (R^2 change = 0.042, p ≤ 0.007) and $pTau_{181}$ (R^2 change = 0.042, p ≤ 0.008) related GM patterns each remained significantly associated with their respective CSF biomarker, after adjusting for age, sex, years of education, APOE genotype, hypertension status, and intracranial volume. These results demonstrate that AD-related CSF biomarkers including $pTau_{181}$ and its ratio to $A\beta_{42}$ may be associated with individual differences in regional topographies of GM volume, involving temporal and cerebellar brain regions, in healthy cognitively unimpaired older adults. Together, these findings provide further support for the use of CSF fluid biomarkers in evaluating the earliest preclinical effects of AD and their relation to the effects of brain aging.

Title: Quantitative analysis of calbindin-D28K immunoreactivity in locus coeruleus neurons of young and aged human brains

Authors: *S. LAMERAND[1], R. SHAHIDEHPOUR[1], I. AYALA[1], M.-M. MESULAM[1], E. BIGIO[2], C. GEULA[1];
[1]MCCNAD, [2]Northwestern Univ., Chicago, IL

Abstract: We have previously shown that calbindin is present in some noradrenergic locus coeruleus (LC) neurons, while other calcium binding proteins such as parvalbumin and calretinin are absent. The LC is vulnerable to early degeneration in Alzheimer's disease (AD) with tangles present as early as the third decade of life. The cholinergic neurons of the basal forebrain (BFCN) are also vulnerable to early degeneration. BFCN are rich in the calcium binding protein, calbindin-D28K (CB) which displays significant loss over the course of aging. In AD, CB loss is associated with tangle pathology and BFCN loss. The purpose of the present study was to quantitatively determine the density of CB immunoreactive LC neurons in the human brain, and to assess potential age-related changes in the density of these neurons. Blocks of brainstem containing the LC from five young (20-63 years old) and five aged (70-77 years old) cognitively normal human brains were fixed in 4% paraformaldehyde for 30-36 hours at 4º C and taken through sucrose gradients for cryoprotection. Blocks were sectioned at a thickness of 40 µm on a freezing microtome and 1 in 24 series of sections were stored in 0.1 M phosphate buffer until use. One series of sections from each brainstem were immunohistochemically stained using a double chromogen procedure for the monoaminergic synthetic enzyme tyrosine hydroxylase (TH) and CB, using diaminobenzidine (brown reaction product) and benzidine dihydrochloride (blue / black granular reaction product) as chromogens respectively. Quantitative analysis was performed on digitized images to determine the total number of TH- and CB-positive LC neurons in each case. Overall, a relatively small proportion of TH-positive LC neurons contained CB. There was no significant difference ($p>0.05$) in the percentage of CB-positive LC neurons when young individuals (5.28% - 14.01%) were compared with the aged (8.33% -20.75%). Similarly, there was no significant difference ($p>.05$) between the young and aged groups in the average number of TH-positive (young=435, old=305) or the average number of CB-positive LC neurons (young=49, old=37). While CB immunoreactivity is present is a proportion of LC neurons, there does not appear to be any age-related changes in the number or proportion of CB-positive LC neurons. Therefore, unlike the BFCN, CB immunoreactivity in LC neurons is unlikely to contribute significantly to the vulnerability of these neurons to neurodegeneration.

Title: High sensitivity detection of misfolded protein aggregates implicated in Alzheimer's and Parkinson's disease by prion-like seeding assays

Authors: *S. PRITZKOW, M. SHAHNAWAZ, M. PINHO, N. MENDEZ, C. SOTO; UTHealth Sci. Ctr., Houston, TX

Abstract: A hallmark event in several neurodegenerative diseases is the cerebral accumulation of misfolded protein aggregates. Recent evidences indicate that soluble misfolded oligomeric versions of these proteins circulate in biological fluids and may serve as a specific biomarker for sensitive diagnosis. Recently, we have developed a technology for ultra-sensitive detection of soluble misfolded oligomers implicated in Alzheimer's (AD), Parkinson's (PD) diseases and related synucleinopathies and tauopathies. The technique, termed PMCA and also referred as RT-QuIC, is based on the cyclic amplification of protein misfolding, and mimics the seeding/nucleation model of aggregation in a highly efficient manner by combining phases of polymer growing with their fragmentation to multiply the number of seeds for the exponential amplification of the reaction. PMCA was first adapted and optimized for amplification of prion protein (PrP^{Sc}) implicated in prion diseases and more recently has been extended to detect amyloid-beta (Aβ), Tau, and α-synuclein (α-syn) misfolded oligomers. After the technology was optimized for reproducibility and sensitivity using synthetic protein aggregates, we tested the utility of PMCA to detect misfolded oligomers composed by each of these proteins coming from CSF of patients affected by AD, PD and other neurodegenerative disorders, using as controls people affected by other neurological disorders or healthy subjects. Our results showed that PMCA enables highly sensitive and specific detection of misfolded Aβ, Tau, and α-syn oligomers and can be used to detect these biomarkers in CSF of patients with >90% overall sensitivity and specificity. The simultaneous application of the various PMCA assays may enable to differentiate distinct types of mixed pathologies and perhaps to detect the disease process before the onset of clinical symptoms. Ongoing studies re aiming to optimize the technology for detection of protein aggregates in blood samples. Our findings suggest that PMCA represents a platform technology for the detection of misfolded oligomeric proteins implicated in various neurodegenerative diseases and offer a great promise for a much needed non-invasive, early biochemical diagnosis of these diseases.

Title: Detection and quantification of free brain levels of cholesterol in freely moving mice utilizing i*n vivo* microdialysis

Authors: *J. ROESER, C. CIARDIELLO, E. WEBER, M. VAN DER HART, H. B. JANSSENS, A. RASSOULPOUR;
Charles River Labs., South San Francisco, CA

Abstract: Cholesterol is an essential component for neuronal physiology not only during development stage but also in the adult life. Cholesterol metabolism in brain is independent from that in peripheral tissues due to blood-brain barrier. Defects in brain cholesterol metabolism has been shown to be implicated in neurodegenerative diseases, such as Alzheimer's disease (AD), Huntington's disease (HD), Parkinson's disease (PD), and some cognitive deficits typical of the old age. The brain contains large amount of cholesterol, but the cholesterol metabolism and its complex homeostasis regulation are currently poorly understood. The aim of the present study was to detect free cholesterol levels by microdialysis sampling in murine brain.
Water insoluble cholesterol was successfully sampled *In Vitro* by addition of hydroxypropyl-β-cyclodextrin which promotes solubility of lipophilic compounds in the aqueous microdialysis perfusion fluids. Next, *In Vivo* experiments combined with a sensitive, in-house developed, LC-MS/MS assay allowed for the quantification of cholesterol in microdialysate extracts of freely moving mice.
This is to the best of our knowledge the first occurrence of microdialysis sampling and detection of free brain cholesterol levels. These data demonstrate the feasibility of monitoring free brain cholesterol levels and has the potential to be extended to similar class of compound such as steroid hormones and/or sphingolipids. Our efforts have the potential to bring new insights in the CNS space and help the discovery of therapies for neurodegenerative diseases.

Title: Methods for diagnosing Alzheimer’s disease based on cell growth rate, size and protein amount

Authors: *F. V. CHIRILA, D. L. ALKON;
NeuroDiagnostics LLC, Rockville, MD

Abstract: Drugs to treat Alzheimer’s disease (AD) have been unsuccessful in preventing its devastating cognitive deficits and progressive neurodegeneration. The lack of a definitive diagnostic for AD has been a major obstacle to AD drug discovery. Our novel approach to AD screening based on a collection of markers rather than just one has a greater chance to capture the complexity of this disease. Here we show novel methods for diagnosing Alzheimer’s disease in a symptomatic human subject. These methods comprise of measuring the growth rate, size and/or protein amount of a subject’s skin fibroblasts and/or lymphocytes, and determining whether these values differ in certain ways from those of corresponding non-Alzheimer’s disease dementia cells. We also provide potential methods for determining whether an asymptomatic human subject is at risk from becoming afflicted with Alzheimer’s disease.

Title: Transcranial magnetic stimulation neurophysiology in patients with Alzheimer’s disease: A systematic review and meta-analysis

Authors: *Y. MIMURA[1], H. NISHIDA[1], S. TSUGAWA[1], S. MORITA[1], K. YOSHIDA[2,1], F. MASUDA[1], K. OGYU[1], M. WADA[1], T. MIYAZAKI[1], S. L. NAKAJIMA[1,3], M. MIMURA[1], Y. NODA[1];

[1]Dept. of Neuropsychiatry, Keio Univ. Sch. of Med., Tokyo, Japan; [2]Campbell Family Mental Hlth. Res. Institute, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [3]Multimodal Imaging Group, Res. Imaging Centre, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Background: Transcranial magnetic stimulation (TMS) is a non-invasive neurophysiological tool which allows us to investigate motor cortical excitability in the human brain. Paired-pulse TMS paradigms such as short- and long-interval intracortical inhibition (SICI/LICI), intracortical facilitation (ICF) and short-latency afferent inhibition (SAI) can assess and quantify neurophysiological functions of GABA, glutamate, and choline associated circuits, respectively. Accumulating evidence suggest that TMS neurophysiology can be novel biomarkers for the diagnosis of Alzheimer's disease (AD). In this study, we conducted meta-analyses to compare neurophysiological functions associated with monoaminergic neurotransmissions between patients with AD and healthy controls (HC). Methods: A systematic literature research was conducted using Embase, Medline, PsycINFO, and Pubmed up to September 2018. Original studies that examined resting motor threshold (RMT), SICI, ICF, LICI, SAI in patients with AD and HC, were included. Standardized mean differences (SMDs) were calculated to determine the difference in these neurophysiological markers in both groups. Results: Out of 695 initial records, 80 articles were identified the included studies, and dataset from 34, 20, 16 and 13 articles were available for further analyses for RMT, SAI, SICI, and ICF, respectively. RMT and SICI were significantly lower in patients with AD than in HC (SDM=-1.574, CI=-2.22 to -0.930, $p<0.001$ for RMT, SDM=0.394, CI=0.13 to 0.66, $p=0.004$ for SICI). SAI was significantly higher in patients with AD than in HC (SDM=1.54, CI=1.08 to 2.00, $p<0.001$ for SAI), whereas ICF was not significantly different in both groups.
Conclusions: The meta-analyses demonstrated that patients with AD had decreased RMT and SICI but increased SAI. These findings suggest that motor cortical excitability, GABAergic and cholinergic function were altered in patients with AD. Our results warrant further study with larger samples to replicate the current findings and identify the excitatory and inhibitory balance in AD for an appropriate assessment of the pathophysiology in this disorder.

Title: Identification of plasma cytokine biomarkers of disease severity for the lysosomal storage disorder mucolipidosis IV

Authors: *L. WOOD[1], L. WEINSTOCK[2], A. FURNESS[3], A. MISKO[3], Y. GRISHCHUK[4]; [2]Dept. of Biomed. Engin. and Inst. for Bioengineering and Biosci, [1]Georgia Inst. of Technol., Atlanta, GA; [3]Massachusetts Gen. Hosp., Boston, MA; [4]Ctr. for Human Genet. Res., Massachusetts Gen. Hospital/Harvard Med. Sch., Boston, MA

Abstract: Problem Statement: Mucolipidosis IV (MLIV) is an orphan disease that causes severe motor and cognitive dysfunction and loss of vision. It is caused by loss of function of the lysosomal channel mucolipin-1, also known as TRPML1. Knockout of the *Mcoln1* gene in mice mirrors clinical and neuropathological signs in humans and shows robust activation of microglia and astrocytes in early symptomatic stages of disease. Although there is currently no therapy for MLIV, the research community is rapidly advancing treatment strategies. Therefore, identification of peripheral biomarkers of disease severity will be essential for rapidly quantifying the effects of treatment in advance of cognitive or motor changes. **Objectives:** Since neuroinflammation is a central feature of MLIV in humans and mice, we hypothesized that cytokines quantified from blood plasma would serve as biomarkers of pathology and neurologic function. **Methods:** Plasma was collected from *Mcoln1*$^{-/-}$ or CTRL mice and from human patients under an IRB approved protocol. We used multiplexed immunoassays to quantify 32 cytokines from mice and 41 cytokines from human samples. Motor function scores were assessed by a neurologist. Cytokine data were correlated against genotype in mice using a discriminant partial least squares regression (D-PLSR) and against motor function in humans using PLSR. **Results:** *Mcoln1*$^{-/-}$ mice possessed a plasma cytokine signature that correlates with disease severity by age. The profile includes IP-10 and IL-17 in the early symptomatic phase (1-2mo), and IL-12p40 and M-CSF in the late phase (6mo). In humans, we identified profiles of cytokines that significantly correlated with reduced motor function, including IL-1b, IFN-g, IFN-a2, IL-17and cytokine signature correlations with motor function scores were R= 0.65, p= 0.002 for deglutition, R=0.58, p=0.009 for articulation, R=0.73, p<0.009 for fine motor. **Conclusion:** Our data suggest that cytokines/chemokines quantified from blood plasma reflect disease severity in mice and in MLIV patients. The strength of the correlations between cytokine profiles and motor function suggests that cytokines/chemokines will serve as an effective biomarker for MLIV. Moreover, we have previously identified the interferon pro-inflammatory axis to be up-regulated in brains of *Mcoln1*$^{-/-}$ mice, suggesting the peripheral signature reflects the brain microenvironment.

Title: Retinal pathology correlates with brain pathology in MCI and AD patients

Authors: *Y. KORONYO[1], A. RENTSENDORJ[1], D.-T. FUCHS[1], J. SHEYN[1], G. C. REGIS[1], H. SHI[1], N. MIRZAEI[1], E. BARRON[3], K. L. BLACK[1], D. R. HINTON[4], C. A. MILLER[5], M. KORONYO-HAMAOUI[1,2];

Abstract: The retinae of patients with Alzheimer’s disease (AD) display several abnormalities, including the presence of Aβ deposits, tauopathy, and retinal ganglion cell (RGC) degeneration. Although inflammatory responses are tightly correlated with AD brain pathology, the processes in the retina are underexplored. Here, we study retinal pathology including amyloidosis, gliosis, RGCs, and vascular cell integrity in mild cognitively impaired (MCI) and confirmed AD patients as compared to age- and sex-matched cognitively normal controls (CN). We quantified extra- and intra-cellular amyloid beta (Aβ) load as well as macro- and micro-gliosis (Müller glia, GFAP, s100β, Iba1) in defined retinal layers and sub-geometrical regions in MCI and AD patients versus CN and compared to brain pathology. We further used an analytical biochemistry assay (ELISA) to quantify $A\beta_{42}$ in the retina of patients and CN. We found a wide range of pathological changes in retinal tissues isolated from MCI and AD patients. Aβ deposits were more abundant in inner retinal layers with substantial 4- to 10-fold increases in total Aβ and especially $A\beta_{42}$-specific burden in peripheral regions in AD patients as compared to CN. Retinal $A\beta_{42}$-containing plaques strongly correlated with brain Aβ plaques and predicted plaques in the entorhinal and primary visual cortices. Retinal $A\beta_{42}$ immunoreactive area significantly correlated with cerebral diffuse, immature, and mature plaques, as well as with NFTs and neurophil threads. Retinal $A\beta_{42}$ immunoreactive area predicted cognitive status (MMSE). Intracellular Aβ oligomer (AβO) burden in the innermost retinal layers of MCI and AD patients was 2-fold higher than CN, and strongly correlated with levels of $A\beta_{42}$ in the temporal hemiretina. Intriguingly, a strong

inverse correlation was found between retinal AβO burden and pre-mortem cognitive performance. Increasing retinal Aβ burden was tightly associated with gliosis, including reactive astrocytes and activated microglia. The greatest observed change was in astrogliosis in far peripheral regions with a 3.3-fold change in AD compared to CN. Retinal astrocytosis tightly associated with retinal $A\beta_{42}$ and predicted cognitive loss**.** Müller glias were also activated by 1.7-fold in AD retina compared to CN. Studying retinal vascular cell integrity showed that retinal pericyte loss inversely correlated with brain CAA. Our findings suggest that early and progressive accumulation of retinal Aβ and retinal inflammation such as astrocytosis are tightly associated with brain pathology in MCI and AD patients. These studies support non-invasive retinal imaging as a biomarker for early detection and monitoring of AD.

Title: Dynamic bayesian model to study the sequential belief updates in early Alzheimer's disease

Authors: *Q. LIU[1], H. WU[2], D. PUNIA[3], X. ARAKAKI[3], A. N. FONTEH[3], M. G. HARRINGTON[3];
[1]Caltech, Pasadena, CA; [2]Inst. of Psychology Chinese Acad. of Sci., Beijing City, China; [3]Huntington Med. Res. Inst., Pasadena, CA

Abstract: Introduction Participants respond more rapidly and accurately to a stimulus if it reinforces a local pattern in stimulus history. A Bayesian perspective provides optimal prediction for control processes, to reveal hidden neurocomputational processes. Here, we used a Go-nogo-rarego paradigm to study cognitive processes of elderly participants for probability prediction, probability updates, and proactive control in early Alzheimer's disease (AD) pathology. **Experiment Participants:** 52 elderly participants diagnosed as cognitive healthy with the Uniform Data Set (UDS-3) assessment, and sub-classified into two CSF biochemical groups: normal amyloid/tau (NAT), or pathological amyloid/tau (PAT) ratios. **Task:** Go-Nogo-rarego task contains 60% ‘go’ trials, 20% ‘rarego’ and 20% ‘nogo’ trials. In each trial, a cue is

presented for 400ms, and fixation for 1000ms. Participants respond to ‘go’ and ‘rarego’ cues as quickly as possible, while withholding responses to ‘nogo’ cues. No feedback is provided. EEG was collected using the DSI-24 dry electrode EEG.

Method

Model: We propose a three-category Dynamic Bayesian Model (DBM) for a standard go-nogo-rarego task (Fig1A). We use Dirichlet distribution for the prior belief. We update the belief distribution from trial t-1 to trial t, $P=\alpha*P(\boldsymbol{\lambda};;;^{i}_{t-1}=\boldsymbol{\lambda};;;^{i}|x_{t-1})+(1-\alpha)*P_0(\boldsymbol{\lambda};;;^{i})$ The Bayesian estimate of probability is a categorical process. After evidence is presented, prediction error (PE) can be computed, and posterior belief distribution in trial t is updated. We fit behavioral data to estimate model parameters. **Results** CSF amyloid positively correlated with accuracy (for go, r=0.41, p<0.01; for rarego, r=0.27, p<0.05), and negatively correlated with RT (for go, r=-0.29, p<0.05). Tau did not correlate significantly with accuracy or RT, but correlated with the model parameter α (r=0.34, p<0.05), Fig B-C. The nogo ERP (N400) significantly differed between PAT and NAT (FigD-E).

Conclusion: Neural activity and the DBM parameter α predict early AD pathology (PAT).

Title: μ Opioid receptor agonism, not antagonism, for the treatment of L-DOPA-induced dyskinesia in Parkinson’s disease

Authors: *E. Y. PIOLI[1], Q. LI[1], H. HULME[2], E. FRIDJONSDOTTIR[2], A. NILSSON[2], P. ANDREN[2], A. CROSSMAN[1], E. BEZARD[3];

Abstract: Parkinson’s disease (PD) is characterized by severe locomotor deficits and is commonly treated with the dopamine (DA) precursor L-DOPA, but its prolonged usage causes dyskinesias referred to as L-DOPA induced dyskinesia (LID). Several studies in animal models of PD have suggested that dyskinesias are associated with a heightened opioid co-transmitters tone, observations that have led to the notion of a LID-related hyperactive opioid transmission that should be corrected by μ opioid receptor antagonists. Reports that both antagonists and agonist of μ opioid receptor may alleviate LID severity in primate models of PD and LID associated to the failure of non-specific antagonist in pilot clinical trials to improve LID in patients raised concerns about the reliability of the available data on the opioid system in PD and LID. After in vitro characterization of the functional activity upon μ opioid receptor, we selected prototypical agonist, antagonist and partial agonist at μ opioid receptor. We then show that both oral and discrete intracerebral administration of a μ receptor agonist, but not of an antagonist as long thought, ameliorate LIDs in the gold-standard bilateral MPTP-lesioned macaque model of PD and LID, calling for a re-appraisal of the opioid pharmacology as well as for the development of brain nucleus-targeted μ opioid agonists.

Title: Beta-synuclein as treatment for Parkinson's disease in *drosophila*

Authors: *G. D. PAUL[1], D. FLORES[2], M. CUNNINGHAM[2], S. KHOO[2];
[1]Cell and Mol. Biol. and Biomed. Sci., [2]Cell and Mol. Biol., Grand Valley State Univ., Grand Rapids, MI

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder that impacts 1-2% of the elderly population. PD is characterized by the loss of midbrain dopaminergic neurons, leading primarily to motor impairment with the four cardinal signs being rigidity, tremors, postural instability, and bradykinesia. Another hallmark of PD is alpha-synuclein (aSyn) protein aggregates, also known as Lewy bodies. Lewy bodies can be targeted by beta-synuclein (bSyn), a protein homolog of aSyn that has been shown to reduce aSyn aggregation in SH-SY5Y cell lines and mouse models. In *Drosophila melanogaster*, aSyn can be expressed within its central nervous system (CNS) by inserting human aSyn gene into its 3rd chromosome. In this study, aSyn transgenic flies are fed bSyn peptide in a dose dependent, controlled environment to determine the effects of bSyn on PD symptoms. Assessment of motor function will be evaluated by locomotion assays while Lewy bodies inhibition will be observed using immunofluorescence microscopy within the flies CNS. The use of bSyn to treat motor impairment and protein aggregation in fly can potentially lead to more effective and noninvasive treatments for patients with PD.

Title: Single intrathecal administration of Resiniferatoxin, TRPV1 agonist, rescue motor deficits in AAV-A53T-induced mouse model of Parkinson's disease

Authors: A. NAHAMA[1], R. RAMACHANDRAN[1], J. TOIVANEN[2], T. BRAGGE[2], J. RYTKÖNEN[2], A. SUHONEN[2], ***T. T. AHTONIEMI**[2], D. MISZCZUK[2];
[1]Sorrento Therapeut., San Diego, CA; [2]Charles River Discovery, Kuopio, Finland

Abstract: Transient receptor potential vanilloid 1 (TRPV1) activity in the brain plays a role in regulating glial activation resulting in the modulation of neuronal function such as control of motor behavior. Evaluation of post-mortem brain samples of PD patients and animal models has revealed astrocytic TRPV1 overexpression in substantia nigra (SNc). Moreover, TRPV1 activation by systemic administration of its agonist, capsaicin, protects nigrostriatal dopaminergic neurons via inhibition of glial activation-mediated oxidative stress and neuroinflammation in the MPTP and AAV-A53T human α-synuclein mouse model of PD (Chung et al., 2017, Nam et al., 2015).
We have assessed the efficacy of resiniferatoxin (RTX), an ultrapotent agonist of TRPV1, in AAV-A53T mouse model of PD. C57Bl/6J mice (n=110) were unilaterally infused with AAV-A53T or AAV-Null vector (5.1x1012vg/mL) into the SNc. Following AAV infusion, the mice were treated with a single intrathecal infusion of RTX (0.04 or 0.125 µg/mouse) at week 1 and week 2. At 7 weeks post AAV infusion, motor functions and gait were assessed using fine motor kinematic gait analysis system. Two principal component analysis (PCA) based overall scores were assessed - one focusing on gait changes manifested bilaterally and the other with emphasis to unilateral changes, i.e. left-right asymmetry of gait. Eight weeks after AAV infusion, dopamine and its metabolites levels were analyzed from ipsilateral and contralateral striata by HPLC.
As expected, AAV-A53T infusion significantly impaired the motor performance and gait accompanied by depletion of ipsilateral striatal dopamine and its metabolites levels as compared to contralateral striatum and AAV-Null treated group. No adverse effects, including no significant effect on body weight, were observed at any of the used RTX doses or dosing paradigm. Intrathecal administration of RTX at low and high dose at wk 1, but not at wk 2 after AAV-A53T infusion, significantly improved the motor function and the unilaterally differential overall gait score (gait asymmetries recovered in both low and high RTX dosed groups), and in bilateral overall score in high dose RTX group. However, RTX treatment did not have a significant rescuing effect against dopamine degradation in striatum.
The findings demonstrated efficacy of intrathecal administration of RTX at the early intervention paradigm to rescue motor deficits in AAV-A53T model. The lack of effect on dopamine levels suggest that behavioral recovery is driven by mechanisms other than direct protection of nigrostriatal dopaminergic neurons, including modulation of neuroinflammation and/or analgesic effect of RTX after IT delivery.

Title: Combined anti-alpha-synuclein therapy for disease modification in multiple system atrophy

Authors: *M. LEMOS[1], V. REFOLO[1], D. WECKBECKER[2], A. HERAS-GARVIN[1], P. GRUBER[3], G. STAFFLER[3], C. GRIESINGER[4], A. GIESE[5], G. K. WENNING[1], N. STEFANOVA[1];
[1]Neurol., Med. Univ. of Innsbruck, Innsbruck, Austria; [2]MODAG GmbH, Wendelsheim, Germany; [3]AFFiRiS AG, Vienna, Austria; [4]Max Planck Inst. for Biophysical Chem., Göttingen, Germany; [5]Ludwig-Maximilians-Universität, Munich, Germany

Abstract: Multiple system atrophy (MSA) is an adult-onset neurodegenerative disorder, clinically characterized by a highly variable combination of Parkinsonism, cerebellar ataxia and autonomic failure. The presence of aggregated α-Synuclein (α-Syn) within oligodendrocytes forming glial cytoplasmic inclusions (GCIs) is considered the main pathological hallmark, thus leading to glial and neuronal dysfunction and neurodegeneration. At present, there is no effective disease-modifying therapy. Previous studies reported that the active immunization with short immunogenic peptides (AFFITOPEs), targeting toxic forms of α-Syn, improved motor impairment and reduced α-Syn oligomer levels and microglial activation in a mouse model of MSA. Also, previous experiments showed that the aggregation inhibitor, Anle138b, reduced neurodegeneration and behavioural deficits in mouse models of α-Synucleinopathy and other proteinopathies.
Transgenic mice overexpressing α-Syn in oligodendrocytes under the proteolipid protein promoter (PLP-α-Syn mice), received either AFFITOPEs or Anle138b. Both approaches were also tested in a combined therapy to evaluate if a synergistic effect is able to potentiate the effects of the single therapy. Motor behavior was assessed. Brains and plasma samples were collected for neuropathological and immunological analysis.
We confirmed the efficacy of the single therapy with AFFITOPEs or Anle138b, observing motor improvement, a significant reduction in α-Syn oligomers and GCI density, and preservation of dopaminergic neurons. The combination of Anle138b+AFFITOPEs was also beneficial showing reduced motor deficits, preservation of dopaminergic neurons, decrease of GCI density and microglia activation in the substantia nigra of treated PLP-a-Syn mice, without further cumulative effect.

We conclude that both approaches show beneficial effects ameliorating the α-Syn pathology in MSA transgenic mice. Simultaneous application of Anle138b and AFFITOPEs in PLP-α-Syn mice do not potentiate the effects of single drug therapy.

Title: Targeting alpha synuclein and amyloid beta proteins by a multifunctional brain penetrant dopamine agonist D520: Potential therapeutic application in Parkinson's disease with dementia

Authors: *A. K. DUTTA[1], D. YEDLAPUDI[1], D. LUO[1], G. JOSHI[2], L. XU[1], G. MARSH[2], S. V. TODI[2];
[1]Pharmaceut. Sci., [2]Pharmacology/Neurology, Wayne State Univ., Detroit, MI

Abstract: A significant number of people with Parkinson’s disease (PD) develop dementia in addition to cognitive dysfunction and is diagnosed as PD with dementia (PDD). This is characterized by cortical and limbic alpha synuclein (α-syn) accumulation; and high levels of diffuse amyloid beta (Aβ) plaques in the striatum and neocortical areas. In this regard, we have evaluated the effect of a brain penetrant novel multifunctional potent dopamine D2/D3 agonist, D-520 on the inhibition of Aβ and α-syn aggregation as well as on disintegration of α -syn and Aβ aggregates in vitro using purified proteins. In a cell culture model with human neuroblastoma MC65 cell lines which produce intracelluar Aβ induced toxicity, D-520 was evaluated to observe its effect on Aβ aggregation and Aβ induced toxicity. We further evaluated the effect of D-520 in *in vivo Drosophila* models of synucleinopathies and $A\beta_{1-42}$ dependent toxicity. We report that D-520 inhibits the formation of α-syn and Aβ aggregates *in vitro* and promotes disaggregation of

both α -syn and Aβ aggregates. In the cell culture model with MC65 cells, D-520 was shown to reduce both Aβ aggregates and Aβ induced toxicity to rescue the cells. Finally, in *in vivo Dorosophila* models, D-520 exhibited efficacy by rescuing fly eyes from retinal degeneration caused either by α-syn or Aβ toxicity. Our current experimental data indicates the potential therapeutic applicability of D-520 in addressing motor dysfunction and neuroprotection in PD and PDD, as well as attenuating dementia in people with PDD. Title: Investigation of neuroinflammation in the brain of Parkinsonian monkeys with and without L-DOPA treatment and dyskinesias

Authors: M. MORISSETTE[1], L. GRÉGOIRE[1], N. MORIN[1], ***T. DIPAOLO**[1,2]; [1]Neurosciences, Ctr. de Recherche du CHU de Québec (CHUL), Quebec, QC, Canada; [2]Faculté de Pharmacie, Univ. Laval, Québec, QC, Canada

Abstract: Inflammation is documented to play a major role in the degeneration of dopamine neurons in Parkinson’s disease (PD). Proinflammatory markers, such as activated microglia, were found in the brains of PD patients and their presence correlates with damage to dopamine neurons in the nigrostriatal pathway. While neuroinflammatory responses seem to be associated with L-Dopa treatment, it is still unclear whether they are dependent from the dyskinetic outcome of the L-Dopa treatment and are causally linked to L-Dopa-induced dyskinesias (LID). We thus investigated the striatal inflammatory response and development of LID in MPTP-lesioned monkeys. Monkeys received MPTP and after stabilization of their motor behavior (6.6 months) they received for one-month daily L-DOPA inducing dyskinesias as compared to MPTP monkeys that received L-Dopa and MPEP (a metabotropic glutamate receptor negative allosteric modulator) that developed less dyskinesias as well as compared to intact controls and vehicle treated MPTP monkeys. Monkeys were euthanized 24h after their last L-Dopa treatment to study the brain long-term changes associated with L-Dopa and dyskinesias. We analyzed striatal changes by Western blot of the pan-macrophage/microglia marker Iba-1 and the astroglial protein GFAP as markers of neuroinflammatory response. Iba1 contents decreased in the caudate

nucleus of vehicle-treated MPTP monkeys. The L-Dopa treated dyskinetic MPTP monkeys had caudate nucleus Iba1 content not different from controls or MPTP-vehicle treated monkeys whereas MPTP monkeys that received L-Dopa + MPEP has decreased Iba1 content similar to untreated MPTP monkeys. In the putamen, Iba1 content was unchanged in vehicle-treated MPTP monkeys as well as MPTP monkeys treated with L-Dopa + MPEP whereas MPTP+ L-Dopa treated monkeys has elevated Iba1 contents. GFAP contents in the caudate nucleus were unchanged by the MPTP lesion and were elevated in MPTP + L-Dopa treated monkeys with or without MPEP treatment. In the putamen, GFAP content was elevated in all MPTP monkeys and this increase was larger in MPTP + L-Dopa treated monkeys. The present results showed a different effect of the MPTP lesion on GFAP and Iba1 in the caudate nucleus compared to the putamen; the latter region is associated with motor control. Moreover, we measured a greater increase of GFAP and Iba1 levels in the putamen of the MPTP + L-Dopa dyskinetic monkeys compared to the MPTP monkeys treated with L-Dopa + MPEP with less dyskinesias. In conclusion, these results showed an increase of inflammatory markers in the putamen associated with LID and that MPEP inhibition of glutamate activity reduced LID and levels of inflammatory markers.

Title: DT095435: A novel “pan” group III metabotropic glutamate receptor positive allosteric modulator for Parkinson’s disease

Authors: ***M. FRAULI**[1], A. BARRE[1], S. MAYER[1], A. COURTIN[1], L. DESHONS[1], M. HEYER[1], C. FRANCHET[1], M. BOURQUE[2], T. DI PAOLO[2], S. SCHANN[1];
[1]Domain Therapeut., Strasbourg, France; [2]Axe Neurosciences, Ctr. de Recherche du CHU de Québec-Université Laval and Faculté de Pharmacie, Univ. Laval, Laval, QC, Canada

Abstract: Most common medication for Parkinson's disease is L-DOPA. Effective early on, this treatment requires increasing doses that induce, in long term, abnormal and involuntary movements called dyskinesias. Amantadine (ionotropic glutamatergic receptor antagonist) is the only drug approved to treat dyskinesias; however, it has significant side effects and loses effectiveness after one year. Research is now turning to metabotropic glutamatergic receptors (mGluRs), which offer an alternative target for normalizing glutamatergic activity in Parkinson's disease.
High concentrations of neurotransmitters in some strategic basal ganglia synapses are involved in

the development of L-DOPA-induced dyskinesias (LID). The mGlu4 receptors are located pre-synaptically at these synapses, and their activation reduces neurotransmitter release. This explains the recently described anti-dyskinetic activity of Foliglurax, a selective mGluR4 Positive Allosteric Modulator (PAM), in a non-human primate model. Foliglurax is currently evaluated in Phase II clinical trials for its potential to reduce motor complications of L-DOPA therapy in Parkinson's patients.

During the optimization that led to the identification of Foliglurax, a new quinazolinone (QZ) series of PAMs was discovered. QZ compounds are “pan” group III mGluR PAMs, meaning that they do not only present single digit nanomolar PAM activity on mGluR4, but also comparable activities on other group III mGluRs (6, 7 and 8). Interestingly, the mGlu7 and mGlu8 receptors are also expressed at basal ganglia strategic synapses, suggesting that synergistic activation of mGluR4, 7 and 8 may provide better control of dyskinesias.

We present here PK data of our mGluR4/7/8 PAM candidate DT095435 in mouse, rat and monkey after oral administration at 10 mg/kg. Free brain concentrations ranged between 30 and 55 ng/mL in the different species: when compared to corresponding in vitro potency in calcium functional assay, this insured EC_{50} coverage of 0.5 to 0.9, thereby suggesting strong target engagement.

We also present *in vivo* evaluation of DT095435 in package of gold-standard PD models in mouse, rat and monkey. As expected from its PK profile, our candidate exhibited robust pro-motor activity after oral administration and remained active at dose as low as 0.1 mg/kg in mouse haldol-induced catalepsy model. Using two more advanced PD models, i.e. unilateral 6-OHDA lesioned rats & monkeys lesioned with MPTP toxin (both rendered dyskinetic by prolonged L-DOPA treatment), we have also compared efficacy of our non-selective mGluR4/7/8 PAM QZ candidate with that of selective mGluR4 PAM Foliglurax and/or amantadine in reducing LID.

Abstract: Objective The purpose of the present study was to evaluate the toxicity of SiO2/DA loaded hydrogel, before been implanted in the brain (caudate) of rat in an induced hemiparkinsonism model. It is work mentioning that SiO2 with dopamine (SiO2/DA) hydrogel has achieved to reduce the dopamine oxidation and it allows its release in tissue through the nanopores that has. Results Significant dopamine depletion in the caudate ipsilateral to the side of infused with 6-hydroxydopamine (6-OHDA) in the substatia nigra. These animals displayed apomorphine-induced contralateral rotational behavior, when examined on the 21th day and attenuate motor abnormalities in 6-OH/DA model of hemiparkinsonism was observed after 7th days SiO2/DA implantation. Histological examination showed a hydrogel encapsulated without evidence of the inflammatory response of surrounding tissues caused by the foreign body and surrounding tissue remained well vascularized after implant. Conclusions The results of this acute analysis suggest that attenuate motor abnormalities in 6-OH/DA model of hemiparkinsonism, there is no contamination across the organs due to the implants. So, It has justified more investigations about it's the potential use of hydrogel as biomaterial for storing and releasing drugs.

Abstract: L-DOPA therapy represents the gold-standard for Parkinson's Disease (PD). However, long-term administration results in treatment-related motor complications named L-DOPA-induced dyskinesia (LID). The pathophysiology of LID involves both classical neuronal mechanisms, as altered glutamatergic transmission and synaptic plasticity in the basal ganglia, and unconventional non-neuronal mechanisms. Indeed, preclinical studies have suggested a role of microglia-mediated neuroinflammatory responses and aberrant angiogenic processes in the development of dyskinetic movements. Among inflammatory mediators, TNF-α is a pro-inflammatory cytokine which affects recognized components of dyskinesia pathophysiology, such as angiogenesis and synaptic plasticity. Thalidomide and related analogues have immunomodulatory and antiangiogenic properties by inhibiting TNF-α; they are used clinically for inflammatory diseases and cancer and they are under investigation for neurological disorders. To test the efficacy of thalidomide and the more potent derivative 3,6'-dithiothalidomide on attenuating dyskinesia, rats were stereotaxically infused in the medial forebrain bundle with 6-OHDA and after 3 weeks they received 10 days treatment with L-DOPA plus benserazide (6 mg/kg each) and thalidomide (70 mg/kg) or 3,6'-dithiothalidomide (56 mg/kg). Dyskinesia as well as contralateral turning were recorded daily. Rats were euthanized 1 hr after the last L-DOPA injection, and levels of TNF-α, IL-10, OX-42 and vimentin immunoreactivity were measured in their striatum and substantia nigra reticulata (SNr) to evaluate neuroinflammation and angiogenesis. Striatal levels of GLUR1 were measured as a TNF-α-mediated postsynaptic dysfunction. Thalidomide and 3,6-dithiothalidomide significantly reduced the severity of LID while not affecting contralateral turning. Furthermore, both compounds inhibited the L-DOPA induced microgliosis and excessive TNF-α, while restoring physiological levels of the anti-inflammatory cytokine IL-10 in the striatum and SNr. L-DOPA-induced angiogenesis was inhibited in both basal ganglia nuclei, and L-DOPA-induced GLUR1 overexpression in the dorsolateral striatum was restored to normal levels. Our findings suggest that decreasing TNF-α levels may be a valuable strategy to reduce dyskinesia severity, and thalidomide and more potent derivatives might provide an effective therapeutic approach to dyskinesia.

Title: RGS4 inhibition potentiates the antidyskinetic effect of NOP receptor agonist AT-403

Authors: *C. A. PISANÒ[1], D. MERCATELLI[2], I. MORELLA[3], J. LEIPPRANDT[4], S. FASANO[3], K. BEHIRDA[4], N. T. ZAVERI[6], R. BRAMBILLA[3], R. R. NEUBIG[5], M. MORARI[7];

Abstract: L-dopa-induced dyskinesia (LID) is the most disabling side effect of dopamine replacement therapy for Parkinson’s disease. We previously reported that the nociceptin/orphanin FQ opioid peptide (NOP) receptor agonist AT-403 reduced LID expression without causing sedation in a narrow dose-range(1) We therefore investigated whether pharmacological inhibition of Regulators of G protein Signaling (RGS) type 4 (RGS4), an accessory protein that accelerates the extinction of signal mediated by GPCRs coupled to Gαi or Gαq, widens the therapeutic window of AT-403. Western blot analysis revealed a dramatic reduction of RGS4 protein levels in rats after 6-OHDA lesion and a normalization after chronic administration of L-dopa, both in the lesioned and unlesioned striatum (OFF L-dopa). Conversely, an increase of RGS4 was found in the lesioned compared to the unlesioned striatum ON L-dopa. To confirm an involvement of RGS4 in LID, the RGS4 inhibitor, CCG203920, alone and in combination with AT-403, was administered to L-dopa-primed 6-OHDA hemilesioned rats. AT-403 delayed the onset of axial, limb and orolingual abnormal involuntary movements (AIMs) (the rodent correlate of dyskinesia) without affecting maximal dyskinesia severity. CCG203920, ineffective alone, extended the anti-dyskinetic effect of AT-403, further delaying AIMs appearance by 20 min. To confirm that RGS4 blockade had an impact over biochemical pathways underlying LID, Western blot analysis revealed that the AT-403/CCG203920 combination normalized the striatal levels of phosphorylated ERK (pERK), a biochemical correlate of LID, whereas AT-403 and CCG203920 alone were ineffective. To confirm that RGS4 inhibition amplifies the negative modulation of D1 receptor signaling induced by NOP receptor stimulation, AT-403 attenuated the elevation of pERK-positive cell number induced by the D1 agonist SKF38393 in striatal slices of naïve mice, and CCG203920, ineffective alone, potentiated this effect. This study represents the first evidence of an interaction between RGS4 and the NOP receptor, and provides preliminary evidence of the potential of

RGS4 inhibitors to amplify the antidyskinetic effect of NOP receptor agonists. 1. Arcuri et al., Br J Pharmacol 175, 782-796 (2018)

Title: Evaluation of carnosine intervention in the Thy1-aSyn mouse model of Parkinson's disease

Authors: M.-L. BERMÚDEZ[1], ***K. B. SEROOGY**[2], M. B. GENTER[1];
[1]Envrn. Hlth., [2]Neurol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Parkinson’s disease (PD) is a leading neurodegenerative disease, with multifaceted interacting mechanisms. Although the etiology of PD remains unknown, two well-known hallmarks of PD are the presence of Lewy bodies containing protein aggregates composed primarily of alpha-synuclein (aSyn) in multiple brain regions, and loss of dopaminergic neurons in the substantia nigra, resulting in motor dysfunction. Because no treatments to date slow or halt the degeneration of nigral dopaminergic neurons and progression of the disease, new therapeutic approaches for PD are urgently needed. Thy1-aSyn mice exhibit many features of PD patients, including sensorimotor dysfunction and aSyn protein aggregation. We tested the hypothesis that the dipeptide carnosine (beta-alanyl-L-histidine), which has anti-aggregating and metal-chelating properties, would provide beneficial effects on the motor and olfactory deficits observed in Thy1-aSyn mice. Two-month-old Thy1-aSyn mice and wild-type BDF1 mice were assessed for baseline motor [challenging beam traversal (CBT) test and spontaneous activity] and olfactory (buried pellet test) function. After baseline behavioral testing, mice were randomly assigned to treatment groups and administered carnosine either intranasally (2 mg/d) or in drinking water (10 mM). After 2 months of daily treatment, mice were re-assessed in the behavioral tests, and the olfactory epithelium was evaluated immunohistochemically for aSyn and expression of the

carnosine transporter PEPT2. Olfactory function was unaffected by carnosine treatment via either administration route. Thy1-aSyn vehicle-treated mice and those receiving drinking water carnosine showed progressive motor deficits in the CBT test over the 2-month treatment period. In contrast, the number of errors per step in the CBT test did not increase in Thy1-aSyn mice receiving intranasal carnosine. Moreover, carnosine-treated Thy1-aSyn mice exhibited decreased aSyn immunostaining in the olfactory epithelium compared to vehicle-treated Thy1-aSyn mice. Furthermore, the carnosine transporter PEPT2 was immunolocalized to the apical surface of the olfactory epithelium. These findings demonstrate that intranasal carnosine shows promise in slowing the progression of motor deficits and aSyn deposition in PD.

Title: Exploiting functional selectivity of dopamine D_1 receptors as therapeutics for Parkinson's disease in mice

Authors: V. M. POGORELOV[1], C. RAY[2], M. L. MARTINI[3], R. CHANDRASEKHAR[2], N. M. URS[4], J. JIN[3], M. G. CARON[2], ***W. C. WETSEL**[1];

Abstract: L-DOPA is used as a common therapy for Parkinson's disease (PD); however, prolonged treatment is often accompanied by L-DOPA-induced dyskinesias (LIDs). L-DOPA is metabolized to dopamine (DA) which binds to the D_1 (D_1R) and D_2 receptors (D_2R) to activate signaling through G protein and β-arrestin (βARR) mediated mechanisms. Emerging evidence suggests that LIDs may be due to G protein-mediated signaling. We hypothesize that developing compounds that are functionally selective for DA receptors may be beneficial to prevent dyskinesias. DA transporter knockout mice were treated chronically with α-methyl-*p*-tyrosine to deplete tissue DA stores (DDD model), were administered L-DOPA plus benserazide (Benz) over 17 consecutive days, and were tested in the open field or a circular arena (20 cm in diameter). Locomotion decreased over time in both tests, while rearing and climbing increased only in the open field. Grooming stereotypies were enhanced more in the circular arena than open field ($P<0.001$), while oral stereotypy increased in both arenas. As a comparison, 6-

hydroxy DA (6-OHDA) lesioned mice were treated chronically with L-DOPA plus Benz and tested in the circular arena. Rotations and LIDs (oral and grooming stereotypies and postural dyskinesia) gradually increased across days. MLM 55-38 was tested with the full agonist SKF81297 as a control. Compared to DA, a Gs-mediated cAMP accumulation assay and a bioluminescence resonance energy transfer βARR assay revealed MLM 55-38 to be a balanced D_1R super-agonist for both G protein and βARR-mediated signaling. In the absence of L-DOPA there were no LIDs in DDD mice given MLM 55-38, whereas SKF 81297 increased face-washing. Compared to vehicle, L-DOPA plus Benz with MLM 55-38 increased rearing, climbing, and face-washing (P-values≤0.033); SKF 81297 augmented oral stereotypies ($P<0.022$). In 6-OHDA lesioned wild-type (WT) and βARR2 knockout mice in the absence of L-DOPA, MLM 55-38 and SKF 81297 facilitated rotations, stereotypies, and postural dyskinesias to a greater extent in mutants than WT controls (P-values≤0.013). However, when MLM 55-38 and SKF 81297 were given with L-DOPA plus Benz postural dyskinesia was more robust in the βARR2 KOs than WT mice ($P<0.001$). Together, these findings suggest that the circular maze may be more conducive to studying LIDs than the open field, the 6-OHDA model may be superior to the DDD model for screening these D_1R-biased compounds, and that D_1R βARR-biased compounds may reduce the incidences of LIDs while still promoting forward motor activity.

Title: A potent, highly selective and brain penetrant orphan receptor GPR6 inverse agonist as symptomatic treatment for Parkinson's disease

Authors: *N. KAUSHAL, J. RUSSO, Y. CHEN, N. ENGLISH, H. SUN, S. KIKUCHI, H. REICHARD, J. BROWN, M. HOPKINS, J. RAY, S. HITCHCOCK, H. H. SCHIFFER; Takeda California Inc, San Diego, CA

Abstract: Parkinson’s disease (PD) is a progressive neurodegenerative disorder caused by the gradual loss of dopaminergic neurons of the substantia nigra that regulate information flow from the striatum to regions of the brain that coordinate movement. The effects of nigrostriatal dopamine are mediated via the dopamine receptors D1 and D2, which are expressed on intermingled gabaergic medium spiny neurons (MSNs) and define two opposing brain circuits:

The D1-type MSN originate the direct (striatonigral) pathway which initiates motor activity. The D2-type MSN originate the indirect (striatopallidal) pathway that suppresses motor activity. Pathological hyperactivity of the indirect pathway has been observed in PD patients and dopamine-depleted animals, and contributes to rigidity and hypokinesia. Normalization of the indirect pathway activity and improvement of motoric function in PD can be achieved by deep brain stimulation of the subthalamic nucleus with bilateral surgically implanted electrodes. Therefore, novel non-dopaminergic therapies for treating the motor symptoms of PD targeting the indirect pathway might have therapeutic potential. We identified the orphan GPR6 as a gene highly expressed in striatal D2-type MSNs of the indirect pathway in rodents, NHP and brain specimens from patients with PD. GPR6 is an excitatory, Gαs-coupled receptor with high apparent constitutive activity in heterologous expression systems. High-through-put screens and *in vitro* SAR strategies identified a potent GPR6 inverse agonist (Compound 1), which showed high selectivity against GPR3, GPR12 and other off targets. Compound 1 reduced striatal DARPP-32 phosphorylation of Thr-34 in brain slices and demonstrated oral bioavailability and GPR6 receptor occupancy *in vivo*. Compound 1 stimulated open-field-activity in wild type rodents, reversed haloperidol-induced catalepsy and completely restored mobility in the bilateral 6-OHDA lesioned rat model of PD. In addition, compound 1 administered once daily for 22 days did not induce abnormal involuntary movements (AIMs), a rodent correlate of dyskinesia, in unilateral 6-OHDA-lesioned rat model of PD. Lipidomic profiling revealed that compound 1 increases sphingomyelin species in the striatum of wildtype mice, but not in GPR6 knock out mice. PD is frequently accompanied by depression. Compound 1 also demonstrated robust efficacy in reversing anhedonia in the unpredictable chronic mild stress (uCMS) model. The nonclinical data obtained from our *in vitro* and *in vivo* studies support the development of compound 1 for the symptomatic treatment of Parkinson's disease.

Abstract: Multiple system atrophy (MSA) is a rapidly progressing neurodegenerative disorder of aging with no effective treatments. MSA pathology is characterized by a toxic accumulation of α-synuclein (aSyn) protein inside oligodendroglia cells (OLGs), the myelinating cells of brain. Protection in MSA models is associated with glial-cell line-derived neurotrophic factor (GDNF) and brain-derived neurotrophic factor (BDNF), which are abnormally expressed in brains of MSA patients and in MSA mice. We previously tested FTY720 in parkinsonian mice and MSA cell models, and found increased BDNF expression. Here we preclinically tested our mitochondria-localizing FTY720-analogue FTY720-Mitoxy, in mice that express aSyn in OLGs under control of the 2,' 3'-cyclic nucleotide 3'-phosphodiesterase (CNP) promoter. Nonimmunosuppressive FTY720-Mitoxy reversed motor impairment, increased soleus muscle size, and improved sweat function in MSA mice. Co-treating 9 mo old MSA mice with FTY720-Mitoxy, protected their motor function and succinate dehydrogenase activity against 3-nitropropionic acid (3NP) in mitochondria isolated from cerebellum, a brain area that regulates movement. FTY720-Mitoxy also reduced levels of stress associated HSP60 and mitochondrial fission factor (MFF) in soleus muscle against 3NP toxicity. Furthermore, FTY720-Mitoxy increased GDNF mRNA and protein levels in frontal hemicortex, an increase that paralleled the downregulation of mir-96-5p, a microRNA that reduces GDNF expression. Moreover, FTY720-Mitoxy reduced pathological aSyn aggregation in spinal cord and cerebellar white matter microglial activation as measured by Ionized-calcium-Binding-Adaptor-molecule1 (Iba1) immunoblot. Thus, FTY720-Mitoxy is a promising nonimmunosuppressive potential therapeutic with the capacity to slow or reverse both pathology and functional impairments of MSA.

Title: Effects of nociceptin/orphanin FQ (NOP) receptor antagonism with BTRX-246040 in animal models of Parkinson's disease

Authors: *T. L. WALLACE[1], E. BEZARD[2,3], E. PIOLI[3], W. J. MARTIN[1];
[1]Blackthorn Therapeut., San Francisco, CA; [2]Inst. of Neurodegenerative Dis., Bordeaux, France; [3]Motac Neurosci., Manchester, United Kingdom

Abstract: Pharmacological treatments for Parkinson’s disease (PD) aim to replace dopamine (DA) or to directly activate DA receptors to improve motor symptoms of the disease, but most have dose-limiting side effects that develop after chronic treatment, and do not improve the non-motor symptoms of PD. The nociceptin/orphanin FQ (NOP) system, which is involved in mood, stress, movement and other functions has revealed a link with PD in both preclinical and clinical studies. To further characterize the involvement of the NOP system in preclinical models of PD, we tested BTRX-246040, a selective NOP receptor antagonist, in a series of studies to evaluate its anti-PD and disease modifying effects. In the first studies, we used the MPTP-treated macaque model of PD. Following acute administration, BTRX-246040 (0.1, 0.3, 1.0 mg/kg, i.m.) elicited a robust anti-PD effect on motor symptoms, comparable to L-DOPA, but unlike L-DOPA, BTRX-246040 significantly reduced the level of dyskinesias in primed NHPs. Subsequently, we conducted two additional studies in the MPTP NHP model of PD to evaluate: 1) the L-DOPA sparing effects of BTRX-246040; and, 2) the impact of chronic administration of BTRX-246040. In both studies, the main findings indicate the compound was well-tolerated, but the anti-PD effects were non-significant despite expected pharmacokinetic properties of the compound. In a separate study designed to investigate the potential neuroprotective and disease modifying effects of BTRX-246040 and SB-61211 (comparator NOP receptor antagonist), we used the alpha-synuclein (α-syn) overexpression rat model, which caused a 23% depletion of the striatal DA level and degeneration of 48% of DAergic neurons in the substantia nigra (SN). BTRX-246040, SB-612111 and vehicle were administered subcutaneously twice daily for 7 weeks and started on day 7 after α-syn overexpression. The results of this study showed SB-612111, but not BTRX-246040, increased the number of TH-positive neurons in the SN. Both drugs had a positive effect on locomotor activity and interfered with synuclein levels suggesting disease-modifying activity. SB-612111 demonstrated neuroprotective properties while BTRX-246040 did not match this effect but displayed an intermediate profile between the vehicle and

the SB-612111 group. Collectively, these data suggest NOP receptor antagonism exhibits beneficial effects on motor symptoms and disease modifying properties in preclinical PD models, but further exploration is warranted to gain confidence around the therapeutic potential of this approach for the treatment of PD.

Title: A metabolically stable PACAP analog with PAC1/VPAC2 receptor selectivity crosses the blood-brain barrier and protects dopaminergic neurons in the substantia nigra of MPTP-treated mice

Authors: *I. J. MERCHENTHALER[1], M. LANE[1], B. DUDAS[2], W. BANKS[3];
[1]Epidemiology and Publ. Hlth., Univ. of Maryland Baltimore, Baltimore, MD;
[2]Neuroendocrinology, Lake Erie Osteo. Med., Erie, PA; [3]Intrnl. Med., Univ. of Washington, Seattle, WA

Abstract: PACAP is a promising molecule for the development of a therapeutic strategy to halt or slow the progression of Parkinson’s disease (PD) because it exhibits anti-apoptotic, anti-inflammatory, anti-oxidant, and cytoprotective activities. However, the short half-life of PACAP *in vivo* precludes its use as a pharmacological intervention in humans. PACAP is degraded by aminodipeptidases, especially dipeptidyl peptidase IV (DPP IV). Only peptides with a free amino group at the N-terminus are substrates for DPP IV, and acetylation of the N-terminus blocks also blocks degradation. The analog studied in these experiments, i.e., [Iaa[1],D-Ser[2]]PACAP38, is acetylated in the N-terminus and L-Ser in position 2 was replaced with D-Ser to further improve the peptide’s resistance to proteolysis. Although, PACAP has been shown to provide

neuroprotection in preclinical models of several neurodegenerative and autoimmune diseases and in humans, it has been administered intraperitoneally (ip) or intravenously (iv) and only occasionally subcutaneously (sc). However, chronic treatment of animals or humans ip or iv is not practical. In these experiments, we tested if a metabolically stable PACAP analog with PAC1/VPAC2 receptor activities, similarly to the native peptide, crosses the blood-brain barrier (BBB) and will protect substantia nigra pars compacta (SNpc) dopaminergic (DA) neurons in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated mice. The analog was administered by daily sc or ip injections or via sc-implanted Alzet pumps delivering 5 ug/mouse analog daily for 9 days. The effect of neuroprotection on the SNpc DA-ergic neuronal system and DA-ergic nerve terminals in the striatum was evaluated with immunoctochemistry. These studies were performed in male mice only as the frequency of PD is higher in men than women. For the BBB penetration studies, performed in the Banks lab, multiple-time regression analysis, the same methodology used to elucidate BBB/endogenous PACAP interactions was utilized. Brain/serum ratios in units of ul/g were determined with the equation: Brain/serum ratio (ul/g) = (cpm/whole brain)/[(wt in g of whole brain)(cpm/ul of arterial serum)]. The analog penetrated the BBB via a saturable transport mechanism. The unidirectional influx rate was 2.5 microliters/g-min and the r value was 0.954 ($p<0.00001$). The immunocytochemical analysis, performed in the Merchenthaler lab, using antibodies against tyrosine hydroxylase showed that the PACAP analog provided protection in the DA-ergic system (SNpc and striatum) independent of the route of administration.

Title: A LRRK2 kinase inhibitor, PFE360, reduces behavioural and striatal dopaminergic deficits in a rat model of Parkinson’s disease alpha-synucleinopathy

Authors: *J. B. KOPRICH[1], S. JAFRI[1], V. OMANA[1], T. H. JOHNSTON[1], M. P. HILL[1], T. PARKKARI[2], N. MOORE[3], M. A. BAPTISTA[4], J. M. BROTCHIE[1];

Abstract: Mutations in the Leucine-rich repeat kinase 2 (LRRK2) gene, are one of the most common genetic contributors to Parkinson’s disease (PD). The clinical and pathological features

of carriers of LRRK2 mutations overlap with those with sporadic PD and links to alpha-synuclein and LRRK2 biology continue to emerge. Given these considerable convergences, LRRK2 inhibitors are actively being pursued in drug development programs targeting PD widely. As PD is an alpha-synucleinopathy, it is important to evaluate LRRK2 kinase inhibition in animal models of PD based on deficits and pathology driven by alpha-synuclein (aSyn) expression. To this end, we have evaluated the prototypical LRRK2 kinase inhibitor, PFE360, in an AAV1/2-human A53T-aSyn (AAV1/2-hA53T-aSyn) rat model of PD. Three groups of 10 female rats were prepared: AAV1/2-empty vector (EV)/ vehicle, AAV1/2-hA53T-aSyn/ vehicle and AAV1/2-hA53T-aSyn/ PFE360. Rats received once daily administration of PFE360 (15 mg/kg, p.o.) or vehicle commencing one day after AAV1/2 delivery to the right substantia nigra [SN], i.e. on day 1 (D1) through to D43 (day of necropsy). Behaviour was assessed, off treatment, using the cylinder test on D21 and D42. Post-mortem, striatal dopamine, dopamine transporter (DAT) and SN dopamine neuron number, defined as tyrosine hydroxylase-positive (TH+ve) cells, were assessed.AAV1/2-hA53T-aSyn/ vehicle-treated animals showed significant forelimb asymmetry on D21 and D42, 35% and 36% increase from control respectively (both $P<0.05$). PFE360-treatment reduced forelimb asymmetry to a 17% and 1% increase from control on D21 and D42 respectively (both $P>0.05$). AAV1/2-hA53T-aSyn produced 44% and 47% reduction in striatal dopamine and DAT levels respectively, compared to control (both $P<0.05$). In contrast, in PFE360 treated rats, no significant deficits were observed in dopamine and DAT (both $P>0.05$). However, there was no effect of treatment with PFE360 on the number of TH+ve remaining in the SN ($P>0.05$). These results suggest an ability of LRRK2 inhibition to protect against at least some of the dopaminergic deficits induced by synucleinopathy and support the continued development of LRRK2 kinase inhibitors for the treatment of PD. Ongoing studies are focussed on determining levels of target engagement required for efficacy.

Title: Preclinical pharmacology of IRL752, a novel compound to treat postural instability and cognitive deficits in Parkinson's disease

Authors: S. WATERS[1,2], C. SONESSON[1], N. WATERS[1], J. TEDROFF[1,3], P. SVENSSON[1], *S. HJORTH[4];
[1]Integrative Res. Labs. AB, Gothenburg, Sweden; [2]Sahlgrenska Univ. Hosp., Gothenburg, Sweden; [3]Clin. Neurosci., Karolinska Inst., Stockholm, Sweden; [4]Pharmacilitator AB (Inc.), Vallda, Sweden

Abstract: In Parkinson's disease (PD) impaired cortical monoamine transmission is a core feature associated with progressive cognitive decline, and certain motor traits. In particular axial motor symptoms, relating to postural instability (balance) and falls, are strongly related to cognitive deficits in PD. This symptom cluster responds poorly to current anti-Parkinson treatment. Novel treatments addressing cognition and postural instability is thus a high priority area in PD.
IRL752 was discovered using phenotypic screening, based on broad data arrays generated *in vivo* (gene expression, monoamine biomarkers, behavioural studies in rats). Effects on extracellular levels of monoamine transmitters were assessed by *in vivo* brain microdialysis. The *in vivo* profile was compared to a comprehensive in-house database of CNS active compounds. Upon oral or parenteral dosing, at 3-100 micromoles/kg IRL752 displays a novel profile, with regio-selective enhancement of cortical DA and NE, along with increased cortical ACh. IRL752 induces IEGs related to neuronal activity, including *Arc, NPTX, NPAS4,* and *c-fos* in the frontal cortex, limbic and striatal areas. The effect on cortical *IEGs* is interpreted as enhanced synaptic activity. The increase of subcortical *IEGs* is presumably related to activation of cortico-striatal pathways. The *IEG* expression profile induced by IRL752 shares features with that induced by cognitive enhancers such as memantine.
IRL752 does not affect motor activity patterns in normal rats or in rats under the influence of psychostimulants, but partly attenuates Mk-801 induced hyperactivity. Thus, behavioural studies may suggest potential efficacy in psychiatric domains. IRL752 reverses tetrabenazine induced hypomotility, indicating efficacy in conditions with impaired catecholamine transmission, and hence, potential to improve motor function in PD. IRL752 also reverses deficits in novel object recognition (NOR) suggesting potential to enhance short-term memory. Main receptor targets and synergies involved in the effects of IRL752 are 5-HT7, alpha-2C and Sigma-1.
In conclusion, the preclinical profile supports a potential use for treatment of cognitive and axial

motor deficits in PD. IRL752 has been explored in Phase I and IIa clinical trials. Data indicates that it is safe and well tolerated in healthy volunteers as well as in patients with PD, with indications of efficacy with respect to improved balance, reduced falls and signs of improved cognition, which will be further explored in Phase IIb trials.

Abstract: Bach1 [BTB (broad-complex, tramtrack and bric-a-brac) and CNC (cap'n'collar protein) homology 1] is transcription repressor that competes with Nrf2 in regulating antioxidant and cytoprotective cellular phenotypes. Mounting evidence accounts for Nrf2 to be a promising target for neuroprotective interventions in various neurodegenerative disease. However, canonical Nrf2 based drugs result in side-effects in part due to their electrophilic chemical properties that leads to irreversible alkylation of cysteine residues of cellular proteins. Genetic Bach1 ablation in experimental models has shown promising effects in neuroprotection studies. Nonetheless, the clinical application of Bach1 inhibition for neuroprotection is nonexistent due to lack of good pharmacological Bach1 inhibitors. Thus, we aimed to develop non-electrophilic Bach1 inhibitors and a screening method that can assist in discovering non-electrophilic Bach1 inhibitors. Using hemin, a physiological Bach1 inhibitor, as a prototype molecule few candidates were synthesized and selected. We validated the Bach1 inhibition in ARE-luciferase cell line in presence of mutated Bach1, followed by Chromatin immunoprecipitation (CHIP) and *in vitro* detection of ROS and glutathione (GSH) depletion. Bach1 inhibitor demonstrated significant MARE-luciferase activity in the presence of WT but not mutant Bach1, and CHIP binding characteristic to Bach1 inhibition, distinctive from canonical Nrf2 activators, with no cellular ROS generation and GSH depletion. We employed Mass spectrometry-based detection of Keap1 cysteine modification that revealed Bach1 inhibitor failed to modify Keap1 cysteine compared to a canonical Nrf2 activator. Parallelly, in a CRISPR/Cas9 mutated cell line carrying Keap1 cysteine 151 mutation, we established non-electrophilic properties of Bach1 inhibitor. In addition, we developed a screening assay employing Mass-spectrometric based Bach1 binding to discover novel molecules exhibiting select Bach1 binding/inhibition. Bach1 inhibitors showed neuroprotective effects in cellular and animal models of Parkinson’s disease. Taken together, our results unearth a successful pharmacological approach for Bach1 inhibition that is non-electrophilic and neuroprotective. Furthermore, we developed an efficient screening method that can be used to screen for novel Bach1 inhibitors.

Title: Neuroprotective effects of beta-caryophyllene in the striatal 6-OHDA mouse model of Parkinson's disease

Authors: *A. VALENTE-AMARAL, R. D. M. GOMES, V. S. L. CARDOSO, L. L. AMADO, E. T. COSTA, E. S. YAMADA;
Federal Univ. of Pará, Belém, Brazil

Abstract: Parkinson's disease (PD) is traditionally classified as a motor disorder characterized by resting tremor, muscular rigidity, postural instability and bradykinesia. These symptoms are caused by progressive loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) and consequently depletion of dopamine on striatum. The search for new therapeutical approaches that may delay or interrupt the neurodegeneration in PD is essential to promote a better quality of life for patients. Thus, beta-caryophyllene (BCP) is a promising dietary phytocannabinoid, because it is a selective and non-psychoactive agonist of type II cannabinoid receptors, with anti-inflammatory and antioxidant properties. Thereby, we investigated whether BCP has neuroprotective effects in a murine model of PD induced by 6-hydroxydopamine (6-OHDA). Forty male Swiss mice were divided in 4 groups: Vehicle/Vehicle (N = 7), Vehicle/BCP (N = 8), 6-OHDA/Vehicle (N = 12) and 6-OHDA/BCP (N = 13). Stereotaxic surgeries were performed in all animals to inject vehicle or 6-OHDA (10 µg) solution into the striatum, and BCP (50 mg/kg) was administrated for 7 days after stereotaxic surgeries. We performed behavioral tests such as apomorphine-induced rotation (2-4 weeks) and exploration in the open field (4 weeks). Immunostaining for tyrosine-hydroxylase (TH) and microglia/macrophages (IBA-1) were performed. In addition, we investigated quantitatively the degree of neurodegeneration and neuroinflammation through stereological estimations from neurons and microglial cells in the SNpc, respectively. For biochemical analyzes, we quantified the total antioxidant capacity against peroxyl radicals from striatum and midbrain. The apomorphine-induced rotation test showed that 6-OHDA/BCP group presented significant decrease of rotations compared to 6-OHDA/Vehicle group at 2 and 4 weeks. In the open field test, 6-OHDA/Vehicle group showed impairment in motor behavior with reduced distance travelled, low velocity and spent more time in the border of the apparatus, suggesting a thigmotaxis behavior. On the other hand, 6-OHDA/BCP did not present impairment in locomotion and remained less time in the peripheral zone. Stereological estimations showed that the BCP treatment was associated with reduced degeneration of TH+ neurons and reduced expression of microglial cells in the SNpc. But, BCP treatment was not able to increase the antioxidant capacity. Hence, BCP treatment has a potential neuroprotective effect in this mouse model of PD, which deserves to be better characterized for translational application.

Abstract: Parkinson's disease (PD) is the second neurodegenerative disease with the highest incidence worldwide. There are different therapeutic strategies to treat this condition in chronic stages, one of them is the use of deep brain stimulation (DBS), however since it is an invasive method and the electrodes remain chronically, various complications can occur such as: nervous tissue damage as a consequence of an inflammatory process that can lead to neuronal death. In addition the formation of gliosis around the implant, results in alterations of the stimulation efficacy. In this work we tested a new polymer in order to improve the physical and chemical characteristics of the interface. Recently, our group has shown that the polypyrrole / iodine (PPy / I) synthesized by plasma is a semiconductive biomaterial with neuroprotective effect and promoter of both motor and sensory functional recovery in models of spinal cord injury. This effect is due to its anti-inflammatory and anti-apoptotic capacity, so these characteristics could make PPy / I a useful material for coating DBS electrodes. We elaborated electrodes which were tested in a PD model induced by the striatal administration of 1-methyl-4-phenylpyridinium (MPP +) in male Wistar rats weighing 270 to 300 grams. The model was validated by subcutaneous administration of apomorphine and the electrodes were implanted in the right subthalamic nucleus (STh). The results showed that the electrodes with PPy / I have a uniform surface which is not altered when is subjected to various mechanical tests, as well the records of the electrical activity in the area of the implant are clearly displayed over eight weeks without increase the amplification of the signal for reading. With the findings of this work we propose that the PPY / I could be a good option to cover deep stimulation electrodes and improve the interphase in the brain of the rat.

Title: Analysis of hippocampal synapses in the PINK1-deficient rats

Authors: *A. A. MEMON[1], R. B. CREED[2], A. W. AMARA[3], M. S. GOLDBERG[3], M. BAMMAN[4], L. L. MCMAHON[5];
[1]Neurol., [2]Ctr. for Neurodegeration and Exptl. Therapeutics, Neurol., Univ. of Alabama at Bimingham, Birmingham, AL; [3]Neurol., [4]Cell Develop. and Integrative Biology; Med. and Neurol., [5]Cell, Developmental and Integrative Biol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disorder of aging. Although the diagnosis is based on motor features, PD is also associated with wide-ranging non-motor symptoms (NMS), including cognitive dysfunction. NMS often precede motor deficits, severely affecting the quality of life in PD. PTEN induced kinase 1 (PINK1) degrades dysfunctional mitochondria and mutations in PINK1 causes autosomal recessive PD. While the pathological hallmark of PD is loss of dopaminergic neurons in the substantia nigra and abnormal accumulation of alpha-synuclein aggregates, studies in PINK1 knockout (KO) mice report deficits in monoaminergic neurotransmitters within the limbic system including the hippocampus, which is implicated in memory functions. Indeed, approximately 14% of patients with PINK1-type PD show cognitive decline. It is unclear why or how alpha-synuclein aggregates and monoaminergic deficits occur in PINK1 KO rats, causing widespread motor and NMS. Synuclein is one of the most abundant synaptic proteins and is essential for synaptic vesicle movement and synaptic transmission, which leads us to hypothesize that defects in excitatory transmission occur in PINK1 KO rats. Also, PINK1 KO rats, in contrast to PINK1 KO mice, develop alpha-synuclein immunoreactive protein aggregates that appear similar to the alpha-synuclein protein aggregates observed in postmortem PD brains, including PINK1-linked PD. To test our hypothesis, we used electrophysiological methods to record extracellular dendritic field excitatory postsynaptic potentials in acute coronal slices (400 μm) of dorsal hippocampus from PINK1 KO and wild-type littermate controls at four months of age. We measure input-output curves, paired-pulse ratio, and long-term potentiation to assess the efficacy of hippocampal synaptic transmission. This novel work in progress allows investigation of possible deficits in the hippocampus that could contribute to learning and memory problems. It also advances the characterization of PINK1 KO rats as a model of PD and can provide valuable

insight into the mechanisms by which PD-linked loss-of-function mutations in PINK1 cause NMS and neurodegeneration.

Title: Relevance of choice of brain region and time point of analysis after MPTP lesioning in wildtype mice

Authors: *J. KEHR[1], V. SCHIFFER[2], S. YOSHITAKE[1], T. LOEFFLER[2], V. NIEDERKOFLER[2], S. FLUNKERT[2], E. AUER[2], T. YOSHITAKE[3], B. HUTTER-PAIER[2]; [1]Pronexus Analytical AB, Stockholm, Sweden; [2]QPS Austria GmbH, Grambach, Austria; [3]Dept. of Physiol. and Pharmacol., Karolinska Institutet, Stockholm, Sweden

Abstract: Introduction: Parkinson's disease (PD) is a common neurodegenerative disorder which cardinal clinical features include tremor, slowness of movement, stiffness, and postural instability. These symptoms are primarily attributable to the degeneration of dopaminergic neurons in the substantia nigra pars compacta and the consequent loss of their projecting nerve fibers in the striatum. Mice treated with MPTP selectively loose significant numbers of nigrostriatal dopaminergic neurons. MPTP-induced dopaminergic cell loss in the substantia nigra mimics clinical conditions of PD and is therefore a useful preclinical model to test anti-parkinsonian drugs. To use this model for compound tests against PD, it is important to understand the progressive development of MPTP lesioning to choose the correct timing for analysis after the MPTP lesion. Method: C57Bl/6 mice were treated with a MPTP regime and analyzed for Dopamine (DA), DOPAC and HVA in the substantia nigra at various time points after the MPTP injection. Furthermore, animals were MPTP lesioned and the striatum was analyzed for the same biomarkers 4 days after the treatment. In the latter group of animals, 7-nitroindazole was used as a positive control. Results: Analyses of DA levels shortly after the MPTP lesioning resulted in increased DA levels in the substantia nigra at very early and later time points but decreased levels after 12 hours. Similar effects could be observed for DOVAC while HVA levels stayed almost constant. Evaluations in the striatum 4 day after MPTP lesioning showed severely reduced DA, DOPAC and also HVA levels that could partially be rescued by 7-nitroindazole treatment. Conclusion/ Summary: Our results show that it is of high importance to select the correct brain region and time point after MPTP lesioning for evaluation of different readouts.

Title: Increased glutamatergic transmission at the corticostriatal synapse of PINK1 KO rats

Authors: *R. B. CREED[1], C. B. FARMER[2], R. C. ROBERTS[2], L. L. MCMAHON[3], M. S. GOLDBERG[1];
[1]Neurol., [2]Psychiatry and Behavioral Neurobio., [3]Dept Cell, Developmental, and Integrative Biol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Mutations in the PTEN induced kinase 1 (PINK1) gene cause autosomal recessive Parkinson's disease (PD). The main pathological hallmarks of PD are loss of dopamine neurons in the substantia nigra pars compacta and the formation of α-synuclein rich aggregates termed Lewy body inclusions. We and others have demonstrated that PINK1 knockout (KO) rats have mitochondrial dysfunction, locomotor deficits, and α-synuclein aggregates in different brain regions including the substantia nigra, striatum, and cortex. PINK1 is a mitochondrial targeted kinase involved in the clearance of damaged mitochondria. In neurons, mitochondria are prominently located in the pre-synaptic terminal, where they provide energy needed for vesicle movement and synaptic transmission. Additionally, α-synuclein is also important in synaptic vesicle movement and synaptic transmission. Given the importance of mitochondria to synaptic transmission, and the effect of PINK1 deficiency on mitochondrial health and α-synuclein aggregation, we sought to determine whether PINK1 KO rats have altered synaptic transmission. We hypothesize that PINK1 KO rats have changes in cortical excitatory neurotransmitter release onto spiny projection neurons (SPNs) of the dorsal striatum. Using whole cell patch clamp electrophysiology recordings from SPNs in acute striatal slices of WT and PINK1 KO rats at ages 2, 4, and 6 months, we observed an age-dependent increase in frequency spontaneous glutamatergic EPSCs onto SPNs. In addition, glutamatergic synapses on SPNs in PINK1 KO rats took longer to recover following depletion of the readily-releasable pool of synaptic vesicles with a 50 Hz train. These studies reveal that PINK1 is required for normal corticostriatal synaptic transmission. Ongoing studies will measure the extent to which the altered presynaptic release could be due to impairments in dopaminergic neurotransmission or due to impairments in

presynaptic mitochondrial buffering capacity. Furthermore, we will measure whether the impairments in synaptic recovery following depletion may be due to perturbations in synaptic vesicle distribution or alpha synuclein homeostasis.

Title: Ataxin-3 isoforms confer differential toxicity in *Drosophila melanogaster*

Authors: *J. R. BLOUNT, S. L. JOHNSON, K. LIBOHOVA, B. RANXHI, W.-L. TSOU, S. V. TODI;
Pharmacol., Wayne State Sch. of Med., Detroit, MI

Abstract: The most commonly inherited dominant ataxia, Spinocerebellar Ataxia Type 3 (SCA3), is caused by a CAG repeat expansion that encodes an abnormally long polyglutamine (polyQ) repeat in the disease protein ataxin-3, a deubiquitinase. Two major, full-length isoforms of ataxin-3 exist, both of which contain the same N-terminal portion and polyQ repeat but differ in their C-termini; one (denoted here as isoform 1) contains a motif that binds ataxin-3's substrate, ubiquitin, whereas the other (denoted here as isoform 2) has a hydrophobic tail. Most SCA3 studies have focused on isoform 1, the predominant version in the brain, yet both forms are expressed and a better understanding of their relative pathogenicity is needed. We took advantage of the fruit fly *Drosophila melanogaster* to model SCA3 and examine the toxicity of each ataxin-3 isoform. Our *Drosophila*-based assays reveal isoform 1 to be markedly more toxic than isoform 2 in all fly tissues. Reduced toxicity from isoform 2 coincides with much lower protein levels as a result of expedited degradation. When isoform 2 protein levels are engineered to be comparable to isoform 1, isoform 2 is no less toxic. Additional studies indicate that isoform 1 is more aggregation-prone than isoform 2 and that the C-terminus of isoform 2 is critical for its enhanced proteasomal degradation. According to our results, although both full-length ataxin-3 isoforms are neurotoxic, isoform 1 is likely the primary contributor to SCA3 disease pathogenesis due to its expression at higher levels. Ongoing work focuses on the possibility that the hydrophobic tail of isoform 2 functions as a proteasome degradation signal, or degron, that may be applicable in the clearance of other proteins outside the context of SCA3. Overall, our

findings provide new insight into the biology of this ataxia and the cellular processing of the underlying disease protein.

Title: Repeat associated non aug initiated translation as a disease factor in spinocerebellar ataxia type 3

Authors: *S. JOHNSON, K. LIBOHOVA, W.-L. TSOU, S. TODI;
Wayne State Univ., Detroit, MI

Abstract: Spinocerebellar Ataxia Type 3 (SCA3) is an age-related neurodegenerative disease and the most frequent dominant ataxia in the world. It is caused by anomalous expansion in the polyglutamine (polyQ) repeat domain of the deubiquitinase, ataxin-3. The full scope of SCA3's toxicity remains unclear and there are currently no effective treatments in the clinic. Our exploration into the pathogenesis of SCA3 takes a step back from the causative protein in SCA3, ataxin-3, and looks into the potential involvement of the mRNA produced from the *ATXN3* gene. mRNA may play a toxic role in polyQ-induced degeneration beyond encoding for the polyQ protein. One primary notion for mRNA-induced toxicity in polyQ and other repeat expansion disorders is the possibility of repeat-associated non-AUG (RAN)-initiated translation. RAN translation allows for translational initiation and elongation through a nucleotide repeat strand, in the absence of an AUG initiation codon and in multiple reading frames, resulting in the production of multiple homo-polymeric repeat-containing proteins. This type of translation not only opens the door to the possibility of translation of CAG repeats into toxic polyQ fragments, but also the translation of polyalanine and polyserine fragments in alternate reading frames. Here, we present new evidence from mammalian cell- and *Drosophila*-based models of SCA3 that utilize novel *ATXN3* transgenes to examine the role of mRNA toxicity and RAN translation in SCA3. We observe RAN translation from *ATXN3* constructs in mammalian cells, as well as increased toxicity from transgenes that allow for RAN translation in flies compared to counterparts that prevent RAN translation. Our ongoing work is delving into tissue specific and molecular mechanisms that underlie the possibility of RAN translation and mRNA toxicity in SCA3.

Abstract: Polyamines, spermidine and spermine, are important in cell function and proliferation. However, the biological significance of polyamine catabolism under normal physiological conditions remains unknown. Studies described here demonstrate that mice with global deletion of the two main polyamine catabolic enzymes, spermine-oxidase (SMOX) and spermidine/spermine-N^1-acetytransferase (SAT1), are normal at birth, but develop age-dependent progressive ataxia; whereas wild type, *Sat1*-KO or *Smox*-KO mice show no apparent neurological phenotypic abnormalities. The *Smox/Sat1*-double KO (dKO) mice only exhibit cerebellar pathology, with no abnormalities in any other tissues. Microscopic and magnetic resonance imaging studies reveal severe cerebellar atrophy, myelin damage, neurodegeneration and late-onset leukocytic infiltration. Comparison of polyamines in the cerebellum and cerebral cortex of Wt, *Smox*-KO, *Sat1*-KO, pre-ataxic and ataxic-dKO animals revealed that polyamine levels of pre-ataxic- and ataxic-dKO mice were significantly different from those of aged matched Wt and *Sat1*-KO mice. Analysis of cerebellar transcriptomes shows increased expression of transcripts for transglutaminases and proteins associated with microglia and

astrocyte activation and neurodegenerative response polarization. Significant reduction in the expression levels of transcripts coding for Purkinje cell proteins, including those associated with movement disorders were detected. The expression of the aforementioned transcripts was not affected in the cerebrum of dKO mice. Examination of the cerebellum of dKO mice revealed the onset of Purkinje cell loss and gliosis prior to the development of severe white matter demyelination, ataxia and leukocyte infiltration. The α-synuclein expression, aggregation and polyamination levels were also significantly increased, while the expression of myelin basic protein decreased in the cerebellum of dKO mice. Pharmacological inhibition of transglutaminases significantly reduced the severity of ataxia and cerebellar injury, highlighting their critical role in tissue injury in dKO mice. These results indicate that the disruption of polyamine catabolism causes Purkinje cell damage and gliosis. The latter changes will ultimately lead to white matter demyelination, ataxia and severe neuroinflammation. These studies further highlight the importance of the concerted role of transglutaminases and polyamines in the mediation of neuronal injury. We propose that the *Smox*/*Sat1* double KO mice will be a useful model to study the molecular and mechanistic basis of neurodegenerative, demyelinating diseases.

Abstract: Activation of an essential translation initiation factor, eIF2B, releases the global translational brake induced by the integrated stress response (ISR) and attenuates induction of transcriptional ISR targets. Partial loss-of-function mutations in eIF2B cause the rare neurodegenerative disorder Vanishing White Matter (VWM) Disease, which is characterized by

progressive deterioration of white matter in the central nervous system and consequent neurological deterioration, impaired motor function, and ultimately death. No treatments exist for this fatal leukodystrophy. In addition to VWM, a chronically activated ISR has been linked to neurodegeneration, oncology, and fibrosis. Thus, molecules that activate eIF2B have potential to treat pathologies characterized by prolonged and excessive induction of the ISR.
We have assessed pharmacology in a mouse model of VWM having a mutation in the eIF2B5 gene (e.g., R195H human/ R191H mouse) that causes the severe "Cree leukoencephalopathy." These R191H homozygous (HO) mutant mice provide a model that recapitulates many aspects of VWM disease, such as spontaneous myelin loss, progressive ataxia and motor skill deficits. Administration of the potent eIF2B activator, 2BAct, demonstrated robust efficacy in this VWM mutant mouse model (Wong et al. eLife 2019;8:e42940. DOI: https://doi.org/10.7554/eLife.42940). Here we present work of a 2BAct analog.
The eIF2B activator was given in diet to R191H HO mice starting around 21-24 weeks of age and continued until tissue collection. Behavior and neural imaging data was assessed longitudinally. Brains and spinal cord were collected around 34-37 weeks of age and were assessed for changes in motor behavior, ISR gene induction, histological markers, and MR imaging. Treatment with 30 mg/kg, but not 0.3 or 3 mg/kg of the eIF2B activator in R191H mice was associated with a reversal of motor impairments in inverted grid and balance beam assays. In the cerebellum and spinal cord, induction of ISR-associated gene expression (e.g. TRIB3, ATF3, eif4ebp1) and increased protein levels of ISR markers were dose-dependently attenuated in HO mice that received the eiF2B activator. In the corpus callosum, elevated MRI T2w ratio (a measure of inflammation) and protein levels of GFAP in HO mice were also significantly reduced in a dose-dependent manner. Findings from this study are consistent with earlier findings that eIF2B activators can reverse or attenuate various aspects of the disease pathology and motor impairments when given after appearance of behavioral symptoms *in vivo*.

Abstract: The Golgi apparatus plays an indispensable role in posttranslational modification and transport of proteins to their target destinations. Although it is well established that the Golgi apparatus requires an acidic luminal pH for optimal activity, morphological and functional abnormalities at the neuronal circuit level because of perturbations in Golgi pH are not fully understood. In addition, morphological alteration of the Golgi apparatus is associated with several neurodegenerative diseases, including Parkinson's disease, Alzheimer's disease and amyotrophic lateral sclerosis. Here, we used anatomical and electrophysiological approaches to characterize morphological and functional abnormalities of neuronal circuits in Golgi pH regulator conditional knockout mice. Purkinje cells (PCs) from the mutant mice exhibited vesiculation and fragmentation of the Golgi apparatus, followed by axonal degeneration and progressive cell loss. Morphological analysis provided evidence for the disruption of basket cell (BC) terminals around PC soma, and electrophysiological recordings showed selective loss of large amplitude responses, suggesting BC terminal disassembly. In addition, the innervation of mutant PCs was altered such that climbing fiber terminals abnormally synapsed on the somatic spines of mutant PCs in the mature cerebellum. The combined results describe an essential role for luminal acidification of the Golgi apparatus in maintaining proper neuronal morphology and neuronal circuitry.

Title: Knockdown of Rubicon, a negative regulator of autophagy, suppresses polyglutamine-induced toxicity in *Drosophila*

Authors: *M. OBA[1,2], Y. NAGAI[3], K. FUKUI[2], K. SANGO[1], M. SUZUKI[1];
[1]Diabetic Neuropathy Project, Tokyo Metropolitan Inst. of Med. Sci., Setagaya, Japan; [2]Dept. of Biosci. and Engin., Shibaura Inst. of Technol., Saitama, Japan; [3]Dept. of Neurotherapeutics, Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Accumulation of pathogenic misfolding proteins is thought to be a common mechanism of neurodegenerative diseases, such as Alzheimer's disease, Parkinson's disease and polyglutamine (polyQ) diseases. The autophagy-lysosome degradation system may have therapeutic potential against these diseases, because it can degrade even large protein aggregates. In this study, we focused on Rubicon, a negative regulator of autophagy, and examined whether suppression of Rubicon shows beneficial effects on polyQ disease model. We employed *Drosophila* as a model animal, which is suitable for genetic analysis. RNAi-mediated knockdown of a *Drosophila* homolog of Rubicon (dRubicon) was induced either in a whole body or specifically in neurons. Autophagic activity was analyzed by using GFP-mCherry-Atg8a and it was confirmed that steady-state autophagosome and autolysosome pools are significantly increased in the brain of dRubicon knockdown flies. Then, we examined the effects of dRubicon knockdown on locomotor dysfunction and shortened lifespan of the flies expressing polyQ in neurons. Knockdown of dRubicon in neurons dramatically suppressed locomotor dysfunction and shortened lifespan of polyQ-expressing flies. Furthermore, dRubicon knockdown markedly reduced polyQ inclusion bodies in the brain, which is accompanied with no change in the polyQ mRNA level, suggesting that increased autophagic activity by dRubicon knockdown may lead misfolding polyQ proteins to be degraded. To further confirm the effect of dRubicon, we established transgenic fly lines either expressing wild-type (WT) dRubicon or dRubicon deleted for the RUN domain (delta RUN), which is known to be required for suppression of the class III phosphatidylinositol 3-kinase in mammalian cells. Overexpression of WT dRubicon in neurons exacerbated locomotor dysfunction and shortened lifespan of polyQ-expressing flies. However, on the contrary to our expectation, delta RUN dRubicon also exacerbated the phenotypes of the polyQ flies as well as the WT, suggesting that the RUN domain of dRubicon is indispensable for the suppression of autophagy in *Drosophila* neurons. Taken together, we demonstrate that the expression level of dRubicon is critical for the polyQ-induced toxicity in the fly model. Our study will provide basic insights into the possibility of Rubicon as a molecular target for treatment of misfolding protein-associated neurodegenerative diseases.

Title: Neuromagnetic resting state functional connectivity in Friedreich ataxia

Authors: G. NAEIJE[1], V. WENS[1], M. SJOGARD[1], M. VAN DER GHINST[1], S. GOLDMAN[2], M. PANDOLFO[1], *X. DE TIÈGE[2];
[1]Lab. de Cartographie Fonctionnelle du Cerveau, ULB Neurosci. Inst. (UNI), Univ. Libre de Bruxelles (ULB, Brussels, Belgium; [2]Unité De Magnetoencephalographie, ULB-Hôpital Erasme, Brussels, Belgium

Abstract: Background: Friedreich ataxia (FRDA) is the commonest spinocerebellar ataxia in Caucasian. Over 95% of patients are homozygous for expanded GAA triplet repeats in the first intron of the frataxin (*FXN*) gene. Most residual FXN expression is from the chromosome with the shorter repeat (GAA1). GAA1 explains 30-50 % of the variability in age of symptoms onset but fails to predict clinical evolution or disability. Pathologically, cerebellar dentate nuclei are progressively atrophied in FRDA. Clinically, cerebellar dysfunction leads to ataxia symptoms and, through the cerebellar connections with multiple cortical areas, to reduced cognitive processing speed, lower performance in complex visuospatial tasksand altered executive functions. Here, we used magnetoencephalography (MEG) to assessif impaired functional resting state connectivity (rsFC) in FRDA reflected disease pathology and seek if rsFC could serve as neurophysiological marker for disease pathophysiology and evolution.Methods: Neuromagnetic signals were recorded at rest during 5 min in 18 right-handed FRDA patients (mean age 27 yrs, 9 females; mean SARA score: 21.4) and matched healthy individuals. The MEG connectome was estimated as rsFC matrices involving thirty-seven nodes from the six major resting-state networks and the cerebellum. Source-level rsFC maps were computed in a broad-band (3-40 Hz) frequency bands using leakage-corrected envelope correlations. Post-hoc median-split was used to contrast source-level rsFC maps based on clinical characteristics of FRDA patients. Non-parametric permutations and Pearson rank correlation test were used for statistics.Results: Increased functional connectivity was found in FRDA with later age of onset compared to healthy subjects. High correlation rank indexes were found between rsFC and age of symptoms onset in FRDAmainly across ventral attention network, default mode network and cerebellar network nodes, patients with higher rsFC developing symptoms at older age.No correlation was found between rsFC and other clinical parameters. Conclusion: Higher rsFC in FRDA, that correlates with age of symptoms onset, suggests compensatory mechanisms for widespread neuronal network dysfunction and position rsFC as potential marker of disease evolution in FRDA.

Title: Identification of biphasic effects of frataxin deficiency on TID1 protein levels in Friedreich ataxia cellular models

Authors: Y. DONG, N. A. WARREN, E. MERCADO AYON, *D. R. LYNCH;
Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Friedreich ataxia (FRDA) is the most common recessive inherited ataxia resulting from homozygous GAA repeat expansion in intron 1 of the *FXN* gene, which leads to the deficiency of frataxin. Frataxin is a mitochondrial protein crucial for iron-sulphur cluster biogenesis, but its precise cellular function is controversial. Using Co-Immunoprecipitation (Co-IP) combined with mass spectrometry, we identified tumorous imaginal disc 1 (TID1), a mitochondrial J-protein cochaperone critical for apoptotic signal transduction, as an interacting protein of frataxin both *in vivo* in mouse cortex and *in vitro* in mouse cortical neurons and human embryonic kidney (HEK) 293 cells. The interaction between frataxin and TID1 was confirmed by both Co-IP and GST pulldown assays. Acute depletion of frataxin using RNA interference markedly increases TID1 protein levels in human skin fibroblasts. Similar results were also observed in cerebellar homogenates from doxycycline-inducible frataxin knockdown mice. In contrast, chronic frataxin deficiency decreases TID1 protein levels in multiple cell types from FRDA patients including skin fibroblasts, buccal cells, platelets and peripheral blood mononuclear cells. Our results show biphasic effects of frataxin deficiency on TID1 protein levels and suggest that TID1 might function as a downstream signaling molecule for frataxin and contribute to the pathogenesis of FRDA. The precise role of TID1 in FRDA remains to be examined.

Title: The novel protein FAM171B is recruited into intracellular polyQ aggregates

Authors: J. KIRLIN, *G. M. GOELLNER;
Minnesota State Univ., Mankato, MN

Abstract: Expansion mutation within polyglutamine (polyQ) tract proteins is known to underlie a number of severe neurodegenerative disorders such as Huntington's Disease and Spinocerebellar Ataxia. One of the pathologic hallmarks of polyQ expansion disease is the aggregation of mutant proteins into intracellular inclusion bodies. Our lab is actively investigating FAM171B- a relatively uncharacterized protein that also contains a stretch of consecutive glutamines within its primary amino acid sequence and is likely expressed in the nervous system. Since it too contains a short polyQ stretch, we surmised that FAM171B may also be recruited into polyQ aggregates formed by known pathologic proteins. To test this hypothesis, we transfected cells with an expanded version of SCA7-GFP to form intracellular aggregates, and utilized FAM171B specific antibodies, immunofluorescence, and confocal microscopy to assay FAM171B's intracellular location in relation to the SCA7 inclusion bodies. Our findings indicate that a portion of FAM171B does indeed alter its normally dispersed cytoplasmic subcellular distribution into SCA7 aggregates that locate near the peri-nuclear region of human glioblastoma tissue culture cells. Thus, the novel protein FAM171B may play a role in the molecular mechanisms underlying polyQ disease pathology.

Abstract: FXTAS is a neurodegenerative disorder characterized by tremor and cerebellar gait ataxia. It occurs in some carriers of a 55-200 CGG repeat size premutation in the *fragile X mental retardation 1* gene. However, early predictors of FXTAS onset are needed and quantitative measurements of tremor, bradykinesia and coordination may be useful in natural history studies, response to medications and as outcome measures in future clinical trials. The objective of our work was to quantify the severity of upper extremity (UE) tremor subtypes, bradykinesia and incoordination in FXTAS and potentially identify preclinical symptoms in premutation carriers (PMC) without a diagnosis of FXTAS using an inertial sensor system. 39 PMC with FXTAS (Mean age = 67.8$\pm$ 8.5), 20 PMC without FXTAS (Mean age = 53.5 $\pm$ 10.6), and 27 healthy controls (Mean age = 65.4 $\pm$ 9.1) performed a series of UE motor tasks while wearing an *ETsense*™ sensor with the *Kinesia One* system which quantifies several types of tremor, bradykinesia and rapid alternating movements. Regression analyses controlling for age, sex and CGG repeat size with FXTAS diagnosis group as the main predictor was performed to detect potential group differences. The FXTAS Rating scale (FXTAS-RS) was administered to determine whether these clinician-rated scores correlate with severity scores from the *Kinesia* system.We found that PMC with FXTAS had significantly worse postural and kinetic tremor compared to PMC without FXTAS (p=0.04; 0.03) and controls (p=0.001; 0.0001), respectively, and worse finger tap (p=0.0009), hand movement (p=0.0001) and rapid alternating movement speed (p=0.003) and amplitude (p=0.04) than controls. PMC without FXTAS had significantly worse finger tap (p=0.004), hand movement (p=0.01) and rapid alternating movement speed (p=0.003) and amplitude (p=0.02) than controls. All quantitative scores were significantly correlated with the FXTAS-RS scores (p=0.02 to < 0.0001) except for finger tap speed and amplitude. The *ETSense*™ system is a feasible, portable and low-cost method for quantifying UE tremor, bradykinesia and dysdiadokinesia in FXTAS and may have potential in detecting preclinical symptoms of UE speed and coordination deficits in PMC without FXTAS. Further validation of these measures and confirmation of preclinical disease identification in longitudinal studies with higher subject numbers is needed.

Title: Blocking ran translation enhances FMRP and reduces toxicity in unmethylated full mutation fragile X stem cells

Authors: *S. E. WRIGHT[1], C. RODRIGUEZ[1], J. HAENFLER[1], F. RIGO[4], M. A. SUTTON[2], S. BARMADA[5], J. M. PARENT[1], P. K. TODD[3];

Abstract: Expansion of a CGG repeat in the 5' UTR of the FMR1 gene underlies a heterogeneous set of human clinical disorders, including Fragile X Syndrome and Fragile X-Associated Tremor/Ataxia Syndrome. While full mutations (>200 repeat expansions) result in FXS typically lead to methylation and silencing of FMR1 expression, patients often display mosaicism of FMR1 methylation and CGG repeat length in individual cells. Large transcribed CGG repeats are potentially toxic as RNA or by triggering Repeat associated non-AUG initiated translation (CGG RAN). Moreover, large repeats can impede translation of FMRP even when transcription is sufficient. Therefore, effective therapies targeting large transcribed repeats will simultaneously block CGG RAN and enhance production of FMRP. To this end, our group developed a series of antisense oligonucleotides that selectively target RAN initiation sites (RAN ASOs) on the FMR1 transcript. Using patient-derived induced pluripotent stem cells (iPSCs) from an unmethylated full mutation (UFM) carrier, we generated human neurons that exhibit normal FMR1 mRNA transcription but very low FMRP expression. Application of RAN ASOs on these neurons effectively reduced accumulation of CGG RAN products and enhanced neuronal FMRP expression, suggesting that CGG RAN acts normally to inhibit FMRP synthesis. These biochemical corrections were associated with enhanced UFM neuronal survival. Blocking endogenous CGG RAN also altered activity dependent FMRP synthesis in response to mGluR5 stimulation, a critical regulatory component of long-term depression. Together, these data suggest a native function for CGG RAN in regulating FMRP synthesis and demonstrate that targeting CGG RAN has the potential to correct multiple disease relevant features in Fragile X-associated disorders.

Title: Assessing benefits of antisense oligonucleotide therapy in a pre-symptomatic mouse model of spinocerebellar ataxia type 3

Authors: *A. J. ZALON[1], K. C. O'DONNELL[1], H. L. PAULSON[3], H. S. MCLOUGHLIN[2]; [2]Neurol., [1]Univ. of Michigan, Ann Arbor, MI; [3]Prof, Neurol, Univ. of Michigan Dept. of Neurol., Ann Arbor, MI

Abstract: Of the dominantly inherited ataxias, spinocerebellar ataxia type 3 (SCA3) is the most common. This polyglutamine repeat expansion disorder is characterized by progressive cerebellar ataxia and to date has no cure. Knockout of the disease-causing ATXN3 gene produces no overt phenotype in mice suggesting that SCA3 is a promising target for gene suppression therapies. Utilizing a well characterized SCA3 mouse model that expresses the full-length mutant ATXN3 (Q84) gene, we recently assessed proof-of-concept studies via CNS delivery of antisense oligonucleotides (ASOs) targeting mutant ATXN3 into an adult post-symptomatic mouse. In our recent reports, we determined anti-ATXN3 ASOs are therapeutically efficacious at reducing SCA3 disease protein levels and neuropathology. Additionally, a longitudinal ASO treatment beginning at 8 weeks of age in SCA3 Q84 mice was sufficient to rescue motor impairments, a result reported for the first time in this mouse model. One important aspect of the longitudinal ASO trial is that SCA3 mice did not show a recovery in weight overtime. Differences in weight between SCA3 and wild-type mice are not well understood. We asked the question, if peripheral SCA3 phenotypes, such as weight loss, are secondary to neuronal dysfunction in the CNS. We surmised that pre-symptomatic sustained delivery of anti-ATXN3 ASOs to the CNS may protect against secondary peripheral effects. Successful weight restoration of SCA3 mice treated pre-symptomatically will show that weight loss typical of SCA3 mice may be linked to primary CNS dysfunction.

Title: Movement initiation and motor output error in SCA6

Authors: *S. DELMAS[1], A. CASAMENTO-MORAN[1], B. YACOBI[1], S. SUBRAMONY[2], D. E. VAILLANCOURT[1,2], E. A. CHRISTOU[1];
[1]Applied Physiol. and Kinesiology, [2]Biomed. Engin. and Neurol., Univ. of Florida, Gainesville, FL

Abstract: Spinocerebellar Ataxia Type 6 (SCA6) is an autosomal-dominant neurodegenerative disease resulting in almost pure cerebellar degeneration. A major role of the cerebellum is the integration of sensory consequences of movement (efference copy) with sensory feedback to adjust the motor command and improve motor performance. The current hypothesis is that, due to the degeneration of the cerebellum, SCA patients rely on feedback mechanisms such as visual feedback and react to visual stimuli rather than relying on the sensory prediction for movement control. The purpose of this study was to determine whether SCA6 use a different strategy to initiate a movement relative to healthy controls. Fourteen healthy controls and seventeen individuals diagnosed with SCA6 performed 15 trials of an isometric ankle dorsiflexion constant task and traced a target with their force outcome. The target consisted of 4s of rest, followed by increasing force and matching a 1.5s ramp at a rate of 10%MVC/s, and maintaining force for 20 s at 15% MVC. We quantified the initiation of force, as the first time point where the force trace was greater than 0.075% MVC. Force initiation was significantly different for healthy controls and SCA6 ($p = 0.01$). Specifically, healthy controls initiated their force ~100 ms before the targeted ramp, whereas SCA6 initiated their force ~100 ms after the targeted ramp. The adaptation across the fifteen trials, quantified as the change from the first to the last 3 trials, was similar for the two groups. SCA6 also exhibited greater error than healthy controls in matching the first 150 ms of the ramp ($p<0.05$; 27.5±6.5 vs. 13.6±2.5). Finally, the time of force initiation correlated with the ramp rate error during the first 150 ms ($R^2=0.25$; $p<0.01$) indicating that ramp error was greater with delayed force initiation. These findings suggest that SCA6 use a different strategy to match the ramp force than healthy adults. Specifically, SCA6 appear to use a reactive feedback strategy, whereas healthy controls use a predictive strategy for performing the movement. The reactive feedback strategy used by SCA6 relates to movement errors during the feedforward part of the contraction, further suggesting an impaired motor command.

Title: Factors associated with functional mobility and falls of individuals with hereditary degenerative cerebellar diseases

Authors: *V. F. GIANGIARDI, M. PERRACINI, M. SILVA, G. B. R. SETTI, M. VEGAS, S. ALOUCHE;
Univ. Cidade De Sao Paulo, Sao Paulo, Brazil

Abstract: Introduction: The dysfunctions related to hereditary degenerative cerebellar diseases (HDCD) cause substantial limitation to functional mobility and negative impact on individual independence. However, the increased impairment and limitations that follow the progression of HDCD are not well characterized. Furthermore, which signs can predict the loss of mobility and the risk of falls in these individuals are not known. The understanding of these outcomes may facilitate the comprehension of functional prognosis and may help to guide rehabilitation interventions, promoting the independence of individuals with HDCD. **Objectives:** The present study aimed to characterize the factors associated with functional mobility and falls in individuals with HDCD. **Methods:** Individuals with spinocerebellar ataxia diagnosis were categorized into different ranges of impairments of using the Scale for the Assessment and Rating of Ataxia (SARA). Aspects of the body function, activity, and participation were also assessed. Linear regressions models were conducted to investigate the main predictors of functional mobility and falls in individuals with HDCD. For functional mobility, individuals were assigned into three groups according to their mobility status: independent, walking with assistant devices and restricted to wheelchair. Regarding falls, individuals were divided into two groups characterized by the number of falls in the last year: fallers and non-fallers. Groups comparisons were conducted using One-way ANOVA. **Results:** The BEST-test is the main outcome measure that explains the loss of mobility in individuals with HDCD ($\beta_0 = 3{,}34$, $\beta_1 = -.030$; CI 95% - .035, - .024). Of all BEST-test items, only the limit of stability was not different among the independent group and the walking with assistant devices group ($p = 0{,}184$), and among the wheelchair group and the walking with assistant devices group ($p = 0{,}161$). Regarding falls, SARA is the outcome measure most associated with the history of falling. **Conclusion:**

Balance and the severity of ataxia are respectively associated to functional mobility and falls in individual with HDCD and should be carefully assessed. Future longitudinal studies may be conducted to identify what are the main predictors that compromise these outcomes over the progression of the disease.

Title: Ataxic phenotype with altered Cav3.1 channel property in a mouse model for spinocerebellar ataxia 42

Authors: *H. DOI[1], S. HASHIGUCHI[1], M. KUNII[1], Y. NAKAMURA[2], M. SHIMUTA[2], E. SUZUKI[2], M. OKUBO[1], T. SASAOKA[3], H. TAKEUCHI[1], T. ISHIKAWA[2], F. TANAKA[1]; [1]Dept. of Neurol. and Stroke Med., Yokohama City Univ. Sch. of Med., Yokohama-shi, Japan; [2]Dept. of Pharmacol., The Jikei Univ. Sch. of Med., Tokyo, Japan; [3]Brain Res. Institute, Niigata Univ., Niigata,, Japan

Abstract: Spinocerebellar ataxia 42 (SCA42) is a neurodegenerative disorder recently shown to be caused by c.5144G>A (p.Arg1715His) mutation in *CACNA1G*, which encodes the T-type voltage-gated calcium channel Cav3.1. To determine whether this mutation causes ataxic symptoms and neurodegeneration, we generated knock-in mice harboring c.5168G>A (p.Arg1723His) mutation in *Cacna1g*, corresponding to the mutation identified in the SCA42 family. Both heterozygous and homozygous mutants developed an ataxic phenotype from the age of 11 weeks and showed loss of Purkinje cells at 50 weeks old. Degenerative change of residual Purkinje cells and atrophic thinning of the molecular layer were conspicuous in homozygous knock-in mice. Electrophysiological analysis of Purkinje cells using acute cerebellar slices from young mice showed that the point mutation altered the voltage dependence of Cav3.1 channel activation and reduced the rebound action potentials after hyperpolarization, although it did not significantly affect the basic properties of synaptic transmission onto Purkinje cells. Finally, we revealed that the resonance of membrane potential of neurons in the inferior olivary nucleus was decreased in knock-in mice, which indicates that p.Arg1723His Cav3.1 mutation affects climbing fiber signaling to Purkinje cells. Altogether, our study not only shows that a point mutation in *CACNA1G* causes an ataxic phenotype and Purkinje cell degeneration in

a mouse model, but also reveals that the electrophysiological abnormalities at an early stage of SCA42 precede the loss of Purkinje cells.

Title: New knock in mouse models with hyper-expansion of the murine polyQ tract show massive progressive aggregate formation and moderate motor phenotype

Authors: E. HAAS, R. INCEBACAK, Y. MARINGER, N. CASADEI, T. HENTRICH, J. SCHULZE-HENTRICH, T. SCHMIDT, *O. RIESS, J. HUEBENER-SCHMID;
Inst. for Med. Genet. and Applied Genomics, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Spinocerebellar ataxia type 3 (SCA3) is the most common dominantly inherited ataxia worldwide. Though the disease causing mutation in the ATAXIN-3 gene is long known, there is no cure available and symptoms can only be treated with limited success. Mouse models available for the disease do not represent the situation in a satisfactory way as most of them are transgenic and therefore simulate the disease under quite artificial conditions. In the few existing knock in (KI) models the polyglutamine (polyQ) tract is expanded within a similar length as in human patients. This seems not to be efficient to trigger a disease-relevant phenotype in mice. To overcome this obstacle, we generated three new KI mouse lines by zinc-finger-technology, one with a polyQ tract of 97Q, comparable to the length found in human patients, and two lines with a hyper-expansion of the polyQ tract containing 305 or 326 glutamines in the murine ataxin-3 protein. These mice were either heterozygous (WT/97, WT/326Q, WT/305Q) or homozygous (305Q/305Q) for the expanded murine ataxin-3 protein and were characterized over 18 months using molecular biological, histological, behavioral and RNA sequencing methods. In all lines we could show the expression of the expanded ataxin-3 in brain and peripheral organ tissue and in the lines with hyper-expansion observed massive aggregate formation starting with 3 month of age and rapidly progressing over time. Brain regions especially affected in these two models are the deep cerebellar nuclei, the pons (both associated with SCA3 pathology) and the

hippocampus. Further, we observed reduction in body weight and size accompanied by massive hunchback formation in the hyper-expanded lines but not so for the line expressing 97Q in the ataxin-3 protein. These changes led to gait and posturing abnormalities comparable to those seen in SCA3 patients and abnormal anxiety behavior in these mice. Moreover, RNA sequencing of cerebellar tissue of symptomatic and pre-symptomatic 305Q/305Q mice revealed 400 differentially expressed genes affected in symptomatic animals. Interestingly, eight of these genes were already affected in the pre-symptomatic stage, indicating mis-regulation of gene expression before aggregate manifestation. Taken all our data together we state that 97Q in the ataxin-3 protein is not enough to trigger a phenotype in mice and that our hyper-expanded KI lines are great models for SCA3 as it allows following the progression of the disease over time. This makes them ideal for testing treatment options like drug delivery or external stimuli (e.g. enriched environment, stress, etc.) and their effect on aggregate formation and motor phenotype development.

Title: Analyzing the ubiquitin-proteasome system in SCA3 *in vivo*

Authors: J. SCHMIDT[1,2,3], A. GRUN[1,2,3], M. PRADELA[1,2,3], O. RIESS[1,2,3], ***T. SCHMIDT**[1,2,3]; [1]Med. Genetics, Univ. of Tuebingen, Tuebingen, Germany; [2]Ctr. for Rare Dis. ("ZSE"), Univ. Hosp. Tuebingen, Tuebingen, Germany; [3]NGS Competence Ctr. Tuebingen (NCCT), Tuebingen, Germany

Abstract: Spinocerebellar ataxia type 3 (SCA3) or Machado-Joseph disease (MJD) is an inherited neurodegenerative disorder caused by the expansion of a CAG repeat within the *ATXN3* gene resulting in an expanded polyglutamine repeat in the encoded protein ataxin-3. SCA3/MJD therefore belongs to the group of polyglutamine diseases. Up to now, no treatment is available for this disease. One hallmark of this and other neurodegenerative diseases is the formation of inclusion bodies (protein aggregates) in the brain. Ataxin-3 is a deubiquitinating enzyme and involved in the degradation of proteins via the ubiquitin-proteasome system by

editing ubiquitin chains. Ubiquitin chains can be assembled by the attachment of ubiquitins to different lysine residues. Ubiquitins linked via lysin 48 (K48) represent the main signal for proteasomal degradation. In order to further study the role of ubiquitination in SCA3, we crossed one of our previously generated mouse models for SCA3 with mice transgenic for mutated ubiquitin (K48R mice). The mutation in K48R mice (Lysine at position 48 is replaced by Arginine) leads to premature termination of K48 poly-ubiquitin chain assembly, hence to the formation of higher amounts of short K48-linked ubiquitin chains. We used RotaRod and CatWalk tests to measure the motor-coordinative abilities and observed that transgenic SCA3 mice which simultaneously express the mutant ubiquitin transgene (MJD/K48R) showed an alleviated motor phenotype compared to single transgenic SCA3 mice. To investigate the cause of these improved motor abilities in detail we performed immunoprecipitation and Western blot analyses. Aggregate load was checked via filter trap and immunohistochemistry. We further characterized the proteasomal activity and distribution of proteasomal subunits using immunohistochemistry. We hypothesize that the presence of higher amounts of short K48-linked ubiquitin chains leads to a higher proteasomal turnover of the expanded transgenic ataxin-3 protein resulting in the alleviated phenotype in MJD/K48R mice. We aim to further explore the feasibility to translate this approach into a therapeutic strategy.

(University of Coimbra), Coimbra, Portugal

Abstract: Blood-brain barrier (BBB) disruption is a shared feature for several neurodegenerative diseases, such as Alzheimer's and Huntington's. Impairments in the assembly of tight junctions (TJ) between adjacent brain endothelial cells along with neuroinflammation have been reported to contribute to BBB dysfunction. However, in spinocerebellar ataxias such as Machado-Joseph Disease (MJD), BBB integrity has not been assessed. In this disorder, an expansion of CAG repeats in the *MJD1* gene that codifies for mutant ataxin-3 results in neurodegeneration and further progressive cerebellar ataxia. Accordingly, the aim of this work was to evaluate the BBB integrity in MJD, by analyzing a transgenic mouse model and human *post-mortem* brain tissues. In order to assess BBB permeability in MJD transgenic mice, Evans blue (EB) was intravenously injected and quantified in the brain by spectrophotometry. Additionally, immunofluorescence against fibrinogen and quantification of its extravasation across BBB was performed. Mechanisms involved in BBB disruption were explored by analyzing: i) the presence of mutant ataxin-3 aggregates in brain blood vessels and ii) the levels of TJ proteins in mice cerebella by Western blot. Brain vascular permeability was also evaluated in live animals by Dynamic Contrast Enhanced-Magnetic Resonance Imaging (DCE-MRI).
Regarding EB concentration in the cerebella of MJD mice, we observed a 5-fold increase in comparison to wild-type mice. Likewise, fibrin extravasation and DCE-MRI corroborated a higher vascular permeability in the cerebella of transgenic mice. Interestingly, mutant ataxin-3 aggregates, the hallmark of MJD, were found in brain blood vessels, which also indicated occludin fragmentation and redistribution of Claudin-5. Concerning human brain tissues, immunofluorescence images suggest a higher fibrinogen extravasation across BBB in MJD tissues when compared to the control group, as well as the presence of ataxin-3 aggregates in brain blood vessels, supporting the evidences found in the transgenic mouse model.
In conclusion, the present work reports for the first time BBB alterations in a transgenic mouse model of MJD and in *post-mortem* brain tissues of MJD patients.

Title: Characterization of molecular and clinical phenotypes in a rat model for Griscelli syndrome type 1

Authors: *D. R. MICHAUD[1], P. P. NGHIEM[1], G. STOICA[2], R. SRINIVASAN[3], S. MATA LOPEZ[1], C. BALOG-ALVAREZ[1];
[1]VIBS, [2]VTPP, Texas A&M Univ., College Station, TX; [3]Dept. of Neurosciecne and Exptl. Therapeudics Texas, Texas A&M Univ. Col. of Med., Bryan, TX

Abstract: Background. Griscelli Syndrome (GS) type 1 is an ultra-rare, autosomal recessive disease caused by a mutation in the *Myosin-Va* gene, leading to a loss of respective protein expression and altered vesicle and membrane trafficking (Çağdaş et al., 2012). Myosin-Va (MYOVA) is an unconventional motor protein that is essential for transporting mRNA (McCaffrey & Lindsay, 2012; Salerno et al., 2008) and mRNPs (Yoshimura et al., 2006), smooth endoplasmic reticulum (Wagner, Brenowitz, & Hammer Iii, 2010), secretory granules (Eichler, Kögel, Bukoreshtliev, & Gerdes, 2006), and other proteins in the neuron to dendritic spines. Due to the loss of intracellular neuronal transportation, patients with type 1 GS exhibit severe neurological deficits such as developmental delays, intellectual disabilities, seizures, and motor impairment, as well as hypopigmentation of the hair and skin. We have a line of rats that spontaneously exhibited a point mutation in a donor splice site early in the *MyoVa* gene, which leads to a premature stop codon and the subsequent loss of MYOVA protein expression and function (Landrock et al., 2018). These affected rats are an ideal model for GS type 1 that show the characteristic dilute hair color, loss of dopaminergic neurons, muscle weakness, seizures, and a shortened life-span that is observed in Griscelli patients (Landrock et al., 2018; Stoica et al., 2012). Hypothesis. We hypothesize that the affected rats exhibit abnormal molecular mechanisms related to decreased resistance to neuronal oxidative stress compared to wildtype littermates, as well as impaired motor function. Methods. Naïve wildtype, heterozygous or homozygous (mutant) rats will be measured for weight and grip strength for up to 30 days of age. Brain and muscle tissue will be harvested and analyzed for RNA, protein, and morphological differences using qPCR, western blots, and immunofluorescent microscopy. Results. We have found significant evidence that the affected and heterozygous rats exhibit higher levels of susceptibility to oxidative stress compared to their wildtype littermates by measuring sensors of oxidative stress such as Park7. Furthermore, we have shown significant clinical loss of muscle function in the affected rats compared to wildtype, and have evidence of histological abnormalities in muscle tissue in the affected rats. Future work. We will continue to assess the role of oxidative stress in this model rat model of Griscelli syndrome type 1, and will explore the changes in mitochondrial function in the affected and carrier rats.

Title: Cerebellar dysfunction in spinocerebellar ataxia type 3

Authors: *K. PALARZ[1], A. CARVALHO[2], P. E. MACIEL[2], K. KHODAKHAH[3];
[1]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Life and Hlth. Sci. Res. Inst. (ICVS), Braga, Portugal; [3]Dept Neurosci., Albert Einstein Col. Med., Bronx, NY

Abstract: Ataxia (uncoordinated movement) is a debilitating disorder that interferes with a patients' ability to perform activities of daily living. Ataxia is often caused by dysfunction of the cerebellum, a brain area involved in motor coordination and maintenance of balance. Spinocerebellar ataxia type 3 (SCA3) is the most common dominantly inherited ataxia, caused by a trinucleotide CAG repeat expansion of the ATXN3 gene. A mouse model of SCA3, CMVMJD135, recapitulates the progressive, adult onset phenotype seen in humans. However, it is still not clear if and how cerebellar dysfunction is contributing to disease in this SCA3 mouse model. This project seeks to elucidate potential cerebellar abnormalities in SCA3 through behavioral, electrophysiological, and proteomic analysis of the cerebellum in the CMVMJD135 SCA3 mouse model.
As assessed by the parallel rod floor test and using the disability scale, SCA3 mice have a progressive ataxic motor phenotype from 12-60 weeks of age. It has previously been shown that regularity of the cerebellar output nuclei can predict disability in several mouse models of ataxia. With *in vivo* single unit recordings, we demonstrate that the firing of cerebellar nuclei neurons and the Purkinje cells (the principle neuron of the cerebellar cortex) is irregular at 12, 34, and 60 weeks of age in the SCA3 mice. To determine if abnormal intrinsic pacemaking of Purkinje cells contribute to the irregular firing seen *in vivo*, as noted in a number of mouse models of ataxia, we performed extracellular recordings from Purkinje cells in acutely prepared cerebellar slice from 34 week old mice. Consistent with a contribution of abnormal pacemaking to the irregular firing of Purkinje cells *in vivo*, we found that with fast synaptic transmission blocked the activity of mutant Purkinje cells was irregular. Our data suggests that defects both in intrinsic pacemaking and in synaptic transmission may contribute to cerebellar dysfunction in SCA3. To help identify the potential molecular and signal transduction pathways that might be defective in the cerebellum of SCA3 mice, we performed a quantitative proteomic analysis on cerebellar lysates from mutant mice and littermates. This approach has identified a number of signaling pathways

that warrant further scrutiny. Taken together, these data implicate the cerebellum in the pathogenesis of SCA3, and provide a path for future work aimed at identifying the potential mechanisms that contribute to cerebellar dysfunction.

Title: Elucidating the mechanism underlying stress and caffeine induced attacks in episodic ataxia type 2

Authors: *H. D. SNELL[1], A. VITENZON[2], E. TARA[1], K. KHODAKHAH[3];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Albert Einstein Col. of Medicince, Bronx, NY; [3]Dept Neurosci., Albert Einstein Col. Med., Bronx, NY

Abstract: Episodic ataxia type 2 (EA2) is a disorder that arises from loss of function mutations in the *CACNA1A* gene which encodes for the P/Q-type voltage-gated calcium channels. These mutations cause a decrease in the calcium current density through the P/Q type calcium channels. In this disorder, a mild baseline ataxia is interrupted by attacks of severe motor dysfunction that are triggered by physical or emotional stress, or consumption of caffeine or alcohol. Previous work using the *tottering* mouse, a model of EA2, showed that Purkinje cell (PC) firing in these mice becomes markedly more erratic during attacks triggered by the stressors. Stress, and caffeine induce attacks by increasing PC irregularity via activation of the α1 adrenergic, and inhibition of the adenosine 1 (A1) receptors, respectively. Both receptors have been shown to modulate the activity of mGluR1-mediated signaling: α1 adrenergic activation, and A1 receptor inhibition, increase mGluR1 activity. **We hypothesized that stress and caffeine might induce attacks in the *tottering* mice by increasing mGluR1 activity.** *In vivo*, caffeine- and stress-induced attacks were blocked by systemic, or intra-cerebellar infusion of an mGluR1 antagonist. Additionally, we found that systemic injection of a positive allosteric modulator (PAM) of mGluR1 receptors was sufficient to induce attacks in the *tottering* mouse. To better understand the mechanism by which these stressors induce attacks, we recorded the activity of PCs in acutely prepared cerebellar slices from *tottering* and wild type (WT) mice. Caffeine and norepinephrine (NE) increased the irregularity of PC activity in cerebellar slices. Similar to the *in vivo* studies, caffeine and NE-induced irregularity was blocked by pre-application of an

mGluR1 receptor antagonist, suggesting involvement of mGluR1 mediated signaling. Acute application of a α1 adrenergic receptor agonist did not induce irregularity of firing of PC in WT or *tottering* mice slices. To test basal mGluR1 activity, we acutely applied an mGluR1 PAM. This caused a significant increase in PC irregularity in WT, but not in *tottering* slices. Co-application of both α1 adrenergic agonist and mGluR1 PAM induced PC irregularity in *tottering* mice, but not WT mice slices. Taken together these data suggest stress-induced increases of NE in the cerebellum affect PC activity through activation of α1 adrenergic receptors, and indirect activation of mGluR1s. Caffeine, through the block of A1 receptors, indirectly activates mGluR1s on PCs. This data highlights the usefulness of α1 adrenergic receptor blockers, A1 adenosine receptor agonists, and mGluR1 blockers as potential therapeutic agents for EA2.

Title: Exploring drivers of regional vulnerability in spinocerebellar ataxia type 1 reveals diverse functions of ataxin-1 and the mechanisms underlying neurodegeneration

Authors: *C. J. ADAMSKI[1], V. GENNARINO[2], E. CRAIGEN[2], A. DE MAIO[2], H. YALAMANCHILI[2], A. JAIN[3], S. YUN JUNG[3], H. T. ORR[4], H. Y. ZOGHBI[5];

Inst., Houston, TX

Abstract: Spinocerebellar ataxia type 1 (SCA1) is a neurodegenerative disease caused by expansion of a CAG repeat encoding a polyglutamine (polyQ) tract in Ataxin-1 (Atxn1). SCA1 is characterized by loss of balance, and breathing and swallowing difficulties leading to premature death. Both the cerebellum and brainstem are vulnerable in SCA1, however, whether such vulnerabilities are mediated by the same pathogenic mechanism is unclear. We have shown in *SCA1*$^{154Q/2Q}$ mice that recapitulate SCA1 features, that halving the levels of the Atxn1 native partner, Capicua, rescues motor deficits but not survival. We also showed that abolishing the interaction between Atxn1 and Capicua prevents Purkinje cell degeneration and ataxia, suggesting that Capicua is the main driver of Purkinje cell but not the brainstem degeneration. To

gain insight into the driver(s) of brainstem pathogenesis we searched for *in vivo* binding partners of Atxn1 in the cerebellum and brainstem and identified regional and polyQ specific interactors. Interestingly, apart from Capicua, there is very little overlap in Atxn1 binding partners between these two brain regions. In wild-type mice, the brainstem interactors were enriched for RNA binding proteins (RNAbps) but no such enrichment was detected in the cerebellum. This suggested that Atxn1 might have different functional consequences to mediate degeneration in these two different brain regions. To explore this possibility, we performed RNA-seq on SCA1 mice to investigate the transcriptional and splicing changes mediated by polyQ Atxn1 in the two regions. Overall, there was very little overlap in gene expression changes and splicing alterations between the cerebellum and brainstem and distinct biological pathways were enriched in each region. The majority of changes seen in the cerebellum are transcriptional while those in the brainstem mostly involved splicing alterations. Using RNAbp motif enrichment analysis and proteomics we identified RNAbps that interacted with Atxn1 in the brainstem and whose binding motif was enriched in the transcripts showing altered splicing. We are currently validating these interactions and splicing changes in both brain regions to pinpoint the molecular changes driving regional vulnerability. Our studies, thus far, suggest that SCA1 pathogenesis may be mediated by distinct by polyQ expanded Atxn1 driven mechanisms in different regions.

Title: AnkyrinR is required for cerebellar Purkinje cell survival

Authors: S. R. HA, ***M. N. RASBAND**;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Ankyrin (AnkR, AnkB, AnkG) proteins are the primary link between the submembranous spectrin-based cytoskeleton and the cytoplasmic domain of multiple transmembrane proteins in the nervous system and other tissues. Although AnkG and AnkB are well recognized as important domain organizers within the nervous system, few studies have

investigated AnkR's role. Our lab recently showed a pre-existing pool of AnkR protein can compensate for a loss of AnkG and cluster Na^+ channels at nodes of Ranvier. Additionally, disruptions in AnkR have been indicated in multiple studies of various neurological disturbances, including cerebellar dysfunction. However, the role of AnkR in the nervous system remains poorly understood. Our expression analyses show, unlike the other ankyrin proteins found widely throughout the brain, AnkR is highly expressed in just a subset of neurons, including cerebellar granule and Purkinje cells (PCs). To elucidate the role of AnkR in the nervous system,we created AnkR conditional knockout mice (AnkR cKOs) by flanking exons26 and27 of*Ank1* with*loxP* sites, upstream of the spectrin binding domain. We used Nestin-Cre, Viaat-Cre, and Pcp2-Cre to mediated removal of these exons, causing a frame-shift mutation resulting in a premature stop codon, selectively removing AnkR from neural stem cells, GABAergic neurons, and PCs, respectively. We found that all AnkR cKO mice have progressive PC degeneration marked by increasing amounts of abnormal protein accumulation and dystrophic axons, resulting in PC loss by 6-months of age. Interestingly, most of the degeneration seen in cKO mice occurs in the anterior cerebellum, lobules I-V. Coronal images reveal PCs in cKO animals degenerate in a striped pattern, suggesting specific populations of PCs may be more susceptible to degeneration following loss of AnkR. Additionally, gait analyses show disrupted gait, action tremor, and ataxia in all cKO animals. Interestingly, mutations of beta-III spectrin underlie spinocerebellar ataxia type 5 (SCA5), characterized by disrupted gait and progressive PC degeneration, phenotypically similar to AnkR cKO mice. Indeed, our data confirms AnkR and beta-III spectrin co-localize in PCs and interact in the cerebellum. Taken together, these data suggest AnkR plays an important role in stabilizing the spectrin cytoskeleton in PCs; however, loss of AnkR may be more detrimental to certain PC populations. Future studies using our novel AnkR cKO will further explore the role of AnkR in PCs, including investigating candidate membrane proteins that AnkR could interact with in the cerebellum to determine precise molecular mechanisms underlying these changes.

Title: Exercise and 4-AP work as an effective combination therapy in a mouse model of spinocerebellar ataxia type 6

Authors: *A. A. COOK[1], S. JAYABAL[2], T. C. LEUNG[1], K. C. SHENG[1], A. J. WATT[1]; [1]Dept. of Biol., McGill Univ., Montreal, QC, Canada; [2]Dept. of Neurobio., Stanford Univ., Stanford, CA

Abstract: Spinocerebellar ataxia type 6 (SCA6) is a late-onset neurodegenerative disease characterised by a loss of motor coordination and eventual cerebellar degeneration. The disease is caused by a CAG expansion mutation in the *CACNA1A* gene. The underlying pathophysiology is poorly understood and treatment options are limited, but our lab has recently identified several promising therapeutic approaches. We have used a knock in mouse model harbouring a CAG expansion mutation in the *CACNA1A* gene (SCA6 84Q/84Q). At 7 months these mice display significant deficits in motor coordination as well as in the precision and frequency of Purkinje cell firing. We found that the FDA-approved drug 4-Aminopyrimidine (4-AP) was able to ameliorate motor coordination deficits. 4-AP rescued Purkinje cell firing precision but not Purkinje cell firing frequency (Jayabal et al., 2016). Since brain-derived neurotrophic factor (BDNF) levels are reduced in post-mortem brain tissue from SCA6 patients, and BDNF is upregulated with exercise, we wondered whether exercise might improve motor deficits in SCA6. Here we show that 1 month of voluntary exercise can act therapeutically to rescue motor coordination and Purkinje cell firing deficits in SCA6 84Q/84Q mouse. In contrast to 4-AP, exercise improved Purkinje cell firing frequency without affecting firing precision. We therefore hypothesised that a combination therapy approach would be able to rescue the deficits in both Purkinje cell firing and regularity, proving more effective than either exercise or 4-AP alone. Providing 4-AP and exercise to SCA6 84Q/84Q mice, we rescued both firing frequency and precision deficits from Purkinje cells. Performance on an accelerating rotarod protocol was also ameliorated, indicating a rescue of motor coordination. Our results suggest that both the firing frequency and precision deficits in Purkinje cells contribute to motor coordination deficits in SCA6, and a combination therapy approach represents a promising strategy for the treatment of this disease.

Title: Assessment of locomotion, learning, and memory post-seizure recovery in *Drosophila melanogaster*

Authors: *S. CHEN, D. LENT;
California State University, Fresno, Fresno, CA

Abstract: People of all ages are affected by epilepsy, a neurological disorder characterized by seizures that often lead to other health concerns and current therapeutics are not universally effective. The focus of this study is to induce single and multiple seizures to observe its effects on locomotion, learning, and memory. *Drosophila melanogaster* serves as ideal model systems due to current genetic tools. Seizure sensitive flies were generated using the Gal4/UAS system to express temperature sensitivity and mechanosensitivity (bang) channels in the nervous system, which enabled the activation of seizures at any time. Pan-neuronal flies (458) was the Gal4 driver crossed with temperature sensitive flies (26701) and bang-sensitive flies (458) to express seizure sensitivity in all neurons. In the first experiment, male and female virgins were collected and a single seizure was induced at 1 day old by placing them in separate vials into a hot water bath at 39C for 10 seconds. Flies that received multiple seizures underwent the same treatment every hour for 24 hours. After a 24 hour recovery period, the flies were observed using a negative geotaxis assay to assess its climbing behavior for any deficits. Controls did not have activation of seizures and underwent the same assay. Results showed single seizure flies completed the task at similar times to the control. Flies with multiple seizures took longer to complete the assay. In the second experiment, seizures were induced to male and female virgin bang-sensitive flies at 1 day old using a vortex at maximum speed for 10 seconds. Again, flies that received multiple seizures had the same treatment each hour for 24 hours and the controls did not receive seizures. These flies were given 24 hours to recover before a visual place learning assay. The flies were examined to see if they can recall the location of the cool spot using visual cues in a heated arena. Results showed flies with single seizures were still able to associate visual cues with the cool spot. Flies that received multiple seizures exhibited greater decline in their cognitive abilities. These experiments showed that single seizures have no lasting effects on behavior, but flies that received multiple seizures over 24 hour periods had lasting deficits.

Title: Structural magnetic resonance imaging measures of neurodegeneration in a spinocerebellar ataxia type 7 cohort

Authors: *J. PARKER[1], S. MERCHANT[3], S. ATTARIPOUR ISFAHANI[1], P. MCGURRIN[1], L. A. HURYN[2], M. HALLETT[1], S. G. HOROVITZ[1];

Abstract: Spinocerebellar Ataxia type 7 (SCA7) is an autosomal dominant neurodegenerative disease characterized by progressive cerebellar ataxia and retinal degeneration. Postmortem neuropathology has revealed that while atrophy is primarily restricted to the cerebellum and brainstem, subtle microstructural abnormalities are found throughout the CNS. Despite the ability of neuropathology to reveal structural abnormalities, it cannot be used to track how this pathology evolves *in vivo*. Therefore, the spatiotemporal pattern of neurodegeneration and how it relates to disease progression remains unclear. Conventional imaging analyses such as voxel-based morphometry and diffusion tensor imaging (DTI) are unable to fully assess structural abnormalities *in vivo* as they are normally limited to specific tissue types. Additionally, an increase in CSF-like free water in and around the tissues, as can happen in neurodegeneration, can dramatically affect the measures derived from the classical DTI model. To address these challenges, we used two recently developed DTI methodologies. First, we registered subject DT images to a study-specific template using information from the full diffusion tensor, which means the alignment was accurate across all anatomical structures. This enabled us to assess microstructural abnormalities, as measured by diffusion metrics such as Trace and fractional anisotropy, across the whole brain. The transformations computed from this method also enabled us to quantify volume loss across the whole brain through diffusion tensor-based morphometry. Second, we fit a dual-compartment DTI model that can account for an increase in CSF-like free water in order to control for possible neurodegeneration-related biases. Using these methodologies, we find *in vivo* a pattern of neurodegeneration similar to the one revealed by neuropathology. Gross volumetric decreases were found to be constrained to specific areas including cerebellar gray matter and white matter (WM), cerebellar peduncles, brainstem, cerebral peduncles, optic tract, thalamus, and superior corona radiata. Microstructural abnormalities were found not only in these areas, but also throughout much of the brain including areas potentially involved in clinical manifestation such as the optic radiation, occipital lobe, the corticospinal tract, and the sensorimotor cortices. Additionally, we found a correlation between the average Trace of the WM in patients with a clinical scale of ataxia severity. These methodologies could be used in a longitudinal analysis to characterize the full spatiotemporal pattern of pathological changes taking place during SCA7 progression.

Title: Developmental characterization of brain structure and motor function in SCA1$^{154Q/2Q}$ mice

Authors: *J. HESKJE[1], L. SPENCER NOAKES[3], S. NOPOULOS[1], A. JYOTIS[1], T. KOSCIK[1], D. THEDENS[2], E. AXELSON[1], L. DUVICK[4], H. T. ORR[4], P. C. NOPOULOS[1], K. L. PARKER[1];
[1]Psychiatry, [2]Univ. of Iowa, Iowa City, IA; [3]Mouse Imaging Ctr., The Hosp. for Sick Children, Toronto, ON, Canada; [4]Univ. of Minnesota, Minneapolis, MN

Abstract: Spinocerebellar ataxia type-1 (SCA1) is a dominantly-inherited, late-onset neurodegenerative disorder characterized by cognitive decline, motor dysfunction, and premature death. The genetic basis of SCA1 is a CAG trinucleotide repeat encoding for a polyglutamine expansion in the ataxin-1 protein. While transcriptional dysregulation and Purkinje cell pathology caused by mutant ataxin-1 are believed to be crucial for development of the SCA1 phenotype, little is known about regional changes in brain structure that accompany disease progression. In juvenile-onset Huntington's disease, another polyglutamine neurodegenerative disorder, decreases in striatal volume are accompanied by proportional enlargement of the cerebellum suggesting a compensatory role of the cerebellum for striatal loss. We hypothesized an inverse relationship for SCA1, whereby proportional decreases in cerebellar volume may be accompanied by proportional enlargement of the striatum. Using MRI, longitudinal changes in brain structure were assessed from SCA1$^{154Q/2Q}$ mice (N=40) in a sex and genotype balanced design from postnatal week 1 to 20, at which point the disease phenotype is manifest. Preliminary analyses include volumetric measures of the striatum and cerebellum in proportion to whole brain volume, as global atrophy is known to occur. Motor assays including rotarod, balance beam, open field, and gait analysis with DigiGait™ were performed on the same timeline as neuroimaging. Correlation between regional changes in brain structure, motor performance on the different tasks, and CAG repeat length were analyzed. Associative motor learning distinguishable from motor impairment was also assessed in a separate cohort of SCA1$^{154Q/2Q}$ mice using the Erasmus Ladder™. Preliminary results indicate that relative to whole brain volume, there are no significant differences in proportional cerebellar or striatal volume at any developmental timepoint up to week 20 between SCA1$^{154Q/2Q}$ mice and wildtype littermate controls. Future analyses will investigate the precise regional differences in the cerebellum by parcellating white and grey matter, lobules, and deep nuclei using advanced cerebellar masks.

Furthermore, ataxin-1 aggregates have been reported in the cerebellum only after 20 weeks but are prominent in cerebral cortex, hippocampus, and thalamic nuclei by postnatal week 6 so these regions represent additional candidates for analysis. Ultimately, the identification of a specific brain region(s) as a predictive index of disease progression could enable better tracking of SCA1 in both clinical treatment and for the evaluation of new therapies.

Title: The contribution of the cerebello-thalamo-cortical circuit to interval timing performance in rats

Authors: *J. R. LEWIS, H. E. HALVERSON, B. J. DECORTE, K. L. PARKER;
Dept. of Psychiatry, Univ. of Iowa, Iowa City, IA

Abstract: Despite a body of work implicating the cerebellum in cognition, its precise role is unknown. One mechanism through which the cerebellum may mediate frontal cortex dependent executive functioning is through lateral cerebellar nucleus (LCN) relays via the ventrolateral thalamus. This is clinically significant as many psychological disorders (e.g., schizophrenia, depression, and autism spectrum disorder) are characterized by dysfunction of the frontal cortex. Our work and that of others has shown that cerebellar stimulation may modulate frontal cortex and may help to recover cognitive functioning in patients with schizophrenia which involves disrupted frontal cortex activity. Currently, it remains unknown which aspects of cognition are influenced by this cerebello-thalamo-cortical circuit. The current study aims to probe the role of this pathway through systematic pharmacological inactivations of the LCN, ventrolateral thalamus, and the medial frontal cortex (MFC) in rats. We have previously shown that the cerebellum is involved in a simple interval task that requires time estimation in the suprasecond range. Here we have improved on this task by using two-intervals (4-second and 12-second) that require the animal to respond at a specific location to demonstrate temporal discrimination

between two cues (a light and a tone) in the same session. Male Long Evans rats were trained on the task and implanted with drug infusion cannulae bilaterally in the medial prefrontal cortex, the ventrolateral thalamus, and the LCN. To investigate the contributions of each area in this proposed pathway to performance of this task, inactivations of each location were done both bilaterally and unilaterally using direct infusions of muscimol, a $GABA_A$ agonist. Additionally, we tested the effect of pharmacological stimulation of the LCN using GABAzine, a $GABA_A$ antagonist, during simultaneous disruption of MFC functioning with D1-receptor antagonist (SCH23390). In concurrence with previous reports, preliminary data suggest that inhibition of the MFC causes impaired accuracy of cue discrimination, while LCN inhibition resulted in a subtle shift toward earlier responding. Bilateral ventrolateral thalamic inhibition caused a complete abolition of task performance and results from unilateral infusions are ongoing. These results support the need for further work probing the role of the cerebello-thalamo-cortical circuit in frontal-dependent cognitive processes which may require more precise tract based techniques such as DREADDs or optogenetics.

Title: Transcranial direct current stimulation (tDCS) in multiple sclerosis: Is one application of 2 ma before or during a 6 minute walk test sufficient to improve walking distance?

Authors: *C. D. WORKMAN[1], B. J. POSTON[2], E. JESTER[1], J. SMITH[1], V. SMITH[1], K. MCALLISTER[1], J. KAMHOLZ[1], T. RUDROFF[1];
[1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Approximately 85% of people with Multiple Sclerosis (PwMS) in the U.S. report gait difficulty as a major disabling impairment. Transcranial direct current stimulation (tDCS) over the motor cortex (M1) has been used to improve motor and cognitive function in PwMS, but the optimal timing of tDCS (before or during) is still unclear. Recent evidence suggests that tDCS may be more effective during a task than before as it may enhance normal increases in cortical excitability and synaptic efficiency in task-activated cortical circuits. The efficacy of a single tDCS session on motor function in PwMS is also inconclusive. The purpose of this exploratory randomized, double-blind study was to determine the effect of a single dose of tDCS (2 mA),

applied before or during a 6 Minute Walk Test (6MWT) in seven moderately-disabled PwMS. Distance walked in the 6MWT was the primary outcome. Gait characteristics (velocity, cadence, stride length (SL), and lumbar and trunk angles) were secondary outcomes. It was hypothesized that tDCS applied during the 6MWT would result in a longer distance walked. PwMS were randomized into BEFORE (n = 3) and DURING (n=4) groups and attended three sessions. In the first, baseline 6MWT and maximum voluntary isokinetic extension/flexion contractions of the hip, knee, and ankle joints of both legs were performed. The more-affected leg was determined via right/left asymmetry ≥ 10%. tDCS or sham over M1 of the more-affected leg were randomly allocated to sessions two or three. The results indicated that the distance walked during the 6MWT was not different between groups or stimulation conditions ($p > 0.12$). However, a stimulation*group interaction ($p = 0.03$) indicated that BEFORE had smaller coronal trunk angles with tDCS (4.9° ± 2.1°) compared to sham (6.1° ± 2.7°; $p = 0.05$; Cohen's **d** = 0.5). A stimulation*group interaction trend ($p = 0.05$) indicated that DURING had smaller lumbar sagittal angles with tDCS (6.7° ± 1.0°) compared to sham (8.0° ± 0.8°; $p = 0.03$; Cohen's **d** = 1.36). There was a stimulation*group interaction trend for the SL of the more-affected leg ($p = 0.06$) and a stimulation trend for the SL of the less-affected leg ($p = 0.09$). These preliminary results indicate that a single application of tDCS at 2mA before or during a 6MWT is insufficient to improve the distance walked in PwMS. However, a significant interaction, along with statistical trends and large effect sizes, suggest that tDCS may alter walking characteristics in PwMS and may help improve other aspects of gait (e.g., SL and trunk/lumbar control). Future studies should include larger sample sizes, multiple tDCS sessions, higher tDCS intensities with longer durations, and measures of perceived effort.

Title: Analysis of tongue strength and swallowing in COPD and healthy ageing

Authors: *I. EPIU[1], C. BOSWELL-RUYS[2], S. GANDEVIA[2], J. E. BUTLER[3], A. HUDSON[2]; [1]Neurosci. Res. Australia - UNSW, Sydney, Australia; [2]Neurosci. Res. Australia, Sydney, Australia; [3]Neurosci. Res. Australia, Randwick, NSW, Australia

Abstract: Swallowing disorders seen in ageing and other neurodegenerative disorders impact the quality of life of patients and caregivers. Muscle wasting in ageing and disease affects the coordination and muscle strength needed for swallowing. This dysphagia contributes to malnutrition and dehydration, and is a major predisposing condition for aspiration, leading to pneumonia, and in some cases, death. The aim of our study was to evaluate tongue strength in chronic obstructive pulmonary disease (COPD) which has not been done before.
Tongue strength measures of peak anterior pressure were obtained with the Iowa Oral Performance Instrument in 11 of 18 participants with COPD age 75±10.2 (mean±SD) and 18 age-matched controls (AMC) age 71±6.3. Using a two-sample t-test our results were compared to published weighted averages in subjects >60 years old who had a mean pressure of 57.4±13.0 kPa. Swallowing function was assessed using the eating assessment tool (E10), timed water swallow test (TWST) and test of mastication and swallowing of solids (TOMASS) and compared to published reference values.
Tongue strength was 48.55±12.44 kPa in the COPD group and 46.28±10.12 kPa in the AMC group, both significantly lower than published weighted averages (p=0.03; CI for the difference: 1.18-16.56
COPD, and p<0.001; CI for the difference: 6.00-16.28, AMC). For swallowing function, none of the AMC participants and 18% COPD had TWST scores, and 11% AMC and 36% COPD participants had TOMASS scores below the lower limit of normal (< 2SD from the mean). Our COPD group had a longer E10 when compared to AMC 3.3(4.9) and 0.9(1.6) respectively; p = 0.06 (CI for the difference, -0.73 to 5.53).
In conclusion, tongue strength in our Australian sample is 18% lower than published data and is associated with impaired swallowing function in some participants. These groups may benefit from exercises to increase tongue strength, improve swallowing and airway protection to reduce the risk of aspiration.

Title: Neuro-cardio-autonomic modulations in children with Duchenne muscular dystrophy

Authors: *T. N. SATHYAPRABHA, A. MEGHANA, V. PREETHISH-KUMAR, A. JOHN, P. PRATHUYSHA, T. R. RAJU, A. NALINI;
NIMHANS, Bangalore, India

Abstract: Background: Duchenne muscular dystrophy (DMD) is an X-linked devastating progressive muscle disease. Death is usually secondary to cardiorespiratory complications. Preclinical /early detection of cardiac autonomic disturbances prior to routine identification by standard techniques of cardiac assessment, may help in timely initiation of cardio-protective therapy. **Methods:** A prospective study of 38 DMD boys and 37 age-matched healthy controls was conducted. Heart rate variability (HRV), blood pressure variability (BPV; DMD=34, control=10) and baroreceptor sensitivity (BRS; DMD=35, control=10) data was analysed and correlated with disease severity and genotype according to Multiplex Ligation-dependent Probe Amplification (MLPA). **Results:** In the DMD group**,** the median age at assessment was 8 years [Interquartile range 7-9 years], median age at onset of illness was 3 years [Range, 2-6 years] and mean duration of illness was 4 years [Range, 2.5-5] years. MLPA showed deletions in 34/38 (89.5 %) and duplications in 10.5 % patients. The mutation was distal in 29/38 and proximal in 9 cases. The median heart rate was significantly higher in DMD children compared to controls [101.19 (Range, 94.71-108.49)] /min vs [81 (Range, 76.2-92.76)] /min. All the assessed HRV and BPV parameters were significantly reduced in DMD cases except diastolic BP, mean BP and aortic impedance. BRS parameters were also significantly reduced in DMD cases except the alpha-LF. A positive correlation was found between alpha HF with age at onset and duration of illness. There were no significant changes in HRV/BPV/BRS parameters between the proximal and distal mutation groups. **Conclusion:** This study shows a definite early impairment of neuro-autonomic control in DMD. Simple non-invasive tests like HRV, BPV and BRS can thus be used to identify pre-clinical cardiac dysfunction in DMD patients making early institution of cardio-protective therapies possible.

Title: Incretin hormones attenuate motor axon dysfunction in a mouse model of type 2 diabetes mellitus

Authors: *C. KRARUP[1], C. HOLSCHER[2], M. MOLDOVAN[3];
[1]Rigshospitalet, Copenhagen, Denmark; [2]Res. and Exptl. Ctr., Henan Univ. of Chinese Med., Zhengzhou, China; [3]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: BackgroundAnalogues of incretin hormones glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) provide various degrees of neuroprotection in sensory-motor diabetic polyneuropathy (DPN) as well as in other neurodegenerative disorders. Muscle weakness occurs at late stages of DPN. We hypothesize that the slow progression of motor impairment allows a time-window to investigate the effects of incretin hormones on motor axon dysfunction preceding axonal degeneration in DPN.AimThe aim of this study was to assess the effect of treatment with a dual GLP-1/GIP receptor agonist (DA-CH5) on motor axon dysfunction in the most widely used mouse model of Type 2 diabetes mellitus, the genetically leptin receptor-deficient mouse (db/db).MethodsInvestigations were carried out in mature (5-month old) female db/db in a double-blind, sham-controlled trial. A daily dose of DA-CH5 (30 nmol/kg i.p.) or vehicle was administered for 3 weeks. Motor nerve function was investigated by in vivo neurophysiology using conduction studies and multiple measures of excitability by threshold-tracking, a clinically available method that can inform on membrane potential and axonal ion channel function. The tibial nerve was stimulated distally at ankle and the evoked compound muscle action potential (CMAP) was recorded from plantar muscles under anesthesia and temperature control. Age-matched wild-type (WT) mice were used for comparison.ResultsAs compared to WT, the db/db were severely overweight and hyperglycemic. Conduction studies in db/db showed a prolonged CMAP latency and a borderline reduction in amplitude. Their rheobase was reduced, indicating a hyperexcitable state of the distal axon. Consistently, the other excitability measures showed a reduced deviation during both depolarizing and hyperpolarizing threshold electrotonus and a marked increase in refractoriness at the expense of the superexcitable period of the recovery cycle. These abnormalities were attenuated in db/db treated with DA-CH5. Mathematical modeling predicted that effect of DA-CH5 could largely be explained by a hyperpolarizing shift in membrane potential.ConclusionOur data suggest that motor axons are depolarized in the DPN of db/db. Treatment with a dual GLP-

1/GIP receptor agonist attenuated this depolarization. It is possible that improved energy metabolism increased the resting Na^+/K^+ pumping with a net hyperpolarizing effect. Motor nerve excitability studies could thus provide translational biomarkers to assess the axonal effect of incretin neuroprotection.

Title: Vulnerability of fast- and slow-twitch motor units in a mouse model of spinal and bulbar muscular atrophy

Authors: *E. MOLOTSKY[1], A. PLUCIENNIK[2], D. E. MERRY[3];
[1]Biochem. and Mol. Biol., [3]Dept Biochem & Molec Biol, [2]Thomas Jefferson Univ., Philadelphia, PA

Abstract: Spinal and bulbar muscular atrophy (SBMA) is an X-linked neuromuscular disease caused by a polyglutamine repeat expansion in the androgen receptor (AR). The symptoms of muscle atrophy, weakness, and fasciculations occur due to the combined loss of lower motor neurons in the spinal cord and brainstem and atrophy of the associated innervated muscle fibers. While it is known that lower motor neuron degeneration contributes to the disease phenotype, it is unknown why certain motor neurons are more susceptible than others to the toxic properties of the mutant AR. In SBMA patients, fiber type grouping and decreased tongue pressure and grip power reveals fast motor unit-selective degeneration. Fast-fatigable motor units atrophy earliest in SOD1 mouse models, SMA patients, and during normal aging, as well as in a myogenic model of SBMA. Using a transgenic mouse model of SBMA that expresses the AR with a polyglutamine expansion of 112 repeats (AR112Q) primarily in neuronal tissue, we analyzed spinal cord motor neurons and the neuromuscular junctions (NMJs) of multiple hindlimb muscles in order to study the vulnerability differences of motor units. Mouse tibialis anterior (primarily fast-twitch) and soleus (primarily slow-twitch) muscles stained for synaptophysin

(presynaptic) and α-bungarotoxin (postsynaptic acetylcholine receptors (AChRs)) were analyzed for histological measurements of pre- and post-synaptic area, post-synaptic compactness, and synaptophysin/α-bungarotoxin colocalization. Preliminary data revealed an early decrease in compactness prior to significant loss in NMJ area (pre- and post-synaptic) in the tibialis anterior (TA). Histological analysis of the soleus showed early changes in colocalization and compactness, implicating a change in both the pre- and post-synaptic structures at the NMJ. Further evaluation of neurofilament heavy chain (NF-H) phosphorylation revealed decreases in unphosphorylated NF-H in the soma of anterior horn motor neurons as well as a decrease in phosphorylated NF-H at the axon terminal of the TA, concomitant with disease motor phenotype. These aspects of neuromuscular junction pathology may provide insights into the mechanisms underlying vulnerability of motor neurons and muscle in patients with SBMA.

Title: Brain derived neurotrophic factor is an important factor for pudendal nerve motor branch functional recovery

Authors: *B. M. BALOG[1,2,3], T. L. ASKEW[4], D. LI[5], B. HANZLICEK[2], M. S. DAMASER[6]; [1]Biomed. Engin. Dept., Cleveland Clin. Lerner Res. Inst., Cleveland, OH; [2]Res., Louis Stokes VA Med. Ctr., Clevleand, OH; [3]Dept. of Biol., Univ. of Akron, Akron, OH; [4]Biomed. Engin., [5]Biomed. Engin. Dept., [6]Dept of Biomed. Engin., Cleveland Clin., Cleveland, OH

Abstract: Increased motor nerve latency in women with stress urinary incontinence (SUI) suggests that pudendal nerve (PN) function and recovery are important to the multifactorial continence mechanism. A PN crush (PNC) model of SUI in female rats demonstrates that brain derived neurotrophic factor (BDNF) is upregulated after PNC, suggesting that it is necessary for PN regeneration. We hypothesized that BDNF is essential to PN functional recovery following PNC. In this experiment, we reduced active BDNF by administering its receptor, TrkB, to block the action of BDNF and determine if this reduces recovery from PNC. Sprague-Dawley rats were divided into three groups; 1/3 of the rats received sham bilateral PNC with implanted osmotic pumps (Alzet model 2002) containing saline (SPNC + S). The other 2/3 rats received bilateral PNC with osmotic pumps, containing either saline (PNC + S) or Fc-TrkB chimera (PNC +

TrkB). Three weeks later the animals underwent functional testing consisting of leak point pressure (LPP) with simultaneous PN motor branch potential (PNMBP) recording and PN sensory branch potential recording during clitoral brushing (PNSBP). With PNC + S serving as the control, a One-way ANOVA on Ranks followed by a Dunn's test was used to indicate significant differences ($p<0.05$). After functional testing, plasma and the urethras were harvested and fresh frozen and cryosectioned. Plasma underwent ELISA analysis for BDNF concentration. Urethra sections were stained with Masson's trichrome for identification of muscle and extracellular matrix and immunofluorescence for identification of innervation of neuromuscular junctions. Slides were evaluated by two blinded observers. PNC + TrkB BDNF plasma concentrations were significant decreased compared to PNC + S, while SPNC + S BDNF concentration was not significantly different compared to PNC + S. PNC + TrkB PNMBP firing rate was significantly decreased compared to PNC + S, while PNC + S was not significantly different from SPNC + S. PNSBP firing rate & amplitude was not significantly different between any of the groups. LPP was not significantly different between the groups. PNC + Trkb neuromuscular junction staining showed neuromuscular junctions were not well reinnervated by axons, while PNC + S were well reinnervated. PNC + S neuromuscular junction morphology were similar to SPNC + S neuromuscular junctions. BDNF is essential to PN motor branch regeneration after PNC; however, BDNF may be necessary but not essential for PN sensory branch regeneration. Continence is maintained by multiple factors, explaining why a decrease in PN motor function did not lead to a decrease in LPP, a comprehensive measure of continence.

Title: Glyceryl tribenzoate, a flavoring ingredient, inhibits glycine encephalopathy

Authors: *M. KUNDU[1], A. ROY[2], K. PAHAN[1];
[1]Rush Univ. Med. Ctr., Chicago, IL; [2]Rush Univ. Med. Ctr., CHICAGO, IL

Abstract: Glycine encephalopathy (GE) or non-ketotic hyperglycinemia is a rare genetic disorder of glycine metabolism where high levels of glycine are accumulated in the body. Clinically, GE is characterized by lethargy, seizures, cognitive impairment, developmental delays, and myoclonic jerks, ultimately leading to apnea and even death in early childhood. Mutations in glycine decarboxylase (gldc) gene, an important member of the glycine cleavage system located in mitochondrial membrane, are frequently observed in patients with GE. In this

study, we have generated a preclinical model of GE by knocking down GLDC with lenti shRNA. After lenti-gldc-shRNA insult, the level of glycine increased in serum, urine and cortex of mice. Accordingly, after GLDC knockdown, mice also exhibited impairment in memory and learning. Glycerol tribenzoate (GTB) or tribenzoin belonging to the family of benzoic acid is a flavoring ingredient. Here, we delineate that oral GTB treatment was capable of lowering the level of glycine in serum, urine and cortex of lenti-gldc-shRNA-insulted mice. GTB-treated mice also showed improved motor function and advanced memory compared to untreated lenti-gldc-shRNA-insulted mice. Taken together, these data suggest that GTB may have therapeutic implication in GE.

Title: Activation of the integrated stress response contributes to the disease mechanism of tRNA-sythetase related peripheral neuropathy

Authors: *R. W. BURGESS, E. L. SPAULDING, T. J. HINES;
Jackson Lab., Bar Harbor, ME

Abstract: Charcot-Marie-Tooth type 2D (CMT2D) is a dominant axonal neuropathy caused by mutations in glycyl tRNA-synthetase (*GARS*). The GARS enzyme charges glycine onto its cognate tRNAs for translation, but like many neurodegenerative diseases, this “housekeeping gene” causes a very specific disease phenotype when mutated. To better understand the disease mechanism underlying mutations in *GARS* and CMT2D, we profiled transcription and translation specifically in motor and sensory neurons in mouse models of CMT2D. Consistent with findings in Drosophila, *in vivo* non-canonical amino acid tagging showed reduced protein synthesis in motor neurons. To determine if this was directly due to the disease mechanism, due to cell stress, or a combination of these mechanisms, we also performed gene expression profiling, using ribosome tagging to specifically examine the motor neuron “translatome,” and also using whole spinal cord RNAseq. Both approaches revealed signatures consistent with activation of the integrated stress response (ISR). Confirmation of upregulated ATF4 target genes by *in situ* hybridization showed the ISR was selectively activated in alpha-, but not gamma-motor neurons,

and in medium and large sensory neurons that constitute a mix of mechanoreceptors and proprioceptors. We postulated that the ISR was activated through GCN2 kinase, one of four sensors of various cell stresses best known for responding to amino acid insufficiency. To test this, we combined the *Gars*/CMT2D mouse model with a knockout of *Gcn2*. We found that double mutant mice no longer had gene expression changes indicating activation of the ISR. In addition, the phenotype of the double mutant mice was much milder than *Gars* mutations alone, suggesting that chronic activation of the ISR contributes to the severity of the neuropathy. We are currently using a combination of *in vivo* and *in vitro* approaches to test hypotheses about how dominant mutations in *GARS* might lead to activation of GCN2 in such a cell type-specific manner, including by the presence of uncharged tRNAs or stalled ribosomes. Interestingly in humans, dominant mutations in at least five tRNA synthetase genes lead to peripheral neuropathy. Preliminary studies in a mouse model of dominant intermediate CMT type C (DI-CMTC), caused by mutations in tyrosyl tRNA-synthetase (*YARS*), indicate a very similar signature of gene expression changes, consistent with activation of the ISR and a similar mechanism in this related disease.

Title: A novel mouse Tubb4a$^{D249N/D249N}$ to model hypomyelination and atrophy of basal ganglia and cerebellum and development of potential therapeutic strategies

Authors: *S. SASE[1], A. ALMAD[2], A. BOECKER[4], P. GUEDES-DIAS[6], J. LI[4], A. TAKANOHASHI[2], T. MCCAFFREY[2], D. SIRDESHPANDE[2], Q. PADIATH[7], E. HOLZBAUR[5], S. SCHERER[8], A. VANDERVER[3];
[1]CHOP, Philadelphia, PA; [3]Neurol., [2]Children's Hosp. of Philadelphia, Philadelphia, PA; [5]Dept. of Physiol., [4]Univ. of Pennsylvania, Philadelphia, PA; [6]Fac. of Pharmacy, Univ. of Porto, Porto, Portugal; [7]Univ. of Pittsburgh, Pittsburgh, PA; [8]Neurol., Univ. of Penn, Philadelphia, PA

Abstract: Hypomyelination and Atrophy of Basal ganglia and Cerebellum (H-ABC) is a rare hypomyelinating leukodystrophy with causal variants in tubulin alpha 4 (*TUBB4A*) and p.Asp249Asn (D249N) is a recurring heterozygous variant occurring in the majority of affected individuals. H-ABC typically begins in infancy characterized by dystonia, ataxia, altered gait and progressive motor dysfunction. To date, there is no therapeutic approach available. To facilitate

development of therapeutic strategies, our group has developed a knock-in mouse model harboring heterozygous (*Tubb4a*^{D249N}) or homozygous (*Tubb4a*$^{D249N/D249N}$) *Tubb4a* mutations using a CRISPR-Cas9 approach. This H-ABC mouse model (*Tubb4a*$^{D249N/D249N}$) displays progressive motor dysfunction with tremor, abnormal gait, ataxia and decreased survival. Neuropathological and electron microscopy analysis of *Tubb4a*$^{D249N/D249N}$ mice shows initial delay of myelination followed by ultimate demyelination along with loss of oligodendrocytes (myelinating cells in CNS). Further, *Tubb4a*$^{D249N/D249N}$ shows severe cerebellar atrophy and significant striatal neuronal loss. Cell-autonomous effects were observed in neurons and oligodendrocytes in culture along with unstable microtubule dynamics in neurons of *Tubb4a*$^{D249N/D249N}$ mice. Thus, *Tubb4a*$^{D249N/D249N}$ mouse recapitulates H-ABC disease with decreased survival, making it a unique model to develop pre-clinical strategy for H-ABC disease. One approach to treat H-ABC is to reduce the TUBB4A expression as partial phenotypic data displays that *Tubb4a Knockout* (KO) mouse are developmentally normal, suggesting that TUBB4A is redundant in a cell. To reduce TUBB4A expression in the mouse, ongoing studies are focused on screening a panel of anti-sense oligonucleotide (ASO) *in vitro* to establish the most effective ASOs. Subsequently, the best candidate ASO will be administered in *Tubb4a*$^{D249N/D249N}$ mouse at different time points and different route of administration to test if ASO treatment can rescue the hypomyelination, cerebellar ataxia and tremors observed in the *Tubb4a*$^{D249N/D249N}$ mice. Additionally, dose escalation experiments will be performed to establish dose response curve in mice. This work will serve as pre-clinical proof of principal for testing if use of ASO is a viable approach in treatment of H-ABC.

Title: Forced expression of MuSK in dystrophic (mdx) mouse muscles partially restores expression of utrophin and beta-dystroglycan to the sarcolemma

Authors: J. BAN, J. HUANG, ***W. D. PHILLIPS**;
Physiol., The Univ. of Sydney, Sydney, Australia

Abstract: *Mdx* mice lack dystrophin and are used to model the changes in muscle structure and function that occur in Duchenne muscular dystrophy (DMD). Muscle Specific Kinase (MuSK; a transmembrane tyrosine kinase) is vital for stabilizing the mammalian neuromuscular junction (NMJ) and *mdx* muscles have been found to express lower levels of MuSK compared to wild-type muscles. We have used Adeno-associated viral (AAV) expression vector (serotype 6) to supplement MuSK in the tibialis anterior muscle of 8-week old male *mdx* and wild-type (C57BL10) mice. We previously reported that, when studied one month later, *mdx* muscles injected with AAV-MuSK were less fragile. Fragility was assessed by the drop in maximum isometric contractile force that occurs after the dystrophic muscle is challenged with a series of four eccentric contractions. Here we describe changes in the sarcolemmal expression of dystrophin-associated proteins that might explain the protective effects of AAV-MuSK. Within fast twitch muscles, such as the tibialis anterior, endogenous MuSK is concentrated mainly at the motor endplate. The most obvious effect of injecting AAV-MuSK upon MuSK expression was the appearance of MuSK immunofluorescence throughout the extrasynaptic sarcolemma of muscle fibers, at densities comparable to endplate levels. This is distinctly different from wild-type muscles and *mdx* contralateral control muscles (injected with empty AAV vector), which showed only weak anti-MuSK labeling outside the endplate. Consistent with previous reports *mdx* (control) muscles showed relatively low intensity staining for β-dystroglycan in their extrasynaptic sarcolemma, when compared to wild-type muscles. Importantly, injection of AAV-MuSK-GFP significantly increased the sarcolemmal density of β-dystroglycan in *mdx* muscles. This was associated with a significant increase in total muscle β-dystroglycan protein, assessed by immunoblotting. Immunofluorescent labeling also revealed a marked increase in the density of utrophin in the sarcolemma of *mdx* muscles expressing MuSK-GFP, which may help explain the partial restoration of β-dystroglycan in AAV-MuSK muscles. These results suggest that expression of MuSK in the extrasynaptic sarcolemma can reduce the fragility of dystrophic *mdx* muscle fibers by restoring the sarcolemmal expression of utrophin and β-dystroglycan. This might help explain why the soleus muscle (which naturally expresses MuSK throughout it's sarcolemma) seems to be less fragile than the fast-twitch muscles of *mdx* mice.

Title: Kinase inhibitors improve neurofilament distribution in Charcot-Marie-Tooth 2E human motor axons

Authors: *R. MACIEL, R. CORREA, J. BOSSO TANIGUCHI, I. P. ARAUJO, M. A. SAPORTA;
Neurol., Univ. of Miami, Miami, FL

Abstract: Length-dependent axonal degeneration is the pathologic hallmark of several neurodegenerative disorders, including inherited peripheral neuropathies (or Charcot-Marie-Tooth disease, CMT). CMT is currently an untreatable disorder. This is partially due to lack of translational models suitable for drug discovery. *In vitro* models of CMT have been hindered by the two-dimensional configuration of neuronal cultures, which limits visualization and orientation of axons. To overcome these limitations, we cultured iPSC-derived spinal motor neurons in agitation to form three-dimensional spheroids, which grow axons in a centrifugal fashion when plated. Using these iPSC-derived spinal spheroids, we demonstrate a consistent and reproducible phenotype, namely discrete deposits of neurofilament protein in the motor neuron axons of three independent patients with CMT type 2E, caused by mutations in neurofilament light chain (*NEFL*) gene, but none of four unaffected controls (p=0.001). NEFL is a component of the neuronal cytoskeleton, which provides structural support for the axon and regulate radial axonal growth, determining its final diameter. Other neurofilament subtypes, including NEFM, NEFH and phosphorylated NEFH, co-accumulated is these deposits. We also demonstrate that measuring neurofilament light chain protein in culture supernatant of motor neurons is a sensitive strategy to detect axonal degeneration in CMT2E, both at baseline conditions and in response to axon toxic drugs, such as the chemotherapy agent Vincristine, and may be a useful phenotype for use in high throughput screening. Despite advances in understanding its pathophysiology, there is no disease-modifying therapy for CMT2E. By targeting kinases involved in neurofilament phosphorylation, including PLK1 and CK2, in our tridimensional system, we identified two kinase inhibitors that promoted over 50% reduction in the normalized area of neurofilament deposits (p=0.001), in three patients with CMT2E. In summary, we developed a human tridimensional *in vitro* system that models axonopathies, recapitulates key pathophysiologic features of CMT2E, is particularly useful to study length-dependent processes and may facilitate the identification of new therapeutic compounds for neurodegenerative disorders where axon degeneration plays a key role in pathogenesis. We also identified candidate kinase inhibitors as potential therapies for CMT2E.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative motor neuron disorder which causes an individual to be in locked-in state (LIS) and later in a completely locked-in state (CLIS). When the individuals are still in LIS and can communicate with eye trackers different studies have shown that these patients report to have a good quality of life (QoL). Once these individuals lose the means of communication, i.e., they are either on verge to CLIS or in CLIS, it becomes difficult to ascertain their quality of life, therefore there is no QoL data available on such patients. Recently we developed an auditory electrooculogram (EOG) + electroencephalogram (EEG) based BCI which enabled individuals who cannot use the eye-trackers for communication because of their inability to fixate the gaze but can perform micro movement of the eyes, not discernible by naked eyes, to answer “yes” and “no”. Four individuals on the verge of CLIS answered QoL questionnaire. The QoL questionnaire was developed based on the QoL questionnaire for patients in LIS and for patients with the spinal cord injuries. The sample questions asked were, “Are you happy today?”, “Are you tired?”.
Questions with reference to time were also included to evaluate the change in emotional levels, e.g., “You feel relaxed today”. The results show that the QoL in individuals on verge to CLIS answered positively to questions pertaining to good quality of life. The study will be repeated several times. The results of this study might help ALS patients to make an informed decision about their life in the later stages of the disease and the healthcare programs could be tailored as per the requirement of these individuals.

Title: Label free imaging of abnormal lipid accumulation in muscle fibers from inclusion body myositis patients using Raman spectroscopy

Authors: *Y. NAGASHIMA[1], J. SHIMIZU[1,2], A. IWATA[1], K. YOSHIOKA[3], J. OMACHI[5], J. YUMOTO[4], M. KUWATA-GONOKAMI[4], T. TODA[1];

Abstract: [Background] Inclusion body myositis (IBM) is the most common late-onset myopathy, characterized by progressive asymmetric weakness predominantly affecting the quadriceps and/or finger flexors. Muscle biopsy usually shows inflammatory cells surrounding and invading non-necrotic muscle fibers, rimmed vacuoles, congophilic inclusions, and protein aggregates. Disease pathogenesis remains to be elucidated and it is hypothesized to include inflammatory and degenerative aspects. [Aims] In this study, we aimed to measure molecular vibrational spectra of abnormal muscle fibers from IBM patients. Vibrational spectra obtained using Raman spectroscopy provides vibrational information characteristic of chemical groups or bonds in a molecule without any labeling procedures. Measuring vibrational spectra enables us to locate and quantitate accumulated molecular species within tissues in a molecular specific manner. [Methods] Vibrational spectra of frozen sections of muscles biopsied from IBM patients were obtained using spontaneous Raman microspectroscopy and compared with the spectra in the local database of major lipid species measured *in vitro*. [Results] We found that the Raman spectra measured in the internal edges, i.e., the “rim” of rimmed vacuoles showed prominent peaks such as 1305cm^{-1}, 1450cm^{-1} and 1650cm^{-1}, which is typical of phospholipid backbone structures. From detailed correlation analysis of its spectral pattern with the spectral database, phosphatidylcholine showed the highest correlation. [Discussion] Previous reports have shown that rimmed vacuoles found in IBM are colocalized with various protein aggregates, such as β-amyloid, α-synuclein and TDP-43, which is considered as an evidence of degenerative aspect of the disease. These protein aggregates are usually co-stained immunohistochemically with p62 and LC3B, which is the marker molecule of autophagosome. In our observation, Raman spectra

of rimmed vacuole demonstrated a pattern of phospholipid backbone structures, lacking any spectral signature indicative of protein, such as Raman shift of phenylalanine breathing mode around 1000cm^{-1}. Because peak intensity in Raman spectrum reflects stoichiometric amount of material, our result showed the primary component of rimmed vacuole is probably phospholipids. [Conclusions] Raman spectroscopic observation showed the primary molecular species constituting rimmed vacuoles in IBM patients are phospholipids. This result supported the idea that rimmed vacuoles are disrupted autophagosomes and IBM has a degenerative aspect in its disease pathogenesis.

Title: Dissecting the transcriptome of the myotonic dystrophy type 1 CNS

Authors: ***B. A. OTERO**[1], T. KIMURA[2], K. A. HAGERMAN[3], J. B. SAMPSON[3], J. W. DAY[4], C. A. THORNTON[5], E. T. WANG[1];
[1]Mol. Genet. and Microbiology, Univ. of Florida, Gainesville, FL; [2]Intrnl. Med., Hyogo Col. of Med., Hyogo, Japan; [3]Neurol., Stanford Univ., Stanford, CA; [4]Neurol., Stanford Univ., Palo Alto, CA; [5]Univ. of Rochester, Rochester, NY

Abstract: Myotonic Dystrophy type 1(DM1) is an autosomal dominant multisystemic disease caused by a CTG microsatellite expansion in the 3' UTR of the dystrophia myotonica protein kinase (DMPK) locus. Although patients report that CNS symptoms significantly diminish quality of life, little research has been done to understand underlying pathomechanisms in this tissue relative to muscle and heart. CNS symptoms are significant yet variable and include mental illness, hypersomnolence, and visuospatial/executive dysfunction. There is a variety of tissue pathology, including grey matter atrophy, white matter lesions, gliosis, and neurofibrillary tangles. A critical gap exists in our knowledge of molecular mechanisms causing CNS dysfunction in DM1, as well as why there is extreme variability across patients. To elucidate underlying causes of CNS dysfunction in patients, we have generated RNAseq transcriptomes from the frontal cortex of 26 DM1 patients and 8 age-matched unaffected individuals. We have identified numerous splicing and expression changes, many of which correlate with one another in a manner possibly reflecting disease severity. Analyses reveal mis-regulation of multiple

synapse-related transcripts such as neurotransmitter receptor subunits, ion channels and signaling molecules. Interestingly, within this group of synapse-related transcripts, several splicing changes produce isoforms that may enhance inhibitory versus excitatory balance. This project will be valuable to understand the pathogenesis of DM; the variability of CNS phenotypes experienced by patients, and broadly, how changes to RNA regulation can cause CNS disease symptoms.

Title: Increased white matter volume may explain resting motor threshold maintenance in individuals with a history of traumatic musculoskeletal injury

Authors: *S. D. FLANAGAN[1], F. PROESSL[1], A. J. STERCZALA[1], A. Z. BEETHE[1], C. DUNN-LEWIS[1], B. C. NINDL[1], W. J. KRAEMER[2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]The Ohio State Univ., Columbus, OH

Abstract: Introduction: Increasing evidence is pointing towards corticomotor involvement in loss of function subsequent to traumatic musculoskeletal injury, as exemplified by anterior cruciate ligament rupture (ACLR). Nevertheless, little is known about structural sensorimotor adaptations, and their functional implications in individuals with ACLR. **Purpose:** Compare structural morphology in individuals with previous ACLR and healthy controls (CON) and determine the association between brain volume and corticospinal excitability. **Methods:**Twenty age-, physical activity-, height- and weight matched females (10 CON; mean age: 20.9±2.9 years) completed 3-Tesla T1-weighted structural magnetic resonance scans to determine cortical thickness, grey- and white matter at a voxel-level, and in 95 regions of interest (ROI). Using transcranial magnetic stimulation, resting motor thresholds (RMT) in both legs were determined and the average was computed. Between-group differences in RMT and brain volume were analyzed *a priori*for sensorimotor regions (bilateral precentral [M1] and postcentral gyrus [S1], paracentral lobule) via independent t-tests (α=0.05). Pearson correlations were used to assess the relationship between ROI volume and rMT. **Results:** Individuals with ACLR completed rehabilitation on average 3.1±1.1 years prior to enrollment. Five injured the left leg. RMT was

similar between groups (CON: 76.56±3.10, ACLR: 79.69±2.41, p=0.50). Voxel-wise comparisons revealed cortical thinning in sensorimotor regions in ACLR relative to CON. ACLR further demonstrated increased white matter volume in the left M1 compared to CON (10.81±0.78 vs. 8.97±0.32 cm^3, p=0.04), and increased, yet non-significant in the left S1 (8.59±0.3 vs. 1.04±0.71 cm^3,p=0.07). No differences were found for the paracentral lobule. Left M1 white matter volume was strongly correlated with RMT in CON (r= -0.75, p=0.02) but not in ACLR (r= -0.46, p=0.21). **Discussion:** Individuals with ACLR demonstrated corticomotor differences from CON, as indicated by decreased cortical thickness and increased white matter volume in sensorimotor regions. The association of left M1 white matter with RMT in healthy, but not in individuals with ACLR suggests a potential structural compensation in order to maintain function, which warrants further investigation.

Title: Social isolation and loss of physical function: Defining a novel neuromuscular phenotype

Authors: *D. CHUGH, C. IYER, P. BOBBILI, M. L. HALLEY, W. ARNOLD;
The Ohio State Univ., Columbus, OH

Abstract: Social connections are critically important for physical and psychological resiliency across the lifespan, from early stage development to senescence in older adults. Social isolation and loneliness may affect close to one half of older adults. A recent meta-analysis of studies examining the effect of social isolation and loneliness on mortality demonstrated a 29% increased risk of mortality from social isolation and 26% increase in mortality risk from loneliness. Social networks are more likely to diminish as people get older due to a variety of factors including age-associated loss of independence and immobility. Likewise, social isolation further worsens physical and mental health of older adults. Hence, social isolation, loneliness, and loss of physical function form a vicious cycle of decline and loss of resilience in older adults. In the present study, we asked whether social isolation exacerbates loss of physical function in aging mice. Baseline measures of compound muscle action potential (CMAP) and motor unit number estimate (MUNE) were performed in group-housed 27-month-old male and female C57BL/6J mice. Mice were then randomized into group- and single-housed cages. Longitudinal

in vivo assessments were performed blinded to the housing condition. Isolated female mice showed a significant decline in CMAP amplitude, as well as in motor coordination and muscle endurance as assessed by Rotarod behavioral test at week 4 after social isolation. We next wanted to determine if social isolation induced neuromuscular decline was age-dependent. In contrast to aged mice, young mice showed no differences in CMAP or MUNE but interestingly did show findings of neuromuscular junction transmission failure on single fiber electromyography. We are exploring the potential maladaptive mechanisms underlying our social isolation-related neuromuscular effects. Preliminary analyses revealed age- and gender-specific alterations in fecal corticosterone levels. We are also exploring spinal cord gene-expression changes using Nanostring Neuroscience Gene Expression panel to better understand the neuromuscular phenotype in socially isolated mice.
Social isolation related stress is a well-established stressor in social species with a range of adverse effects. Our results demonstrate that social isolation in young and aged mice impacts neuromuscular health and function. Understanding this phenomenon could have translational implications in older adults experiencing traumatic life events such as losing a spouse or a loved one, retirement, or hospitalization which may all be associated with dire mental and physical health implications.

Title: RANTES-induced increased trafficking of Th17 cells in substantia nigra potentiates dopaminergic cell loss in MPTP-induced mouse model of Parkinson's disease

Authors: *D. DUTTA[1], M. KUNDU[1], S. MONDAL[1], A. ROY[1], K. PAHAN[1,2];

Abstract: Enhanced gliosis, inflammation and accumulation of peripheral T cells are unequivocally found in substantia nigra (SN) of Parkinson's disease (PD) brains. RANTES (regulated on activation, normal T cell expressed and secreted) is one of the major chemokines which was found to be up-regulated in SN and serum of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-intoxicated mice, monkeys and in postmortem PD patients.

RANTES supplementation was also found to help continuous trafficking of T cells in SN of MPTP-intoxicated mice and thereby it promotes progressive loss of nigral DAergic neurons. However, which particular T cell subsets are recruited in the brain by RANTES was not clear. In the present study, immunodeficient Rag1 (-/-) mice, which are known to resist MPTP toxicity, were adoptively transferred with Th1, Th17 and Treg cells isolated from Tomato red mice followed by acute MPTP insult. RANTES was supplemented in mice following MPTP treatment twice in a week, 3.5 days apart from each. The data revealed that infiltration of Th1 and Treg cells is not perturbed by exogenous Rantes administration. However, invasion of Th17 polarized cells in SN of MPTP-challenged mice was significantly increased following RANTES supplementation. Furthermore, RANTES could significantly increase the percentage of MPTP-induced TH cell loss in mice receiving Th17 polarized cells. The aggravated loss of nigral TH neurons also paralleled with significant DA loss in striatum and significant motor deficits in RANTES supplemented MPTP-intoxicated animals. The findings clearly suggest that RANTES specifically recruits peripheral Th17 cells in the brain and thereby promotes progressive DAergic neuronal loss and associated PD pathology.

Title: PET imaging studies of neuroinflammation in a nonhuman primate model of Parkinson

Authors: H. LIU[1], Y. ZHOU[1], Z. LUO[1], J. GU[1], Y. YU[1], H. WHITE[1], S. A. NORRIS[1], H. FLORES[1], L. L. DUGAN[2], Z. TU[1], ***J. S. PERLMUTTER**[1];
[1]Washington Univ. Sch. of Med., St. Louis, MO; [2]Dept Medicine/Geriatrics & Vanderbilt Brain Inst., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Objectives Neuroinflammation plays a key role in the pathogenesis and progression of Parkinson disease (PD). Herein we reported our initial evaluation of 2 new PET radioligands targeting neuroinflammation, along with ^{11}C-PBR28 for translocator protein (TSPO), in an MPTP-induced PD model in nonhuman primates (NHPs). ^{11}C-TZ3321 binds to sphingosine-1-phosphate receptor 1 (S1P1) that is highly expressed in inflammatory cells. ^{11}C-GSK1482160 targets P2X purinoceptor 7 (P2X7 receptor) which reflects glial activation. **Methods** Four male adult macaques underwent a series of 2-hour PET scans (36 scans in total) before and after unilateral internal carotid MPTP. Post-MPTP scans of the ^{11}C-DTBZ and 3 inflammation-targeting tracers were done at week 4 and week 7-8 respecitively. A simplified reference tissue model was used to analyze PET data. **Results** Test-retest variability analysis of baseline scans revealed good reproducibility for all tracers. Ipsilateral nigrostriatal injury was confirmed by an 80% reduction in ipsilateral striatal ^{11}C-DTBZ uptake. The tracer uptake of all 3 tracers remarkably increased throughout the whole brain post MPTP. The increase percentages were 89% for ^{11}C-TZ3321, 32% for ^{11}C-GSK1482160, and 12% for ^{11}C-PBR28. The tracer uptake in right frontal cortex (ipsilateral to MPTP) was significantly higher (1.19-1.37 fold) than the left side. Post-MPTP DVR values in all 11 brain regions of these 3 tracers had strong positive correlations with each other (r^2 = 0.7-0.8). **Conclusion** All 3 tracers for neuroinflammation showed small test-retest variability and were able to detect inflammatory responses in NHP brains post MPTP. ^{11}C-TZ3321 had the highest tracer uptake post MPTP relative to baseline with excellent reproducibility in this animal model. Immunohistological examination is in progress to explore the correlation of increased tracer uptake with glial activation. Further investigations are warranted to demonstrate the S1P1 ligand as a reliable biomarker for quantitative assessment of inflammatory responses and without genotype polymorphism in humans.

Title: Imaging microglia and astrocytes activation using diffusion MRI

Authors: *S. DE SANTIS[1], R. GARCIA-HERNANDEZ[1], N. TOSCHI[2,3], C. MAINERO[2], S. CANALS[1];
[1]Inst. de Neurociencias de Alicante, San Juan de Alicante, Spain; [2]A. A. Martinos Ctr. for Biomed. Imaging, Boston, MA; [3]Univ. of Rome 'Tor Vergata', Roma, Italy

Abstract: Neuroinflammation is currently a hot topic in brain research, due to its involvement in the pathogenesis of several neurodegenerative and psychiatric disorders. However, non-invasive techniques capable to characterize brain inflammation *in vivo* are lacking. Here, we present a strategy to image microglia and astrocyte activation in grey matter using diffusion MRI in rats, and demonstrate its translational value in humans.We used a rat model of inflammation based on intracerebral lipopolysaccharide (LPS) administration, which activates microglia and astrocytes with different delays. We injected LPS (2 µl at 2.5 µg/µl,) in the dorsal hippocampus of 18 rats in one hemisphere, and saline in the contralateral side. After different post-injection delays, the rats were scanned in a Bruker 7T MRI scanner using a diffusion-weighted sequence and immediately perfused for immunohistological analysis of microglia (Iba-1+) and astrocytes (GFAP+). Imaging data were fitted to a multi-compartment microstructural model (MCM), developed ad hoc to model brain parenchyma, and which accounts for the different glia compartments. Histology showed a reduction in microglial cell process density at 8 h, that progressed at 24 h with an additional increase in the microglial cell body size. Astrocytes showed no alteration at 8 h but an increase in cell size at 24 h. Importantly, these differential time courses were mirrored by distinct imaging parameters. At 8 h, the MCM model predicted a decrease in cell process density, reflecting microglia activation and, at 24 h, an increase in the cell size compartment, coincident with the concomitant microglia and astrocytic activation. To disentangle the contribution of both cell types to the 24 h imaging signature, we treated 10 additional animals with PLX5622 to deplete the microglia. At 24 h after LPS injection and with a 99% microglial depletion, we observed only an increase in the cell size compartment, unveiling the fingerprint of the astrocytic reaction. Finally, as a proof of concept for the translational validity of these results, we adapted the MRI protocol to a human 3T scanner and acquired data from a healthy cohort (n=6, age/SD 30/11, 2 females). The MCM model applied to these data returned values for process density and cell sizes comparable to those measured in rats. We demonstrate, for the first

time, that diffusion MRI captures the imaging fingerprint associated to a microglial and/or astrocytic reaction. An instrument to characterize relevant aspects of tissue microstructure during inflammation *in vivo* and non-invasively, is expected to have a tremendous impact on our understanding of the pathophysiology of many brain diseases.

Title: Peripheral inflammation induced cognitive impairment is attenuated by the regulation of activated glial cells and histone deacetylase

Authors: N. TAKADA, *Y. NAKAMURA, K. NAKASHIMA, N. MORIOKA;
Pharmacol., Hiroshima Univ., Hiroshima, Japan

Abstract: [BACKGROUND] Microglia are the major type of glial cells in the central nervous system and crucial in inflammatory responses such as the release of pro-inflammatory cytokines. Several studies showed that inflammation in central nerve systems induces the impairment of cognitive functions. Thus, microglia could be a candidate for therapeutic target for cognitive disorders including Alzheimer's disease. In addition, it has been demonstrated that peripheral inflammation also evoked cognitive disfunction in animal studies. In fact, suppression of peripheral inflammation by chronic treatment with NSAIDs could reduce the risk of Alzheimer's disease. However, the mechanisms underlying peripheral inflammation-evoked cognitive disfunction are unclear. The current study investigated the effect of minocycline, which inhibits microglial activation, and a histone deacetylase (HDAC) inhibitor on peripheral inflammation-evoked cognitive disfunction. [METHOD] Male ddY-mice (6 weeks) were intraperitonially injected with lipopolysaccharide (LPS). Either minocycline or a non-selective HDAC inhibitor suberoyl anilide hydroxamic acid (SAHA, Vorinostat) were injected 1 hour before LPS injection. Twenty-four hours after LPS injection, the cognitive function was determined by novelty objective recognition test. Morphological analysis of glial cells and inflammatory cytokine levels were evaluated by immunohistocal study and real-time PCR, respectively. [RESULTS] The treatment with LPS reduced the discrimination ability, indicating peripheral inflammation induced the cognitive impairment. Moreover, LPS treatment induced activation of microglia/astrocytes and the upregulation of interleukin-1β mRNA in the hippocampus.

Pretreatment with either minocycline (50 mg/kg) or SAHA (50 mg/kg) significantly suppressed the LPS-evoked cognitive impairment and the upregulation of IL-1β mRNA. [CONCLUSION] These data suggest that the glial activation in hippocampus and epigenetic modification such as acetylation of histone could be involved in peripheral inflammation-induced cognitive disfunction. Therefore, HDAC inhibitors and the regulation of activated glial cells might be potential therapeutic targets for cognitive disorders.

Title: Apobec1 knockout is a genetic risk factor that exacerbates effect of mild traumatic brain injury (mTBI)

Authors: *E. M. O'CINNEIDE[1], K. GAGNIDZE[3], J. MARROCCO[2], N. F. PAPAVASILIOU[4], K. BULLOCH[1];
[1]Neuroimmunology and Inflammation Program, Lab. of Neuroendocrinology, [2]Lab. of Neuroendocrinology, The Rockefeller Univ., New York, NY; [3]Preclinical Res., Bluebird bio, Cambridge, MA; [4]German Cancer Res. Ctr., Heidelberg, Germany

Abstract: Recent work has shown that post-transcriptional modifications, such as RNA- editing by *Apobec1* (Apolipoprotein B Editing Complex 1), is an important regulator of myeloid phagocytic cell function and diversity (Harjanto et al., 2016). Microglia (MG) are a heterogeneous population of phagocytic cells that reside within the central nervous system (CNS), maintain brain homeostasis and act as sentinels for the immune system. Within the CNS, microglia are the only cell type that expresses obligatory components for the RNA-editing function of *Apobec1*. Deletion of *Apobec1* in mice initiates age-related disruption of microglial homeostasis leading to neuroinflammation with increases in pro-inflammatory cytokines, abnormal myelin formation/maintenance and behavioral deficits (Cole et al., 2017). Although these abnormalities are not apparent in the younger *Apobec1* KO mice, we hypothesize that certain inflammatory challenges may provoke the early onset of such deficits in younger mice. mTBI is known to involve a microglia-mediated inflammatory reponse underlying behavioral deficits. Thus, in the current study we examined the effect of *Apobec1* deletion in young adult and middle-aged male mice following a single mTBI. Our results show that young adult *Apobec1*

KO mice display a severe acute neurological response, evident by longer loss of righting reflex following mTBI compared to young adult WT mice. Impairment in Rotarod motor performance following mTBI in young adult *Apobec1* KO, but not young adult WT mice was also observed. Interestingly, injured young adult *Apobec1* KO mice showed similar acute neurological response and motor learning impairment to KO and WT middle-aged mice. Taken together, these findings indicate that *Apobec1* deletion increases vulnerability to mTBI resulting in MG dysregulation and an accelerated aging phenotype following injury. This study identifies *Apobec1* polymorphisms as a novel genetic risk factor for poor outcome following mTBI.

Abstract: Introduction: Epilepsy is characterized by the development of recurrent and spontaneous seizures. Neuronal death and inflammatory processes mediated by reactive glia have been described as the pathophysiology that plays an important role in the mediation of the damage so that an inadequate regulation in the activation of this neuronal system might contribute to the progression of the pathology and its chronicity. **Objective**. The main aim of this study is to evaluate the effect of TRF on the activation of astrocytes, microglia, and neuronal cell death after 1 and 5 days post-*status epilepticus*. **Methodology.** Male Wistar rats weighing 200 g were divided into four groups (Control AL, *SE,* TRF and TRF plus *SE*). Control group had free access to water and food. TFR group had only access to food for two hours daylight during 21 days with free access to water. Lithium injection was made 18 h previous and scopolamine

injection was performed 30 min previous pilocarpine injection. Pilocarpine dose injection was 60 mg/kg s.c. and diazepam injection to attenuate seizures was 5 mg/kg after 90 min of SE. All animals were euthanatized at 1 and 5 days post SE and their brains were embedded in paraffin to obtain coronal sections. Reactive astrocytes and microglia were morphologically evaluated by immunofluorescence (GFAP and Iba1, respectively) and neuronal cell death was evaluated with FluoroJade C (FJC) staining. **Results**. Our preliminary results indicate that TRF reduces GFAP marker optical density in CA1 and CA3 fields in both time points and hilus and dentate gyrus (DG) only were reduced after 1 day post-SE. In addition, optical density of Iba1 marker was reduced only in CA1 field in both time points and hilus after 5 days following SE. Moreover, TRF significant reduces FJC-positive cells in DG after 24 post SE and CA1 and hilus region after 5 days following SE. **Conclusion:** TRF exerts a direct effect on the modulation of the quantity and distribution of the resident immune system (microglia) and diminishes the activation of astrocytes Moreover, TRF generates neuroprotection in some regions from hippocampus and this effect might contribute to diminish the early damage and seizures during the development of SE.

Title: Relevance of scavenger receptor-A for the neurotoxic outcome of the inflammatory activation of glial cell

Authors: *R. VON BERNHARDI[1], F. MANZUR[1], L. F. VELASQUEZ[1], P. MUNOZ[1], E. PONCE[1,2], S. BELTRAN[1], J. J. TRIVINO[1], V. RODRIGUEZ[1,2], S. MARCA[1,2], C. ZUNIGA-TRASLAVINA[1], M. TRIOLO-MIESES[1], F. NOVILLO[1], J. EUGENIN[2];
[1]Neurol., Pontificia Univ. Catolica de Chile, Santiago, Chile; [2]Biol., USACH, Santiago, Chile

Abstract: The main risk factor for late onset Alzheimer's disease (LOAD) is aging. Neuroinflammation is a characteristic finding in aging and a conspicuous actor even at early stages of AD. Our "glia-dysregulation" hypothesis states that AD is caused by the impairment of glial cell regulation leading to a neurotoxic environment responsible for neuronal dysfunction and neurodegeneration. In aged mice, microglia show increased expression of cytokines and an exacerbated inflammatory activation of glia. Interestingly, expression and protein levels of

scavenger receptor-A (SR-A) are reduced in 12-month old WT mice, compared with 3-month old mice; whereas SR-A is already reduced at 3 months of age in APP/PS1 mice, compared with WT mice. We reported that SR-A is involved in β-amyloid (Aβ) uptake and the inflammatory activation of glia. Thus, we compared the activation of microglia (MG) obtained from WT, SR-$A^{-/-}$ and APP/PS1/SR-$A^{-/-}$ mice, to evaluate the role played by SR-A in determining the profile of microglia activation. Signal transduction pattern, inflammatory- and regulatory- cytokines production, and the neurotoxicity of microglia conditioned media (CMs), on hippocampal neurons, was assessed. Cytokine levels were measured by ELISA, and the activation of various signaling pathways by western blot. Neuronal apoptosis was evaluated by TUNEL. Glia from SR-$A^{-/-}$ and APP/PS1/SR-$A^{-/-}$ mice had basal levels that were up to 7-fold higher for pro-inflammatory cytokines (TNFα and IL1β), and several-fold lower for anti-inflammatory cytokines (IL10 and TGFβ), compared with WT cells. SR-$A^{-/-}$ cells showed complex changes in both the activation of signaling pathways and the release of cytokines in response to inflammatory stimulation. In terms of cytotoxicity, conditioned media (CMs) of non-stimulated microglia from SR-$A^{-/-}$ mice was more neurotoxic than that of WT mice. In contrast SR-$A^{-/-}$ microglia stimulated with LPS was less neurotoxic that WT cells, whereas Aβ and Aβ+LPS-stimulated microglia induction of hippocampal neurons apoptosis was similar for all the genotypes. Our results show that activation by LPS results in reduced cytotoxicity in SR-$A^{-/-}$ mice in contrast to the preserved activation by Aβ.Thus, SR-A appears to participate in a complex regulation of the inflammatory activation of microglia, which depends on the nature of the stimulus.

Title: Activating Nrf2/HO-1 pathway alleviates inflammatory activation of microglia in theoptic nerves and protects retinal ganglion cells from ischemia-reperfusion injury in acute intraocular hypertension model of glaucoma

Authors: L. SHENG[1], B. LU[1], C. CHEN[1], W. CAI[2], Y. YANG[3], Y. ZHOU[1], Y. DU[1], W. YIN[2], *S. LIN[3], G. YAN[1];

Abstract: Elevated intraocular pressure (IOP) is considered the most important risk factor for acute glaucoma, which is one of the leading causes of irreversible visual-field loss. The increasing clinic evidence demonstrated that the inflammatory response and oxidative stress induced by IOP play the key role in the axonal degeneration in optic nerves (ONs) and retinal ganglion cells (RGCs) loss. Moreover, it is reported the depletion of NF-E2-related factor 2 (Nrf2), a master regulator of the antioxidant response, account for the damages of the trabecular meshwork, optic nerve head astrocytes, retinal Müller glial cells, and RGCs as well. But whether the Nrf2 pathway involves in the regulation of microglia in optic nerves is largely unknown. We here use an acute intraocular hypertension (AIH) model of glaucoma and a previously demonstrated neuroprotective steroid of 5α-androst-3β, 5α, 6β-triol (TRIOL) which exhibit antioxidative activities with unclear mechanisms to explore the role of NRF2 in microglia. We find that 10 μM TRIOL significantly inhibits the inflammatory activation of BV2 microglia induced by 100 ng/mL LPS treatment for 12 hours, and notably activates the NRF2 pathway characterized by the nuclear accumulation and enhanced the protein level of NRF2 along with its downstream heme oxygenase-1 (HO-1) by negative regulation of Kelch-like ECH-associated Protein-1 (Keap1). Next, intravitreal injection of TIROL (80 μg /eye) significantly protects RGCs and its axons/dendrites from ischemia-reperfusion (I/R) injury in the rat and mice AIH models. Meanwhile, the effects of Triol on the activation of the NRF2 pathway and suppression of inflammatory activation observed in vitro are further confirmed in microglia of the optic nerves in vivo. Furthermore, the microglia in the optic nerves of the Nrf2 knockout mice are extensively activated after the AIH treatment, which accompanied by the significant RGCs lose and axons/dendrites damage, indicating Nrf2 deletion contribute to the activation of microglia and abrogate the neuroprotective benefits of Triol observed in wild type mice. In summary, our study sheds new light on the inflammation modulation for Nrf2 to the optic nerves microglia and provide a promising neuroprotectant candidate for the therapeutics of acute glaucoma.

Abstract: Epilepsy is accompanied by microglial-induced neuroinflammation in both epilepsy patients and animal models, mainly at seizure-associated brain regions such as the hippocampus. Although putative pharmacological microglial activation seems to promote seizures, there are reports contradicting this notion. To address this, we selectively modulated hippocampal microglia with optogenetics and tested its effects on cortical and hippocampal epileptiform activity induced with 4-aminopyridine (4AP) in anesthetized mice. We found that optogenetic modulation of hippocampal microglia alters cortical and hippocampal network activity and changes microglial morphology towards an amoeboid-like shape. Moreover, optogenetic microglial modulation aggravates cortical and hippocampal 4AP-induced epileptiform activity, in a stimulus duration-dependent manner. Our study revealed that microglial activation promotes seizures, providing new insights on epileptogenesis and revealing new targets against epilepsy.

Title: Microglia mediated neuroinflammation and endogenous regeneration. Are they connected?

Authors: *P. NIKOLAKOPOULOU[1], D. VOULGARIS[2], I. MATTHIESEN[2], T. E. WINKLER[2], A. HERLAND[2,1];
[1]Dept. of Neurosci., Karolinska Inst., Stockholm, Sweden; [2]Div. of Micro and Nanosystems, KTH Royal Inst. of Technol., Stockholm, Sweden

Abstract: Neurodegenerative diseases result in both neuronal injury and subsequent neuronal loss, as well as in an extensive and sustained neuroinflammation. Microglia are the resident immune cells of the brain. Originating from the yolk sac, they infiltrate the central nervous system just before the blood-brain-barrier is fully formed and they play a crucial role in neurogenesis. In adulthood and throughout life, activated microglia mediate and regulate the vast majority of inflammatory processes while resting microglia continuously survey their microenvironment to facilitate brain homeostasis maintenance. Adult brain regeneration can be achieved via endogenous neural stem cell (eNSC) activation. eNSCs share common characteristics with microglia; they are highly plastic cells, they self-renew, and they differentiate upon certain stimuli. Recent findings support the active interaction between microglia and neural stem cells, which may play a crucial role in adult neurogenesis and neuroprotection.
Multipotent cytokines such as microphage migration inhibitory factor (MIF) can be activated rapidly upon stimuli and show both mitogenic and proinflammatory functions. MIF regulates NSCs and improves their survival and proliferation *in vitro*. It also regulates cytokine production in immune cells, such as microglia for the brain tissue. Metformin, a very common treatment for diabetes, suppresses plasma MIF concentrations in obese patients; thus, it might be regulating the interplay between microglia induced neuroinflammation and NSC survival in the human brain. It is therefore indispensable to understand if and how microglia activation regulates NSC survival, proliferation and differentiation upon inflammatory stimuli.
Here we aim to recapitulate *in vitro* the microenvironment of the human neurovascular unit (NVU) using human induced pluripotent stem cell derived (hiPSC) brain microvascular endothelial cells (BMVEC), long-term neuroepithelial stem cells (lt-NES) and microglia to study the impact of neuroinflammation on NSC survival and differentiation. Our NVU-on-a-chip xeno-

free co-culture system aims to utilize microfluidics and novel materials to mimic the 3D *in vivo* state in an elegant *in vitro* setup. This may pave the way towards a better understanding of the capacity of the human brain to repair itself as well as towards the development of novel agents for effective therapeutics in neurodegenerative diseases.

Title: The inflammatory responses in aging brain of rats

Authors: *J.-Y. WANG[1], C.-L. CHEN[2], S.-Y. CHEN[1];
[1]Dept Nursing (Basic Med. Sci), Hungkuang Univ., Taichung, Taiwan; [2]Li-Shin Hosp., Chungli, Taiwan

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder in central nerve system (CNS). The prevalence of AD increasing with age and life expectancy is constantly increasing in civilized countries. It will become more important in health problems in the future. Some characteristic lesions in brain of AD: extracellular deposits of β-amyloid peptides (Aβ), so called neuritic or senile plaques (NP or SP), and the intracellular neurofibrillary tangles (NFT) of hyperphosphorylated tau protein. It is known that the intracellular Aβ load in the onset of cognitive dysfunction. Furthermore, Aβ may promote neurodegernation by activation of glial cells. In response to neurogenerative events, astrocytes and microglial cells release variety of inflammatory mediators including cytokines (such as TNF-α), free radicals and nitric oxide (NO), all of which can contribute to neuronal dysfunction and cell death, ultimately creating a vicious cycle. Aβ stimulates a nuclear factor κB (NFκB)-dependent pathway that is required for cytokine gene transcription and induces the inducible NO synthase (iNOS). It indicates that neuroinflammatory response may play a key role and an initial step in pathological mechanisms of AD. The activated astrocytes in aged brain may be acting as a positive feedback loop of chronic inflammation, astrocyte activated, and further inflammation. But the other evidence had shown an astrocyte-mediated protective effect over Aβ-induced damage and modulation of the activation of microglial cells. As far the roles of astrocytes and microglial cells in Aβ-induced injury is still not clear. In this study, we want to investigate the inflammatory responses in aging brain. Aβ1-42 is the major subtype deposited in the brain as an efficient stimulator to induce

neuroinflammatory response in AD. The rat cortical mixed neuronal-glial cultures will be subjected to various experiments. Cell density and morphology will be observed by phase-contrast microscopy. Cell injury will be assessed by 3-(4,5-Dimethyl thianol-2-yl) 2,5 di-phenyltetrazolium bromide (MTT) reduction. The production of NO will be measured to estimate the inflammatory responses. The aging rats (18-22 months) were sacrificed and prepared brain section for immunocytostaining. Our results indicated that Aβ1-42 (5 μM) treated for 24 hr significantly decreased MTT reduction and increased the nitrite accumulation in mixed neuronal-glial cultures. And the results of immunocytostaining of brain revealed that the number of neurons decreased significantly in prefrontal cortex and hippocampus (CA1); however, the activation of microglial cells and iNOS were increased.

Title: TNF decreases GFAP+ human neural stem cells and upregulates inflammasome component AIM2 in 3D hydrogel cultures

Authors: *H. CELIKKAYA[1,2], M. I. COSACAK[1,2], U. FREUDENBERG[2,3], C. WERNER[2,3], C. KIZIL[1,2];

Abstract: Neuroinflammatory cytokines such as TNF are implicated in neuropathologies and their effects on human neural stem cell (NSC) plasticity require further elucidation. We investigated the impact of TNF treatment on human NSCs cultured in 3D cell instructive starPEG-heparin hydrogels. TNF led to a 4-fold reduction in GFAP+ NSC number. The neuronal networks that formed in the presence of TNF treatment displayed morphological differences from control cells such as having lean connected paths with few side branches and cells with elongated nuclei. Stem cell markers were downregulated, while cortical markers remained either unchanged or were downregulated except for cortical layer I marker reelin that was upregulated more than 50-fold as demonstrated by whole transcriptome analysis. Additionally, reactive

astrocyte markers and NFκB pathway were markedly upregulated in the presence of TNF. Interestingly, these changes were accompanied by an upregulation of inflammasome component AIM2. Our results indicate that TNF may negatively affect human NSC plasticity by depleting the GFAP+ neurogenic cells, limiting stem cell and cortical layer marker expression, and promoting reactive astrocyte activation. We suggest that the aforementioned TNF effects on human NSCs may be exerted by AIM2 inflammasome activation.

Title: Necroptosis activation and low-grade chronic inflammation in age-associated neurodegeneration

Authors: *M. S. ARRÁZOLA, F. COURT;
Ctr. for Integrative Biol., Univ. Mayor, Santiago, Chile

Abstract: Brain aging is associated with a decrease in brain function as result of progressive neurodegeneration and increased neuro-inflammation. In addition, low-grade inflammation during aging has been implicated in the pathogenesis of several age-related neurodegenerative diseases. Collective evidence indicates that systemic pro-inflammatory status of an aged organism could affect brain function. We recently demonstrated thatnecroptosis, a regulated necrotic-like cell death pathway that participates in the pathogenesis of several neurodegenerative diseases, regulates axonal degeneration. In this study, we aim to determine whether age-progressive neurodegeneration is mediated by necroptosis activation and potentiated by low-grade chronic and systemic inflammation. Mice of different ages: young (6 month), mild-aged (12-15 month) and old (more than 24 month), were injected (i.p.) with low doses of LPS twice a week during 1 month to induce inflammation. After treatment, animals were subjected to several brain-associated behavioral tests. Microglia and necroptosis activation was evaluated by flow cytometry and immunocytochemistry in different brain areas. The progression of neurodegeneration was assessed with FluoroJade C staining in brain sections. Microglia numbers

($CD45^{low}$/$Cd11b^{+}$) increased in hippocampus, cortex and striatum of young mice after systemic inflammation, accompanied by a morphological change associated with steady-state microglia. Activation state of microglia was confirmed evaluating the percentage of pro-inflammatory M1 Microglia (CD206-/CD16CD32+) over reparative M2 Microglia (CD206+/CD16CD32+). LPS decreased microglial activation in all brain regions analyzed, corroborating our morphological results and suggesting that our model of low-grade and chronic inflammation silence brain immune response, which might favor neurodegeneration.Necroptosis activation, analyzed by pMLKL and pRIPK3 levels, was evidenced only in the striatum of young mice after LPS, suggesting a susceptibility of striatal neurons to undergo necroptosis under chronic inflammation. Degeneration was also observed in striatal terminals. Throughout aging, neurons of the hippocampus progressively degenerate. LPS potentiated hippocampal degeneration in young mice. Hippocampal-dependent memory function was assessed by the Novel Object Recognition test. Only young mice were capable to identify the new object, and LPS inhibited this memory performance, suggesting that systemic inflammation promotes degeneration of neurons in different areas of the aging brain, affecting their functions.

Title: Cannabidiol prevents microglial inflammatory-type reactions by inhibiting ROS-dependent NF-kB activation and glucose consumption

Authors: ***P. P. MICHEL**[1], M. DOS-SANTOS-PEREIRA[1,2], F. S. GUIMARÃES[3], E. DEL-BEL[2], R. RAISMAN-VOZARI[1];
[1]Inst. du Cerveau et de la Moelle Epinière, Paris, France; [2]Faculdade de Odontologia, Univ. de São Paulo, Ribeirão Preto, Brazil; [3]Faculdade de Medicina, Univ. de São Paulo, Ribeirão Preto, Brazil

Abstract: We studied, here, the anti-inflammatory potential of cannabidiol (CBD), the major non-psychoactive component of cannabis. For that, we used microglial cells in culture that were

isolated from post-natal mouse brain through a procedure that relies on the adhesion preference of these cells to the polycation polyethyleneimine (Sepulveda-Diaz et al, Glia, 2016; dos-Santos Pereira et al, Glia, 2018). We established that CBD (1-10 μM) was highly efficient in reducing inflammatory-type responses triggered by the Toll-like receptor4 (TLR4) agonist, lipopolysaccharide (LPS, 10 ng/ml). In particular, CBD strongly reduced the release of two pro-inflammatory cytokines TNF-α and IL-1β and that of glutamate, a non-cytokine mediator of inflammation. Interestingly, CBD was also highly effective against other inflammatory signaling molecules, the TLR-2 agonist Pam3CSK-4 and the P2X7 agonist BzATP, indicating that CBD inhibitory effects were not restricted to a particular inflammatory pathway. The effects of CBD were predominantly receptor-independent; they were only marginally blunted by SCH336, a selective antagonist/inverse agonist at CB2 receptors and insensitive to antagonists of CB1 receptors and PPAR-γ. Additional experiments revealed that CBD had the capacity to restrain LPS-induced inflammatory events by interfering with a signaling cascade involving the ROS producing enzyme NADPH oxidase and subsequently NF-κB-dependent signaling. Importantly, we noticed that NF-κB inhibition by either CBD (1, 10 μM) or TPCA-1, an IκB kinase inhibitor counteracted the rise in glucose uptake that is observed after exposure of microglial cells to LPS, suggesting that CBD occluded pro-inflammatory events by lowering glucose consumption. Comforting this view, CBD anti-inflammatory effects were mimicked by 2-deoxy-D-glucose (2-DG), a synthetic, non-metabolizable glucose analog. Interestingly, CBD and 2-DG led to a reduction of glucose-derived NADPH, a requisite factor for ROS production by NADPH oxidase. Altogether, our findings suggest that CBD possesses potent anti-inflammatory effects towards microglial cells through an antioxidant mechanism that restrains glucose utilization and NADPH synthesis. Present data also further confirm that CBD may have a therapeutic interest in conditions where neuro-inflammatory processes are prominent.

Title: Production of purified fractions from garcinia mangostana l. (mangosteen) pericarp containing bioactive compounds and testing in anti-inflammatory cellular *in-vitro* assays (C8-B4 cell line)

Authors: *A. LEUNG[1], C. BARROW[2], M. BERK[3], O. DEAN[3], A. NEALE[3], C. BORTOLASCI[3], K. WALDER[3], S. DODD[3], B. HARVEY[4];

Abstract: Over the last 15+ years there has been a dearth of new successful pharmaceutical treatments for mental health conditions such as bipolar and schizophrenia. Existing pharmaceutical treatments for these conditions have a wide variability of effectiveness and also have significant negative side effects. Mangosteen pericarp is the rind from the mangosteen fruit, longed used in traditional South East Asian medicine. Constituents of the mangosteen pericarp including alpha-Mangostin and some of the other xanthone compounds have been investigated for their effect in other medical conditions including their potential cytotoxic, anti-microbial and metabolic pathway modulating behaviour. Previously, extracts have been used anecdotally by the general population for minor skin conditions and gastrointestinal illness. Mangosteen pericarp extract is being used by a Deakin University (AUS) clinical research group in large-scale randomised placebo-controlled clinical trials. In particular, the mangosteen pericarp extract is being investigated for its bioactive compounds in relation to oxidative and inflammatory mechanisms and their role in psychiatric disorders such as bipolar, schizophrenia and depression. It has only been in more recent decades that research has been undertaken to investigate inflammatory cytokines possible effect in causing neurocognitive changes and neuropsychiatric diseases, with previous research predominantly focusing on their actions and effect on the immune and metabolic systems.
Our objective was to prepare a number of different Mangosteen extracts and purified fractions derived from these extracts in order to test their anti-inflammatory nature. We investigated methods and processes that resulted in the isolation of bioactive compounds for the use in LPS stimulated C8-B4 cell line assays. We undertook cellular assays using different mangosteen pericarp extracts and purified fractions derived from these extracts. We observed changes in TNF-alpha levels in some of the assays at certain concentration levels. These results will prompt further cell line assays and zebra fish assays to investigate the anti-inflammatory effect of Mangosteen bioactive compounds in more detail.

Title: Anti-neuroinflammation effects of neurosteroids

Authors: *S. J. MENNERICK[1], M. KEISER[2], A. BENZ[3], D. COVERY[3], C. ZORUMSKI[3], **H. SHU**[3];
[1]Psychiatry, Washington Univ. Sch. of Med., St Louis, MO; [2]Psychiatry, [3]Washington Univ. in St Louis, Saint Louis, MO

Abstract: Depression is one of the most common psychiatric disorders and affects patients throughout the lifespan. Existing treatments are good but have drawbacks including side effects, slow onset, and low efficacy in some patients. Neurosteroids have captured recent attention as rapidly acting antidepressants. Their best-known action is that of positive modulation of $GABA_A$ receptors. However, other $GABA_A$ modulators, as far as known, do not exhibit antidepressant actions. We hypothesize that neurosteroids may have anti-inflammatory actions that participate in antidepressant effects. Here we began to evaluate structural attributes important for anti-inflammatory effects. We challenged the microglial BV2 cell line with lipopolysaccharide (LPS). As expected, transcripts for pro-inflammatory cytokines IL-1β, IL-6 and TNF-α increased with 6 h LPS treatment. The neurosteroid allopregnanolone decreased LPS-induced proinflammatory transcription in a concentration-dependent fashion. Surprisingly, and unlike $GABA_A$ receptor effects, the enantiomer of allopregnanolone also decreased pro-inflammatory cytokines at similar concentrations. Pre-administration of neurosteroids did not increase the effectiveness or potency. Our results are consistent with a different structure-activity profile for neurosteroids than that exhibited for $GABA_A$ receptor modulation. Thus, our results may suggest a structure-activity profile that selectively engages neuroinflammation.

Title: Inhibition of microglial activation differently affects hormone secretion during sepsis

Authors: *L. H. A. COSTA[1], N. N. SANTOS-JUNIOR[1], C. H. R. CATALÃO[1], M. J. A. ROCHA[2];

[1]Ribeirao Preto Med. School, Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Sch. of Dent. of Ribeirao Preto, Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Sepsis, a dysregulated inflammatory response to an infection, promotes deleterious consequences on brain function, including alterations in the neuroendocrine system. The increased production of inflammatory mediators in the hypothalamus, the major central area of hormonal control, could be involved in the complex pathophysiology of sepsis-associated brain dysfunction. Given the essential contribution of microglia, brain innate immune system cells, on neuropathologic conditions, our objective was to access the effect of the activation of these cells on hormone secretion during sepsis. Male Wistar rats (300-350g) received a single intracerebroventricular injection of minocycline (100μg), an inhibitor of microglial activation, or vehicle just before sepsis induction by cecal ligation and puncture (CLP) surgery (10 punctures, 16-gaude needle). Six and 24 hours after the surgery, the animals were decapitated and blood and hypothalamus were collected for hormone and cytokines analysis (ELISA) and protein expression (western blot). A second group was perfused for immunohistochemical processing. Sepsis differently affected endocrine secretion in the acute (6 hours) or late phase (24 hours) of the disease, with decreased (ACTH, prolactin), increased (corticosterone), or a dual response (vasopressin, oxytocin) depending on the hormone. It was accompanied by neuroinflammation and increased markers of hypothalamic apoptosis. Minocycline diminished microglial activation in the hypothalamus, reduced central inflammatory mediators, and prevented cell death, notably at 24 hours. At 6 hours, the inhibition of microglial activation decreased plasma oxytocin and increased corticosterone and vasopressin levels, while in the late phase it diminished oxytocin and increased ACTH and corticosterone. Prolactin secretion was not affected by minocycline administration at any timepoint. We conclude that the activation of microglial cells promotes differential effects on the secretion of different hormones during sepsis.

Title: Impaired visuomotor adaptation following stroke

Authors: *R. T. MOORE[1], S. P. DUKELOW[2], T. CLUFF[3];
[1]Med., [2]Clin. Neurosciences, [3]Fac. of Kinesiology, Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: It is estimated that over 700,000 Canadians are living with stroke-related disability. Previous research suggests that up to 70% of stroke survivors have sensory and/or motor impairments. Many of these individuals participate in neurorehabilitation to improve sensory and motor function. While it is widely accepted that motor learning is critical for neurorehabilitation, comparatively little is known about how stroke impacts motor learning. Here we compare how healthy adults and adult stroke survivors adapt to a novel visuomotor rotation while performing goal-directed reaching movements. We recruited 30 stroke survivors [median age (IQR): 57.5 (14.75); 10 female; median time since stroke (IQR): 58 (553); median Fugl-Meyer upper-limb score (IQR): 60 (17)] and 30 healthy adults [median age (IQR): 59 (12); 14 female]. Experiments were performed with a KINARM exoskeleton robot. The robot supported the participant's arms while they interacted with a virtual reality system through the movement of their arms. The position of their fingertip was displayed in real time using a white cursor (0.8 cm diameter). Direct vision of the arm and hand were occluded throughout the experiment. We instructed subjects to reach back-and-forth between two targets (2 cm diameter) positioned 10-cm apart. Subjects first completed 25 movements with true feedback of their hand position. We then introduced a 30-degree counter-clockwise rotation so that the hand-aligned feedback cursor traveled 30-degrees leftward when making straight movements. Participants adapted to the rotated hand feedback over the course of 125 trials. We then unexpectedly removed the rotation and participants performed another 25 movements with true hand feedback. For each trial, we calculated the angular deviation of the hand's path from a straight trajectory between the targets at 150 ms after the onset of movement. We then fit each participant's hand path deviations to exponential models to determine the overall amount and rate they adapted their movements. We found that stroke survivors adapted their movements less than healthy adults ($p < 0.05$). Stroke survivors also adapted at slower rates ($p < 0.05$) and required more trials to adapt to the rotation ($p < 0.05$). Notably, stroke survivors with more severe motor impairments, as measured by the Functional Independence Measure, also learned to a lesser extent ($r = 0.4852$; $p < 0.05$). Our results suggest that stroke survivors adapt more slowly and to a lesser extent than healthy age-matched adults. Understanding the processes underlying motor learning may be important for designing novel rehabilitation programs that may enhance sensorimotor recovery after stroke.

Title: Voluntary activation deficits contribute to post stroke lingual weakness in a rat model

Authors: *M. J. CULLINS, J. A. RUSSELL, N. P. CONNOR;
Univ. of Wisconsin Madison, Madson, WI

Abstract: Lingual weakness after stroke is associated with dysphagia and is often targeted by exercise interventions. Chronic weakness after stroke is attributed to both impaired ability to centrally activate target muscles and reduced force generating capacity within muscles. However, how these factors contribute to lingual weakness after stroke is not known. We used middle cerebral artery occlusion (MCAO) to model lingual weakness and deficits in swallowing function in rats after stroke. Our hypotheses were both reduced muscle force generating capacity (maximum *stimulated* force) and reduced ability to activate the muscle (Percent Voluntary Activation) contribute to lingual weakness (maximum *voluntary* force). Six-week-old male Sprague-Dawley rats were randomly assigned to MCAO (N = 14) or sham (N = 12) surgeries and trained to press an instrumented disk with the tongue for a water reward. Maximum voluntary tongue force was determined prior to MCAO and 8 weeks post-surgery. Bilateral stimulation of the medial hypoglossal nerve was used to determine maximum protrusive force generating capacity, muscle twitch properties, and a force-frequency curve. Maximum stimulated force was not significantly different between groups (MCAO = 394.2 ± 149.4 mN, Sham = 345.8 ± 105.9 mN, p = 0.182). Voluntary Activation (voluntary force/stimulated force) was significantly reduced with MCAO (MCAO = 23.7 ± 14.8 %, Sham = 37.8 ± 11.2 %, p = 0.007) and moderately correlated with mean bolus area (*Pearson's r* = 0.602, p = 0.002), a measure of swallowing function previously found to be reduced in the MCAO model. No significant differences between groups were found for muscle twitch properties, cross sectional area of the lingual genioglossus muscle, or force-frequency curves. These data suggest that the primary cause of chronic lingual weakness after stroke is an impairment in central control of muscle activation rather than a deficit of force generating capacity in lingual muscles. Percent Voluntary Activation deficits in the absence of muscle force deficits have also been reported in select hand and leg muscles.

Title: Quantifying the effect of trunk postural control deficits on arm reaching in hemiparetic stroke

Authors: *K. C. SUVADA, J. DEOL, A. ACOSTA, J. P. A. DEWALD;
Physical Therapy and Human Movement Sci., Northwestern Univ., Evanston, IL

Abstract: Our trunk provides a stable base of support during movement to facilitate not only gait but also reaching movement to interact with the environment. When this stable base is compromised due to stroke, trunk and arm coordination during reaching is impaired. Activities that were achievable are now difficult because the trunk cannot counteract the forces imposed by the limbs.

Both arm and trunk motor control is impaired in individuals with hemiparetic stroke. In the arm, this is expressed as weakness, hyperactive stretch reflexes and involuntary coupling of shoulder abduction with elbow, wrist, and finger flexion, commonly known as the flexion synergy. In the trunk, previous studies have shown earlier and excessive trunk movement during reaching with the paretic limb and larger sway area when sitting upright compared to controls. While these studies show that trunk motor control is impacted following stroke, little is known about how these trunk deficits affect reaching or whether trunk function is also impacted by the flexion synergy. Furthermore, since the flexion synergy has only been studied with the trunk restrained, the interaction between trunk and arm movement remains unknown.

The goal of this study is to measure the effect of trunk impairments arising from a stroke on reaching ability during various shoulder abduction loading conditions. I hypothesize that when the trunk is unrestrained there will be a negative impact on reaching for both arms and the impact will be amplified with shoulder abduction loading.

Participants will sit in a chair with their pelvis restrained and their hips in slight extension using a cushion. The arm will be placed in a haptic device that allows motion on a horizontal plane while applying vertical loads. The position of the hand, trunk, and shoulders will be tracked using a motion tracking system. Participants will be asked to reach as far as possible while maintaining the trunk posture with simultaneous feedback of the position of the hand on a computer monitor. Participants will receive feedback after the trial if the trunk was outside of preset circular bounds.

The effect of trunk restraint, shoulder abduction loading and limb on reaching distance will be tested via a three factor repeated measures ANOVA. We expect to find an effect of trunk restraint on reaching distance with reduced reaching ability in the unrestrained conditions across shoulder abduction load levels for both limbs. However, we expect shoulder abduction load will only affect reaching distance of the paretic limb due to the flexion synergy.
The results from this study will further our understanding of the effect of stroke on trunk motor control and its effect on reaching ability.

Title: Cognitive impairments mediated by the non-injured hippocampus after focal cortical ischemic stroke in mice

Authors: ***W. ZHONG**[1,2], Y. YUAN[1], X. GU[1], M. QU[1], M. R. MCCRARY[1], A. WU[1], L. WEI[1], S. YU[1,2];

Abstract: Stroke is a serious threat to human life and health in the US and around the world. Around 8 million people in the US and 15 million people worldwide experience a stroke each year. Among them, 30%-60% of survivors suffer from cognitive impairment in the first year after stroke. However, the pathophysiology of post-stroke cognitive impairment remains unclear. In the present investigation, we tested the development of post-stroke psychological disorders in a focal ischemic stroke mouse model with select damages in the sensorimotor cortex. These stroke animals showed significant sensorimotor deficits soon after stroke followed by a gradual spontaneous recovery within 2-4 weeks after the ischemic insult. Besides the ischemic cortical damage, no TUNNEL-positive cells were detected acutely or chronically in the hippocampus, indicating that this brain region was not primarily damaged by the ischemic insult. Meanwhile, significantly enhanced neurogenic activities were observed in the sub-granule zone (SGZ) starting from 2-3 weeks after stroke. However, in the Morris Water Maze test, the hippocampus-dependent working memory was significantly impaired at 3 weeks post stroke and the deficit maintained at least till 6 weeks after stroke. Electrophysiology assays revealed functional deficits of the long-term potentiation (LTP) and pair-pulse ratio (PPF) in the CA1 region at 3-6 weeks

poststroke, suggesting a long-lasting impairment of synaptic plasticity. Our data demonstrate that a focal cortical ischemic insult may cause functional deficits in a remote non-injured region such as the hippocampus. Interestingly, the observed SGZ neurogenesis showed no functional benefits while it is possible that, based on some previous observations, stroke evoked aberrant SGZ neurogenesis might contribute to the cognitive impairment.

Title: Monoaminergic drive modulates post-stroke flexion synergy expression

Authors: *J. R. PATTERSON[1], **C. HECKMAN**[2], J. P. DEWALD[3];
[1]Interdepartmental Neurosciences, [2]Dept. of Physiol., [3]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: The role of descending monoaminergic drive in human motor control, particularly in disease states such as chronic stroke, is still largely unknown. Animal work indicates that monoamines modulate the gain of spinal motoneurons. Evidence suggests that following a stroke-induced loss of cortical inputs to the cord, a subsequent increase in monoaminergic drive may increase the gain of diffuse reticulospinal inputs to compensate for voluntary motor control. The diffuse innervation of the reticulospinal tract is suggested to contribute to the flexion synergy, a prominent impairment in chronic stroke in which lifting up at the shoulder of the paretic arm coactivates elbow, wrist, and finger flexors, pulling the arm in as the individual lifts up. Thus, an increase in monoaminergic drive post-stroke may negatively contribute to reaching function. The goal of this preliminary research is to determine the role of descending monoaminergic drive in post-stroke motor control by pharmacologically manipulating norepinephrine supply to spinal motoneurons and measuring resulting reaching function. Three individuals with chronic hemiparetic stroke participated in 1) pre-medication measures of reaching function followed by 2) the administration a single oral dose of 4mg Tizanidine, followed by 3) on-medication measures of reaching function. Tizanidine is a selective noradrenergic alpha-2 (spinal action) and imidazoline (brainstem action) agonist demonstrated to decrease norepinephrine release. Individuals were instructed to ballistically reach towards a virtual target while lifting their paretic upper limb at the shoulder under varying levels of robot assisted limb support. Medication administration resulted in significant increases in reaching distance in conditions when participants had to actively support their paretic arm and significant

increases in reaching velocity in all conditions. These preliminary results suggest that Tizanidine reduces the flexion synergy post-stroke, and that monoaminergic drive modulates the gain of the reticulospinal tract in voluntary motor control post-stroke. A supraspinal reduction in monoaminergic drive may reduce the expression of the flexion synergy and improve reaching function for individuals with chronic hemiparetic stroke.

Title: Transcutaneous cranial nerve stimulus in individuals with a chronic hemiparetic stroke

Authors: *J. A. BEAUCHAMP[1,2], J. YAO[1], J. P. A. DEWALD[1,2];
[1]Physical Therapy & Human Movement Sci., [2]Biomed. Engin., Northwestern Univ., Chicago, IL

Abstract: Chronic stroke induced limitations in upper extremity motor function are commonly manifested as the emergence of hyperactive stretch reflexes (spasticity) and a loss of independent joint control, such as the abnormal coupling between shoulder abduction with elbow, wrist and finger flexion (flexion synergy). Evidence suggests these motor impairments can be attributed to a loss of corticofugal projections, inciting a greater dependence on contralesional corticobulbospinal tracts and an increased monoaminergic drive. This is believed to increase spinal motoneuron excitability, generating the observed spasticity and amplifying the diffuse descending commands postulated to be responsible for the flexion synergy expression. This yields a potential avenue, whereby modulating monoaminergic drive (norepinephrine) may causally manipulate spinal motoneuron excitability and flexion synergy expression in this population. We therefore hypothesize that use of non-invasive transcutaneous cranial nerve stimulation via the trigeminal or auricular branch of the vagal nerves to modulate monoaminergic brainstem areas, such as the locus coeruleus (LC) and raphe nuclei (RN), will alter motoneuron excitability in individuals with a chronic hemiparetic stroke. Thus, we recruited four individuals with moderate to severe upper extremity impairment at least one-year post stroke. Motoneuron excitability was quantified via the tonic vibration reflex in the biceps brachii of an individual's paretic limb following both sham and real transcutaneous ophthalmic trigeminal nerve stimulation (TNS; 100 Hz, 300μs, avg: 4.5mA). Specifically, participants were instructed to generate and maintain 15% of maximum voluntary elbow flexion torque for 20s, with vibratory stimulus (128 Hz) applied to the paretic biceps brachii muscle from 10-15s. The reflexively generated elbow flexion torque during this vibratory stimulus was then assessed before, during, and after one hour of TNS. Compared to an active sham stimulus, TNS applied

bilaterally to the supraorbital nerve elicited greater decreases in reflexively generated elbow flexion torque in all four participants. This was observed as a significant decrease in reflexively generated elbow flexion torque between the sham and TNS conditions. This suggests that greater monoaminergic drive may increase spinal motoneuron excitability in this population. Further work to understand the effects of TNS on spasticity and flexion synergy in individuals with a stroke will be conducted.

Title: Silent stroke to the medial dorsal nucleus of the thalamus impairs olfactory circuitry

Authors: H. VAN DER GIESSEN[1], D. BARWICK[1], ***A. N. CLARKSON**[2];
[2]Anat., [1]Univ. of Otago, Dunedin, New Zealand

Abstract: Introduction: Olfactory impairments are common and have been reported to affect up to 43% of chronic stroke patients, however, the mechanisms associated with olfactory impairments remain poorly understood. Several human clinical studies have shown stroke to the MDNT results in olfactory deficits. Therefore, we aimed to establish a model of stroke targeting the MDNT in mice to investigate connections between the orbitofrontal cortex and piriform cortex; and whether disruptions in these circuits alter olfactory behavior. **Methods:** Young C57BL/6 mice (2-3 month old, n=20) received either an injection of the vasoconstrictor N5-(1-iminoethyl)-L-ornithine (L-NIO: 2.50µl; infused at 0.3ul/min, n=10) to induce a stroke or saline (n=10) as sham controls. Behavioral assessments, both buried food and odor discrimination, were undertaken on weeks one and four post-stroke. On the final day of behavior, the retrograde tracer Cholera Toxin subunit B (CTB-488; 200nl infused at 0.125µl/min) was injected into the orbitofrontal cortex and the anterograde tracer Biotinylated Dextran Amine (BDA; 300nl infused at 0.125µl/min) was injected into the piriform cortex to assess changes in olfactory circuitry. Infarct volume and differences in reactive astrogliosis were assessed histologically and immunohistochemically. **Results:** Histological assessments revealed no overt signs of an infarct, whereas assessment of GFAP-labeling revealed extensive reactive astrogliosis in the MDNT ($p=0.0178$) 5-weeks post-stroke indicating widespread injury compared to sham controls. Assessment of tract-tracing studies revealed injury to the MDNT results in a significant loss of connections between the orbitofrontal cortex and piriform cortex ($p=0.0396$), indicating olfactory function could potentially be compromised. **Discussion:** To the best of our knowledge, we believe the current study is the first to report a model that could represent silent stroke that when

induced in the MDNT disrupts olfactory circuitry (connections), which could underpin the development of a behavioral deficit.

Title: Examining the interplay between movement control and resting posture after stroke

Authors: *A. M. HADJIOSIF[1], S. T. ALBERT[2], K. KITA[1], R. SHADMEHR[2], J. W. KRAKAUER[1];
[1]Neurol., [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: A common characteristic of the post-stroke motor phenotype is abnormal coupling of muscles that move different joints - such as shoulder vs. elbow - a coupling which disrupts movement. These *synergies* define the motor phenotype to the point that breaking out of them is widely considered a recovery milestone, as described in Twitchell's seminal work and used in scales of post-stroke motor impairment such as the Fugl-Meyer. In addition, patients often have abnormal arm postures and heightened stretch reflexes at rest, i.e., when they are not trying to make a voluntary movement.
Here, we aim to examine the interplay between such resting abnormalities and the control of reaching and holding by measuring both in the same workspace. We hypothesize that deficits in the motor control of reaching may be, to a degree, explained by the abnormal muscle contraction patterns that stroke patients produce at rest. For example, the direction and amount of resting postural forces on a position may explain why and how movements to that target may be impaired.
We first evaluated movement control during reaching and holding. Stroke patients (so far N=14) and healthy controls (so far N=5) made repeated, arm-supported 2D reaches between 5 different targets. Patients' (unperturbed) movements were impaired compared to the non-paretic arm and controls: they were slower and took a longer path to reach the target. Since postural abnormalities may differentially affect regular movement vs. responses to perturbations, we also examined patients' responses to perturbing forces applied during reaching and/or holding. During a fraction of reaches, force-pulses pushed the arm lateral to the ideal trajectory; during some hold-on-target periods, forces pulled the arm away from the target. Patients exhibited deficits in responding to both perturbation types, taking longer times and/or longer paths to

stabilize the arm.
To evaluate postural abnormalities in these patients, we built upon previous work (Simo et al *SfN 2013*) and measured resting postural forces by passively moving the arm to different locations in the same workspace where movement control was assessed. We found that stroke patients displayed remarkably stronger resting postural force biases in their paretic arm compared to the non-paretic arm and controls, and that these resting force biases were even greater when measured without weight-bearing arm support.
We will proceed to relate these resting postural forces to the quality of reaching and holding control within the same workspace. This will enable as to assess the degree to which abnormal resting postural forces explain the post-stroke motor control phenotype for the arm.

Title: Passive ankle joint stiffness compensation by a novel ankle-foot-orthosis: Improving spastic paretic ankle motor control after stroke

Authors: *K. E. RODRIGUEZ[1], J. H. DE GROOT[2], F. BAAS[3], M. STJINTJES[2,4], F. C. VAN DER HELM[4], H. VAN DER KOOIJ[4], W. MUGGE[4];
[1]Biomechanical Engin., Delft, Univ. of Technol., Delft, Netherlands; [2]Rehabil. Med., Leiden Univ. Med. Ctr., Leiden, Netherlands; [3]InteSping, Delft, Netherlands; [4]Delft Univ. of Technol., Delft, Netherlands

Abstract: Patients with spastic paresis of the lower leg have lost neuromuscular control of the ankle joint due to affected active and passive components. Muscle paresis and increased passive joint stiffness (~100%, mainly originating from calf muscles) substantially reduce (~30%) the active range of motion (aROM) of the ankle[1], which impairs gait causing disability. Although standard Ankle-Foot-Orthoses (AFOs) for spastic paresis show clinical relevant improvements of gait parameters, their designs limit the aROM even more due to the additional stiffness they add to the joint. We propose a (non-powered) AFO with negative stiffness (nAFO) that aims to compensate for the pathologically increased passive ankle joint stiffness in spastic paresis. A spring- loaded CAM follower mechanism generates the negative stiffness that can be adjusted to the user's passive torque-angle characteristic modelled as an exponential curve with 3 parameters

($T=c_1e^{c2(\theta-c3)}$) where T is the passive torque and θ is the ankle angle. We hypothesize that compensating the passive ankle joint stiffness would 'augment' the patient's muscle capabilities to achieve a higher aROM. The first nAFO design proved the principle and walking-ability in a healthy subject. In this study, a redesign of the nAFO attains important improvements in adaptability, weight, hysteresis and range of motion of the orthosis. The brace of the nAFO has a modular design: the foot and calf parts are exchangeable to fit the user's lower leg. The weight of the nAFO is below 1.0kg (max foot size 42). Results of technical tests show a maximum negative stiffness of 1.4Nm/° at 10 ° dorsiflexion (DF) (patients up to 1.5Nm/deg[1], knee extended) with energy loss of 10% (hysteresis) throughout its range of motion of 60° (50° plantarflexion to 10° DF). Pilot tests in 3 healthy male subjects (~25 years) show that the nAFO can (over)compensate their passive ankle joint stiffness up to 170% between 0° and 10° DF (knee 30° flexed). We conclude that the current nAFO is a promising design to compensate for high passive ankle joint stiffness of multiple patients with spastic paresis. We have started a clinical trial in which the aROM is assessed at joint level (ankle rotations applied by an ankle manipulator while sitting) and at activity level (during walking on an instrumented treadmill). We expect patients to use their remaining (mainly dorsiflexion) muscle force to enlarge the aROM at both single joint and activity level.

Johns Hopkins Univ., Baltimore, MD; [4]Kennedy Krieger Inst., Baltimore, MD; [5]Cereneo Advanced Rehabil. Inst. (CARINg), Vitznau, Switzerland

Abstract: It has been argued that reduction of motor impairment mainly occurs within a 'sensitive period' early after a stroke. The mechanisms underlying the behavioral gains are unclear, but mouse models suggest a causal link to a peri-ischemic milieu of heightened plasticity that lasts ~3weeks (Wahl et al. 2014). Since humans also experience a period of rapid motor recovery in the upper extremity in first 3months after stroke, we ask whether the capacity for motor learning is also increased during this period, perhaps mediated by the heightened plasticity described in animal models. In a cross-sectional study, we tested the ability of patients with supratentorial strokes to learn two motor tasks during the acute (<2months; n=22) vs. chronic recovery stage (>6months; n=29), and in healthy controls (n = 11). Across these groups, we compared learning of a reinforcement-based motor task that likely predominantly relies on corticomotor-basal ganglia loops with a visuomotor adaptation task that relies mostly on error-based processes driven by cerebellar plasticity. We hypothesized that if a peri-ischemic hyperplastic state indeed promotes learning, patients in the acute stage will experience higher rates of reinforcement motor learning relative to patients in the chronic stage and controls, with no group differences in adaptation. To assess learning, participants sat in a Kinarm robot and made 10cm reaching movements from a start position through a visual target. During learning, (both tasks were designed to shift movement directions by the same 15°) the adaptation task by gradually imposing a visuomotor rotation upon the cursor, and the reinforcement task by hiding the cursor and providing binary, endpoint feedback that rewarded movements directed closer and closer to a 15° shift. Total learning was defined as changes in reach angles from baseline to late perturbation. Preliminary results show that while adaptation learning was not affected by time after stroke, learning in the reinforcement task was reduced in the acute stroke group relative to the chronic and healthy controls.Further, reinforcement learning was also reduced compared to adaptation in the acute group. Importantly, these differences were not explained by execution abnormalities in baseline point-to-point reaches, reinforcement rate, the severity of motor and cognitive impairment, or age. Our findings are opposite to the original prediction, showing impaired rather than enhanced reinforcement learning in the acute stage. This suggests that if there is heightened plasticity in humans, it might not be engaged in motor learning, which has important implications for rehabilitation training strategies.

Title: The relationship between stroke-induced changes in motor unit firing behavior and the expression of motor deficits

Authors: *A. S. HASSAN[1], M. Q. CUMMINGS[1], C. K. THOMPSON[3], F. NEGRO[4], R. K. POWERS[5], C. HECKMAN[2], L. M. MCPHERSON[6,7], J. P. DEWALD[1];

Abstract: Over half of stroke survivors experience long-term motor deficits in the upper extremity. Previous studies have shown that following a stroke there is a reduction in individual motor unit firing rates, impaired motor unit firing rate modulation, and atypical motor unit recruitment order. However, the relationship between the change in motor unit firing patterns and movement disabilities in individuals with stroke has not been thoroughly investigated. One possible explanation for the reduced motor unit firing rates and motor unit firing rate modulation may be a reduction in direct drive from corticospinal pathways, which has been partly replaced by activation of reticulospinal pathways, leading to abnormal muscle synergies and less efficient activation of motor units. Using a quantitative metric (change in firing rate (pps) as a function of % increase in maximum voluntary torque), our preliminary results show that motor unit firing rate modulation decreases as impairment level increases in individuals with stroke. However, the relation between this impaired modulation and specific motor impairments is still unknown. This work utilizes high-density surface EMG and a blind source separation algorithm to identify firing patterns of tens of motor units from multiple muscles, simultaneously. We sought to determine the relationship between motor unit firing rate modulation and interlimb weakness in individuals with chronic hemiparetic stroke across impairment levels. In preliminary data from 3 stroke subjects, we have found a positive correlation between elbow extension strength ratio and the motor unit firing rate modulation of the paretic triceps. We also aimed to identify differences in motor unit rate modulation between voluntary and synergy-driven contractions, in individuals expressing the prevalent flexion synergy following chronic hemiparetic stroke. In 38 motor units discriminated from 2 moderately impaired chronic stroke subjects, we found a reduced firing rate modulation of -0.31 ± 0.072 pps/%MVT during synergy-driven contractions, compared to 0.16 ± 0.161 pps/%MVT during voluntary contractions. These results show not only a reduction in rate modulation linked to losses of the corticospinal system (weakness) but further reductions when indirect corticoreticulospinal systems are increasingly being used such as during the expression of the flexion synergy.

Title: Characterization of reaching distance and velocity in individuals with childhood-onset hemiplegia

Authors: *N. M. HILL[1], J. P. A. DEWALD[2];
[1]Biomed. Engin., [2]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Introduction: Children use their arms to complete several tasks over the course of a typical day. A unilateral injury to the brain resulting from a diagnosis of cerebral palsy or pediatric stroke can markedly impair the ability to use one arm, making routine tasks difficult or impossible. Previous work in this population has demonstrated that in isometric conditions, individuals with later injuries have decreased ability to isolate shoulder abduction torque generation from elbow, wrist, and finger torque generation. In contrast, individuals with earlier injuries are more similar to typically developing controls in being successful in isolating torque generation across joints. The purpose of this study was to investigate the ability of the brain to selectively control the shoulder and elbow joints during a high effort, ballistic reaching task in individuals with childhood-onset hemiplegia and determine if there are differences based on injury timing during a dynamic task. Methods: Participants were seated in a Biodex chair and cued to reach ballistically to a virtual target on a screen. The arm was rigidly attached to an admittance controlled robotic device that allows movement in the X, Y, and Z planes and is able to modulate the amount of shoulder abduction torque required to lift the arm off of the haptic table. Participants were instructed to reach with the arm fully supported on the haptic table or while lifting a percentage of their maximum torque effort (up to 80%). Reaching distance and velocity was measured for each condition tested. Results: A total of 18 participants ages 6-19 years old completed the reaching tasks on the non-dominant arm for typically developing controls and paretic arm for participants with hemiplegia. Reach distance is normalized to maximum distance achieved across all trials for comparison between participants. Reaching

results show a trend towards decreased reach distance at higher shoulder abduction torques in individuals with later injuries compared to earlier injuries and typically developing controls. Overall velocity results show slower reaching velocities for individuals with hemiplegia compared to typically developing controls and a greater effect of shoulder abduction torque on reaching velocity in individuals with later injuries compared to earlier injuries.

Title: Asymmetry of reflex thresholds between contralateral limbs in hemispheric stroke survivors and dominant limbs in neurologically intact individuals

Authors: T. AFZAL[1], M. K. CHARDON[4], N. L. SURESH[2], *W. Z. RYMER[3];
[1]Physical Med. & Rehabil., [2]Sensory Motor Perf Prgm, [3]Shirley Ryan Ability Lab., Chicago, IL;
[4]Physiol., Northwestern Univ., Chicago, IL

Abstract: Spasticity, characterized by increased stretch reflex excitability, is a major consequence of stroke. One possible cause of hyperreflexia in chronic stroke survivors is increased motoneuron (MN) excitability. Based on findings from animal studies, there are multiple potential sources of increased spinal MN excitability after a stroke, including increased vestibulospinal and/or reticulospinal (RS) drive, potentially due to disruption of cortico-bulbar inhibitory pathways projecting to these brainstem nuclei. Spasticity, as clinically assessed in stroke survivors is highly lateralized, thus the involvement of the vestibulospinal tract is obviously relevant. On the other hand, RS nuclei project bilaterally to the spinal cord, thus RS contributions to lateralized spasticity, are difficult to reconcile. We hypothesize that after hemispheric stroke, alterations in the excitability of the RS tract affect both sides of the spinally innervated musculature and thereby contribute to hyperexcitability of reflex pathways on both sides of stroke survivors (as compared to neurologically intact subjects). In this work, we report on stretch reflex threshold measurements in biceps brachii muscles of hemispheric stroke, as well as in controls. Thresholds were obtained using progressive indentation of the biceps tendon using a linear motor. We tested spastic and contralateral limbs and dominant limbs of four hemispheric stroke survivors (2 males, 2 females) and in four age and gender matched intact subjects. We recorded surface EMG from the biceps (and triceps) muscle. The reflex threshold was identified as the indentation level where the rectified-integrated EMG in a 50 ms window, measured 20 ms

after the tap, increased above mean + 3SD of the pre-tap EMG. For consistency across subjects, we indented the biceps distal tendon up to a depth of 25 mm. The mean reflex threshold in the stroke survivors was 14.5 (4.7) mm on the contralateral limb. For intact subjects, the mean threshold was 24.3(1.0) mm. The difference between the reflex thresholds was statistically significant ($p < 0.05$). Our findings, i.e., a reduction of reflex threshold on the contralateral limb with respect to intact controls, supports our contention that the disruptions in the RS tract subsequent to stroke-induced lesions increases MN excitability in both affected and contralateral muscles of stroke survivors. Indeed, there is a high correlation between the (individual) reflex thresholds measured on both sides of our stroke participants.

Title: Event related cortical activity during simple motor task post stroke

Authors: *P. BALASUBRAMANIAN[1], S. Z. ALQAHTANI[2], A. S. HYNGSTROM[2], B. D. SCHMIT[1];
[1]Biomed. Engin., [2]Physical Therapy, Marquette Univ., Milwaukee, WI

Abstract: Introduction: In this study, we examined the ability of stroke survivors to modulate brain activity in a cued fingertap task. Event related desynchronization (ERD), a measure of cortical activity during a motor task, has reduced signal strength and somatotopic organization during self-paced fingertap in people with stroke. Our study identified changes in magnitude, spatial distribution, and time course of beta ERD during a cued task, which also distinguishes cortical modulation during a motor task.
Methods: Six stroke (mean age 69.5 ±12.4, 1 male and 5 females) and six healthy adults (mean age 24 ±1.2, 3 males and 3 females) made fingertap movements using their paretic/dominant index finger, to visual cues on a computer screen. Cues lasted 500ms and the cue interval randomly varied between 5-7 s. EEG signals were recorded using 64 active electrodes, arranged on the ACTi Cap (Brain Products GmbH) EEG cap, set in the conventional 10-20 international system of electrodes. The signals, sampled at 1000Hz, were band pass filtered (0.3 and 200Hz), notch filtered (60Hz), and amplified using the Scan 4.5 software and a Synamps 2 EEG system (Compumedics™ Neuroscan™). EEGLab and Fieldtrip toolboxes were used to epoch, filter, and artifact clear the EEG data, to compute changes in the power of the signals in beta (13-26 Hz) frequency band.
Results: Cortical activation measured using beta ERD indicated lateralized reduction in power in

healthy adults, at movement onset. Their beta ERD was at 30% below baseline for <1s, followed by resynchronization up to 20%. In stroke survivors, reduction in power measured as beta ERD was larger (45% below baseline) and the cortical activation was longer (about 2s) before returning to baseline. Spatially, beta ERD was seen in medial central sensorimotor areas in people with stroke, compared to lateralized activity in controls. In addition, stroke survivors lacked resynchronization post movement, which typically denotes end of cortical processing. **Conclusion**: Increased and sustained beta ERD with the absence of resynchronization in stroke adults showed their reduced ability to modulate cortical activity during a motor task.

Title: Coordinated asymmetrical bimanual reaching strategies used by C57/BL6 mice in a novel bimanual skilled reaching task

Authors: *D. MIRANDA-SOHRABJI[1], S. KUMAR[2], E. NUDI[1], N. DONLAN[2], T. A. JONES[3];
[1]Univ. of Texas at Austin, Austin, TX; [2]The Univ. of Texas at Austin, Austin, TX; [3]Psychology, Univ. Texas Austin, Austin, TX

Abstract: The synapse to circuit level plasticity involved in unimanual skill learning has received a wealth of attention, but that of bimanual skill learning has not. This project was motivated by a need to better understand how the two may vary in the context of stroke recovery. Upper limb hemiparesis after stroke leads to compensatory reliance on the other hand, exacerbating disuse and dysfunction in the paretic side. Prior findings in rodents with unilateral motor cortical infarcts indicate that learning new unimanual skills with the nonparetic hand is particularly maladaptive for the paretic side. This is in contrast to bimanual skill training (BiT). After motor cortical infarcts, training rats in a novel skilled bimanual reaching task (the popcorn retrieval task) improved unimanual performance with the paretic side. Mouse models would be advantageous for investigating distinctions in synaptic structural correlates of bimanual vs.

unimanual skill learning effects on paretic forelimb function, but no suitable mouse BiT tasks were available for the purpose. Thus, we developed a new one, the Puff Retrieval Task, and characterized performance strategies across a 2 month period in mature adult male C57/BL6 mice. In this task, both paws reach through a window to grasp and retrieve a food reward (a shaped piece of puffed wheat, Quaker Oats Co.). Wheat puffs were chosen as a suitably large and motivating reward of low caloric density, avoiding satiety. Food reward size and the resistance created by anchoring the puff on a pin encouraged use of both paws. Mice were found to use coordinated asymmetrical bimanual reaching and grasping strategies to perform the task. The majority of successful bimanual retrievals were initiated by extending and contacting the puff with one forepaw followed by the other, after which the puff was pulled from the pin with both paws for retrieval. Adjustments in contact position(s) with one or both limbs after initial contact were common. Most mice had a preferred limb (left or right) for reach initiation. Work is ongoing to refine the behavioral analysis approach for characterizing task acquisition, and to assess reliability across experimenters and across video vs. real time measures. Assuming replication of prior findings in rats of beneficial effects of post-stroke BiT, the new BiT task will then be extended to the question of the synaptic structural correlates of its post-stroke influence on paretic forelimb function.

Title: Robotic assessment of upper limb function in a nonhuman primate model of chronic stroke

Authors: *Y. CHEN[1], M. C. POOLE[1], J. Y. NASHED[1], A. CHAMPAGNE[1], D. J. COOK[2]; [1]Ctr. for Neurosci. Studies, [2]Neurosurg., Queen's Univ., Kingston, ON, Canada

Abstract: Stroke is a leading cause of death and disability worldwide and survivors are frequently left with long-term disabilities that diminish their autonomy and result in the need for chronic care. There is an urgent need for the development of therapies that improve stroke recovery, as well as accurate and quantitative tools to measure function. Nonhuman primates

closely resemble humans in neuroanatomy and upper limb function, and may be crucial in randomized pre-clinical trials for testing the efficacy of stroke therapies. In this study, two cynomolgus macaques were trained to perform a visually guided reaching task and were assessed in a passive stretch task on the Kinesiological Instrument for Normal and Altered Reaching Movements robot. Strokes were then induced in these animals by transiently occluding the middle cerebral artery and their motor performance on the same tasks was assessed after recovery. Relative to pre-stroke, post-stroke hand movements of the affected limb became slower and less accurate, similar to motor deficits revealed in the same task in human stroke patients. Regression analyses reveal both recovered and compensatory movements to complete movements to different areas in space. Lastly, we note decreased range of motion in the elbow joint of the affected limb post-stroke associated with spasticity. Taken together, these studies highlight that sensorimotor deficits in reaching movements following stroke in cynomolgus macaques resemble those in human patients and validate the use of robotic assessment tools in a nonhuman primate model of stroke for identifying and characterizing such deficits.

Title: Entrainment of stepping frequency to vertical motion of walking surface in stroke and age-matched controls

Authors: *D. GOBESKI[1], B. ROBERTSON-DICK[3], T. ONUSHKO[1], S. C. RAAB[2], L. RIEM[1], N. GREGG[1], A. S. HYNGSTROM[2], B. D. SCHMIT[1];
[1]Biomed. Engin., [2]Physical Therapy, Marquette Univ., Milwaukee, WI; [3]Physical Med. and Rehabil., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Introduction: Gait entrainment to external stimuli is used as a rehabilitative technique in different neurologically-injured populations. Previous research has focused on repetitive sensory stimuli, e.g. auditory and tactile, and has shown that individuals can synchronize their stepping frequency to the stimulus, with less work done on the effects of entrainment to walking surface motion. As walking surface motion interacts directly with an individual's gait dynamics, synchronization of the gait cycle to the walking surface motion is expected to be readily attainable as the motion cannot be passively ignored and filtering out its effects on gait would require additional effort. In this study, the walking surface was oscillated up and down while research participants walked on it. Participants were chronic stroke survivors

and age-matched controls.
Methods: All trials were performed while a participant walked on a motion base: a split-belt treadmill mounted on a platform capable of six degree of freedom motion (x-, y-, and z-translation, yaw, pitch, and roll). Kinematics data was obtained using the Helen Hayes marker set and a multiple-camera OptiTrack motion capture system. Kinetics data was obtained using single-axis force transducers mounted beneath the treadmill belts. EMG was obtained for 4 muscles on each leg. Gait parameters were calculated from the marker and force data during post-processing.
Each 4minute trial started with ~1 minute of the motion base stationary, then 2 minutes of sinusoidal vertical oscillations (ztranslation only; no rotation), then ~1 minute of the motion base stationary. The vertical oscillations were set to 90/100/110/180/200/220 percent of the participant's preferred stepping frequency, and the order of the 6 trials was randomized separately for each participant.
Results: Vertical oscillation of the motion base resulted in varying amounts of gait entrainment, with no oscillation frequency consistently showing best or worst results across all individuals. When averaged across trials and participants, the stroke and control groups spent comparable amounts of time entrained during the oscillations (53% for stroke, 57% for control). The two groups experienced similar reductions in step length asymmetry [100% x ABSOLUTE VALUE of (RIGHT STEP LENGTH – LEFT STEP LENGTH) / (RIGHT STEP LENGTH + LEFT STEP LENGTH)] when comparing the section of each trial immediately before and after the oscillations (-12% for stroke, -16% for control).
Conclusion: Control and chronic stroke participants both exhibit gait entrainment and accompanying reductions in step length asymmetry, with the exact results being individual-specific.

Title: An *in vivo* model of microglia phagocytosis of aged red blood cells in the mouse brain

Authors: *J. WAN[1], J. WANG[2];
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Anesthesiology/Critical Care Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Intracerebral haemorrhage (ICH) is a devastating subtype of stroke associated with high mortality and morbidity, however lacks effective treatment to date. Initial brain injury occurs in the first few hours after ICH as a result of mass effect by hematoma formation. Microglia represents the primary phagocytic function to mediate hematoma clearance, which has not been well studied. In this project, we obtained red blood cells (RBCs) from UBC-GFP mouse (C57BL/6J background) and artificially aged them by raising intracellular calcium concentration to stimulate microglia phagocytosis; we observed microglia engulfment in an *ex vivo* organotypic slice cultures of the mouse striatum model, and in *in vivo* aged RBCs-induced, normal RBCs-induced, and whole blood-induced ICH models at different time points after injury. We found aged RBCs enhanced microglia phagocytosis *ex vivo* and *in vivo* when compared with those of normal RBCs. Moreover, in aged RBCs-induced ICH model, the hematoma size increased to peak at 3 days post injury and neurological deficits outcomes were more severe at 1 and 3 days post injury and tended to recover at 7 days post injury, which were similar to those of whole blood-induced ICH model, a more clinically relevant model. We further observed microglia activation and phagocytosis increased and reached to peak at 5 days after aged RBCs-induced ICH, which were significantly more prominent in comparison to normal RBCs-induced ICH model. Our experiments establish an *in vivo* mouse model to observe microglia phagocytosis, demonstrate that aged RBCs enhanced microglia phagocytosis both *ex vivo* and *in vivo*, and provide new strategies for studying microglia functions and hematoma clearance after ICH.

Title: Inhibition of NBCs activity protects hippocampus CA1 delayed neuronal death induced bytransient global cerebral ischemia in gerbils

Authors: M. JIA[1,2,3], W. SHAN[1], S. LIU[4], N. CHEN[4], A. GUO[1], Q. WANG[1], Y. WANG[1], *J. WU[1,2,3,4];

Clin. Res. Ctr. for Neurolog. Dis., Beijing, China; [4]Wuhan Univ. of Technol. Sch. of Chemistry 、 Chem. Engin. and Life Sci., Wuhan, China

Abstract: Metabolic acidosis plays key role in ischemia reperfusion (I/R) induced hippocampus delayed neuronal death, the underlying mechanism remains obscure. Sodium bicarbonate co-transporters (NBCs) contribute cellular acid-base homeostasis in pathophysiological processes, and may lead to intracellular sodium over influx and calcium dyshomeostasis during I/R hippocampus injury. We speculated that blockage of NBCs activities would be beneficial for neuronal surviving during I/R injury. Using an well established gerbils transient global cerebral ischemia model, we examined the protective effect of S0859, a NBCs specific inhibitor, on the hippocampus delayed neuronal death and animal behavior alterations induced by I/R. Compared with the sham-operated group, ischemia-operated group animals exhibited hyperactivity in open field which tested at 3d post-ischemia; Histological study confirmed that I/R selectively impaired hippocampal CA1 pyramidal neurons; TUNEL positive neurons(apoptosis) were not detected in all the hippocampal subregions including CA1 region in the sham-operated group, but could be observed in the stratum pyramidal of the CA1 region as early as 12h, which peaked at 3d and declined at 7d post-ischemia, the later might be due to the neuronal loss in hippocampal regions. Pretreatment of ischemia-operated animals with S0859 (300ug/Kg, *i.p* , 3d before I/R) attenuated markedly I/R induced hyperactivity and hippocampus delayed neuronal death. Apoptosis neurons were significantly reduced in S0859 pretreated group, compared with that in no-treated group. The result indicated that NBCs activation during I/R induced a “pH regulation dependent sodium influx and calcium dyshomeostasis” ,which in turn lead to neuronal apoptosis and neuronal death. S0859 protects hippocampus CA1 pyramidal neurons delayed death through an anti-apoptosis mechanism (Supported by NSFC 81870935 to WJ).

Title: Investigating the molecular and cellular basis of moyamoya disease using patient derived induced pluripotent stem cells

Authors: *S. P. RAO, Q. ZHANG, H. UCHINO, A. PENDHARKAR, M. Y. CHENG, G. K. STEINBERG;
Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: Background: Moyamoya disease (MMD) is a progressive steno- occlusive disease affecting terminal regions of the cerebral internal carotid artery (ICA), leading to stroke. Revascularization surgery is the only treatment option. Analysis of the affected arteries showed thickening of the intima, depletion of the elastic lamina as well as the media, indicating a dysfunction of the vascular smooth muscle cells (VSMCs) and endothelial cells (ECs). However the pathogenesis of the disease is still unclear. We aim to address this gap in knowledge and determine the cellular and molecular mechanisms underlying MMD by using patient derived induced pluripotent stem cells (iPSCs), to generate VSMCs and ECs.
Methods: Peripheral blood mononuclear cells (PBMCs) from controls and MMD patients (n=3 per group) were utilized for generating iPSCs. Immunocytochemistry and qPCR confirmed the expression of pluripotency markers, SSEA4, TRA1-60, OCT4 and NANOG in all iPSC samples. iPSCs were induced to differentiate into neuro-ectoderm (NE) derived VSMCs. BrDU incorporation within the cells was measured to assess cell proliferation. Scratch and transwell migration assays were performed to measure cell migration. VSMCs were exposed to either normoxia or hypoxia model (1%O_2) to investigate how cells respond to the insult. HIF1α activation was determined using western blot.
Results: Control and MMD VSMCs were characterized by immunocytochemistry, qPCR and flow cytometry analysis, to confirm the expression of VSMC specific proteins CNN1, TAGLN and MYH11. Pluripotency markers were undetectable. Under normoxia MMD VSMC's proliferated and migrated to a lesser extent, while being more contractile compared to controls. Western blot analysis showed that hypoxia inducible factor 1α (HIF1α) protein expression was already elevated in normoxic MMD VSMC and hypoxia caused a further increase.
Conclusions: Our preliminary results indicate that MMD VSMCs are dysfunctional and may be related to the elevated basal expression of HIF1α, possibly contributing to MMD pathology. We are currently determining the angiogenic properties of MMD ECs followed by co-culturing the cells and transcriptome analysis, which will provide a better understanding of the cellular and molecular mechanisms underlying MMD.

Title: Automated assessment of motor deficits after experimental stroke using Erasmus Ladder

Authors: *T. C. CHIANG, S. HARVEY, A. PENDHARKAR, Z. CAO, M. Y. CHENG, G. K. STEINBERG;
Stanford Univ., Stanford, CA

Abstract: Background: Traditional behavior assessment of motor deficits using manual scoring can be subjective and labor intensive. The bias between individuals can lead to incorrect and inconsistent assessment, resulting in variability and non-reproducible data. Here we demonstrate the feasibility of an automated motor behavior assessment in adult mice via two experimental stroke models. Methods: Adult male C57Bl6 mice (11-13 weeks) were subjected to transient middle cerebral artery occlusion (tMCAO, n=15) or distal middle cerebral artery occlusion (dMCAO, n=10). Naïve mice (n=10) were prepared as no stroke control. Brains were collected at PD 30 and sections were processed for immunostaining using antibodies targeting neurons (MAP2) or activated microglia/macrophage (CD68). Mice with infarcts in both cortex and striatum were included in the study. Mice behavior were evaluated by Erasmus Ladder at pre-stroke baseline (4 unperturbed and 4 perturbed sessions) and post-stroke days (PD) 7, 14, 21 and 28 (all perturbed sessions). Mice were grouped via assessment of several parameters recorded by Erasmus Ladder: trial time, pre-perturbed time, post-perturbed time, and HH-long step percentage. Results: In the tMCAO model, stroked mice show a significant deficit in pre- and post-perturbed times and various step types after stroke. While significant changes were altered in many step types between PD7-14 after tMCAO, only HH-long step and reaction time to perturbation were significantly different when compared to control. Specifically, we observed a sustained decline in the usage of affected limb over unaffected limb until PD28. This imbalance in limb use is also observed in the dMCAO model, however, other step types and reaction times were not altered in the dMCAO model. Interestingly, in both models the stroke mice exhibit lower trial time when compared to control mice, indicating a faster completion of each trial despite the limb deficit. Conclusions: Our results indicate that the Erasmus Ladder can provide automated, unbiased assessment of motor deficit in mice after stroke, at least until post-stroke day28. Furthermore, Erasmus Ladder allows tracking of the affected and non-affected limb use after stroke. Greater motor variable differences were detected in the tMCAO versus dMCAO model. Ongoing studies are elucidating the Erasmus Ladder's capability to detect recovery in mice treated with therapeutic interventions such as optogenetic stimulation.

Title: Center of mass fluctuations in stroke survivors as a response to unexpected lateral support surface perturbations during gait

Authors: *S. C. RAAB[1], L. I. RIEM[2], T. ONUSHKO[2], N. GREGG[2], D. GOBESKI[2], A. S. HYNGSTROM[1], B. D. SCHMIT[2];
[1]Physical Therapy, [2]Biomed. Engin., Marquette Univ., Milwaukee, WI

Abstract: High fall risk during walking is a common problem for many individuals post-stroke. Balance responses during walking are not well described, particularly when the support surface is providing the perturbation. The ability to control the excursion of center of mass (COM) within the base of support (BOS) is central to the maintenance of an upright posture when a perturbation is delivered. Although previous research supports that stroke survivors have greater excursion of COM both in quiet stance and during gait without perturbations, less COM excursion in response to an unexpected perturbation suggests a more rigid and simpler control strategy that is not optimal for maintaining reactive posture. In the present study, 4 chronic stroke survivors and 4 healthy age- and gender-matched controls walked at self-selected walking speeds on a treadmill system that is programmed to medially/laterally shift 2.5 cm immediately after initial heel strike. Spatial and temporal changes to medial lateral (ML) COM movement during the first 5 COM fluctuations in response to lateral destabilizing perturbations of the treadmill were quantified. Perturbations were randomized between the side of heel contact and direction of perturbation. As a group, stroke survivors' COM fluctuations exhibited less reactive change in amplitude and timing between COM shifts when compared to the control group. Amplitude fluctuations increased from a mean of 8.0 cm to 10.84 cm during the last step before perturbation delivery and the first step after perturbation delivery in the stroke group, but decreases in the control group from 6.41 cm to 3.65 cm. Temporally, stroke survivors' fluctuations in COM decreased by 0.036 s while controls' fluctuations decreased by 0.200 seconds. These results combined with future research elucidate post-stroke COM control during gait and will contribute to developments of therapy techniques to improve dynamic balance in response to perturbations.

Title: The role of cofilin in intracerebral hemorrhage-induced neuroinflammation

Authors: *D. A. ALMARGHALANI[1], M. AMIRA[2], D. TA[2], A. KONDAKA[2], Z. A. SHAH[2]; [1]Dept. of Pharmacol. and Exptl. Therapeut., [2]Dept. of Medicinal & Biol. Chem., Col. of Pharm. and Pharmaceut. Sciences, The Univ. of Toledo, Toledo, OH

Abstract: Intracerebral hemorrhage (ICH) is a devastating disease associated with high mortality and accounts for about 15% of all stroke cases. About 50% of patients die within the first month of attack and those who survive have a long-term disability and neurological deficit; however, only 20% of patients who survive ICH achieve functional independence after 6 months. The understanding of the pathological changes and the repair mechanisms after ICH are not clearly understood. Our previous study demonstrated a major role of the cytoskeletal protein, cofilin in ICH-induced brain injury. We reported that knockdown of cofilin in a mouse model of collagenase induced-ICH improved neurobehavioral deficits and decreased hemorrhagic volume as well as blood-brain barrier disruption (BBB) and microglia activation. In the present study, we aimed to determine the cofilin signaling and glial activation up to 14 days following ICH. Therefore, we subjected different cohorts of mice to intrastriatal collagenase injection-induced ICH and mice were sacrificed at different time-points of 1, 3, 7, and 14 days. Using Western blotting (WB), we observed a significant upregulation of cofilin protein levels in the ipsilateral striatum on day 3 and then a decreasing trend was observed from day 7 to day 14. Mice suffered from severe neurobehavioral deficits immediately after ICH which lasted for 7 days and then a gradual improvement was observed in motor deficits. Using immunohistochemistry analysis, activated microglia were observed to be increased after ICH from day 1, especially around the hematoma and lasted until day 7 and there was a gradual decrease observed at day 14. Activated microglia were associated with morphological changes from ramified into an amoeboid shape particularly around the hematoma from day 1 up to day 14. Astrocyte activation observed by WB showed a gradual increase in GFAP protein expression from day 1 and lasted until day 14. In conclusion, we believe that cofilin overactivation plays an important role in the activation of microglia and astrocytes subsequently leading to neuroinflammation and motor deficits following ICH. Developing therapies against cofilin might provide novel alternatives for ICH therapy.

Title: Effect of genistein on age-dependent differences in cerebral ischemia in ovariectomized rats

Authors: *A. OPPONG-GYEBI[1], D. METZGER[1], N. SUMIEN[2], D. A. SCHREIHOFER[3]; [2]Pharmacol. & Neurosci., [1]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX; [3]Dept. of Pharmacol. and Neurosci., Univ. of North Texas Hlth. Sci. Ctr. At, Fort Worth, TX

Abstract: Background: Advancing age increases women's susceptibility to stroke compared to men, especially after the menopausal transition, which has been attributed mainly to a drastic drop in estrogen post-menopause. However, time-dependent mixed beneficial and detrimental effects of estrogen therapy for prevention of stroke and cardiovascular diseases after menopause have contributed to widespread mistrust of estrogen use. This has led to the use of other agents like soy isoflavones including genistein as alternatives to hormone therapy. In this study, we investigated genistein's effect on age-dependent differences in cerebral ischemia in ovariectomized rats. **Hypothesis**: We hypothesized that the neuroprotective effects of genistein, a soy isoflavone, on cerebral ischemia are less sensitive to the aging and duration of hormone deprivation. **Method**: To test this, young (3-4 months old) and retired proven breeder rats (9 months old) were ovariectomized (OVX), grouped into two ovarian hormone deprivation time points (2weeks= short-term and 12 weeks= long-term) and treated with isoflavone-free diet (IF) or genistein diet (GEN). Estrogen (E2) pellet-treated group was added as a control for hormone supplementation post OVX. Animals underwent middle cerebral artery occlusion (MCAO) or sham surgery for 60 mins followed by reperfusion and behavioral tests to assess neurological, motor and cognitive deficits. The extent of brain injury was quantified with immunohistochemical stains of activated calcium-binding protein (Iba1) and glial fibrillary acidic protein (GFAP). **Results**: We observed no effect of GEN on neurological assessment and motor learning ($p>0.05$) across stroked groups. The retired breeder stroked rats performed worse than the young adults ($p<0.05$) revealing an effect of age. Long-term estrogen deprivation in retired breeders worsened gait performance showing a duration effect ($p<0.05$).GEN had no effect on the histological extent of injury ($p>0.05$). GEN, however, improved cognitive flexibility in retired breeder stroked groups compared with IF and E2 groups ($p<0.05$). **Conclusion**: Our results suggests that increasing age increases neurological, motor and cognitive deficits after cerebral ischemia. Long-term estrogen deprivation increases motor deficits. GEN

had little effect on the sensorimotor outcomes, but may improve certain aspects of cognitive function post-stroke.

Title: The role of microglia cell-specific estrogen receptor alpha (ERα) signaling in an ischemic stroke model

Authors: *T. RODRIGUEZ[1,3], J. KYLE[2], C. MELIAN[1], A. HO[2], S. TSYRKA[2], M. ACOSTA-MARTÍNEZ[1];
[1]Dept. of Physiol. and Biophysics, [2]Dept. of Pharmacol. Sci., Stony Brook Univ. Med. Ctr., Stony Brook, NY; [3]Grad. Program in Neurosci., Stony Brook Univ., Stony Brook, NY

Abstract: Stroke is a sexually dimorphic disease, with very strong sex and age interactions affecting risk, pathophysiology and outcomes. For example, stroke is uncommon among premenopausal women; however after menopause the incidence of stroke increases, and women experience worst stroke outcomes compared to men. This protection in the female brain has been attributed to the anti-inflammatory and neuroprotective effects of estradiol (E_2). However the cell types and intracellular mechanisms underlying E_2 anti-inflammatory actions after ischemic injury are poorly understood. Activation of microglia cells is a key component of the post ischemic inflammatory response that contributes to the extent of brain injury. Even though estrogen receptor alpha (ERα) is the primary mediator of E_2 anti-inflammatory actions, evidence of direct regulation of microglia function by E_2-ERα signaling is missing. Therefore, we investigated the contribution of macrophage/microglia cell-specific ERα signaling in the inflammatory response to ischemic injury. Mice with macrophage/microglia-cell specific deletion of ERα were generated by mating floxed ERα mice and Csf1R-Cre animals. Focal ischemia was pharmacologically induced in WT ($ER\alpha^{flx/flx}$) and Csf1R-1-$ER\alpha^{flx/flx}$ mice by intracortical injection of the vasoconstrictive peptide endothelin-1 (ET-1); infarct volume, ERα and microglia (Iba-1) expression was evaluated 24 hours after injection. Infusion of ET-1 resulted in significant cortical infarcts in both genotypes, however compared to WT, Csf1R-1-$ER\alpha^{flx/flx}$ females showed a larger infarct volume (1.18% vs. 2.1 %, WT and Csf1R-1-$ER\alpha^{flx/flx}$ respectively, $p<0.01$). An increase in microglia cell numbers (Iba-1 staining) as well as ERα protein expression was observed in the peri infarct area of male and female mice of both genotypes. However, no genotype effect on Iba-1 or ERα expression was observed. We also tested the

susceptibility of microglia isolated from neonatal WT and KO females to *in vitro* ischemia. Microglia were exposed to oxygen-glucose deprivation for 2 hours followed by 16 of reperfusion (OGD/R) and the effect on microglia activity was assessed by phagocytosis assay. Compared to normal treatment, OGD/R increased the % of phagocytic microglia cells from female mice, regardless of genotype (WT: 15% vs. 32%, normal vs. OGD/R; KO: 15% vs. 48%, normal vs. OGD/R). Our data suggests that the loss of ERα in microglia/macrophage cells leads to deregulation of post-ischemic stroke inflammatory responses and higher vulnerability to ischemic stroke in the female brain.

Title: Pathophysiological characterization of stroke-induced skeletal muscle injury

Authors: *M. BALCH, H. HARRIS, D. CHUGH, W. ARNOLD, C. L. RINK;
The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Ischemic stroke is a leading cause of long-term disability in the United States. Rehabilitation offers therapeutic benefit, but best practices are unclear. Despite the need for evidence-based therapies, less than 3% of ischemic stroke literature over the past decade has addressed the state of skeletal muscle in response to stroke. Previous work identified acute changes in skeletal muscle within 2 weeks of the stroke event, far earlier than chronic manifestations typically noted with stroke disability. Here, we present a detailed characterization of acute skeletal muscle injury following stroke.
Ischemic stroke was induced in male Wistar rats via transient middle cerebral artery occlusion and confirmed using MRI. Animals were followed out to various acute timepoints (post-stroke day (PSD) 3, PSD7, PSD14), after which skeletal muscle from both stroke-affected and contralateral hindlimbs was collected. Tissue analysis included study of neuromuscular junction (NMJ) morphology, fiber phenotype, fetal programming markers, and mediators of satellite cell activity, all compared to naïve healthy controls. An additional cohort of stroke/sham rats underwent *in vivo* muscle contractility and electrophysiology testing at pre-stroke, PSD7, PSD14, and PSD21 timepoints.
To characterize the stroke-induced response of skeletal muscle tissue, we reviewed markers of

skeletal muscle repair after injury. A significant increase in Pax7+ cells and Embryonic Myosin Heavy Chain+ cells was observed at PSD7, suggesting heightened satellite cell renewal and regenerative re-expression of a developmental marker respectively. NADH-TR staining, indicative of mitochondrial distribution, presented a shift in fiber phenotype to more fatigable, fast-twitch isoforms. Electrophysiological study of muscle contractility and motor unit functionality demonstrated a decrease in motor unit number estimation and tetanic force at PSD14 and PSD21. We propose further analysis will present maladaptive changes at the NMJs - to include morphological adaptations and potential polyneuronal innervation - which prompt the fiber type shift and the ensuing cascade of compensatory myogenic activity.
Taken together, this work provides a novel characterization of the stroke-induced physiological response in skeletal muscle tissue. Disruptions to the neuromuscular unit initiate a compensatory response of potentially maladaptive proportions, all contributing to functional loss and motor deficit. Harnessing such understanding will inform tailored, optimized therapeutic paradigms to maximize recovery benefit in stroke survivors.

Title: The stroke paradox: Hypertonicity with weakness

Authors: *D. G. KAMPER[1], **A. BARRY**[2], M. STOYKOV[2], K. TRIANDAFILOU[2], N. J. SEO[3], N. BANSAL[4], M. GHASSEMI[1], L. VIDAKOVIC[2], E. ROTH[2];
[1]North Carolina State Univ., Raleigh, NC; [2]Shirley Ryan Abilitylab, Chicago, IL; [3]Dept of Industrial Engin., Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [4]Marquette Univ., Marquette, WI

Abstract: Weakness, especially of the distal upper extremity, is a hallmark of impairment following stroke. While the sources of this weakness remain a matter of some debate, neurological factors undoubtedly contribute. To address potential mechanisms, we examined voluntary and reflexive muscle activation in 90 stroke survivors participating in a longitudinal intervention trial. Participants had chronic, severe hand impairment, rated as Stage of Hand 2-3 on the Chedoke-McMaster Stroke Assessment (Fugl-Meyer upper extremity scores ranged from 0 to 33). Participants were at least 6 months post-stroke (mean ± standard deviation of 6.7±6.6

years post-incident) and ranged in age from 21 to 80 years old (57.9±11.5 years). All participants signed an IRB approved, written informed consent. Substantial hand weakness was confirmed in all participants. Grip strength in the paretic hand was only 12.2%±9.8 of the force generated with the less impaired hand. Metacarpophalangeal (MCP) flexion torque generated across all four fingers was measured with a custom apparatus to be 2.1±1.4 Nm, much less than the 10.4±2.8 Nm typically produced by neurologically intact individuals. MCP extension torque, also measured with the same apparatus, was largely non-existent (only 7/90 participants generated extension torque), with maximum values of only 1.02Nm across all participants. Despite the weakness, we observed hypertonicity of the long finger flexors. Imposed stretch of the finger flexors through externally controlled MCP rotation resulted in a spastic reflex response in a majority of the subjects (reflex torque = 0.89±0.57 Nm). Hypertonicity was further confirmed by the significantly prolonged time required to relax the finger flexor muscles once activated. EMG recordings from flexor digitorum superficialis (FDS) revealed that stroke survivors required 3.8±3.7 seconds to terminate FDS activity following creation of a maximal flexion force. In contrast, neurologically intact individuals in a prior study required only 0.24±0.11 seconds to terminate activity, or 15% of the time needed by stroke survivors. While this hypertonicity was apparent, stroke survivors appeared to have difficulty in voluntarily activating muscles. In fact, for 17 subjects, MCP reflex torque induced by passive stretch was greater than the voluntary MCP torque that could be produced by the subject. Furthermore, a total of 16 subjects exhibited greater reflex FDS activation than they could generate voluntarily. These results confirm that following stroke, externally applied stretch can generate greater flexor muscle activity and torque than during voluntary activation.

Title: Endogenous zinc proroporphyrin formation critically contributes to hemorrhagic stroke-induced brain damage

Authors: *R. PAN[1], G. TIMMINS[2], Y. YANG[2], X. ZHOU[2], K. LIU[2];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM

Abstract: Hemorrhagic stroke is a leading cause of death in the U.S. with a survival rate being only around 27%. The causes of intracerebral hemorrhage (ICH)-induced brain damage are thought to include lysis of red blood cells, hemin release and iron overload. However, these mechanisms have not proven very amenable to therapeutic intervention, and so other mechanistic targets are being sought. Here, we report that accumulation of endogenously formed zinc protoporphyrin (ZnPP) also critically contributes to ICH-induced brain damage. ICH caused a significant accumulation of ZnPP in surrounding brain tissue, as evidenced by fluorescence microscopy of ZnPP, and further confirmed by fluorescence spectroscopy and supercritical fluid chromatography-mass spectrometry. ZnPP accumulation was dependent upon both ICH-induced hypoxia, and an increase in free zinc accumulation. Notably, inhibiting ferrochelatase, which catalyzes insertion of zinc into protoporphyrin, greatly decreased ICH-induced endogenous ZnPP generation. Moreover, a significant decrease in brain damage was observed upon ferrochelatase inhibition, suggesting that endogenous ZnPP contributes to the damage in ICH. Thus, our findings reveal a novel mechanism of ICH-induced brain damage through ferrochelatase-mediated formation of ZnPP in ICH tissue. Since ferrochelatase can be readily inhibited by small molecules, this may provide a new and druggable target for ICH therapy.

Title: Critical role of formyl peptide receptor 1 on activated splenocytes in brain ischemic injury

Authors: *J. LI, M. CHORDIA, D. PAN, Z. ZUO;
Univ. of Virginia, Charlottesville, VA

Abstract: Background: Formyl peptide receptor 1(FPR1), identified by their ability to bind N-formyl peptides, has been shown to mediate the leukocyte recruitment after ischemia-reperfusion injury. We have synthesized the peptide cinnamoyl-phenylalanine–(D) leucine-phenylalanine-

(D) leucine-phenylalanine (cFLFLF), an FPR1 specific antagonist. This peptide has been shown to be excellent in labeling inflammatory foci in the peripheral tissues but its molecular and biological effects after antagonizing FPR1 are not well studied. We hypothesize that cFLFLF may provide neuroprotection by inhibiting the migration of peripheral immune cells including splenocytes into the brain and reducing the neuroinflammation after stroke.
Methods: Eight-week-old CD-1 male mice weighing 28-32 g were randomly assigned to the following groups: 1) sham, 2) 0 h reperfusion, 3) 4 h reperfusion, 4) 24 h reperfusion, 5) 28 d reperfusion, 6) 0.5 mg/kg cFLFLF treatment +4 h reperfusion, 7) 5.0 mg/kg cFLFLF treatment + 4 h reperfusion, 8) 0.5 mg/kg cFLFLF treatment +24 h reperfusion, 9) 5.0 mg/kg cFLFLF treatment+24 h reperfusion, and 10) 5.0 mg/kg for three days+28 d reperfusion. Brain ischemia was a 90-minutes left middle cerebral artery occlusion (MCAO) that was achieved by an intraluminal filament method. Neurological outcome including neurological deficit scores, motor coordination, brain infarct volume, and spleen weight was evaluated at the corresponding times. Some mice were used for immunofluorescent staining and biochemical analysis. FPR1 knockout mice were used to defy the role of FPR1 in cFLFLF induced neuroprotection.
Results: cFLFLF improved neurological outcomes after MCAO and attenuated MCAO-induced decrease of spleen weights. cFLFLF inhibited the activation and migration of splenocytes as shown by the significant decrease of pro-inflammatory cytokine expression *in vivo* and mitigated chemoattractive movement *in vitro*. The phosphorylated nuclear factor(NF)-κB and chemokine C-C motif ligand 2 (CCL2) were reduced after cFLFLF treatment in the tissues of brain and spleen after MCAO, which may be the molecular mechanisms for cFLFLF-induced neuroprotection. Both phosphorylated NF-κB and CCL2 were reduced in FPR1 knockout mice with or without MCAO.
Conclusions: cFLFLF inhibites the migration and infiltration of splenocytes into the brain, attenuates neuroinflammation and improves neurological outcome after ischemic stroke in mice. Reducing phosphorylated NF-κB and CCL2 expression via a FPR1 dependent inflammatory pathway may contribute to the neuroprotection induced by cFLFLF.

Title: Muscle spasticity and motor performance after botulinum neurotoxin injection in stroke subjects with spastic hemiplegia

Authors: *Y.-T. CHEN[1], C. ZHANG[2], E. MAGAT[1], M. VERDUZCO-GUTIERREZ[1], P. ZHOU[1], Y. ZHANG[2], S. LI[1];
[1]Physical Med. and Rehabil., Univ. of Texas Hlth. Sci. Ctr. - Houston, Houston, TX; [2]Univ. of Houston, Houston, TX

Abstract: There are approximately 20-40% of stroke survivors who suffer from muscle spasticity. Botulinum neurotoxin (BTX) is the first-line treatment for spasticity management. BTX injection is able to effectively reduce spasticity, but at the same time it causes muscle weakness. It is known that a weaker muscle has worse performance in force control. The purpose of this study was to quantify the effect of BTX injection on the spasticity, strength and motor performance of the spastic muscle in stroke survivors. Seven stroke subjects (Age: 52.9 ± 11.8 yrs; 2 women) who received 100 units of onabotulinumtoxinA (Botox) or incobotulinumtoxinA (Xeomin) injection on biceps brachii muscle were recruited. Subjects were assessed within one week before (baseline) and 3 weeks after (3-wks) BTX injection. The spasticity, maximum voluntary contraction (MVC), and motor performance of the spastic biceps muscle were evaluated. MVC and motor performance were also collected from the contralateral non-affected side. Spasticity of elbow flexors was quantified as reflex torque using a computerized passive stretch equipment. Motor performance was quantified as the coefficient of variation (CV) during isometric elbow flexion tasks at 10%, 30%, and 50% of MVC. On average, the MVC (baseline: 12.6 ± 2.5 N-m; 3-wks: 10.6 ± 1.6 N-m; $p = 0.04$), and reflex torque (baseline: 3.8 ± 0.8 N-m; 3-wks: 2.6 ± 0.6 N-m; $p = 0.02$) of the spastic biceps muscle were reduced after BTX injection compared to the baseline. However, motor performance remained unchanged after BTX injection (no significant differences between baseline and 3-wks; all $p > 0.05$). Nonetheless, all the parameters from the non-paretic sides had no significant differences between baseline and 3-wks visits (all $p > 0.05$). Our results provide evidence that BTX injection reduces muscle spasticity of the spastic biceps muscle. Though the spastic biceps muscle became weaker after BTX injection, no reduction in motor performance was observed. Collectively, BTX injection is able to reduce spasticity, while maintaining the motor performance of the weakened spastic muscle.

Abstract: INTRODUCTION: Mild traumatic brain injury (mTBI) is a global public health concern that affects millions of children annually. Mild TBI results in subtle and diffuse alterations in brain tissue, challenging accurate clinical detection and prognostication. The results of studies using advanced MRI techniques like diffusion-weighted imaging (DWI) have been promising but inconsistent. This likely reflects the broadly differing age ranges, injury phases, comparison groups, and brain regions examined. The current study addressed these limitations by comparing post-acute white matter diffusivity in children with mTBI versus a mild orthopedic injury (OI), and by determining whether post-acute white matter diffusivity correlated with post-acute and chronic post-concussive symptoms (PCS). **METHODS:** Data were drawn from a two-site study of pediatric mTBI. Children aged 8-16.99 years with mTBI (*n*=135) or mild OI (*n*=69) were recruited from emergency departments (ED) at two children's hospitals. Injuries and acute signs and symptoms were assessed during the initial ED visit, during which parents also rated pre-injury symptoms; participants also completed a post-acute (<2 weeks post-injury) assessment, which included a 3T MRI, and 3- and 6-months post-injury assessments. Parent-proxy ratings of PCS were obtained at each assessment. Diffusion metrics were derived from DWI using Automatic Fiber Quantification (AFQ) software. Multiple multivariable regression analyses were used to compare groups and to examine prediction of PCS, with False Discovery Rate (FDR) used to correct for multiple comparisons. **RESULTS:** Demographic characteristics did not differ between the groups or sites. No significant group differences were found in any of the 28 fibers. Significant main effects were found for age in a number of regions, and there was a significant covariate effect of site. No group, age, and sex interactions were significant. Time post-injury of MRI did not relate to DTI metrics. Post-acute and 3-month PCS ratings were not significantly associated with diffusion metrics in any region. However, significant interactions between group and diffusion metrics were found for 6-month PCS ratings; post-acute diffusivity in posterior regions of the corpus callosum was (negatively for FA and positively for MD) associated with chronic PCS in the mTBI, but not in the OI group. **CONCLUSIONS:** Post-acute diffusion metrics did not differ for children with mTBI versus OI. However, post-acute diffusion characteristics were predictive of chronic PCS in children with mTBI but not OI. This result implies that brain diffusivity may moderate the long-term impact of pediatric mTBI.

Title: Ocular motor abnormalities and shortened telomeres in collision sport athletes

Authors: *S. R. SHULTZ[1], G. FULLER SYMONS[1], R. M. MYCHASIUK[2];
[1]Monash Univ., Melbourne, Australia; [2]Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: Mild brain injuries associated with collision sport participation have been linked to a range of neurological consequences, with evidence suggesting that these athletes are more vulnerable to developing neurological syndromes later in life. Consequently, there is a need to understand how potential neurological changes manifest and whether abnormalities are specific to concussion history or whether sub-concussive impacts also contribute. With female participation in collision sports rising, there is also further need to determine whether changes manifest differently between sexes. This study investigated the neurological implications of collision sport participation in male (n=72) and female (n= 28) amateur Australian rules footballers, with and without a history of concussion, in comparison to male (n=29) and female (n=21) non-collision sport control athletes. Effects of collision sport participation was investigated in two ways: (1) ocular motor assessment, a demonstrated sensitive marker of brain and namely cognitive functioning in a range of collision sports; (2) telomere length, found to be reduced in rodents given mild brain injuries. Overall, footballers exhibited reduced spatial accuracy to a remembered location on an ocular motor memory guided task ($p < 0.01$), and reduced telomere length ($p < 0.05$) in comparison to controls; both findings were independent of concussion history and sex. Notably, shortened telomere length was associated with shortened memory guided latencies among Australian rules footballers ($p < 0.001$). These finding suggest that, even at the amateur level, Australian rules footballers have demonstrable neurological abnormalities relative to non-collision sport control athletes. Importantly, these changes are measurable through both ocular motor assessment and analysis of telomere length, suggesting these methodologies might be sensitive biomarkers to monitor long-term neurological health of collision sport athletes.

Title: Circulating microRNAs as biomarkers of concussion in amateur Australian rules footballers

Authors: *W. T. O'BRIEN[1], C. J. TAYLOR[2], G. A. NEOCLEOUS[2], G. H. FULLER SYMONS[1], A. A. HARDIKAR[3], M. V. JOGLEKAR[3], S. R. SHULTZ[1], S. J. MCDONALD[1,2]; [1]Dept. of Neurosci., Monash Univ., Melbourne, Australia; [2]Dept. of Physiology, Anat. and Microbiology, La Trobe Univ., Melbourne, Australia; [3]NHMRC Clin. Trials Centre, Fac. of Med., The Univ. of Sydney, Sydney, Australia

Abstract: Background: Concussion is a mild traumatic brain injury that is highly prevalent in collision sports such as Australian rules football. Currently the diagnosis and management of concussion involves objective measures such as clinical symptomology. As such, there is a need for an objective biomarker that can guide the diagnosis, and recovery from concussion. One possible class of molecules is microRNAs (miRNAs). MiRNAs have shown much promise as circulating indicators of various neurological disorders, including schizophrenia and depression. Little is known, however, about the temporal profile of circulating miRNAs following concussion. Methods: Here we aimed to compare the expression of plasma miRNAs in amateur Australian rules footballers at baseline and three time points post-concussion. Blood was collected from nine male Australian rules footballers during the 2017 pre-season, at 24-48 hours, 6- and 13-days post-concussion. Five controls were also included from sex-, age-, and education-matched athletes without a history of concussion, or previous involvement in collision sport. Blood from a further five male and four female footballers, at baseline and three post-concussion time points, as well as nine matched controls was collected during 2018. Plasma miRNA expression of 754 known miRNAs was analysed using OpenArray. Results: Preliminary findings from the 2017 samples showed that the levels of a number of miRNAs were significantly altered at 24-48 hours post-concussion when compared to baseline. These findings were validated with low throughput RT-PCR using a different normalization technique. Of particular interest, the plasma expression of miR-328 significantly correlated with both concussion symptom number and severity at 24-48 hours post-concussion. The miRNA analysis from these additional participants is currently ongoing and will be completed with the additional analysis of the concussion associated miRNA pathways, prior to the Society for Neuroscience annual meeting in

October 2019. Conclusion: The initial findings from amateur Australian rules footballers suggest that miRNAs may have the potential to indicate the occurrence of sports-related concussion.

Title: Investigation of the relationship of vocal, eye-tracking, and fMRI ROI time-series measures with preclinical mild traumatic brain injury

Authors: *D. E. STURIM[1], T. F. QUATIERI[1], H. M. RAO[2], J. WILLIAMSON[1], A. LAMMERT[1], T. TALAVAGE[3];
[2]Bioengineering Systems and Technologies, [1]MIT Lincoln Lab., Lexington, MA; [3]Sch. of Electrical and Computer Engin., Purdue Univ., West Lafayette, IN

Abstract: In this work, we are examining correlations between vocal articulatory features, ocular smooth pursuit measures, and features from the fMRI BOLD response in regions of interest (ROI) time series in a high school athlete population susceptible to repeated head impact within a sports season. Initial results have indicated relationships between vocal features and brain ROIs that may show which components of the neural speech networks effected are effected by preclinical mild mTBI.
The data used for this study was collected by Purdue University on 32 high school athletes over the entirety of a sports season (Helfer, 2014), and includes fMRI measurements made pre-season, in-season, and postseason. The Immediate Post-Concussion Assessment and Cognitive Testing suite (ImPACT) was used as a means of assessing cognitive performance (Broglio, 2007). The test is made up of six sections, which measure verbal memory, visual memory, visual motor speed, reaction time, impulse control, and a total symptom composite. Using each test, a threshold is set for a change in cognitive performance. The threshold for each test is defined as a decline from baseline that exceeds one standard deviation, where the standard deviation is computed over the change from baseline across all subjects' test scores.
Speech features were extracted from audio recordings of the Grandfather Passage, which provided phonetically balanced speech. Oculomotor testing included two experimental conditions. In the smooth pursuit condition, a single target moving circularly, at constant speed.

In the saccade condition, a target was jumped between one of three location along the horizontal midline of the screen. The fMRI features are derived from the bold time-series data from resting state fMRI scans of the subjects. The pre-processing of the resting state fMRI and accompanying structural MRI data (for Atlas registration) was performed with the toolkit CONN (Whitfield-Gabrieli 2012). Functional connectivity was generated using cortical and sub-cortical atlas registrations. This investigation will explores correlations between these three modalities and a cognitive performance assessment.

Title: Monitoring axonal damage in neurological disorders: detection and quantification of neurofilaments light and heavy chain (NF-L/ pNF-H) as potential biomarkers of neurodegeneration

Authors: *Y. NOAM[1], T. A. LIBERMANN[2], S. T. DILLON[2], V. SHEEN[2], S. KARUMANCHI[3], E. SCHOELL[1], D. PERREGAUX[1], T. MUNN[4], P. YOUNGE[4], I. O'BRIEN[4], N. STEERE[4], M. ANDERSON[4];
[1]ProteinSimple, Bio-Techne, Wallingford, CT; [2]Beth Israel Deaconess Med. Center, Harvard Med. Sch., Boston, MA; [3]Div. of Nephrology, Cedars-Sinai Med. Ctr., Los Angeles, CA; [4]R&D Systems, Bio-Techne, Minneapolis, MN

Abstract: Axonal damage is a hallmark of neurodegenerative disorders. In various neuropathologies, injured or degenerated axons release their intracellular components into the extracellular space, resulting in circulation of these molecules in the cerebrospinal fluid (CSF) and peripheral blood. Consequently, monitoring the levels of these molecules in biological fluids can serve as a potent biomarker for the diagnosis, prognosis, and evaluation of treatment in neurodegenerative diseases.
Of the various axonal molecules, neurofilaments are major structural components of the cytoskeleton. There are three distinct axonal neurofilament subunits: light (NF-L, ~68 kDa),

medium (NF-M, ~145 kDa), and heavy/phosphorylated (pNF-H, ~200 kDa). In recent years, neurofilaments (and in particular NF-L and NF-H) have emerged as promising biomarkers across a wide range of neurological disorders, including neurodegenerative dementia, multiple sclerosis, Parkinson's disease, traumatic brain injury, stroke, and amyotrophic lateral sclerosis (ALS). The ability to detect neurofilaments not only in CSF but also in blood is important in order to allow minimally-invasive diagnosis and monitoring of disease progression. However, whereas neurofilaments are readily detected in the CSF, their substantially lower levels in blood pose a challenge for standard immunoassay-based methods.
Here, we employed the Ella^{TM} platform to establish a novel, microfluidics-based assay for detecting and quantifying NF-L and pNF-H in CSF and blood samples. The automated nature of the assay facilitated a high degree of precision and reproducibility across trials, while requiring $\leq$ 25 ul of sample per measurement. Applying our assay to a physiologically-relevant context, we first studied the role of neurofilaments in aging by assessing NF-L and pNF-H in blood and CSF samples of healthy controls across ages. We next applied our assay to evaluate the potential of NF-L/ pNF-H as non-invasive bio-markers by measuring their levels in blood samples of patients diagnosed with neurodegenerative diseases. Taken together, our results support a role for neurofilaments as valuable markers of neurodegeneration and provide a novel and efficient platform for their detection in various biological samples.

Title: Eeg evidence of phonemic processing is severely brain-injured patients

Authors: *P. JAIN[1], M. M. CONTE[2], J. D. VICTOR[2], N. D. SCHIFF[2];
[1]Physiol. and Biophysics, Weill Cornell Grad. Sch. of Med. Sci., New York, NY; [2]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Assessment of cognitive function in severely brain-injured patients is critical to long-term recovery and rehabilitation. However, many patients with profound motor deficits lack the

ability to demonstrate reliable overt behaviors indicative of consciousness or speech comprehension. In these patients, EEG has been used to assess language processing at the level of command following, but the level of phonemic processing has not been explored. It has been previously reported that, in normal subjects, the EEG responses to natural speech encode distinct phonetic features (Khalighinejad, et al, 2017). Here, we determined whether a similar EEG signature of phonemic processing is present in severely brain-injured patients. We studied a cohort of 15 severely brain-injured patients (13 traumatic, 2 anoxic; 10 M) and nine healthy controls. Patients were assessed for motor function and overt cognitive function via the Coma Recovery Scale - Revised (CRS-R); scores ranged from 5 to 23. EEG was recorded using an augmented 10-20 montage (250 Hz, 37 electrodes; impedances ≤ 5kOhms), during presentation of a 148-sec audio clip of *Alice in Wonderland*. EEG responses to consonant phoneme classes (approximants, fricatives, nasals, and plosives) were extracted by averaging the EEG (60 Hz notch; 2-15 Hz bandpass filtered) with respect to time markers placed using PRAAT (Boersman, et al, 2002). We focused on the period from 200 ms prior to phoneme onset to 500 ms afterwards. Since the number of fricatives and plosives within the audio clip was twice that of the nasals and approximants, analyses were performed for only plosives and fricatives. In all healthy controls (HCs), we found phoneme class-specific responses to fricatives and plosives. Preliminary results show significant differences between the responses to plosives and fricatives 200-400 ms after phoneme onset, in agreement with previous reports (Khalighinejad, et al, 2017). The majority of significant responses were lateralized to left centroparietal, posterior-occipital and posterior mid-line channels. Patients emerged from minimally conscious state (eMCS) (CRS-R = 23) had responses that closely resembled those of HCs, whereas EEG responses in patients categorized as low MCS (CRS-R = 6-7) showed more variable differences between phoneme classes. Patients with cognitive-motor dissociation (fMRI and/or EEG evidence of command-following but no motor responses, n = 11) had responses that were similar to those of HCs and eMCS. These results support the claim that preserved phonemic processing, a necessity for language processing, can be assessed by EEG.

Title: Osteopathic manipulative treatment changes cerebral blood flow after concussion injury

Authors: *L. D. HENDERSON[1,4], R. KALKAT[1], S. K. GILL[1], D. J. GORBET[2,1,3], L. E. SERGIO[2,1,3], L. M. HYNES[1,3,2];**

[1]Sch. Kinesiol & Hlth. Sci., [2]Ctr. for Vision Res., [3]York Univ. Sport Med. Team, York Univ., Toronto, ON, Canada; [4]Canadian Col. of Osteopathy, Toronto, ON, Canada

Abstract: Altered cerebral blood flow (CBF), is seen in both animal[1-2] and human[3] models of concussion and represents one of the longest lasting biomarkers of concussion injury. Current research in humans has shown a significant decrease in CBF at 8-days post-concussion relative to 24h,[4] and others have found decreases in CBF in the dorsal midinsular cortex up to 1 month post-concussion[3], supporting the potential use of CBF as a biomarker for concussion recovery. Colour duplex-doppler ultrasongraphy (CDU) is a comparable CBF measure to phase contrast magnetic resonance imaging (PC-MRI)[5] making it a cost-effective and accessible evaluation tool. Concussion symptomology has been strongly associated with CBF[6], leading to our hypothesis that targeted therapy will cause a change in one or more factors associated with CBF (blood flow velocity or vessel cross-sectional area) and symptom severity. In the current study, we used CDU to measure blood flow velocity and volume of the right and left internal carotid (ICA) and vertebral arteries (VA) to measure CBF[5] and evaluate changes in concussion symptoms after osteopathic manipulative treatment (OMT). We recruited 11 healthy participants (mean age 27.3 yrs, n= 6 female) and 13 symptomatic concussed participants (mean age 27.5 yrs, n= 7 female) who were screened using a health questionnaire and the Standardized Concussion Assessment Tool, version 5 (SCAT5). CDU measurements were taken before receiving treatment at two different timepoints; first at the time of enrollment in the study and then 1-2 weeks later. Participants completed the SCAT5 and CDU evaluation again at the start of the next visit before the second treatment was provided. Final SCAT5 and CDU measurements were collected 5-6 weeks post enrollment in the study to evaluate if the effects of treatment were maintained. Preliminary analyses show that osteopathic manipulative treatment elicited a statistically significantly decrease in CBF velocity (76.5cm/s to 65.7cm/s; p= 0.002) in symptomatic concussed participants while demonstrating no significant changes in the healthy group. These results provide support that OMT may provide benefit to individuals who have sustained a concussion by improving blood vessel compliance.

Title: An exploration of biological markers of post-concussion syndrome using transcranial magnetic stimulation

Authors: *M. B. LOCKE[1], S. L. TOEPP[1], C. V. TURCO[1], D. HARASYM[2], M. P. RATHBONE[3], M. D. NOSEWORTHY[2], A. J. NELSON[1];
[1]Kinesiology, [2]Biomed. Engin., [3]Med., McMaster Univ., Hamilton, ON, Canada

Abstract: Post-concussion syndrome (PCS) affects ~15-30 % of adults who incur a concussion, yet no objective marker of PCS has been identified in humans. Identifying a neurological marker of PCS development may enhance our ability to identify those whom are vulnerable to secondary injury long-term, and further our understanding of the underlying pathophysiology of PCS. This study sought to identify a physiological marker of PCS using transcranial magnetic stimulation (TMS) over motor cortex (M1) of adults with PCS (n = 15, 4 male; mean age = 28.8 ± 8.7 years) compared to healthy adults with no history of concussion (n = 13, 3 male; mean age = 26.8 ± 7.7 years). A single session featuring symptom measures (post-concussion symptom scale (PCSS) and Beck's Depression Inventory (BDI-II)) and multiple TMS measures related to excitability (resting motor threshold, active motor threshold, motor evoked potentials, intracortical facilitation), intracortical inhibition (short-interval intracortical inhibition, cortical silent period (CSP)), and transcallosal inhibition (ipsilateral silent period, interhemispheric inhibition) were acquired. A between-group difference was found in CSP ($p = 0.021$, $g = 0.960$), suggesting reduced intracortical $GABA_B$ receptor activity in the PCS group. All other measures, including measures of intracortical $GABA_A$ and glutamate receptor activity, were similar between groups. No significant differences in transcallosal inhibition were found. Secondary regression analyses tested the predictive value of symptom scales (PCSS, BDI-II) for all outcome measures. Interestingly, greater scores on BDI-II were related to reduced CSP length, while PCSS scores did not significantly predict CSP length. While this study did expose differences in cortical function in those with PCS, these changes may in fact be due to existing depressive symptoms rather than concussion symptoms. Further investigation is warranted to determine whether measures of cortical $GABA_B$ function provide a useful biomarker for PCS development.

Title: Exosomal and plasma biomarkers relate to chronic symptoms in veterans with history of mild traumatic brain injury

Authors: *V. DE ALVARENGA GUEDES[1], C. LAI[1], C. DEVOTO[1], B.-X. QU[2], K. KENNEY[2], J. M. GILL[1];
[1]NIH, Bethesda, MD; [2]Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD

Abstract: Individuals who sustained a mild traumatic brain injury (mTBI) are at increased risk of developing chronic neurobehavioral symptoms. Posttraumatic stress disorder (PTSD), depression, and post-concussive (PCS) are highly prevalent in military populations and frequently occur comorbidly with TBI, resulting in substantial health risks. This study examined associations among chronic mTBI, peripheral blood biomarkers, including exosomal proteins, and symptoms of PTSD, depression, and PCS. Exosomal and plasma levels of neurofilament light (NFL), tau, p-tau, amyloid beta (Aβ)-40, Aβ-42, interleukin (IL)-6, IL-10, tumor necrosis factor (TNF)-alpha, and vascular endothelial growth factor (VEGF) were measured using an ultrasensitive assay in a cohort of 195 Veterans, enrolled in the Chronic Effects of Neurotrauma Consortium (CENC) Longitudinal Study. PTSD, depression and PCS were evaluated using PTSD Checklist Military Version (PCL), patient health questionnaire-9 (PHQ-9), and neurobehavioral symptom inventory (NSI), respectively. Individuals with history of TBI reported significantly worse PTSD ($p = 0.0002$), depression ($p =0.0002$) and PCS ($p<0.0001$) symptoms than controls. Biomarker levels were compared among those with no TBI (controls), 1-2 mTBIs and repetitive (3 or more) mTBIs. Higher levels of exosomal ($p = 0.0105$) and plasma ($p = 0.0024$) NFL were observed in individuals with repetitive mTBIs than in those with 1-2 TBIs. In individuals with TBI, PCL scores were correlated with exosomal ($r= 0.497$, $p<0.0001$) and plasma ($r= 0.2955$, $p= 0.0004$) NFL, and plasma TNF-alpha ($r= -0.2267$, $p= 0.0255$). PHQ9 was positively correlated with exosome ($r= 0.4368$, $p<0.0002$) and plasma ($r= 0.2041$, $p<0.0156$) NFL, and plasma Tau ($r = 0.1858$, $p = 0.0266$). NSI scores were correlated with exosomal ($r = 0.5516$, $p<0.0001$) and plasma ($r = 0.3425$, $p<0.0001$) NFL, and plasma TNF-alpha ($r = -0.2328$, $p = 0.0211$). Our results suggest that elevations in NFL, Tau and TNF-alpha levels are associated with symptom severity in individuals with history of mTBI, while increased levels of NFL are elevated in those with multiple head injuries.

Title: Cognition, mood, and cortisol circadian profiles following mild traumatic brain injury in college students: Confirmation of subjective reports of impairment with objective cognitive measures

Authors: *E. VILLEGAS, Jr[1], B. ABEN[2], M. J. HARTSOCK[1], M. VALDEZ[1], M. MCQUEEN[1], R. L. SPENCER[3], T. D. HERNANDEZ[3];
[2]Psychology and Neurosci., [1]Univ. of Colorado Boulder, Boulder, CO; [3]Psychology and Neurosci., Univ. of Colorado at Boulder, Boulder, CO

Abstract: Mild Traumatic Brain Injury (mTBI) is the most common form of TBI accounting for approximately 80% of the annual (2.8M) TBI cases. More importantly, this number is likely an underestimation as it does not include the number of individuals who sustain mTBI and do not seek medical care or are inaccurately diagnosed. An additional obstacle to effective assessment and treatment is that there are often no readily observable signs through commonly used neuroimaging techniques and symptom presentation may vary from person to person. Still, the most common mTBI symptoms reported include those related to cognition, mood and sleep. However, no prior studies have systematically used objective cognitive and circadian measures to assess the severity of these symptoms over the first several weeks following the occurrence of mTBI. The present study was designed to assess the presence and time-course of these symptoms acutely after mTBI in a sample of otherwise young healthy adults (college student sample). To this end, the Automated Neuropsychological Assessment Metric (ANAM) and the Brief Assessment of Mood (BAM) were used in addition to circadian cortisol sampling. Measurements were obtained in students who sustained a recent mTBI (n=46) and in healthy controls (n=44) at baseline and at a one-week follow-up timepoint. The main findings include overall significant differences between the mTBI and control group on several cognitive measures including simple reaction time, procedural reaction time, and code substitution. Furthermore, the mTBI group reported significantly higher mood disturbance at baseline followed by a significant decrease in mood disturbance at the one-week follow-up when compared to controls. Additional findings from the study will be discussed including the relationship of circadian function to cognitive function and mood disturbance, and their changes over time.

Abstract: There is great interest in identifying objective biomarkers to assist in the diagnosis and prognosis of sport-related concussion (SRC). Previous work has demonstrated that an imbalance in neuroactive kynurenine pathway (KP) metabolites measured in serum is associated with mood dysregulation in a variety of psychiatric diseases and potentially SRC. Here, we tested the hypothesis that neurotoxic KP metabolites (3-hydroxykynurenine [3HK] and quinolinic acid [quinA]) are elevated relative to neuroprotective metabolites (kynurenic acid [kynA]) following SRC and are associated with post-injury mood symptoms. Blood was collected at preseason and at 6 hours, 48 hours, and 8, 15, and 45 days post-concussion in high school and collegiate football players (N=63, age=18.00±1.56 years). Matched, non-injured football players were recruited as controls and completed similar visits (N=60, age=18.22±1.71 years). Mood symptoms were assessed using the Brief Symptom Inventory 18 (BSI-18) somatization, depression, and anxiety subscales at each visit except at 6 hours post-injury. KP metabolites were quantified in serum by high-performance liquid chromatography with tandem mass spectrometry, blind to diagnosis, and subsequently natural-log transformed. Linear mixed effects models were used to assess changes across visits with the effect of group and the interaction of group by visit, with participant modeled as a random effect. Generalized linear models were used to determine the relationship between KP metabolites and BSI-18 subscales in concussed athletes, covarying preseason biomarker levels and BSI-18 scores. SRC had elevated anxiety, depression, and somatization symptoms at 48 hours post-injury relative to other post-injury visits

and relative to controls (ps<0.05), while somatization and depression symptoms were still elevated relative to controls at 8 days (ps<0.05). There was a significant group by visit interaction for the ratio of kynA to 3HK (p=0.03). Follow-up tests showed that kynA/3HK was significantly higher in SRC at 6 hours relative to preseason and 8, 15 and 45 days post-injury as well as relative to contact controls (ps<0.05). In addition, kynA/3HK levels in SRC at 45 days post-concussion were significantly lower relative to all other visit (ps<0.05). Higher kynA/3HK at 6 hours post-concussion predicted lower depression scores at 48 hours (p<0.05). This relationship was driven by a positive association between 3HK at 6 hours post-concussion and depression scores at 48 hours (p<0.05). These findings suggest that SRC results in an acute increase in the neuroprotective kynA/3HK ratio that may attenuate post-concussion depressive symptoms.

Title: Measurement of inflammatory cytokines and neurodegenerative/injury biomarkers in acute concussion/mild traumatic brain injury (c/mTBI) serum and saliva samples

Authors: *A. CHENNA, C. J. PETROPOULOS, J. W. WINSLOW;
Monogram Biosci. Inc/Labcorp, South San Francisco, CA

Abstract: An estimated 1.6 to 3.8 million recreational and competitive athletes in the US incur/experience a concussion each year. Elevations in certain central nervous system (CNS) proteins (t-Tau, NF-L, GFAP and UCH-L1) and inflammatory cytokines (IL-6, IL-10, TNFα) in blood and CSF samples have been associated with c/mTBI, representing candidate diagnostic and prognostic biomarkers. Recently the FDA approved GFAP and UCH-L1 as diagnostic biomarkers of TBI. Characterizing the timing and fluctuation in CNS and inflammatory biomarkers following c/mTBI could improve diagnostic and prognostic utility. The SIMOA Neurology 4-plex A and Cytokine 3-plex A immunoassays (Quanterix) were used to measure t-Tau, NF-L, GFAP, UCH-L1 and IL-6, IL-10, TNF-α, respectively. Blood samples were collected from study subjects (n= 30 each) within 1-4 hr and 8-16 hr post-c/mTBI injury, as well as 30 healthy controls. Matching saliva samples were also collected from the 8-16 hr post-c/mTBI subgroup (n= 30). IL-6, IL-10 and TNFα were significantly elevated in the 1-4 hr and 8-16 hr post-c/mTBI serum samples relative to healthy controls (p <0.0001). Receiving Operating Characteristic (ROC) curve analysis indicates that each of the 3 cytokines is highly

discriminatory for c/mTBI patients vs healthy controls (AUC = 0.86-0.99). Cytokine levels were significantly correlated across the 1-4hr and 8-16 hr time groups, with the exception of IL-6 in the 8-16 hr time group, which trended toward significance. With the exception of IL-6, cytokine levels in most saliva samples were near or below the lower limit of quantitation. Median levels of GFAP, NF-L, UCH-L1 and t-Tau were significantly elevated in matched 1-4 hr and 8-16 hr post-c/mTBI serum samples relative to healthy controls. ROC analysis of neuronal biomarkers indicate moderate discriminatory ability for c/mTBI vs controls (AUC = 0.7-0.76), relative to the cytokine 3-plex proteins (AUC=0.86-0.99). The combination of CNS proteins and inflammatory cytokines as biomarkers of c/mTBI may enhance diagnostic capability as well as prognosis with regards to the severity and outcome of brain injuries. Based on our initial findings using a single processing approach, these 3 saliva cytokines may not represent useful biomarkers for concussion patients.

Title: Auditory sensory processing is impaired following mild traumatic brain injury

Authors: *M. C. DUGGINS, Y. KIM, J. DAVIS, K. PAULSON, R. THOMA, J. D. LEWINE; The Mind Res. Network, Albuquerque, NM

Abstract: Following mild traumatic brain injury, many subjects complain of persistent auditory processing problems, such as difficulties tracking conversations in noisy environments (e.g., restaurants). To better understand the relevant neurobiology, a paired-tone auditory evoked response paradigm was used to examine basic auditory processing, rapid auditory processing, and sensory-gating in 70 neurotypical control subjects (45 males, ages 8-74) and 60 patients with persistent (>6 months) post-concussive symptoms following a mild traumatic brain injury (39 males, ages 9-72). Stimuli consisted of single 1 or 2 kHz pure tone pips (to measure basic auditory processing); paired discrepant tone pips (1kHz-2kHz, 2kHz-1kHz, 300 msec inter-tone-interval, to measure rapid auditory processing); and paired identical tone pips (1kHz-1kHz, 2kHz-2kHz, 300 msec inter-tone-interval, to measure sensory gating). For paired conditions, an N100 gating ratio was calculated as the amplitude of the response to the second tone divided by the amplitude of the response to the first tone. No significant differences were seen between the control and mTBI groups on measures of basic auditory processing or rapid auditory processing.

For the sensory gating condition, the average gating ratio for control subjects was 0.38. In contrast, the average gating ratio for TBI subjects was 0.64. A high gating ratio indicates a failure in the normal suppression/gating of brain activity evoked by the second redundant stimulus in a pair of rapidly presented identical stimuli. This difference was highly significant, $F(1,129)=84.32$, $p<0.001$. Using a cutoff gating ratio of 0.05, 84% of all subjects were correctly classified as coming from control versus TBI groups. Thirty-four of the TBI patients also completed the SCAN-III, a behavioral evaluation of central auditory processing abilities. The r-squared correlation coefficient between the sensory gating ratio and SCAN-III score was -0.49, an indication that gating impairments (high S2/S1 ratios) were associated with poor auditory processing abilities. The data demonstrate that mild traumatic brain injury is associated with correlated deficits in central auditory processing as measured by both behavioral and electrophysiological methods.

Title: Anxiety-related alterations of resting-state networks in mild traumatic brain injury

Authors: Y.-T. LEE[1], C.-F. LU[2], N.-C. CHEN[1], L.-C. HSIEH[1,3,4], S.-J. CHENG[1,3], Y.-C. J. KAO[1,4,5], C.-Y. CHEN[1,3,4];

Imaging, Taipei Med. Univ. Hosp., Taipei, Taiwan; [4]Dept. of Radiology, Sch. of Medicine, Col. of Med. Taipei Med. Univ., Taipei, Taiwan; [5]Neurosci. Res. Ctr., Taipei Med. Univ., Taipei, Taiwan

Abstract: PURPOSE
The causes of increased anxiety level after mild traumatic brain injury (mTBI) are complicated and may involve the abnormality in different brain regions. We aim to compare the functional connectivity between mTBI and healthy control (HC) groups to identify the anxiety-related alterations during resting state.
MATERIALS AND METHODS

In total 68 Chinese participants were enrolled in this study, including HC (N=27, 7 males, aged of 33.04), high-anxiety mTBI with scores of Beck Anxiety Inventory larger than 7 (HmTBI, N=18, 3 males, aged of 33.00), low-anxiety mTBI (LmTBI, N=23, 9 males, aged of 35.83) groups. There's no sex difference between groups. Resting-state fMRI and 3D T1-weighted images were acquired using a Siemens Prisma 3T scanner. After standard preprocessing steps, the independent component analysis was performed to extract 27 resting-state networks (RSNs) using GIFT toolbox.

RESULTS

Significant group differences were presented in 6 RSNs (Fig.1). In comparison with the HC, several results were found: a) In default mode network, the LmTBI group has higher connectivity in right superior frontal and middle temporal gyri, and lower connectivity in right calcarine; b) In posterior executive network, the HmTBI group exhibits lower connectivity in right superior frontal gyrus and left calcarine; c) In anterior executive network, the LmTBI group shows higher connectivity in right inferior frontal gyrus, and the HmTBI group shows higher connectivity in left precuneus and lower connectivity in posterior cingulate cortex; d) In frontal-parietal network, the HmTBI group has higher connectivity in right precuneus/posterior cingulate cortex and lower connectivity in right superior frontal gyrus and left cerebellum; e) In visual network, the HmTBI group has higher connectivity in right superior frontal cortex; f) In motor network, the HmTBI group shows higher connectivity in left superior frontal cortex and lower connectivity in left supramarginal gyrus.

CONCLUSION

Increased anxiety level after mTBI involves the changes of functional connectivity in several RSNs.

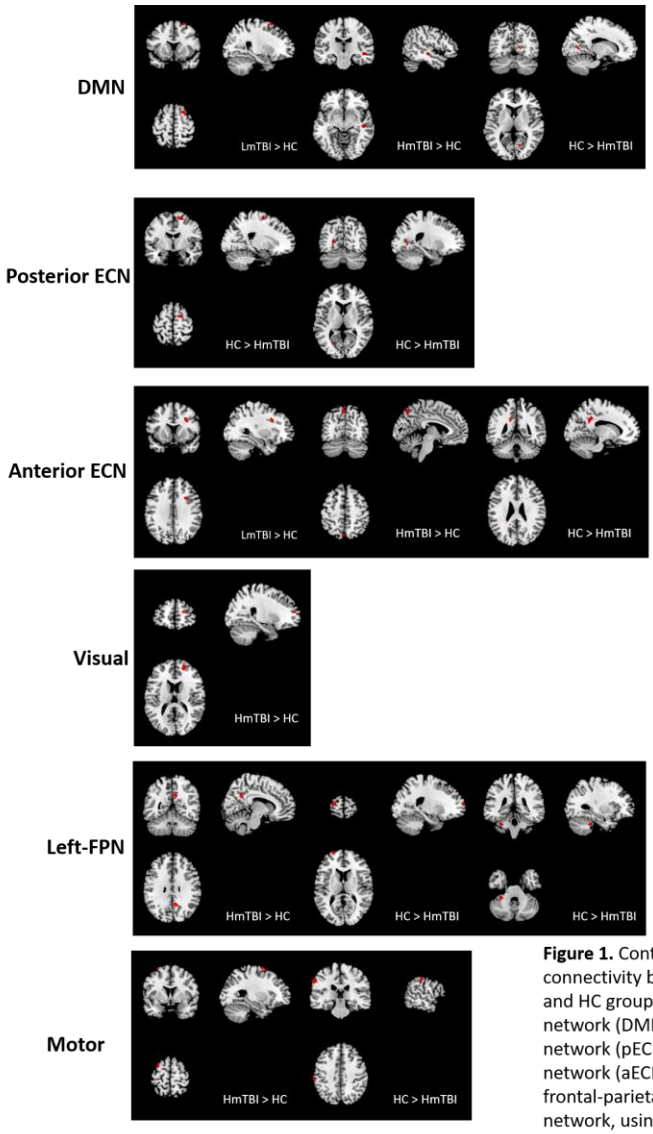

Figure 1. Contrast functional connectivity between HmTBI, LmTBI, and HC group on default mode network (DMN), posterior executive network (pECN), anterior executive network (aECN), visual network, left frontal-parietal network, and motor network, using uncorrected p <0.001 with cluster size >10 as threshold.

Title: Functional connectivity patterns of the lesioned default mode network

Authors: *A. RIVERA-DOMPENCIEL[1], J. E. BRUSS[2], D. TRANEL[2], M. VOSS[3];
[2]Neurol., [3]Psychological and Brain Sci., [1]Univ. of Iowa, Iowa City, IA

Abstract: The Default Mode Network (DMN) is involved in crucial processes for autobiographical memory and is susceptible to aging and mental disorders such as Alzheimer's (Damoiseaux et al., 2007; Grecius et al., 2004). It has been proposed to consist of Core regions that interact with a dorsomedial prefrontal cortex (dmPFC) subsystem and a medial temporal lobe (MTL) subsystem (Andrews-Hanna et al, 2010) based on resting state functional connectivity magnetic resonance imaging (rs-fcMRI). Having a clear idea of the DMN's functional connectivity (fc) pattern is useful for understanding the relationship between severity of network disruption and subsequent reorganization and recovery. One way to address this is by studying the effect of focal lesions on DMN fc, yet this remains unclear. Here, we evaluate the consequences of damage to the proposed components of the DMN by using rs-fcMRI and the lesion method to test two predictions: when one subsystem is damaged, its fc decreases while fc of the undamaged subsystem increases; when the Core is damaged, fc between the two subsystems will decrease further. An additional exploratory analysis will be performed by creating sham lesions on the rs-fcMRI data of the demographically-matched non-lesioned participants to test whether their fc patterns remain intact; this would help elucidate the effect of physical damage on DMN fc patterns. We predict that sham lesions would cause minimal impact, since physical damage would be necessary to significantly alter fc patterns.
We gathered rs-fcMRI data of patients with stable, circumscribed lesions in different components of the DMN (N=29) and compared to rs-fcMRI data of demographically-matched non-lesioned participants (N=29) and brain-damaged controls (N=18).
A repeated measures ANOVA with one between-groups factor and one repeated factor of subsystems was performed.
Contrary to our predictions, preliminary results of patients with dmPFC-restricted lesions do not have significant group fc differences within the MTL, but do show significant changes within other DMN components compared to the non-lesioned data with no sham lesions. When all three proposed DMN components had lesions, we found significant group fc differences within and between DMN components.
These results bring further insight into DMN organization based on resting fc patterns, which could expand the characterization of memory subsystems in relation to normal aging, eventually leading to improvements in predicting clinical outcomes for neurological and psychiatric patients, and expediting the development of memory performance-improving interventions and more effective and personalized treatments.

Title: Brain structural connectivity predicts cognitive performance in TBI patients

Authors: *P. LI, W. SCHNEIDER;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Traumatic brain injury (TBI) affects 2.5 million people each year and has a detrimental impact on people life. Patients often suffer from widely distributed axonal damage, named diffuse axonal injury after TBI. Although the behavioral and cognitive deficit is conspicuous in TBI patients, brain structures and networks that were disrupted by TBI are complicated and widely distributed throughout the brain. The current study aimed at examining if brain structural connectivity between different brain regions can predict TBI patients cognitive outcome in different cognitive domains. 68 TBI patients and 100 control subjects were recruited in the study. Subjects were scanned using a multi-shell protocol on a 3T Siemens Tim Trio magnet with a 32-channel head coil. Diffusion imaging data were reconstructed using Generalized Q-Sampling Imaging in the subject's DWI space and then whole-brain fiber tracking was performed by DSI studio. A whole brain structural connectivity matrix with the mean quantitative anisotropy(QA) values between each pair of brain regions as inputs was generated for each subject. We explored if brain structural connectivity can predict cognitive performance in control and TBI patients by applying the connectome based predictive modeling (Finn et al.2015; Rosenberg et al.2016). We found that brain structural connectivity between prefrontal, motor cortex to subcortical regions successfully predict individual differences in processing speed performance in TBI patients ($r=0.48$, $p<0.0001$). Structural connectivity between parietal lobes and subcortical regions successfully predict TBI patients' working memory performance ($r=0.34$,$p<0.01$). Our results highlight the role of brain structural connectivity on high-level cognitive functions and the disconnectivity and damage of different anatomical pathways could result in cognitive impairment in different cognitive domains.

Title: Chemical and microstructural brain biomarkers of traumatic brain injury-related chronic pain

Authors: *L. E. ROBAYO[1,2], V. GOVIND[3], S. SHERIFF[3], L. FLEMING[2], A. A. MAUDSLEY[3], E. WIDERSTROM-NOGA[1,2,4];
[1]Neurosci. Grad. Program, [2]The Miami Project to Cure Paralysis, [3]Dept. of Radiology, Univ. of Miami, Miami, FL; [4]Res. Service, Dept. of Veterans Affairs Med. Ctr., Miami, FL

Abstract: More than 50% of people that experience a traumatic brain injury (TBI) develop chronic pain that may interfere with their daily activities and quality of life. By identifying important changes in brain chemistry and microstructure that are associated with chronic pain after TBI, so called pain biomarkers, we will be able to understand more about the specific mechanisms of this type of pain. The long-term goal of this study is to develop a basis for treatments tailored to the specific underlying mechanisms of TBI-related chronic pain. This research combines non-invasive, whole-brain imaging techniques to investigate areas of the brain that are significantly involved in the perception and modulation of pain (i.e., the thalamus, insula, cingulate, prefrontal cortex, and hippocampus) and the associations with pain symptoms, sensory and neuropsychological assessments. This dataset focused on the comparison of magnetic resonance spectroscopy (MRS) and diffusion kurtosis imaging (DKI) measures between participants (ages 18-50) with: (1) mild to moderate TBI who experienced chronic pain for a minimum of 6 months (n=9); (2) mild to moderate TBI with no pain (n=8); and (3) pain-free controls (n=30). N-acetyl aspartate (NAA), a marker of neuronal mitochondrial activity; Myo-inositol (Ins), a glial marker involved in the volume and osmoregulation of astrocytes; and a combination of Glutamate-Glutamine (Glx) levels were quantified using a 3T-MRI scanner and compared among the three groups by one-way ANOVA-post-hoc-Tukey test. Two DKI components: axial diffusivity (Dax) and radial diffusivity (Drad), calculated by the anisotropic water diffusion in the nerves, were used to indicate microstructural integrity of neurons and glia. Subjects with TBI that experienced chronic pain exhibited significantly: higher hippocampal levels of NAA ($p<0.05$), higher mid cingulate Glx/Ins levels ($p<0.01$) and greater hippocampal and thalamic Dax ($p<0.01$) and Drad ($p<0.01$), suggesting neuronal hyperexcitability, glial proliferation, and a reduced axonal and myelin integrity in these specific brain regions involved

in pain processing. Further analysis needs to be performed in order to confirm those results and to correlate them with the pain symptoms, sensory and neuropsychological assessments.

Title: Relationship between serum-based biomarkers and MRI measures following mild traumatic brain injury in collegiate athletes post return-to-play

Authors: *T. R. SUSA[1], M. T. MOORE[2], J. M. CARLSON[1];
[1]Psychological Sci., [2]Sch. of Hlth. and Human Performance, Northern Michigan Univ., Marquette, MI

Abstract: With over 1 million emergency room visits a year and 1.7 million new cases annually in the United States, traumatic brain injury (TBI) is widely prevalent. About 80% of all TBIs are classified as mild, more commonly referred to as a concussion. Despite the high prevalence of concussion there are not many studies using neuroimaging techniques to assess the post-injury phase. Magnetic resonance imaging (MRI) is a neuroimaging technique that is used to assess a variety of clinical and research needs including TBI. Recently, there has been a rise in concussion research specifically assessing the effects it may have on protein levels in serum, a derived portion of blood, between concussed and control groups. Brain derived neurotrophic factor (BDNF) has been previously linked to concussion and plays a role in the recovery of brain function. Proteins such as BDNF have been found to have altered levels in serum after TBI. However, there is limited knowledge about the relationship between serum-based biomarkers and MRI-based biomarkers in concussed athletes post return-to-play. This study aimed to bridge this gap by collecting MRI and serum samples from 28 participants across two groups. The first group (n = 14) consisted of recently cleared to return-to-play collegiate athletes after experiencing a sports-related concussion. The second group (n=14) consisted of collegiate athlete controls matched on age, sex, and sport. Neither group had experienced a concussion for at least three years prior to the study. Five ml blood samples were collected to assess the levels of BDNF. All samples were aliquoted and centrifuged for their respective times and then stored at -80 degrees Celsius until further handling. A ChemiKine BDNF sandwich Enzyme-Linked Immunosorbent Assay (ELISA) kit was used in duplicate to analyze the samples. Structural MRI measures were used for analysis. Although there was not a significant effect of group for BDNF, associations of gray matter volume and BDNF were observed in the prefrontal cortex, brainstem,

precuneus, right and left cerebellum regions between groups. In summary, these results suggest lingering effects of concussion, granting a better depiction of the post return-to-play timeframe following sports-related concussions.

Abstract: Suicide is a growing health problem. According to the World Health Organization (WHO), around one million people lose their life for this reason every year. Even though the process of suicide is not clear, several mental disorders such as schizophrenia, depression or drug addiction are thought to be related. It has been known that orbitofrontal cortex is relevant in the decision making, so any alteration in this area could lead to this radical action. The aim of this study is to know the oxidative stress in the orbitofrontal cortex of suicide victims. To reach this aim we measured oxidative stress biomarkers such as BDNF, PSD95, which are related to neuroplasticity. One as a cellular grown factor and the other one as a membrane protein associated with NMDA receptors respectively. The last biomarker that was studied was metallothionein, which is related to the kidnapping of heavy metals. The samples were separated into two principal groups: young (12-30 years) and adults (31-67 years). Having control and cases for each group and each biomarker. The cause of death, gender and age were considerate for each group as any diagnosis in neuropathologies or drug abuse. These biomarkers were measured by using immunohistochemistry staining. Then we got microphotographs which later

were analyzed by counting every reactive cell for each reactive. Our results suggest a decrease in metallothionein in the case young group, without significant changes in the adult group. This could mean that young people are more susceptible to oxidative change. In addition, the young group also showed a decrease in the levels of PSD95. On the other side, in the adult group, we found fewer levels of PSD95 in the control group suggesting a possible compensation mechanism. Finally, our results about BDNF have not been concluded yet. This could lead us to find a clearer way to understand this pathology.

Title: Anti-saccade and sub-concussive loading: Changes in initial and end gain task metrics following head impact exposure in a high school football season

Authors: ***W. J. PRITZLAFF**[1], B. M. BLASS[1], M. Z. ABRAMS[1], D. O'CONNELL[1], M. PAITHANE[1], C. HILE[1], E. HSIEH[1], K. KHYLYSTOVA[1], A. MEHLENBACHER[2], B. CAPEHART[3], C. R. BASS[1], J. F. LUCK[1];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Surgery, [3]Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC

Abstract: An accurate and objective diagnostic tool for mild traumatic brain injury (mTBI) resulting from sub-concussive loading - described as the cumulative effects of sustained low-magnitude head impact exposure (HIE) - in pediatric populations that participate in a contact sport does not yet exist. The objective of this pilot study was to examine the relationship between HIE and eye-tracking performance using two accuracy (gain - % of target; deg/deg) based anti-saccade task metrics in varsity high school football athletes across a season to understand potential neurological deficits resulting from sub-concussive loading. Participating varsity football athletes during the 2017-2018 season (n = 31) were grouped into 10^{th} (low) and 90^{th} (high) HIE percentiles based on weekly HIE frequency scores self-reported through athletic activity/contact exposure questionnaires (AACEQ). Eye-tracking assessments were conducted at the beginning-of-season (BOS), middle-of-season (MOS) and end-of-season (EOS) for each player. Mixed-design ANOVAs were performed for anti-saccade initial and end gain. Task

performance was analyzed at BOS, MOS, and EOS (repeated measures) between low (n = 4) and high (n = 4) HIE groups (between subjects factor). The mixed-design ANOVA indicated a significant interaction between time of season and HIE group on end gain, $F(2,134) = 3.857$, $p = 0.024$, $\eta^2 = 0.053$. A repeated measures ANOVA indicated a significant effect of time of season on end gain, $F(1.536,52.232) = 3.834$, $p = 0.038$, $\omega^2 = 0.030$, in the low HIE group (Greenhouse-Geisser correction). Bonferroni-corrected post-hoc tests revealed that there was not a significant difference between pairwise comparisons at different time points throughout the season. There was not a significant effect of time of season on end gain in high HIE group, $F(2,66) = 1.073$, $p = 0.348$, $\eta^2 = 0.032$. At EOS, end gain was significantly lower in the low HIE group (89.8 ± 29.8, $p = 0.003$) compared to the high HIE group (124.4 ± 58.8). The mixed-design ANOVA omnibus test for initial gain indicated no significant interaction or main effects. These pilot results suggest that anti-saccade end gain may exhibit differences across seasonal time points and between HIE groups of varsity football athletes. However, some limitations that may have skewed true measures of low and high HIE groups include three assumptions: the AACEQ accurately stratifies HIE, the small samples are representative of true low and high HIE, and there was no learning effect. A further investigation controlling for these limitations is necessary to further our understanding of the potential role of accuracy based anti-saccade metrics as objective mTBI indicators.

Title: The role of protein in shunt flow and obstruction

Authors: *K. BEHARRY[1], N. GORELICK[2], R. SERRA[2], B. TYLER[2], H. BREM[2], M. LUCIANO[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Johns Hopkins Med., Baltimore, MD

Abstract: As Cerebrospinal fluid (CSF) surrounds every facet of the central nervous system, CSF disorders can impact neuroscientists greatly. Shunts are neurosurgical devices used in the treatment of hydrocephalus, but 85% of shunts fail within 10 years after implantation. The computer-driven model for testing may not accurately detect variability in flow rate or obstruction. Our benchtop gravity-flow system used commonly implanted valves, each equipped with antisiphon devices (ASDs). We varied position and fluid protein content in diurnal trials of

upright and supine conditions to evaluate the role of protein in flow rate and obstruction.
Within an incubator set to 37° C, saline with or without protein was filled in a reservoir of a gravity-driven apparatus that drove flow continuously via 6 catheters through valves and into their respective collecting flasks. The collecting flask heights were alternated between 28.5 cm and 2 cm below the valves for 14 and 8 hours in upright and supine trials, respectively, to mimic a patient's daily positional changes. Valves were tested in 3 saline studies: protein-free, 1 g/L protein, and 5 g/L protein for up to 30 days. For each trial, the hydrostatic pressure driving force, temperature, and fluid output were recorded for each valve to compare the effects of protein on flow rates.
When comparing the averages of all the trials of protein-free saline and low-protein saline, valve type A increased its supine position flow rates from 0.06 to 3.24 mL/hr ($p = 0.03$ E-8) and in the upright position increased their flow rates from 21.23 to 21.62 mL/hr ($p = 0.34$). Similarly, in valve type B, protein increased its supine flow rates from 0.06 mL/hr to 0.23 mL/hr ($p = 0.04$) and in the upright position the flow rates went from 20.23 mL/hr to 20.13 mL/hr ($p = 0.80$). When tested with high-protein saline, both valve types became fully obstructed after 12 days, with flow rates at 0 mL/hr for the rest of the trial.
The role of protein on flow rate throughout the system could be due to the protein acting like a detergent, possibly by decreasing surface tension and resistance, therefore increasing flow rates. We hypothesize the decrease in flow rates to 0 mL/hr in the high protein trials may be due to the protein concentration being too high, causing the protein to precipitate out of solution and aggregate in the system. The properties of protein through this system have a potential impact both in understanding the molecular fluid dynamics of CSF and in clinical testing of shunt valves and systems. Shunt failures account for more than $1 billion annually in hydrocephalus care in the United States and have devastating effects on patients' morbidity and mortality.

Title: Intermediate-term survival of transplanted bioengineered neural tissue grafts with pharmacological intervention

Authors: B. J. GU[1], *G. MAN[1], D. JGAMADZE[1], V. LIAUDANSKAYA[2], D. KAPLAN[2], H.-C. I. CHEN[1];

[1]Neurosurg., Univ. of Pennsylvania, Philadelphia, PA; [2]Biomed. Engin., Tufts Univ., Medford, MA

Abstract: Introduction: Neural transplantation is a promising approach to repair brain injuries. Three-dimensional constructs emulating the cytoarchitecture of native neural tissue may possess great potential as a therapeutic substrate to replace large brain defects and restore lost circuit functions. A major challenge is the suboptimal survival of neural grafts after transplantation. In a rat motor cortex injury model, we assessed the effects of different pharmacological interventions on the survival of rat embryonic cortical cells seeded on a silk sponge scaffold. Methods: Embryonic day 18 rat cortical cells were isolated and seeded on a silk sponge scaffold. Green fluorescent protein (GFP) expression in these neurons was achieved by AAV vectors. On surgery day, the constructs were embedded in fibrin hydrogel containing either 1) necrostatin-1, a necroptosis pathway blocker, 2) Y-27632, a ROCK pathway inhibitor, 3) methylprednisolone, a corticosteroid, or 4) base media with no drug. For necrostatin-1 and Y-27632 groups, the constructs were also cultured in media with the drug overnight before hydrogel embedding. After embedding, the constructs were grafted into the primary motor cortex of adult male Sprague-Dawley rats after an aspiration lesion had been created. One month after transplantation, the animals were sacrificed, the brains extracted for histological analysis. Results: Considerable survival of grafted neurons was observed, especially in necrostatin-1 group. A high degree of intra-group variability was observed. The majority of the cells and their processes within the grafts were beta-3-tubulin positive, indicating their neuronal phenotype. Glial cells (GFAP+) within the graft were primarily of host origin. The silk scaffold was still present at this time point. There was also evidence of anatomical integration between the graft and the host brain. GFP+ processes from the graft projected into the host brain in all directions but more predominantly in the anterior and posterior directions, reaching as far as 1 mm from the transplantation site.
Conclusion: We have demonstrated the feasibility of transplanting silk constructs seeded with neurons up to 1 month after transplantation in a rat model. Pharmacological intervention was a crucial part of our strategy to improve graft survival. The robust anatomical integration suggests the possibility of functional integration of the graft with the host brain. Ongoing studies are investigating the sources of intra-group variability to further optimize graft survival at longer time points. These efforts will facilitate future studies on the functional integration and behavioral impact of such grafts.

Title: Awareness detection in patients with unresponsive wakefulness syndrome

Authors: *Y. OKAHARA[1,2], K. TAKANO[2], M. ODAKI[3], K. KANSAKU[4,2,5];
[1]Dept Neurol Surg, Chiba Cerebral and Cardiovasc. Ctr., Chiba, Japan; [2]Res. Inst. Natl. Rehab Cent,, Saitama, Japan; [3]Ryogo Ctr., Chiba, Japan; [4]Dept. of Physiol. and Biol. Information, Dokkyo Med. Univ. Sch. of Med., Tochigi, Japan; [5]Cent for Neurosci and Biomed Eng, Univ. of Electro-Communications, Tokyo, Japan

Abstract: Recent neuroimaging studies have revealed that some patients, who diagnosed as unresponsive wakefulness syndrome (UWS; Laureys, et al., 2010), may retain consciousness to some extent, and may be able to modulate their thoughts voluntarily (Monti, et al., 2010, Cruse, et al., 2011). Proper awareness detection in patients with UWS comes to an important issue, because it may provide applicable rehabilitation and then improve their quality of life. In this study, we performed two types of experiments, which consisted of fMRI and brain-computer interfaces using a steady-state visual evoked potential (SSVEP-BCI; Sakurada, et al., 2015). Eight UWS patients participated (4 male, mean: 50.9 years old, JFK Coma Recovery Scale-Revised range: 5-7).We used passive listening tasks in fMRI, which consisted of two different speech conditions to evaluate a level of speech comprehension. In “FN” task, to observe the whole extent of activation elicited by listening to a narrative, the narrative (80 s) was delivered during the four test epochs and no sound was delivered during the control epochs. In “FR” task, to exclude activation elicited by processing of auditory voice in general, the narrative was delivered during the test epochs and the preceding test epochs were replayed in reverse during each control epoch. Following the fMRI, we performed a SSVEP-BCI experiment using “an attention/ignorance task”, where participants are required to use attentional modulation following verbal commands such as “Attend to the LED” or “Ignore the LED”. BCI accuracy in operating the in-house BCI system was evaluated.Four out of 8 participants did not show any response to auditory stimuli, 2 participants showed activation clusters in primary auditory cortex only in FN task, and 2 participants showed significant activation in both FN and FR tasks. In the 2 participants who showed activations in fMRI tasks, reliable responses (30 trials, 80%; 41 trials, 68.2%), which crossed over upper confidence limit of chance results, were found in the BCI task.The results suggested that the combination of fMRI and BCI is effective in awareness detection in patients with unresponsive wakefulness syndrome.

Abstract: Detecting residual consciousness in unresponsive patients is a major clinical concern and a challenge for cognitive neuroscience. Comparing to studies extracting neural markers of residual consciousness from the resting period, recent neuroimaging studies have demonstrated potential approaches for informing diagnosis and prognosis in unresponsive patients. However, these imaging technologies come with considerable expense and difficulty, limiting the establishment of bedside clinical setting. Although resting electroencephalography (EEG) signals were also able to index the state of consciousness, there is still a lack of EEG study of using active paradigms for the validation of improved diagnosis and prognosis of disorders of consciousness patients. Here, using the notion that the process of auditory sequences with regularities at multiple time scales relies on different levels of conscious awareness of the auditory stimulus, we designed an exquisite language paradigm with auditory hierarchical sequences. Electrical activities were recorded from 47 healthy controls, 31 minimally conscious states (MCS) and 30 unresponsive wakeful syndrome (UWS) patients by high density EEG during hierarchal language tasks. Our findings demonstrated that EEG-derived signals, both auditory evoked activity (inter-trial phase coherence) and global dynamic pattern (microstates), in patients were significantly associated with behavioral diagnosis of consciousness and clinical outcomes. In particular, comparing to the EEG signals during the resting period, the correlations were significantly improved during the language task period. Furthermore, such correlations were notably boosted along with the incensement of the level of language hierarchy. Especially, the multiple EEG measurements in the active paradigm were robust enough for the prediction of behavioral diagnosis and future outcomes in individual patients. The predictive accuracy of at least 3-month outcome could reach 87% for positive- and 70% for negative-outcomes. Our study provides a novel approach of objective characterization of states of consciousness and tracking individual patients at bedside longitudinally in clinic.

Title: Colocalization of HGFR/Met and phosphorylated forms this tyrosine-kinase receptor in glioblastoma

Authors: *A. E. KALYUZHNY[1], J. TAYLOR[1], J. HAGEN[1], A. PTAK[1], J. COOPER[1], J. HATLER[1], M. LEVIN[2], D. SCHWARTZ[2];
[1]Bio-Techne, Minneapolis, MN; [2]Cell IDx, Inc., San Diego, CA

Abstract: Hepatocyte growth factor receptor/tyrosine-protein kinase Met (HGFR/Met) is a glycosylated receptor tyrosine kinase that plays important role in the development of cancer in different organs including liver, kidney and brain. Mature HGFR/c-Met is a disulfide-linked dimer composed of a 50 kDa extracellular alpha chain and a 145 kDa transmembrane beta chain. Interaction of HGF with HGFR/Met triggers its internalization and subsequent proteasome-dependent degradation as well as tyrosine phosphorylation in the cytoplasmic region which leads to activation of the kinase domain and expose docking sites for multiple SH_2-containing molecules. It has been found that HGFR/Met is implicated in the progression of glioblastoma which is one of the most aggressive brain tumors, and that expression of high levels of this tyrosine kinase is indicative of a shorter survival period. To investigate spatial distribution of HGFR/Met and its phosphorylated forms, we have generated antibodies against the extracellular domain and phospho-specific antibodies against Y1234/Y1235 in the intracellular kinase domain and Y1349 in the intracellular multi-substrate docking site. Multiplex immunecytochemistry and immunohistochemistry has been used to analyze co-localization of these domains in untreated and HGF-treated glioblastoma cell lines and in tissue sections of human glioblastoma. Treatment of U-251 MG, U-87 MG, U-118MG and A172 cells with recombinant HGF protein induced profound phosphorylation of HGFR/Met, and phosphorylated forms of HGFR/Met were detected in the cytoplasm and cell nuclei. We found that HGFR/Met was co-localized with either phosphorylated Y1234/Y1235 or Y1349 forms. In addition, Y1349 and Y1234/Y1235 immunoreactive profiles either overlapped or not, indicating that the action of HGF on the same cells has differential effects on the phosphorylation of tyrosines in the kinase and in docking domains. In glioblastoma tissue sections phosphorylated and non-phosphorylated forms of HGFR/Met was also detected in cell nuclei and the extent of phosphorylated Y1234/Y1235 immunoreactivity appeared higher when compared to the Y1349 form. Our data reveal that there

is a differential activation of HGFR/Met via phosphorylation at a single cell level which may underly the regulation of tumor progression.

Title: Characterization and classification of glioblastoma multiforme using the novel multiparametric cyclic immunofluorescence analysis system MACSima

Authors: *S. REISS[1], S. TOMIUK[1], J. KOLLET[1], J. DREWES[1], W. BRÜCK[2], M. JUNGBLUT[1], **A. BOSIO**[1];
[1]Miltenyi Biotec GmbH, Bergisch Gladbach, Germany; [2]Inst. für Neuropathologie, Universitätsmedizin Göttingen, Göttingen, Germany

Abstract: Glioblastoma multiforme (GBM), a highly malignant, non-curative brain tumor of the primary central nervous system, has been subclassified into distinct subtypes using a multitude of analysis methods. Here, we introduce the MACSima™ imaging platform which allows for fully automated, multiparametric, cyclic immunofluorescence analysis of specimens with hundreds of antibodies. We applied this method to classify glioblastomas according to published classification schemes and identify novel glioblastoma specific markers. Glioblastoma xenografts derived from primary tumors were dissociated to single cells using the Tumor Dissociation Kit, human and the gentleMACS™ Octo Dissociator (Miltenyi Biotec). Single cells were analyzed for cell surface marker expression by flow cytometry (MACSQuant Analyzer 10) including 371 directly conjugated antibodies (MACS Marker Screen, Miltenyi Biotec). A ranking was applied according to the percentage of positive cells and the stain index, leading to a selection of 96 markers for characterization of primary glioblastoma using the MACSima™ imaging platform. Cryosections were fixed by acetone and each specimen was exposed to 96 fluorescent labeled antibodies by cycles of antibody reaction, image acquisition and erasure of signal. The 2D image stacks were analyzed for antigen quantification and pattern recognition using pixel and segmented single-cell data. The detection of previously published markers, such as PDGFRα, Olig2, p16, p53, CD44, Nestin, Podoplanin, GFAP, MET, Hes-1 and EGFR was used to subclassify the glioblastomas according to i) Motomura (Motomura et al., 2012) into Oligodendrocyte Precursor (OPC), Differentiated Oligodendrocyte (DOC), Astrocytic Mesenchymal (AsMes) or Mixed subtype, and ii) Verhaak (Verhaak et al., 2010) into Proneural, Neural, Classical, or Mesenchymal subtype. The analysis of well-established glioblastoma

marker partially already used in CAR T cell based clinical trials such as EGFRvIII, HER2, or IL-13Rα2 revealed a broad inter- and intratumor diversity of expression. Infiltrating immune cells were present in most of the tumors, but showed varying percentages. Finally, segmentation, clustering, and correlation analysis allowed for identification of new marker which might be used for a more robust classification of glioblastomas. In summary, our analysis using the MACSima™ imaging platform reveals a high heterogeneity of protein expression in glioblastomas along with the ability to deeper classify the diverse tumors and identify novel markers that allow selective detection of tumor cells for their potential use in immunotherapy.

Title: Overcoming 5-FU resistance of GBM by spliceosome inhibitor Pladienolide-B

Authors: *Y.-J. LEE, D.-Y. CHANG, J.-H. JUNG, H.-G. WOO, H. SUH-KIM, S.-S. KIM; Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Glioblastoma multiforme (GBM) is the most common and aggressive brain tumor, responds poorly to current standard therapy. The presence or development of resistance to anticancer drugs is a severe problem in GBM treatment. Recent studies suggest that alternative splicing events occur in various cancers and play a significant role in resistance to cancer therapy. Previously, we reported that cytosine deaminase-expressing mesenchymal stem cells exerted an anticancer activity with a wide therapeutic index by converting 5-fluorocytosine, a nontoxic prodrug, into 5-fluorouracil (5-FU), a potent anticancer drug. In this study, we investigated the effects of Pladienolide-β, a spliceosome inhibitor, combined or not with 5-FU on 5-FU resistance-GBM cell lines. 5-FU resistance cell line (T98FR) was developed by treatment of T98G GBM cells with moderate dose of 5-FU over passages. Microarray analysis revealed that up-regulation of spliceosome related genes in T98FR. Pladienolide-β decreased the cell proliferation of T98FR cells separately and synergically with 5-FU. Pladienolide-β treatment down regulated the expression of 5-FU metabolism related genes in T98FR cell line. Our results showed that Pladienolide-β is able to enhance 5-FU effect in 5-FU resistance cell line suggesting its potential use in 5-FU refractory cancer patients.

Title: The prevalence and impact of preserved functional connectivity within glioblastoma

Authors: *A. G. DANIEL[1], K. PARK[2], J. L. ROLAND[3], D. DIERKER[4], J. GROSS[5], J. HUMPHRIES[1], C. D. HACKER[3], J. SHIMONY[4], E. C. LEUTHARDT[3];

Abstract: Given the heterogeneous growth of glioblastoma, there is variability in its effect on the brain parenchyma. The surrounding tissue can be destroyed or displaced by the invading tumor cells resulting in a gross mass that may still contain functional tissue. In this study, we investigated the prevalence of preserved functional tissue within glioblastoma and adjacent regions using resting-state fMRI. Contrast-enhanced T1-weighted images and T2/fluid attenuation inversion recovery (FLAIR) MR images were used to identify tumor and non-tumor regions in 57 patients with newly diagnosed glioblastoma. Using resting-state functional MRI maps as inputs, a pre-validated feedforward artificial neural network algorithm probabilistically identified the network concordance of each voxel for seven canonical brain networks. The network voxels within the FLAIR hyperintensity, contrast-enhanced and necrotic regions were analyzed. For patients with reported overall survival (N = 33), the prognostic value of functionally connected regions within glioblastomas was determined. The vast majority of tumors had retained functional tissue within the contrast-enhanced boundaries (98.3%, n = 56). The amount of identified network voxels were proportional to tumor size ($r=0.788$, $P<0.001$). With the exception of the dorsal attention network, all networks showed a greater overall survival when their respective functional voxels were not found within the tumor. However, only the language network findings achieved significance ($P = 0.002$). The presence or absence of language function within tumors led to a significant median survival difference independent of demographic, clinical and genetic prognostic variables (hazard ratio: 18.67; 95% CI: 3.85 - 90.49, $P = 0.0003$). Despite the invasiveness of glioblastoma, functional tissue can be found within the tumor and adversely affect overall survival (most notably for the language network). Functional network preservation may provide a novel biomarker for glioblastoma prognosis.

Title: Open science medicinal chemistry: Towards a treatment for DIPG a rare brain cancer

Authors: *C. SCHLUMBERGER[1], S. CRAMP[2], N. HAMBLIN[2], A. EDWARDS[3], O. ROBERTS[4], A. BULLOCK[5], P. BRENNAN[6], **S. ALMOND**[2];
[1]Charles River, Sulzfeld, Germany; [2]Charles River, Saffron Walden, United Kingdom; [3]Ontario Inst. of Cancer Res., Toronto, ON, Canada; [4]Meds4Kids Pharma, Toronto, ON, Canada; [5]Structural Genomics Consortium, Oxford, United Kingdom; [6]Univ. of Oxford, Oxford, United Kingdom

Abstract: Diffuse intrinsic pontine glioma DIPG is a rare, aggressive and uniformly fatal childhood brain cancer with a median survival time of 9-12 months and for which there are currently no effective drug treatments. To accelerate the drug discovery process, Meds4Kids Pharma (M4K) is pioneering an open science approach to generate an orally-available, brain-penetrant therapeutic to treat DIPG. M4K seeks to test the hypothesis that an open science framework can be successfully applied not only to accelerate basic science, using the collective knowledge of the scientific community at large, but also to take an innovative new drug candidate all the way from discovery and clinical proof-of-concept through to product registration, by making use of regulatory data protections and market incentives. Since late 2017, Charles River Early Discovery has been providing in kind drug discovery services to help progress these efforts, including medicinal and synthetic chemistry. DIPG has been shown to be associated with mutations in the ACVR1 gene (activin A receptor, type 1) also known as ALK2 kinase. Early support for the therapeutic hypothesis that an inhibitor of ALK2 kinase would have clinical benefit in DIPG, came from in vivo studies with non-selective ALK2 kinase inhibitors, which both killed DIPG cell lines harboring the ALK2 mutation and extended lifespan in xenograft mouse models. Working collaboratively with M4K and their open science partners, we have made excellent progress towards the identification of potent, selective, brain penetrant ALK2 inhibitors starting from the known inhibitor LDN-214117, previously described for FOP (fibrodysplasia ossificans progressiva). Our current lead compound has an excellent in vitro and

in vivo profile showing high oral bioavailability and brain penetration in a mouse PK study and is progressing to proof of concept studies. In addition we are progressing with the identification of a back-up series. References: 1. https://m4kpharma.com/ 2. Carvalho et. al. Title: Spatial and temporal profile of intracranial vascular calcification in a mouse model with endothelial upregulation of tissue-nonspecific alkaline phosphatase

Authors: *R. L. RAMOS[1], A. UTS[2], P. SINGLA[2], E. KAMPTON[2], Y. MAYR[2], C. ROCHON[3], J. MILLAN[4], O. SAVINOVA[2];

Abstract: Vascular calcification is an important pathophysiological factor contributing to neurodegenerative diseases such as primary familial brain calcification (PFBC). Given the essential role of tissue-nonspecific alkaline phosphatase (TNAP) in calcification, we tested the hypothesis that upregulation of TNAP activity can lead to intracranial calcification. We previously reported that overexpression of TNAP in endothelial Cre-driver mice (eTNAP mice) leads to arterial calcification. Here we analyzed intracranial calcification in this same model. eTNAP mice developed progressive intracranial calcification (0% were affected at 8 weeks, 71% at 13 weeks, and 100% at 23 weeks). At 23 weeks, calcification was associated with microvasculature in the basal ganglia, thalamus, hindbrain, and cerebellum. Calcified lesions

were accompanied by reactive astrocytes and activated microglia. Extravasation of IgG into the brain parenchyma was evident in eTNAP mice suggestive of blood-brain barrier defect. eTNAP mice displayed significant motor deficits in open-field tests (reduced ambulation, rearing, speed, and acceleration). Our results indicate that upregulation of TNAP activity can lead to intracranial vascular calcification. Given the similarities in presentation between eTNAP mice and PFBC patients, this model can advance the understanding of PFBC disease progression.

Title: The effect of repeated anesthesia on learning at different ages

Authors: B. N. VENKAT[1], *C. J. DIXON[2], D. P. AKSENOV[2];
[1]Niles West High Sch., Skokie, IL; [2]Northshore Univ. Healthsystem, Evanston, IL

Abstract: General anesthetics increase the chance of Post-Operative Cognitive Disorder (POCD) in elderly patients. There is a correlation between the age of onset of Alzheimer's disease and exposure to general anesthesia before age 50. Children who had been exposed to anesthetics before age 2 developed learning disabilities and ADHD in their teens. The average American undergoes nine invasive procedures in their lifetime. Currently, there is no consensus on the effects of repeated anesthesia on cognitive function, particularly how it affects the developing and aged brains. The purpose of this study is to compare the effects of single and repetitive anesthesia on brain function at different ages. Repetitive anesthesia induces more severe learning deficit than single exposure to anesthesia and anesthesia-induced learning deficit is greater on the developing and aged brain compared to mature brain. *Caenorhabditis elegans* is a nematode that is a common model for learning in neuroscience. N2 *C. elegans* were purchased from the Caenorhabditis Genetics Center at the University of Minnesota. The standard egg wash procedure was used to control the age of the worms. *C. elegans* at 1-2 days (developing brain), 10-13 days (mature brain), and 14-17 days (aged brain) were used in this study. Each plate of *C.elegans* was treated with 20µL of an aqueous solution (0.0016%) of chloroform or isoflurane. Worms were allowed to recover from anesthesia before a second or third treatment was given. Learning was tested using tap habituation. The plates with the worms were tapped, resulting in the worms swimming in the direction opposite the tap. This is due to reflex, and the reflex

decreases with further taps, because the worms learn to ignore the tap. The number of taps a worm needs to learn to ignore the tap was measured before and after anesthesia. Anesthesia caused a greater learning impairment in aged worms compared to mature worms. Repeated anesthesia with both chloroform and isoflurane caused greater learning impairments than single exposure. Among the worms treated once with anesthetics, chloroform and isoflurane had a similar effect on aged worms, while isoflurane caused a greater impairment on mature worms than chloroform.

Title: Sedation with brexanolone produces markedly less neurotoxicity compared to midazolam in the developing rodent brain

Authors: *J. N. HUFFMAN[1,2], K. M. KAPRAL[1,2], S. L. WILLIAMS[1], B. S. SWINEY[1], R. MORELAND[2], K. K. NOGUCHI[1];

Abstract: The developing brain is susceptible to extensive neurotoxicity following exposure to sedative/anesthetic drugs (SADs). Every year hundreds of thousands of children around the world are exposed to neurotoxic regimens of SADs without viable alternatives, and exposure widely varies as no standardized procedures guide clinical use. Allopregnanolone (ALLO) holds promising neuroprotective capabilities in the adult brain, as well as potent sedative properties in adults and neonates. ALLO and many other SADs produce their sedative/anesthetic effects through allosteric modulation of $GABA_A$ receptors, which is one of two principal mechanisms behind SAD-induced neurotoxicity. Evidence suggests ALLO has the unique capacity to regulate key apoptotic factors in adults, is critical to the development of the central nervous system, and is involved with suppressing fetal neuroapoptosis during gestation. Preclinical studies exploring the possibility of ALLO as a viable sedative/anesthetic and/or neuroprotective agent in the developing brain are virtually non-existent. Here we show a particular FDA approved formulation of ALLO, Brexanolone (BREX), can produce potent SAD-like sedation across a range of dosages in the neonatal mouse. Behavioral observation and quantification of movement

show BREX induces clinically relevant levels of sedation after a single intraperitoneal (i.p.) injection. Because fluctuations in vital signs can quickly lead to medical complications, we established dose-dependent impacts of BREX on heart rate, breath rate, pulse distention, and oxygen saturation, indicating lower doses of BREX can produce clinically applicable levels of sedation while maintaining vital signs within normal ranges. We further examined whether the neurotoxic profiles of BREX were comparable to midazolam (MIDAZ), one of the most commonly used GABAergic SADs. Equally sedative dosages of BREX and MIDAZ were administered via i.p. infusion for 6-hours, revealing markedly less neurodegeneration for BREX treated neonates compared to MIDAZ. These data supply the first evidence that BREX holds potent, clinically relevant sedative capabilities while producing strikingly low levels of apoptosis in the developing rodent brain.

Title: Unrestricted somatic stem cell (USSC) administration reduces post hemorrhagic hydrocephalus (PHH) and alters expression of aquaporin channels (AQP1 & 4) and toll-like receptor-2

Authors: *G. VINUKONDA[1], D. PUROHIT[4], Y. LIAO[2], L. IVANOVA[2], F. HU[5], D. A. FINKEL[5], S. SHAH[6], G. M. KLEINMAN[7], M. S. CAIRO[3], E. F. LAGAMMA[8];

Col., Valhalla, NY; [5]Pediatrics, [4]Maria Fareri Children's Hosp. of Westchester Med. Ctr., Valhalla, NY; [6]Pediatrics, [7]Pathology, Westchester Med. Ctr., Valhalla, NY; [8]Pediatrics, Biochem. and Mol. Biol., New York Med. Col. and Maria Fareri Children's Hosp. of Westchester Med. Ctr., Valhalla, NY

Abstract: Intraventricular hemorrhage (IVH) is a common complication of preterm birth where many infants develop post-hemorrhagic hydrocephalus (PHH); no effective treatment exists. PHH is associated with subependymal gliosis, fibrosis & disruption of ependymal lining (Karimy et al, 2017). Aquaporins are water channels that are associated with cerebrospinal fluid (CSF) secretion (AQP1 at choroid plexus) and absorption (AQP4 at the ependyma). Altered expression of AQP1 & AQP4 is seen in PHH and the expression pattern changes with continued injury & intervention (Verkman et al, 2017). USSCs derived from human cord blood, have anti-inflammatory and regenerative properties that along with multi-lineage differentiation (Liao et al,

2014), may be advantageous to treat PHH. We hypothesize that the intracerebral ventricular (ICV) injection of USSC will reduce inflammation associated histological changes and recover AQP1 & AQP4 expression in the ventricular system, which are associated with reduced ventricular enlargement. We used a glycerol-induced preterm rabbit model of PHH (Chua et al, 2009; Vinukonda et al, 2010). USSCs were isolated and characterized as previously described (Kogler et al, 2004; Liao et al, 2014). After ultrasound confirmation of IVH, we injected ICV $2X10^6$ USSCs & measured the ventricle area at the level of mid-septal nucleus on H&E stained coronal-section images using Image-J. Using immunofluorescence, AQP1 & AQP4 expression was evaluated in choroid plexus and ependymal lining. Total mRNA of laser/tissue dissections was used for gene expression studies. Ventricular area was significantly higher in the IVH-saline group compared to no-IVH controls whereas USSC administration in IVH pups significantly reduced ventricular volume compared to IVH-saline pups at 7 & 14d postnatal age. Histopathological evaluation of IVH pups showed ependymal denudation & loss of cilia accompanied by necrosis & inflammation, which were partially recovered in USSC treated group. Immunoreactivity & mRNA levels of AQP1 & AQP4 were reduced in PHH, whereas USSC administration recovered AQP1 & AQP4 mRNA expression & immunoreactivity by day 7. The inflammatory marker toll-like receptor-2 (TLR2) was significantly increased in IVH, whereas USSC treatment attenuated it at postnatal day 3. These findings support the possibility that USSCs: i) exert anti-inflammatory effects by reducing TLR2 ii) recover ependymal denudation, integrity and ciliary function iii) recover AQP1 & AQP4 mRNA levels which are associated with reduced ventricular volumes. Results represent a proof-of-concept for the translational potential of using USSCs to treat PHH in premature infants.

Title: Interhemispheric relationships in multiple sclerosis

Authors: *J. T. DAVIS[1], I. BELOVARSKI[3], C. FORD[3], K. PAULSON[2], J. LEWINE[2]; [1]Neuroimaging, [2]The Mind Res. Network, Albuquerque, NM; [3]Univ. of New Mexico, Albuquerque, NM

Abstract: Multiple sclerosis (MS) is a chronic, degenerative condition associated with inflammation and demyelination of the central nervous system (CNS). While most treatments target the autoimmune and inflammatory process that are suspected to underlie de-myelination in MS, there is growing interest in the development of treatments that directly impact axonal function and the electrophysiological consequences of the disease with respect to slowed or blocked neuronal conduction. The corpus callosum is known to be especially vulnerable to MS, so identification of inexpensive ways to measure callosal integrity might aid in tracking disease progression and the efficacy of interventions. This project therefore sought to explore the relationships between three novel biomarkers of callosal integrity: (1) Callosal fractional anisotropy [FA] derived from MRI-based diffusion tensor imaging [DTI]; (2) Interhemispheric electrophysiological coherence as derived from MEG/EEG; and (3) a novel behavioral measure of interhemispheric integration time. Eleven patients with MS (ages 25-65) and 15 neurotypical control subjects underwent MRI/DTI, MEG/EEG, and behavioral testing. The novel behavioral stimulus detection test involved presentation of left/right lateralized visual stimuli, with three response conditions - right hand only, ipsi-lateral hand, contralateral hand. The contralateral condition requires coordination of the activities for the two hemispheres, so a comparison of ipsilateral and contralateral response times provides an index of interhemispheric integration time. Compared to neurotypical controls, MS patients showed reduced callosal FA values, reduced beta-band interhemispheric coherence, and markedly increased interhemispheric integration times. Importantly, there was a high correlation between measures such that the simple behavioral measure was highly predictive of electrophysiological and structural measures of callosal integrity (correlation coefficients of -0.84 and -0.78, respectively). That is, the data suggest that simple visual-motor measures, which can be done in a clinician's office, can serve as surrogates for complex structural and functional measures of callosal disease burden.

Title: Pericytes accumulate at EAE lesion sites and concurrently mediate vascular sprouting as well as fibrosis

Authors: E. SEKERDAG[1], D. ATAK[1], C. ULUSOY[3], A. B. YıLMAZ[1], S. SEYAJ[4], G. DENIZ[2], M. ZEYBEL[1], Ö. Ö. ÇAKMAK[1], A. VURAL[1], C. &. KUCUKALI[3], A. TUNCER[5], E. TÜZÜN[3], *Y. GURSOY-OZDEMIR[2];

Abstract: Aim: Pericytes are involved in immunological responses and repair mechanisms in the central nervous system (CNS) such as scar formation, which indicate that pericytes could be the very main players in the pathophysiology of Multiple sclerosis (MS), a chronic inflammatory demyelinating disease of the CNS. This study investigated the role of pericytes in the pathophysiology of Multiple Sclerosis with a special focus on vascular pathology and pericyte differentiation. **Methods:** Experimental Autoimmune Encephalomyelitis (EAE) models were induced with MOG and PLP in C57Bl/6 and SJL mice respectively. Mice were monitored and graded daily for clinical signs of disease. At 15 days post immunization (p.i) (early EAE) and 40 days p.i. (late EAE), mice were sacrificed, blood was collected by cardiac puncture to analyze anti-MOG and anti-PLP antibodies with ELISA, and their brain and spinal cord were isolated in 4% PFA. Cryosections of spinal cord and brain areas were stained with both immunohistochemistry and immunofluorescence methods for blood-brain barrier (BBB) leakage, demyelination, inflammation, vascular pathology, pericytes, and extracellular matrix (ECM) components. All EAE groups were compared to SHAM groups. On the other hand, human brain vascular pericytes (HBVP) were cultured *in vitro* and were exposed to MS and healthy patient serum and CSF to investigate pericyte response in terms of cell differentiation and ECM secretion. **Results:** In EAE disease progression, pericyte numbers were increased at lesion sites, pericyte coverage was decreased on endothelial walls at non-lesional sites and different pericyte types were present according to co-localization studies. Vascular pathology in EAE showed an increased vascular density at lesion sites simultaneously with increased pericyte accumulation and increased extracellular matrix components such as Collagen I and IV at these areas. Pericytes *in vitro* showed also increased Collagen I and IV secretion upon exposure to MS serum and CSF compared to healthy serum and CSF. **Conclusion:** During the course of EAE/MS, pericytes are affected and they leave endothelia and migrate towards lesion sites where they high likely differentiate into myofibroblastic phenotype producing collagen and may mediate fibrosis.

Title: AAV9 gene therapy rescue of an eEF1A2 knockout mouse model

Authors: J. NG[1], H. CHU[1], M. BERTI[1], M. TIJANI[1], J. ANTINAO DIAZ[1], C. ABBOTT[3], S. SCHORGE[2], S. N. WADDINGTON[1], ***R. KARDA**[1];

Abstract: Mutations in the eukaryotic translation elongation factor 1 alpha 2 (eEF1A2) have been associated with severe intellectual disability, autism and epilepsy. There are currently no effective treatments. We used an existing, well-characterised eEF1A2 knock out mouse (Wasted mice) to test the hypothesis that function of the protein could be restored with gene therapy. We designed an adeno-associated virus 9 (AAV9) using a pan neuronal promoter, human Synapsin, to drive expression of the human eEF1A2 cDNA (hSyn-eEF1A2). We interrogated its bio-distribution after single intravenous or intracerebroventricular injections to new born mice. We found widespread transgene expression in the CNS after both routes of administration from injection of a GFP marker gene. Following this we treated cohorts of mice in a randomised, blinded trial with AAV9-hSyn-eEF1A2. Mice with combined intracerebroventricular and intravenous neonatal administration (n=4), or intracerebroventricular (n=3) only were completely rescued by AAV9 hSyn-eEF1A2. Behavioural studies, rota-rod and inverted grid, further validated the efficacy of the treatment. Both treated groups showed no significant difference compared to wild-type controls and survived until the experiment was terminated when the entire cohort had reached 72 days of development. We present for the first time a successful gene therapy approach for the eEF1A2 wasted mice, which raises the potential for a new treatment approach for children affected by mutations in this gene.

Title: Effects of a single sequence of acute intermittent hypoxia (AIH) on motor function in healthy able-bodied persons

Authors: *A. Q. TAN[1,2], A. N. CORSTEN[1,2], S. A. BARTH[1,2], R. D. TRUMBOWER[1,2]; [1]Physical Med. and Rehabil., Harvard Med. Sch., Boston, MA; [2]Spaulding Res. Inst., Boston, MA

Abstract: Neural plasticity is a major contributor to functional recovery after spinal cord injury (SCI). Mild breathing bouts of low O_2 (acute intermittent hypoxia; AIH) is known to induced spinal plasticity, triggering a BDNF-dependent signaling cascade that leads to respiratory and non-respiratory motor recovery in rat SCI models. Previous studies also demonstrated that AIH improves ankle torque generation and walking ability in persons with iSCI. While prior studies suggest similar motoneuron potentiation occurs in rodents without SCI, no studies have addressed this possibility in able-bodied humans. The purpose of this study was to determine if a change in neuromotor excitability is present in the lower limb of neurotypical persons in response to a single sequence of AIH.

Healthy, neurotypical adult humans participated in a single sequence of AIH treatment. During treatment, participants were secured to a semi-reclined seat with the right leg positions and knee constrained in slight flexion and the neutral ankle attached to a single degree-of-freedom rotatory motor system. AIH consisted of fifteen 90-second bouts of hypoxia (FIO_2=0.10) at 60-second intervals. Biomechanical measurements of isometric ankle plantar flexion torque, as well as, electromyograms (EMG) were recorded from 3 major muscles of ankle torque production. Repeated measurements were taken at baseline and immediately post AIH treatment. Blood oxygen saturation, blood pressure, and heart rate were continuously monitored.

In contrast with previous reports in iSCI, we found no differences in maximum plantar or dorsiflexion torque following AIH. Furthermore, we observe small yet inconsistent changes in the mechanically induced soleus stretch reflex amplitude following AIH during the passive and active plantarflexion conditions. These findings suggest that AIH does not induce any discernible bias in excitatory drive to ankle extensors in neurotypical participants. Moreover, the small changes in stretch reflex excitability implies that AIH may modulate Ia afferent transmission in able-bodied person. While the current results provide important mechanistic controls, future work will determine if gains in strength maybe decoupled from reflex excitability following AIH.

Title: Western diet drives CNS insulin resistance and impairs recovery after spinal cord injury

Authors: *H. N. KIM[1,2], M. LANGLEY[1,2], H. YOON[1,2], L. KLEPPE[1], A. MATVEYENKO[2], I. A. SCARISBRICK[1,2,3];
[1]Physical Med. and Rehabil., [2]Rehabil. Med. Res. Center, Dept. of Physiol. and Biomed. Engin., [3]Mayo Clin. Grad. Sch. of Biomed. Sci., Mayo Clin., Rochester, MN

Abstract: A Western diet promotes systemic metabolic dysfunction and is a risk factor for neurodegenerative conditions, but there is limited information regarding mechanisms of action in the intact or injured CNS. To address this gap, we investigated the influence of systemic insulin resistance triggered by consumption of a diet high in fat and sucrose on neuropathophysiological outcomes in an experimental murine model of spinal cord injury (SCI). Ten-week-old female C57BL6 mice were provided a regular diet (RD) or a diet high in fat and sucrose (HFHS) for 7 wk prior to incomplete compression SCI. Our findings show that even without SCI, consumption of a HFHS diet reduced insulin-like growth factor 1 and its receptor in the spinal cord, impaired tricarboxylic acid cycle function, and promoted signs of astrogliosis including enhanced expression of glial fibrillary acidic protein (GFAP). After SCI, mice consuming HFHS experienced impaired sensorimotor recovery compared to those consuming a RD, in addition to increased signs of microgliosis and reductions in markers of myelin and synaptic recovery. To determine mechanisms, HFHS conditions were modeled *in vitro*, with astrocytes demonstrating parallel reductions in insulin signaling intermediates, and increases in GFAP and the pro-inflammatory cytokine interleukin 6. Each of these effects were completely prevented by the insulin sensitizing agent Metformin. Moreover, conditioned media from astrocytes grown under HFHS conditions reduced expression of myelin proteins when applied to cultures of oligodendroglia. However, when astrocytes were also treated with Metformin, the HFHS-astrocyte-driven oligotoxic effects were no longer observed. Together these findings suggest that HFHS impairs insulin signaling and energy homeostasis in the CNS resulting in increases in pro-inflammatory astrocytes and impaired recovery after neural injury. These studies also highlight insulin sensitizing agents such as Metformin as a new intervention to prevent neural injury exacerbated by HFHS and to improve mechanisms underpinning neural repair and functional recovery.

Title: Spinal cord injury in neonatal rats: Understanding the pathways that facilitate spontaneous recovery of forelimb function

Authors: *R. D. SMIT, T. J. CAMPION, J. B. MADRAK, G. M. SMITH;
Shriners Hosp. Pediatric Res. Ctr., Temple Univesity Sch. of Med., Philadelphia, PA

Abstract: Injury to the cervical spinal cord can result in severe paralysis, and presents a permanent disability that requires immense logistical foresight. A hallmark found across most mammalian species is that neonates recover more notably from spinal cord injury (SCI) compared to adults. Research in rodents indicates that the superior recovery is owed to the more robust regeneration of corticospinal neurons (CST) across the injury site. In the absence of intrinsic axonal regrowth, the older animals are more reliant on sprouting from uninjured subcortical populations i.e. propriospinal neurons (PN), reticulospinal neurons (RN), and rubrospinal neurons (RST). Despite this consensus, few studies have simultaneously analyzed the anatomical discontinuation of axonal regeneration with aging and how each pathway's response post-injury translates to functional outcomes. Using a multimodal study, we investigated the exact neuronal pathways (CST, RST, PN, and RN) responsible for recovery following cervical SCI at different post-natal ages (P5, 14, 21, 60). We employ a two-virus vector system to deliver DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) and precisely silence the C3/C4 PN, RN, RST, or CST. We use recombinant virus (Lenti or rAAV) to deliver inhibitory DREADDs (hM4Di) caudal to the lesion, after which we individually silence the appropriate pathway by introducing a transactivator (AAV/Tet-On) at the location of neuronal soma. To map the subcortical populations, we use a retrograde transportable lentivirus (HiRet/Lenti/GFP). To label the descending CST, we inject adeno-associated virus (AAV/mCherry) into the somatomotor cortex. Behavioral assays consist of isometric pull strength, grooming, IBB (Irvine, Beattie, Bresnahan), and single pellet reach. We hypothesize that there is a critical age where intrinsic corticospinal regrowth is no longer viable and any recovery becomes dependent on interneuron plasticity (i.e. PN). In addition, by reproducing functional deficits with DREADDs, we validate the individual contribution of each neuronal pathway in promoting recovery. Our data illustrates that in P5 neonatal rats there is enhanced

axonal regeneration, increased sprouting of supplementary pathways, and superior functional recovery, when compared to the older age groups.

Title: Modulation of integrin signaling in the hydrogel-induced extracellular matrix to facilitate axonal ingrowth following spinal cord injury

Authors: *H. PARK, D. HWANG, Y. OH, H. KIM, B. KIM;
Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Axon regeneration failure beyond lesion site following central nervous system (CNS) injuries is hampered by fluid-filled cystic cavities formed at the lesion epicenter. Previously, we demonstrated that injection of imidazole-poly (organophosphazene) (I-5), a hydrogel with thermosensitive sol-gel transition behavior, prevented cystic cavity formation by promoting extracellular matrix (ECM) remodeling. However, the extent of axonal ingrowth into the hydrogel-induced ECM was limited. We hypothesized that inhospitable microenvironment in newly deposited ECM provides inhibitory influence to regenerating axons and that modifying the ECM environment can facilitate axonal growth into the ECM. I-5 injection results in the formation of fibrotic matrix filled with type I collagen surrounded by highly reactive astrocytes, reminiscent of the fibrotic scar. It has been reported that interaction between collagen in the ECM and integrin expressed in reactive astrocytes drives formation of glial scars, a potent inhibitory factor for axon regeneration. The present study aimed to modify microenvironment of I-5 induced ECM by modulating integrin signaling. Activated integrin beta1 immunoreactivity was observed in migrating astrocytes intermingled with ECM 1 week after I-5 injection. By 4 weeks, integrin immunoreactivity was diminished but still found at the border between reactive astrocytes and collagen-rich ECM. To suppress integrin activation, I-5 hydrogel mixed with integrin beta1 functional blocking antibody was injected 1 week after spinal cord injury in rats. Our data showed that I-5 mixed with integrin beta1 functional blocking antibody increased the extent of 5-HT (serotonin) axonal growth into fibrotic matrix. This study suggests that integrin signaling can be targeted to facilitate axonal growth in the hydrogel-induced matrix following spinal cord injury.

Title: Lasting disruption of eccentric neural control after human spinal cord injury

Authors: *D. BASSO[1], K. O'BRIEN[5], T. FAW[2], S. JANSE[3], G. BROCK[3], L. WORTHEN-CHAUDHARI[4], J. SCHMIEDELER[5];
[1]Sch. of Hlth. and Rehabil. Sciences, Neurosci. Grad. Program,, [2]Neurosci. Grad. Program,, [3]Ctr. for Biostatistics, Dept. of Biomed. Informatics, [4]Res. Scientist, Dept. of Physical Med. & Rehabil., Ohio State Univ., Columbus, OH; [5]Dept. of Aerospace and Mechanical Engin., Univ. of Notre Dame, Notre Dame, IN

Abstract: Spinal cord injury (SCI) causes life-long disability even with advances leading to less neuropathology and more aggressive rehabilitation. We postulate that long-standing impairments result from dysregulation between descending supraspinal drive and afferent input below the SCI. Eccentric motor control is ideal for monitoring this dysfunction since supraspinal input sets motor neuron activation below external forces and lengthening contractions occur. This exploratory study characterized eccentric motor control during overground locomotion after chronic, incomplete SCI (iSCI; n=16) compared to healthy controls with similar BMI and age (n=14). As these factors (i.e. age, mass, stature and gait speed) influence locomotion, controlling for them adds necessary rigor. Using kinematics, kinetics and 14-channel EMG, two distinct eccentric impairment patterns emerged - strut and crouch. When using the leg as a strut, the knee extends more than expected, the ground reaction force (GRF) shifts anteriorly compared to normal, promoting knee extension rather than flexion during the weight acceptance phase. In the crouch strategy, the knee flexes more than expected, the GRF shifts posteriorly, and knee flexion increases beyond normal, risking near collapse during weight acceptance. Principle component analysis (PCA) based on biomechanics and EMG metrics mapped the strut and crouch strategies onto the PCA space defined by healthy control strategies for the hip and knee. Based on factor loadings and within-strategy variability, the strut strategy was farther from normal, while crouch was more intermediate. Loading factors define the primary contributors to each principal component. Specifically, decreased rectus femoris eccentric activity distinguished strut from crouch strategy for the hip and knee after iSCI. The current study identified persistent eccentric neural dysfunction after recovery of some walking in chronic human SCI. Thus, regaining

locomotor function after SCI is not necessarily accompanied by restoration of eccentric motor control. Indeed, at least two patterns of dysregulation exist which will require different, more precise interventions.

Title: Defining boundaries of expected normal variability in outcome measures on the CatWalk gait analysis system

Authors: *M. ACEVES[1,3], V. A. DIETZ[2], J. N. DULIN[2,3], N. D. JEFFERY[1,3];

[3]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: One of the most frustrating problems in spinal cord injury (SCI) research is the failure to translate experimental interventions from laboratory to clinic. While there are a multitude of reasons for this state of affairs, many of which have straightforward solutions, one rarely examined, but crucial, aspect is whether an intervention has sufficient magnitude of effect. This can be difficult to assess from group analysis alone. Effective therapeutic impact in the clinic is defined as a meaningful change from baseline in an individual, which implies the need to know how much natural variability there is in the outcome measurement. In this study we analyzed inherent variability in outcomes derived from the Catwalk gait analysis system so as to be able to apply similar individual-level analysis to putatively translatable laboratory interventions for SCI. Variability in outcome measure is a consequence of intraindividual, interindividual and analytical (*e.g.* measurement 'error') variation and must be determined in individuals at steady-state. In this study, uninjured male Sprague-Dawley rats (N=16) were acclimated to the CatWalk apparatus for 5 days prior to testing and then gait variables measured on each of 8 weeks, with 3 runs recorded at each weekly session. The magnitude of the various sources of variability were elucidated using hierarchical regression and then used to derive the reference change interval (RCI), which defines the boundaries within which an individual's outcome measures can spontaneously vary. As expected, there was considerable variability between different measures of hindlimb function, for example: stand, stride length, paw area, swing time, swing speed have RCIs of baseline +/- 85, 32, 65, 35 and 45% respectively.

Our results provide foundational data for individual-level analysis of laboratory interventions for SCI, which will complement group-level analysis and enhance understanding of effect size. The inherently high level of variability in some outcome measures implies poor sensitivity for detection of benefit because achieving results outside the RCI may not be physiologically plausible. Such analysis thereby also aids in experimental design.

Title: Multisite activity-dependent spinal stimulation to promote motor recovery in chronic cervical spinal cord injury

Authors: *R. L. MURPHY[1], R. B. ROBINSON[1], A. J. WIDMAN[1], K. GILCHRIST[1], B. R. KONDILES[1], S. I. PERLMUTTER[1,2], S. LEE[1,3];

Abstract: Cervical spinal cord injury (SCI) damages descending motor pathways that control movements of the hands and arms. A loss of motor function can be severely detrimental to the quality of life and independence of people with SCI. We use a rat model of moderate-severe cervical spinal contusion to develop activity- dependent, closed-loop, electrical stimulation treatments to improve motor recovery in chronic SCI. We previously showed that a single site of cervical spinal stimulation synchronized to volitional contractions of an impaired forelimb muscle produced robust functional improvements compared to controls in a food pellet reach-and-grasp task. We hypothesized that multiple sites of activity-dependent stimulation synchronized to the volitional activity of multiple impaired forelimb muscles (e.g., triceps, wrist extensors, and digit flexors) will produce greater functional benefits, by promoting plasticity in multiple circuits necessary for reaching and grasping. For this study, male and female rats were trained in 4 behavioral tasks: food pellet reach and grasp, pasta matrix, lever pull, and horizontal ladder walk with irregularly spaced rungs. These tasks assess different aspects of forelimb function. Once proficient at all tasks, rats received a moderate-severe, unilateral C4 spinal

contusion. After 4 weeks, the rats were implanted with an array of penetrating platinum-iridium microwires near the ventral motoneurons in spinal segments C5-C7 and wires in three muscles of the impaired forelimb for electromyographic (EMG) recording of muscle activity. Two weeks after implantation, animals were trained for 14 weeks in all 4 behavioral tasks. During this therapy period, stimulated animals received spinal stimulation in response to muscle activity of the impaired forelimb muscles. For 5 hours per day, including during the trained tasks, EMG from each muscle triggered sub-movement-threshold stimulation through a microwire that could elicit contractions of that muscle with higher stimulus currents. Non-stimulated control animals received only behavioral training during the therapy period. After the therapy ended, all animals were tested once each week to monitor long-term post therapy changes in functional outcomes. Multisite stimulation results in improved functional outcomes compared to unstimulated control animals. Recovery only became apparent after 5 weeks of therapy. Moreover, multisite stimulation appears to be effective in animals with more severe SCI than single site stimulation. These results suggest that multisite activity-dependent stimulation may prove to be a potent intervention to improve motor recovery in humans with SCI.

Title: An innovative suppressor of cytokine signaling-3 (SOCS3) reduction peptide (SRP) to repair spinal cord injury

Authors: Y.-S. LEE, K. LI, A. KIM, ***C.-Y. LIN**;
Neurosci, Cleveland Clin., Cleveland, OH

Abstract: The pathophysiology of spinal cord injury (SCI) involves immediate physical damage and subsequent secondary injury including inflammation, which lead to functional deficiency below the injured level. Suppressor of cytokine signaling-3 (SOCS3) has attracted considerable attention for its prominent roles in affecting a broad range of cytokines/chemokines that mediate inflammation. Indeed, knocking down SOCS3 with Lentiviral delivery of short-hairpin ribonucleic acid (shRNA) can prevent neuronal loss after SCI, as shown in our studies, and it can promote axonal regeneration after optic nerve injury and corticospinal axon sprouting after SCI when genetically deleted. Given that both viral delivery of shRNA and genetic deletion have

limited clinical potential, we have developed an innovative peptide, SOCS3 reduction peptide (SRP), in order to prevent subsequent deleterious effects, including inflammation and functional impairments. Specifically, SRP can be easily delivered by subcutaneous injection and distributes to the spinal cord via its N-terminal blood-spinal cord barrier- and cell membrane-permeable domain, where it specifically binds to SOCS3 by its central SOCS3-binding domain and is then degraded in the lysosome as directed by its C-terminal lysosome-targeting domain. Our preliminary results demonstrate that injected SRP distributes to macrophages/microglia to be co-localized with lysosomes and SCI-upregulated SOCS3. SRP specifically and significantly reduces SOCS3, but does not affect suppressor of cytokine signaling-1 (SOCS1) levels, and it is associated with increased signal transduction and transcription-3 (STAT3) activity. Furthermore, SRP treatment post-SCI significantly decreased pro-inflammatory responses, as indicated by decreased expression of both inducible nitric oxide synthase (iNOS) and tumor necrosis factor-alpha (TNF-α). Importantly, we have exciting data showing that in a T8 contusion SCI model, SRP treatment significantly improves recovery of both locomotion and micturition two months after SCI.

Title: The susceptibility of cardiac disorders after spinal cord crush injury in rats

Authors: S. FERNANDES, J. WEINBERGER, I. W. IREDIA, V. TOM, *S. HOU;
Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: High-level spinal cord injury (SCI) often interrupts supraspinal regulation of sympathetic activity in the heart. The loss of balance between autonomic components renders the exposure of cardiac disorders. However, few animal experiments have successfully been investigated to model the disease for potential therapeutic interventions. In the present study, we employed complete spinal cord crush injury, which is an ideal lesion for further cell transplantation, at the T2/3 or T9 level in rats; naïve rats served as a control. Using a radio-telemeter to record electrocardiogram (ECG) and blood pressure, we analyzed heart rate variability (HRV) and cardio-electric alterations 4 weeks after SCI. With 24-h recording, total HRV was reduced in rats with a T2/3 injury, but not T9/10. The T2/3 SCI cohort showed decreased low frequency (LF) but increased high frequency (HF) powers in frequency domains,

while standard deviation of R-R intervals (SDNN) and its derivations significantly declined in time domains, indicating reduced sympathetic and unopposed parasympathetic activity for the heart. During colorectal distention (CRD)-induced autonomic dysreflexia, more arrhythmia events were triggered in rats receiving T2/3 injury, such as bradycardia with sinus arrest, pause related aberrant conduction, ventricular ectopy, and possible atrial fibrillation. This suggests the vulnerability of cardiac electrical system under stress. Thus, the results illustrate that susceptibility of cardiac dysfunction is prevalent following SCI at high levels due to compromised autonomic homeostasis; rats with T2/3 spinal cord crush injury is a suitable model to study cardiac abnormalities.

Title: Enhancing functional recovery from spinal cord injury in neonatal rats with the application of excitatory DREADDs

Authors: *J. MADRAK[1], R. SMIT[1], T. CAMPION[1], G. M. SMITH[2];
[1]Shriners Pediatric Res. Ctr., Philadelphia, PA; [2]Dept of Neurosci., Temple Univ., Philadelphia, PA

Abstract: Spinal cord injury (SCI) can result in a cascade of problems and functional recovery from SCI is not always achievable. In many species, axonal regeneration has been observed as the primary mechanism of SCI repair in juveniles, while axonal sprouting from subcortical pathways has been observed to be critical for the repair of SCI lesions in older animals. We propose that there is a critical age between postnatal days 5 and 14, in which their neuronal rescue pathways transition from axonal regeneration to axonal sprouting for the repair of a spinal cord lesion. We aim to define and modulate specific sprouting mechanisms of subcortical pathways (i.e. propriospinal, reticulospinal and rubrospinal tracts) through the injection of excitatory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) following cervical SCI in juvenile rats. Initially, experimental rats were injected with recombinant adeno-

associated (rAAV) and modified human muscarinic 3 (hM3) excitatory G-protein (Gq) coupled DREADD (D) receptors (hM3Dq). On postnatal day 14, unilateral C5 hemisections were induced in both rAAV-h3MDq injected rats and control rats. Post-injury, we introduced Cre-recomibinase (CRE) intracranially to transactivate the DREADDs. In the continuation of this study, hM3Dq receptors will be activated with constitutive delivery of clozapine-N-oxide (CNO) to excite the recovery pathways and potentially facilitate supplementary sprouting after injury. Behavioural assays will be used to assess the potential for excitatory DREADDs to promote functional rehabilitation following SCI. Tissue will be collected and analysed using immunohistochemical labels in an effort to map the reorganization of motor neurons terminating within C6-T1 regions and to ensure complete lesions. As this study concludes, we hope to address gaps in literature pertaining to axonal recovery mechanisms in early spinal cord injuries, including the mechanisms of recovery from SCI in juvenile rats, and whether or not constitutively activated excitatory DREADDs can precisely facilitate the sprouting of subcortical pathways to modulate functional rehabilitation after SCI.

Title: Surface functionalized nanoparticles targeting corticospinal tract neurons through the high affinity cell surface receptor binding of brain-derived neurotrophic factor

Authors: *M. CAO[1], D. L. HYNDS[1], S. GHOSH[2];
[1]Texas Woman's Univ., Denton, TX; [2]Southeast Missouri State Univ., Cape Girardeau, MO

Abstract: Spinal cord injured (SCI) individuals endure life-long paralysis and other significant losses to the quality of life. However, the use of therapeutics to treat SCI is complicated by factors that limit the delivery of therapeutics and targeting to particular types of cells among the diverse cell types present in the central nervous system (CNS). Biocompatible nanocarriers that are capable of crossing the blood brain barrier can be used to target therapeutics to particular subsets of neurons. In our work, Ferromagnetic nanoparticles encapsulated in tunable polyethylene glycol (PEG) biopolymers were synthesized and surface functionalized with -COOH and -NH_2groups. They were fluorescently tagged to study the mechanism of cellular uptake and targeted drug delivery to neurons. In the present study, we analyzed the targeting of

nanospheres to cells expressing high affinity neurotrophic factor receptors (TrkA, TrkB, TrkC) using brain-derived neurotrophic factor (BDNF) modified nanospheres. Using BDNF to target specific neurons allows us to direct the nanospheres to the neurons and enhance axon growth from. Together, these results show the feasibility of using functionalized nanocarriers for targeted drug delivery to corticospinal tract (CST) neurons to encourage axon regeneration following nervous system damage.

Title: Extent of corticospinal tract sprouting does not predict behavioral recovery following cervical spinal cord injury in the macaque monkey

Authors: *M. CROWLEY, J. GARNER, C. DARIAN-SMITH;
Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The corticospinal tract (CST) is the main descending pathway mediating voluntary hand movement in primates. Following cervical spinal cord injury (SCI), terminal sprouting of spared motor CST axons is known to occur, and has long been used as a biomarker of recovery. However, there is little evidence that links these sprouting patterns with the recovery of hand function (as measured behaviorally). Here we investigated behavioral function after injury to determine whether CST sprouting is a valid measure of recovery. Previous work in our lab (Darian-Smith et al., 2013; Darian-Smith et al., 2014) has shown that following a cervical dorsal root lesion (DRL), the primary somatosensory (S1) CST terminal projection retracts to 60% of its original domain, while the primary motor (M1) CST projection remains robust. In contrast, when a dorsal column lesion (DCL) is added to the DRL, both the S1 and M1 CST projections extend bilaterally and caudally, well beyond normal range. Considering the prevailing notion that CST sprouting tracks with behavioral recovery, we asked: *do these dramatic differences in terminal sprouting patterns reflect differences in the capacity for functional recovery after injury?*
We addressed this across the two types of primary afferent SCI by comparing the recovery of manual dexterity with CST terminal sprouting patterns. Monkeys were trained to retrieve a target object from a clamp using thumb and index finger opposition. They then received either a DRL (n=4) or a combined dorsal root/dorsal column lesion (DRL/DCL; n=4) that removed cutaneous

sensory input from the first three digits of one hand. Three performance parameters were measured before and after the lesions: 1) percentage of successful retrievals; 2) digit stratagem (the pattern of digit opposition); and 3) contact time (duration of digit contact with the object before retrieval). Current behavioral data from the monkeys receiving a DRL/DCL were directly compared with earlier published work of DRL-lesioned animals (Darian-Smith & Ciferri, 2005). Our findings show a similar capacity for recovery in both groups of monkeys, whereby an initially severe impairment of hand function is followed by significant recovery over many weeks. This indicates that while CST sprouting may play an important role in the recovery of hand function, its extent does not clearly track with behavioral recovery. These findings should be taken into consideration when interpreting any post-SCI data that uses axonal sprouting as a biomarker of functional recovery.

Title: Long term adaptation of dorsal horn circuitry after spinal cord injury in macaques

Authors: *K. M. FISHER, J. GARNER, C. J. DARIAN-SMITH;
Comparative Med., Stanford Univ., Stanford, CA

Abstract: The corticospinal tract (CST) is the major descending pathway controlling movement in primates and its expansion through evolution is linked to improved manual dexterity. It is becoming increasingly clear that the role of the CST is more nuanced than that of a simple motor output pathway and that subdivisions arising from outside motor cortex have an important role to play in sensorimotor function.
Our recent work demonstrates that the somatosensory (S1) CST has a discrete input territory within the dorsal horn which overlaps substantially with the incoming primary afferent population. Following a spinal cord injury that involves primary afferent input from the hand, this zone permanently loses much of its normal input, and becomes a region of immense change, where neuronal circuitry must reorganize for recovery to occur. Here, we asked what happens to the circuitry in this region of the dorsal horn during the chronic phase of recovery from spinal injury.
To do this, we mapped the terminal territory of both afferent and efferent inputs to the spinal cord, and then used various neuronal and molecular markers to probe specific connectivity using

confocal imaging. Three macaques received a combined injury of the dorsal roots and dorsal column (DRL/DCL), affecting sensation in digits 1-3 of the hand. One year post-injury, S1 cortex was mapped and anterograde tracers injected into the region corresponding to digits 1-3, contralateral to DRL/DCL. A week before perfusion Cholera toxin sub-unit b (CT-B) was injected into the finger pads of both hands to label primary afferents. Data from these animals was compared to previous control and DRL/DCL monkeys (4-5 month recovery period).
One year post injury, the afferent and efferent terminal territories were restored to their normal input domains. This indicates substantial pruning of the exuberant S1 CST sprouts present at 4-5 months post lesion (Darian-Smith et al., 2014; Fisher et al., 2018). The S1 CST once again projects to a discrete region of dorsal horn. Primary afferent neurons, though permanently reduced (to <5% of their original innervation), have sprouted considerably in order to repopulate an overlapping area. Since many other elements are known to have been restored at this time point (i.e. hand function, S1 CST terminal territory, peripheral receptor numbers – Crowley et al., 2019), compensatory changes are likely to occur at the circuitry level in this region of the dorsal horn. We will put these changes in the context of sensory gating which is known to take place in this area.

Title: Somatosensory deafferentation produces deficits in predictive control of bilateral upper limb coordination and asymmetries in postural stabilization

Authors: *J. SCHAFFER[1], S. JAYASINGHE[2], C. MAENZA[2], F. R. SARLEGNA[3], R. L. SAINBURG[4];
[1]The Pennsylvania State Univ., University Park, PA; [2]Neurol., Penn State Col. of Med., Hershey, PA; [3]CNRS and Aix-Marseille Univ., Marseille, France; [4]Penn State Univ., University Pk, PA

Abstract: Large fiber sensory neuropathy (LFSN) results in loss of proprioception and discriminative touch sensations, and has been shown to produce deficits in intralimb coordination and in the ability to stabilize the limb, in the absence of visual feedback. We examined bimanual coordination in a LFSN patient (GL; age 70 years; right-hand dominant) and in age-matched control participants. The task required participants to move a single virtual bar with both hands to a rectangular target with horizontal orientation. The participants received visual feedback of the virtual bar, but not of the hand position along the bar-axis. Maintenance of midline positioning of the bar required negatively correlated displacements of the hands along

the axis of the bar. Whereas control participants tended to initiate movements with highly correlated hand displacements (~-0.6 Pearson r), GL initiated movement with poorly correlated hand motions (~-0.2 Pearson r). Because this coordination was measured early in movement, this reflected a deficit in predictive coordination between the hands, and asymmetries in hand kinematics. Deafferentation also produced an asymmetric deficit in stabilizing the hand at the end of motion. Specifically, the dominant arm showed substantial drift following motion, while the non-dominant arm oscillated near the end of motion. While this drift asymmetry occurred without visual feedback of the hand position, it was also substantial with visual feedback. These results indicate 1) predictive control of bilateral coordination is dependent on proprioceptive information, 2) asymmetries in motor control persist in the absence of proprioception, 3) stabilization of position at the end of motion is achieved through feedforward mechanisms for the non-dominant, but not for the dominant arm. This latter finding is consistent with the proposition that the non-dominant hemisphere may be specialized for control of positional impedance. While the findings with GL may reflect a unique adaptation to deafferentation, they suggest that end-position stability of the non-dominant arm can be specified through feedforward mechanisms that might exploit coactivation of muscles, in the absence of somatosensory feedback.

Title: Large fiber sensory neuropathy produces asymmetrical deficits in limb movement and stabilization: in the absence of vision, the dominant arm drifts, while the non-dominant arm does not

Authors: *S. A. L. JAYASINGHE[1], J. E. SCHAFFER[2], C. MAENZA[1], F. R. SARLEGNA[3], R. A. SCHEIDT[4], R. L. SAINBURG[2];
[1]Neurol., The Pennsylvania State Univ., Hershey, PA; [2]Kinesiology, The Pennsylvania State Univ., University Park, PA; [3]CNRS and Aix-Marseille Univ., Marseille, France; [4]Biomed. Engin., Marquette Univ., Milwaukee, WI

Abstract: Large fiber sensory neuropathy (LFSN) results in loss of proprioception and discriminative touch sensations, leading to substantial movement deficits. Previous studies have revealed that such neuropathies produce profound deficits in intersegmental coordination and in limb stabilization following movement. The control processes that mediate coordination of

intersegmental dynamics and limb postural stability have been shown to depend on left and right hemisphere mechanisms, giving rise to lateralization of motor performance (Sainburg 2016). We now ask whether motor lateralization persists after LFSN. We tested an individual who has been living with LFSN for 40 years, following an acute post-viral onset at age 30. Her diagnosis confirmed profound somatosensory loss due to LFSN, bilaterally throughout all the joints of her arms and shoulder girdle. GL (female; age 70 years; right-hand dominant) performed a planar three-direction reaching task (with each hand) with and without visual feedback of movement. We analyzed both initial trajectory accuracy and final position stabilization accuracy, in terms of 1) initial movement direction, 2) final position accuracy (initial movement segment), and 3) final position stability (drift post initial movement segment). Our results indicated that regardless of visual feedback, left hand direction errors were greater than right hand errors. In contrast, final position accuracy of the left and right hands was similar with visual feedback, and while both showed greater errors without feedback, the right suffered from the loss of vision substantially more than the left hand. Following movement, only the right hand drifted substantially, when vision was removed. Thus, our findings indicate that motor lateralization is enhanced following long-term loss of proprioception. LFSN produced greater trajectory deficits in the left arm, and greater stability deficits in the right arm. Our results for the no-vision condition suggest that the lateralized control of initial trajectory accuracy, final position accuracy, and stability are mediated by feedforward process without the benefit of continuous proprioceptive feedback. Most remarkably, limb position drift, which was previously described as a characteristic feature of the LFSN (Sanes et al. 1984, Rothwell et al. 1982) did not occur in the non-dominant arm.

Title: Is transcranial magnetic stimulation a reliable tool for studying neurophysiological changes associated with functional recovery in individuals with incomplete tetraplegia?

Authors: *T. ARORA, K. A. POTTER-BAKER, K. O'LAUGHLIN, X. WANG, E. B. PLOW; Cleveland Clin. Fndn., Cleveland, OH

Abstract: Introduction:
Transcranial magnetic stimulation (TMS) is used to study neurophysiology in individuals with spinal cord injury (SCI). To ensure the changes in TMS are a true reflection of neurophysiological changes, it is important to test its reliability. Since, reliability may vary between the muscles above and below lesion that are more and less spared by injury, respectively, it is important to compare reliability of these muscles. Two types of measurement properties are suggested for studying reliability - agreement i.e. how similar are the test-retest measurements within unchanging individuals, and reliability (reliability$_{MP}$) i.e. how unchanging individuals are relative to others. The objective was to determine agreement and reliability$_{MP}$ of TMS metrics from upper extremity muscles of different impairment levels in individuals with incomplete cervical SCI.
Methods:
16 individuals [51$\pm$12 years (28-68 years) 3F] with chronic incomplete cervical SCI (C2-C6) resulting in tetraplegia (AIS B:4; AIS C:1; AIS D:11) participated in the study. We collected TMS metrics from one strong (MRC $\geq$ 3) and one weak (MRC < 3) upper extremity muscle in each participant during test and retest visits separated by at most 2 weeks. Evaluated TMS metrics included measures of corticomotor excitability, output, gain, and somatotopy. We calculated agreement properties [Standard Error of Measurement (SEM) and Smallest Detectable Change (SDC)], and reliability$_{MP}$ [Intraclass (ICC) and Concordance (CCC) correlation coefficients].
Results:
Data was obtained from 19 strong muscles (Biceps = 9; Deltoid = 3; EDC = 2; Triceps = 5) and 13 weak muscles (Biceps = 2; Deltoid = 2, EDC = 3; FDI = 1; Triceps = 5). Overall, measurement error was found to be high. Reliability$_{MP}$ values for strong muscles were greater than weak muscles. For strong muscles, active motor threshold, center of gravity in x-direction and active motor evoked potential amplitude had an excellent (ICC>0.90 and CCC>0.80) reliability$_{MP}$, whereas for weak muscles only active motor threshold had an excellent reliability$_{MP}$. Strong and weak muscles had moderate to good (ICC = 0.50-0.80 and CCC = 0.40-0.80) reliability$_{MP}$ for all other variables except for cortical map volume and recruitment curve slope, respectively, which had poor reliability (ICC < 0.50 and CCC < 0.40).
Conclusion:
High agreement values suggest a large change in TMS scores is required to be detected as a true change over and above the inherent measurement noise, therefore evaluative interpretations based on individual TMS change should be made with caution. High reliability$_{MP}$ suggests individuals with tetraplegia can be distinguished from one another using TMS.

Abstract: Dynamic task-specific training in the presence of epidural electrical stimulation (EES), termed multi-modal rehabilitation (MMR), has been shown to restore and enhance motor functions that were paralyzed for years in humans with spinal cord injuries (SCI). Evidence from animal models of SCI with EES and motor training suggests MMR enhanced synergistic functional reorganization of spinal neuronal connectivity resulting in the ability to generate independent stepping and standing in individuals with motor complete SCI. Dynamic task-specific training focuses on providing sensory input to spinal networks below the level of SCI via body weight support and tactile cues from trainers to optimize motor output. Kinematics, posture and joint alignment, as well as stepping speed are major contributing factors to spinal sensory input that impact motor output. Optimization of sensory input in order to improve motor output, termed locomotor training, is a therapeutic strategy to enhance muscle activity during standing or stepping after incomplete SCI. However, enhanced muscle activity does not translate to functional mobility nor neurological recovery for individuals with severe, motor and sensory complete SCI. Our team applied 12 months (approximately 2-3 sessions per week) of MMR in two humans with motor and sensory complete thoracic level SCI. Body weight support, sensory cues, and EES parameters were adjusted within, and across, sessions with the goal of facilitating independent standing and stepping performance. Here, we describe the evolution of intentional control over MMR-enabled motor activity in previously paralyzed muscles, recorded using skin

surface electromyography (EMG), during consistent body weight support, treadmill speed, trainer sensory cues, and EES parameters to assess supra-spinal influence on sensorimotor network activity in both subjects. These results, together with prior evidence from animal models of EES after SCI, indicate reorganization of human spinal network activity, and in turn, functionality, occurs over time in response to MMR.

Title: Comparison of transcutaneous and epidural electrical stimulation evoked motor responses during functional tasks in humans with spinal cord injury

Authors: *J. S. CALVERT[1], P. GRAHN[2], M. GILL[3], C. LOPEZ[3], I. LAVROV[4], M. LINDE[1], J. STROMMEN[1], L. BECK[1], D. VEITH[1], Y. P. GERASIMENKO[5], V. EDGERTON[6], D. SAYENKO[7], K. D. ZHAO[8], K. H. LEE[1];

Inst., Houston, TX; [8]Mayo Clin. Dept. of Physiol. and Biomedica, Rochester, MN

Abstract: Introduction: Epidural Electrical Stimulation (EES) and Transcutaneous Spinal Stimulation (TSS) of the lumbosacral spinal cord have enabled a wide range of functions following spinal cord injury (SCI) in both animal and clinical experiments. Motor evoked responses have previously been used to investigate the effects of spinal stimulation on sensorimotor circuitry. However, the effect of descending voluntary control and ascending sensory input on motor evoked responses in humans has yet to be investigated in detail. Here, we report characteristics of human leg muscle evoked responses during EES- and TSS-enabled

standing and while supine. Methods: Two subjects diagnosed with functionally complete paraplegia due to SCI (American Spinal Injury Association Injury Scale A) were implanted with a 16-contact electrode array (Specify 5-6-5, Medtronic, Fridley, MN) placed over the dorsal epidural surface of the lumbosacral spinal cord (T11-L1 vertebral levels). Ten additional subjects with paraplegia due to SCI were tested with TSS of the lumbosacral cord at the lower thoracic and upper lumbar vertebral bodies. Skin surface electromyography (EMG) was collected from proximal and distal flexor and extensor muscles of the leg. ESS and TSS-evoked motor responses were analyzed during motor activities while supine and standing to characterize spinal network facilitation. Results: Evoked responses due to both EES and TSS resulted in similar characteristics such as amplitude, latency, and shape of response when the subjects were relaxed during supine activities. During voluntary efforts at low frequency stimulation, evoked responses were inhibited in both EES and TSS. Evoked responses during standing resulted in changes in shape, number of peaks, and amplitude compared to supine activities across both modalities. Conclusion: These results demonstrate that human spinal networks can modulate motor evoked responses through a combination of descending voluntary control and ascending sensory input, even years after injury.

Abstract: Translating spinal cord injury (SCI) therapies which promote axonal regeneration from preclinical animal models into the human population is challenging. One potential obstacle is that human genetic predispositions may limit the efficacy of such experimental treatments. The clinically relevant ApoE4 (E4) allele, present in about 14% of the human population, corresponds to an increased incidence of Alzheimer's disease—however, its role in recovery from SCI is poorly understood despite suggestive data implicating its involvement. Indeed, two clinical studies found that SCI individuals with the E4 allele had less motor recovery than individuals without the allele despite longer time in rehabilitation. ApoE4 may mediate this diminished recovery by limiting regeneration and sprouting. Robust regeneration is energy intensive and requires efficient mitochondria, and studies have shown that ApoE4 impairs mitochondrial function. Given these mitochondrial deficits, we hypothesize that ApoE4 can impair regeneration and sprouting. To test this hypothesis, we investigated the impact of ApoE4 on sprouting and neurite outgrowth. In our experiments, we cultured dorsal root ganglia neurons from mice expressing human ApoE isoforms—ApoE2 (E2), ApoE3 (E3), or ApoE4—under the control of the endogenous mouse ApoE promoter. We then analyzed differences in 1) neurite complexity and 2) robustness of outgrowth between genotypes. In two of three independent experiments, E4 neurons had decreased neurite outgrowth and decreased neurite branching compared to E2 and E3 neurons. Data from the Spot Assay, an *in vitro* model of the glial scar and CNS regeneration, also suggest that chondroitin sulfate proteoglycans may inhibit regeneration in E4 neurons to an even greater extent than in E3 neurons. In addition, our preliminary *in vivo* data suggests that serotonergic sprouting after lateral C2 hemisection is impaired in E4 animals. Since outgrowth, sprouting, and regeneration all partially mediate recovery after CNS injury, impairments in these processes can adversely affect recovery. These foundational studies address not only the possible genetic influence of ApoE4 on recovery from CNS injury, but also a critical gap in knowledge—whether there is a genetic contribution underlying responses to treatment in SCI individuals.

Title: Apolipoprotein E modulates respiratory motor plasticity following cervical spinal cord injury

Authors: *L. E. STRATTAN[1,2], K. J. RITTER[1,2], C. M. CALULOT[1,2], D. R. BRITSCH[1,2], A. L. SILVERSTEIN[1,2], E. E. HUFFMAN[1,2], W. J. ALILAIN[1,2];

Abstract: Each year, 17,700 Americans suffer a spinal cord injury, most of which occur at the cervical level. These injuries can interrupt neural pathways controlling breathing. One approach to promote breathing recovery is by enhancing plasticity in the spinal cord by strengthening synapses or activating pathways that were spared by the injury. Activating the latent crossed phrenic pathway can lead to motor plasticity known as long term facilitation (LTF), causing a recovery of breathing motor output. LTF can be induced through intermittent hypoxia (IH) or intermittent serotonin (5-HT) dosing. While a portion of the SCI population responds to IH with an increase in respiratory output, others remain non-responders. This inconsistency suggests that variability in the human population may influence how individuals respond to treatments that aim to enhance plasticity. Therefore, we propose that genetic diversity could be a key factor in determining an individual's propensity for plasticity. Apolipoprotein E (apoE) is a promising candidate gene that could be responsible for this variability. The E4 allele of apoE has previously been shown to reduce synaptic plasticity by decreasing expression of glutamate receptors when compared to the E2 or E3 alleles. This study investigates the impact of human apoE4 on respiratory motor plasticity following SCI. Chronically after C2 hemisection, animals were dosed with one isoform of the human apoE protein, E3 or E4, prior to induction of LTF. Concurrent diaphragmatic EMG recordings were analyzed for changes in breathing motor output indicative of LTF. Subsequent histological analysis of the region of the phrenic motor nucleus (C3-C6) demonstrated that LTF induction led to an increase in synaptic AMPA receptors in E3 animals, but this effect was attenuated in E4 animals. These results suggest that the human apoE allele may be inhibitory to respiratory motor plasticity following cervical spinal cord injury. Therefore, genetic diversity among the human SCI population is an important factor to be considered when developing therapeutics.

Title: Longitudinal analysis of gut microbiome composition after experimental cervical spinal cord injury

Authors: *J. S. NEWTON[1,2], E. E. HUFFMAN[1,2], D. R. STOLTZ[1,2], C. M. CALULOT[1,2], L. HAGER[1,2], R. S. MAGGARD[1,2], W. J. ALILAIN[1,2];

Abstract: Following an experimental C2 spinal cord (SC) hemisection in rats, there is a gradual spontaneous recovery process that can take place over time. Additionally, interventions at later time points are more effective chronically after injury. What is not known is the mechanism mediating this observation. To begin to answer this question, we investigated the role of the gut microbiome after injury. Recent studies have emerged suggesting that the gut microbiome has critical implications on the proper functioning of the central nervous system (CNS). Indeed, gut dysbiosis, or a microbiome imbalance, can occur which can negatively impact the CNS. Neurotrauma, including spinal cord injury (SCI), can lead to acute gut dysbiosis leading to impaired recovery. It is our hypothesis that the composition of the gut microbiome is dynamic after injury with dysbiosis improving over time from an acute post-SCI state. In this study, we build upon these initial studies and investigate the impact of cervical SCI on the gut microbiome over time and up to chronic timepoints, as well as its impact on respiratory motor function and plasticity. In order to test our hypothesis, we performed a C2 hemisection on adult female rats and collected fecal samples from these animals, as well as from non-injured animals in order to assess microbiome composition at various timepoints post injury. Preliminary results suggest that following cervical SCI (up to 20 weeks post injury), robust differences in gut microbiome are apparent compared to non-injured animals. Future studies will classify bacterial identities and assess the impact of the post-injury gut microbiome on respiratory motor function and plasticity. As a majority of the SCI population are at the cervical level and at post-acute stages, this study is both important and translationally relevant.

Title: Investigating the link between cervical spinal cord injury and lung injury/ respiratory distress syndrome

Authors: *E. E. HUFFMAN[1,2], J. S. NEWTON[1,2], D. R. STOLTZ[1,2], L. HAGER[1,2], W. J. ALILAIN[1,2];
[1]Spinal Cord and Brain Injury Res. Ctr., [2]Neurosci., Univ. of Kentucky, Lexington, KY

Abstract: The global incidence rate of traumatic spinal cord injury (SCI) is an estimated 768,473 persons per year, the majority of which occur at the cervical level. These high-cervical SCIs disrupt respiratory pathways and disable autonomous breathing, which introduce morbidity and mortality to SCI individuals. It has been shown that SCI individuals are at risk for developing acute respiratory distress syndrome (ARDS) and acute lung injury (ALI). ARDS/ALI are life-threatening diseases of the lung. They are primarily characterized by respiratory failure, widespread lung inflammation, intra-alveolar edema, and alveolar-capillary membrane damage. ARDS represents the most severe form of lung injury, while ALI is its less severe counterpart. However, in SCI individuals, the presence of either of these lung injuries predicts substantial mortality rates. While the correlative relationship between ARDS/ALI and SCI has been explored in retrospective clinical studies, the causal relationship is not well understood. Elucidating the relationship between SCI and ARDS/ALI may enable new ARDS/ALI treatment via techniques previously reserved for high-cervical SCI individuals. The present study attempts to explore the potentially causal relationship between SCI and ARDS/ALI in the rat model. We performed a C2 hemisection injury to the rat model and assessed ARDS/ALI at various timepoints. Our preliminary studies found an increased bacterial presence in the lung microbiome of SCI rats. This has been observed in human ARDS/ALI patients and is suggestive of an increased alveolar membrane permeability that is susceptible to bacterial translocation. Changes to the lung microbiome and alveolar-capillary membrane after SCI will be investigated in continuing studies. Additionally, we will verify the presence of ARDS/ALI by characterizing lung inflammation and evaluating interstitial edema. Collectively, this study and future directions will verify the mechanistic link between ARDS/ALI and SCI. This will be used to identify potential therapies to ameliorate respiratory distress and lung injury after SCI.

Title: Antinociceptive properties of highly potent and selective state-independent inhibitors of Nav1.7

Authors: *J. T. BECKLEY[1], H. PAJOUHESH[2], G. LUU[2], S. KLAS[1], D. MONTELEONE[2], X. ZHOU[2], A. DELWIG[2], D. C. YEOMANS[3], J. C. HUNTER[2], J. V. MULCAHY[2];
[1]SiteOne Therapeut., Bozeman, MT; [2]SiteOne Therapeut., South San Francisco, CA; [3]Stanford Univ., Stanford, CA

Abstract: The voltage gated sodium channel (Nav) isoform Nav1.7 is highly expressed on dorsal root ganglia neurons that transmit nociceptive signals in response to noxious stimuli. Loss-of-function mutations of Nav1.7 result in congenital insensitivity to pain while gain-of-function mutations are associated with severe, episodic pain disorders. These findings implicate inhibition of Nav1.7 as a strategy for the discovery of novel non-opioid pain therapeutics. By leveraging natural guanidinium toxins as a molecular template, SiteOne Therapeutics has discovered a series of selective, small molecule Nav1.7 inhibitors. The objective of this study was to assess the potency and selectivity of these molecules and to evaluate the analgesic efficacy on a broad panel of animal pain models. Potency and selectivity were determined using whole-cell patch clamp electrophysiology with either stably or transiently transfected cell lines. Analgesic efficacy was assessed with acute pain models that evaluated nociceptive sensitivity to noxious thermal, mechanical, and chemical stimuli, and also with models that generated injury-evoked nociceptive hypersensitivity. Experimental procedures were approved by an Institutional Animal Care and Use Committee in accordance with the NIH Guide for the Care and Use of Laboratory Animals and conducted at an AAALAC-accredited facility. Efforts were taken to minimize pain and distress of animals. We have identified compounds with Kd values for human Nav1.7 that are less than 10 nM, with greater than 1000-fold selectivity over other Nav isoforms tested (Nav1.1-Nav1.8). These compounds were near equipotent on resting/closed and state-dependent protocols, indicating that they are state-independent inhibitors. In mice, compounds administered subcutaneously (SC) produced dose-dependent reductions in sensitivity to noxious thermal, mechanical and chemical stimuli. Naloxone did not reverse Nav1.7 inhibitor mediated antinociception in the thermal plantar test, indicating that analgesic efficacy was independent of mu opioid receptor activation. In a mouse model of incisional pain, SC administration of test compounds both reversed the thermal hypersensitivity in the injured paw and produced analgesia to the thermal stimulus in the non-injured paw. Our results support the hypothesis that targeting the extracellular vestibule of the channel is a viable strategy for selectively engaging Nav1.7 and suggest that state-independent Nav1.7 inhibitors may be efficacious pain therapeutics.

Title: GPR160 as a novel target for the treatment of chronic neuropathic pain

Authors: *C. M. HARADA[1], Z. CHEN[1], L. A. GIANCOTTI[1], C. HADDOCK[1], T. M. DOYLE[1], G. KOLAR[2], W. K. SAMSON[1], G. L. C. YOSTEN[1], D. SALVEMINI[1];
[1]Pharmacol. and Physiol., [2]Pathology, St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: Approximately 100 million American adults suffer from chronic pain that half consider to be uncontrolled. Increased medical costs and lost work amount to roughly $600 billion yearly in the United States alone. Over-the-counter drugs for mild to moderate pain often fail to control chronic pain; patients then turn to prescription drugs like antidepressants and opioids. However, antidepressants and opioids are not always effective and come with the risk of severe side effects. Opioids and other prescription pain killers accounted for 40% of accidental overdose deaths in 2015 and are at the heart of the current epidemic. Our research addresses the clear and urgent need for new non-narcotic treatments for chronic neuropathic pain by identifying a novel target: orphan G-protein coupled receptor GPR160 (**GPR160**). We screened a gene library of orphan G protein-coupled receptors to find a novel target for chronic pain treatment. We found GPR160 mRNA to be upregulated in a rodent chronic constriction injury (**CCI**) model of chronic pain. Previously, GPR160 was only known to be upregulated in certain cancers and in maturation and survival of prostate cancer cells. Our lab then established that attenuation of GPR160 gene and protein prevents and reverses mechanical allodynia in a rodent CCI model of pain. In addition, we have identified the endogenous ligand for GPR160. We found exogenous ligand induces mechanical sensitivity in rodents that is attenuated with GPR160 inhibition. Using this ligand we have discovered that GPR160 activation causes pain in a discrete pathway previously unknown to be related to GPR160 (manuscript in review). Interference in this pathway through the use of select small molecule inhibitors reverses established chronic pain. Moving forward, we are investigating GPR160 signaling in other rodent models of chronic pain. Our data suggests that GPR160 signaling is involved in multiple models of chronic pain, forming a novel and common mechanism. Our work establishes the basis

for further investigation into the development of pharmacological agents targeting GPR160 to treat chronic neuropathic pain.

Title: Pepducins derived from the intracellular loops of the neurotensin type 1 receptor relieve pain

Authors: *R. L. BROUILLETTE[1], É. BESSERER-OFFROY[2], C. MONA[3], M. CHARTIER[1], S. LAVENUS[1], J. CÔTÉ[1], M. SOUSBIE[1], K. BELLEVILLE[1], J.-M. LONGPRÉ[1], É. MARSAULT[1], M. GRANDBOIS[1], P. SARRET[1];

Abstract: In recent years, innovative approaches have been developed to better exploit the therapeutic potential of G protein-coupled receptors (GPCRs), a receptor family which has known remarkable success in drug discovery and development. These approaches include the design of cell-penetrating lipopeptides termed “pepducins” that are composed of a peptide sequence mimicking one of the intracellular loops of a GPCR of interest, conjugated to an N-terminal palmitic acid. The lipid moiety effectively anchors the pepducin to the cell membrane and facilitates its translocation into the cell, where it functionally interacts with its cognate GPCR at the receptor-effector interface. By doing so, pepducins may behave as allosteric

agonists or allosteric modulators of their target receptor. We recently designed a series of pepducins derived from the intracellular domains of the human neurotensin type 1 receptor (hNTS1), a GPCR which mediates many of the physiological effects of the neurotensin (NT) tridecapeptide, including analgesia, hypotension and hypothermia. Here, we report the cellular and physiological actions of this pepducin series. In CHO-K1 cells stably expressing hNTS1, we used BRET-based biosensors to monitor the pepducins' ability to engage G protein-dependent and G protein-independent signaling pathways. We found that our pepducin series preferentially promoted GαoA and Gα13 activation over β-arrestin recruitment, and inhibited NT-mediated β-arrestin recruitment, thus acting both as biased allosteric agonists and negative allosteric modulators of NTS1. Additionally, administration of the ICL1-derived pepducin, PP001, enhanced hNTS1 homomerization in a BRET titration experiment. *In vivo*, we found that i.t. administration (275 nmol/kg) of PP001 significantly reduced the rat nociceptive behaviors in acute (tail-flick), tonic (formalin), and neuropathic (chronic constriction injury) pain models. In contrast, ICL2-, ICL3- and C-terminal tail-derived pepducins did not reduce the pain response. Following i.t. injection, we further found by confocal microscopy that a TAMRA-labeled pepducin could reach the sensory neurons of the dorsal root ganglia. Finally, in order to elucidate which residues are critical for these actions, we synthesized an Ala-scan of PP001, monitored its effects on a CHO-hNTS1 cell monolayer by Electric Cell-substrate Impedance Sensing, and identified a critical ARKK motif. Altogether, our results indicate that our pepducin series modulates NTS1 receptor function and may thus serve to inform the design of novel NT-based analgesics.

Title: GPR183 as a novel target for the treatment of neuropathic pain

Authors: *K. I. BRADEN, L. A. GIANCOTTI, Z. CHEN, D. SALVEMINI;
Dept. of Pharmacol. and Physiol., St. Louis Univ., Saint Louis, MO

Abstract: Neuropathic pain is a huge unmet medical need. It is estimated that approximately 7-13% of the general population suffers from neuropathic pain. The current treatment options are associated with unacceptable side effects coupled with minimal efficacy, therefore new targets are necessary. Our receptomic and unbiased transcriptomic approaches have identified the G-protein coupled receptor, **GPR183**, as a major GPCR whose transcript is significantly increased in the dorsal horn of the spinal cord ipsilateral to nerve injury in a model of traumatic nerve-injury induced neuropathic pain caused by constriction of the sciatic nerve in rats (CCI). The role of GPR183 signaling in nociceptive processing is not known. GPR183, also known as Epstein-Barr induced gene 2 (EBI2), was recently de-orphanized and its ligand identified as the oxysterol, 7α,25-dihydroxycholesterol (**7α,25-OHC**). GPR183 is expressed in the central nervous system (CNS) on astrocytes and microglia in humans and rodents.
Our findings reveal for the first time that acute intrathecal injection of 7α,25-OHC (23-240nM) in rodents caused a dose-dependent development of mechano-allodynia, that was blocked by pretreatment with an intrathecal injection of the GPR183 antagonist, NIBR189 (23μM), suggesting that GPR183 activation is pronociceptive. Moreover, systemic administration of NIBR189 (10mg/kg) at the time of peak mechano-allodynia after CCI surgery (D7) reversed allodynia in a time-dependent manner. These findings provide the first insight into the role of GPR183 signaling in neuropathic pain, warranting further investigation towards validating this receptor as a potential therapeutic target for the treatment of pain.

Title: Frequency-dependent modulation of action potential transmission in afferent axons by DRG stimulation

Authors: *L. CHEN, T. GUO, S. SIRI, B. FENG;
Biomed. Engin., Univ. of Connecticut, Storrs, CT

Abstract: Background: Neuromodulation of dorsal root ganglion (DRG) has emerged as an effective therapy to relieve chronic pain. Compared to spinal cord stimulation that evokes paresthesia to mask the area of pain, effective DRG stimulation causes significantly less area of paresthesia and can even relieve pain in some patients with no appreciable paresthesia. We hypothesize that DRG stimulation can alleviate pain in the absence of paresthesia by blocking

action potential transmission in afferent axons. In this study, we implement ex vivo single-unit recordings from split dorsal root to assess the neuromodulatory effect of DRG stimulation on action potential transmission in mouse afferent axons at different frequencies. Methods: The L6 spinal nerve, DRG and dorsal root were harvested in continuity from male C57BL/6 mice (8-12 weeks, 25-35 g) and transferred to a tissue chamber flowed with oxygenated Krebs solution at 30°C. The L6 dorsal root was gently pulled into an adjacent recording chamber filled with mineral oil and carefully split into fine filaments (~ 10 μm) to record single-unit action potentials evoked by electrical stimulation of the L6 spinal nerve (0.5 Hz, 0.2 msec pulse width, cathodic 0.2-2 mA) via a suction electrode. A needle electrode (FHC, platinum-iridium, tip size ~Φ10 μm) contacting the dura mater of L6 DRG was used to deliver neuromodulatory stimuli (bipolar stimulation, cathodic first, constant current, 0.1 msec pulse width) to assess the effect of DRG stimulation on action potential transmission in afferent axons at a wide range of frequencies (10, 50, 100, 500, 1000 Hz). Data were digitized at 24 kHz, stored using a Tucker-Davis Technologies system (RZ5D, PZ5-32) and processed offline with customized programs (Mathworks R2018a). Results: The optimal frequency to achieve transmission block with the least stimulation duration is within 50 to 500 Hz for all tested afferents. Our preliminary data indicate the optimal frequency of 50 Hz to block unmyelinated C-fibers and 100-500 Hz to block thinly myelinated Aδ-fibers. Interestingly, DRG stimulations with frequency below or above the optimal range require longer duration to achieve transmission block, and the highest frequency tested (1000 Hz) can fail to block action potential transmission in some afferents. Conclusion: This study reveals the frequency-dependent blocking of action potential transmission in mouse L6 afferent axons by DRG stimulation. Outcomes of this study strongly suggest the therapeutic potential of DRG stimulation at optimal frequency range to attenuate nociceptive pain by blocking the neural transmission of sensitized afferents.

Title: The effect of music on the pain of adults in the intensive care unit: A systematic review of randomized controlled trials

Authors: *M. RICHARD-LALONDE[1], C. GÉLINAS[1,2], M. BOITOR[1], E. GOSSELIN[1], N. FEELEY[1,2], S. COSSETTE[3], L. L. CHLAN[4];

[1]Ingram Sch. of Nursing, McGill Univ., Montreal, QC, Canada; [2]Ctr. for Nursing Res., Jewish Gen. Hosp., Montreal, QC, Canada; [3]Nursing, Univ. de Montréal, Montreal, QC, Canada; [4]Mayo Clin., Rochester, MN

Abstract: Introduction. Pain is prevalent in the adult intensive care unit (ICU), where clinical guidelines recommend using multimodal analgesic approaches. Music has been shown to reduce pain in other clinical settings. However, the effectiveness of music interventions on pain reduction in the adult ICU remains unknown. The objective was to determine the immediate [MRL1] effects of single-session music interventions on pain in the adult ICU, compared with standard care or noise reduction. Secondary objectives were to conduct subgroup analyses based on music intervention duration, music choice, timing, and provider. **Methods**. The protocol for this review was registered on PROSPERO (CRD42018106889). Medical (e.g. Medline, Cochrane) and music (e.g. Music Index, ViFaMusik) databases were searched for randomized controlled trials (RCTs) on music use in the adult ICU setting with the search terms [“music*” and (“critical care” or “intensive care”)]. Outcomes of pain were included for patients able to self-report (0-10 or 0-100 rating scales) and for patients unable to self-report (0-8 Critical-Care Pain Observation Tool or 3-12 Behavioral Pain Scale). Each study was reviewed by two independent reviewers for screening and data extraction. **Results**. Eighteen RCTs were found. Sample sizes ranged from 17 to 156 and included 1173 participants. The mean age of participants was 60 years old with 60% males and 40% females. Most RCTs included patients able to self-report (83%, n=978/1173). Studies with high risk of bias for randomization, allocation concealment and incomplete data were then excluded, leaving 10 studies to be included in the meta-analysis with a total of 706 participants, with a mean age of 55.9 years, 48.7% male and 51.3% female, all able to self-report. Music was found to be significantly effective in pain intensity reduction, with a standardized mean difference (SMD) of -0.78 [95% confidence interval (CI) -1.48, 0.09] when compared to standard care and a SMD of -0.51 [-1.12, 0.09] when compared to noise reduction. Duration was found to impact effectiveness of the music with interventions of a minimal duration of 20 min leading to a larger decrease in self-reported pain intensity. Subgroup analyses revealed that, compared to standard care 20-30 min of music significantly reduced self-reported pain intensity (SMD -1.07 [-1.63, -0.52]); and compared to noise reduction, 20-30 mins of music significantly reduced self-reported pain intensity (SMD -0.80 [95% CI -1.06, -0.55]). **Conclusion**. In the adult ICU, music interventions of a minimal duration of 20 minutes are effective to reduce pain.

Title: Development of selective kappa opioid receptor antagonists for the treatment of chronic neuropathic pain

Authors: *M. HOSSAIN[1], G. JI[2,3], T. J. ABBRUSCATO[1], V. NEUGEBAUER[2,3,4], N. A. GERMAN[1,3];
[1]Pharmaceut. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., Amarillo, TX; [2]Dept. of Neurosci., [3]Ctr. of Excellence for Translational Neurosci. and Therapeut. (CTNT), [4]Garrison Inst. on Aging, Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Kappa opioid receptor (KOR) plays a vital role in neurological conditions including physiological functions and pathological disorders. KOR agonists modulate analgesia, diuresis, dysphoria, and show antipruritic activity. In addition, KOR antagonists can alleviate many CNS-related conditions, such as chronic pain, cocaine addiction, depression, psychosis, and schizophrenia. There is a need for the development of selective KOR antagonists. We identified a novel highly selective KOR antagonist with a *Ki* of 277 nM. This compound has shown excellent ability to cross the BBB *in vitro* (Papp 15.15) and *in vivo*. This compound is pharmacologically active in the well-established spinal nerve ligation (SNL) model of neuropathic pain in rats. In this experiment, a 40 - 50% reduction in pain-related behaviors was observed, using different outcome measures such as mechanical and thermal sensory thresholds (von Frey filaments and the tail-flick tests), audible and ultrasonic vocalizations. Here we report results from our ongoing work focused on the optimization of potency and drug-like profile of this hit molecule using a variety of medicinal chemistry approaches. Activity data of the proposed library of compounds are combined with the known crystal structure of the human KOR and used to build a comparative molecular field analysis (CoMFA) to enable in silico drug design. A variety of *in vitro* biological assays provide target validation and elucidate toxicity profiles of selected compounds. Overall, we report the development of a new class of highly selective kappa-opioid receptor antagonists with therapeutic potential for the treatment of neuropathic pain.

Title: Spinal electromagnetic stimulation results in immediate pain reduction and induces long-lasting functional improvements in patients with chronic low back pain (LBP). A pilot study

Authors: *H. PETROSYAN[1,2], M. FAHMY[2], A. TESFA[2], L. LIANG[2,1], V. ARVANIAN[2,1]; [1]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY; [2]Northport VAMC, Northport, NY

Abstract: Chronic LBP is one of the main causes of disability affecting general population. About 80 percent of adults experience low back pain at some point in their lifetime. Opioids is the most common prescription drug in US adults with chronic LBP. Many alternative treatments currently used in clinics, including medication, acupuncture, physical therapy, electrical nerve stimulation and even surgery. However, there is no effective treatment available. In this study we have examined the effects of non-invasive electromagnetic stimulation (EMS) applied at lumbosacral level on pain reduction in patients suffering from chronic LBP. EMS is a non-invasive painless method of stimulating central and peripheral nervous systems. EMS is based on the principle of electromagnetic induction of an electric field through intact tissue to underlying structures. Repetitive EMS applied at cranial level (TMS) was found to alter excitability at cortico-motor circuitry and currently is an FDA approved treatment for drug resistant depression. We recently found that low frequency (0.2 Hz) EMS over the spinal cord induced neuromodulation of H-reflex responses, i.e. decrease in threshold intensity and facilitation of H-responses in chronic spinal cord injured rats. Importantly, in healthy human participants EMS applied at 0.2 Hz on L4-S1 spinal levels induced similar neuromodulation of H-reflex responses, i.e. leftward shift in threshold intensity and facilitation of H-responses. In animal models, in contrast with low frequency EMS, administration of high frequency (20Hz) EMS induced significant reduction of H-reflex amplitude and rightward shift of threshold intensities. In this study we have examined how, high frequency 20Hz spinal EMS is affecting humans suffering from chronic low back pain. The patients received up to 10 sessions of spinal EMS administered every other day. During each session participants received total 4000 pulses containing of 5 seconds of stimulation administered at 20Hz with 25 seconds break between. Pain was evaluated before and after each session using Visual Analog Scale (VAS) as well as Oswestry Disability

Index (ODI) was used to assess effects of treatment on functional changes. Our results revealed that spinal EMS resulted in immediate significant pain reduction at each session. Importantly, as the study progressed, prolonged administration of EMS resulted in overall sustained pain relief. These results demonstrate that SEMS can serve as an effective, non-invasive treatment approach for chronic low back pain. Further animal studies are required to examine mechanisms underlying these effects and are currently being conducted in our lab

Title: Development of a NTS2-selective macrocyclic neurotensin (8-13) analog showing a good analgesic benefit/adverse effect profile

Authors: *M. CHARTIER, M. DESGAGNÉ, L. HAROUNE, M.-A. DANSEREAU, J.-M. LONGPRÉ, E. MARSAULT, P. SARRET;
Inst. De Pharmacologie - Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: Neurotensin (NT), which acts as a neuromodulator in the central nervous system produces potent opioid-independent analgesia. These NT's antinociceptive effects are exerted through activation of two NT receptor subtypes (NTS1 and NTS2), that belong to the class A GPCR family. NT is also responsible for other physiological effects, such as hypotension and hypothermia which are exclusively related to NTS1 activation. NTS2 is therefore a target of interest for developing new chemical entities showing good analgesic activity with minimal adverse effects. In addition, as a peptide, NT exhibits low oral bioavailability and poor resistance to proteolytic degradation which further limit its therapeutic use. Herein, Tyr^{11} was replaced by a Trp of NT(8-13), and a side-chain to side-chain macrocyclization was used to constrain the peptide conformation and improve its biological and metabolic properties. This study was thus aimed to characterize the antinociceptive activities of this macrocyclic NTS2-selective analog and to investigate its potential adverse effects. This macrocyclic NT analog exhibits 7.5 nM binding affinity for NTS2, with approximately 110 times lower affinity for NTS1 (871 nM), as well as an improved plasma stability profile (&gt24h) compared to NT (≈ 2 min). Analgesic efficacy was determined in rat pain models following intrathecal administration of escalating doses of the macrocyclic analog (ranging from 3 to 60 µg/kg). This constrained peptide

displayed dose-dependent and long-lasting analgesic effects in acute (ED50 = 17.69 µg/kg) and tonic pain (ED50 = 8.75 µg/kg), as assessed by the thermal tail-flick test and the formalin persistent pain model, respectively. The maximal possible effect in acute pain reached 100% with the highest dose tested. This NTS2-preferring analog also exhibited a potent mechanical antiallodynic effect at 60 µg/kg on days 7 and 14 in the CFA-induced chronic inflammatory pain model. Potential NT's adverse effects were also monitored by measuring changes in body temperature (60 µg/kg, i.t.), mean arterial blood pressure (0.01 and 0.1 mg/kg, i.v.) as well as smooth muscle contraction of isolated rat ileum (10^{-11} to 10^{-5}M). Our results revealed that this compound did not cause hypothermia or ileum relaxation but induced slight and short-lasting hypotension. Altogether, this NTS2-selective compound was found to be effective in reversing the nociceptive behaviors in three distinct rodent pain models without having serious adverse effects. These results thus highlight the strong therapeutic potential of NTS2-selective analogs for the management of chronic pain.

Title: Efficacy of tramadol is lost in the late phase of the MIA-induced OA joint pain model in rat

Authors: H. RASHID, *J. DOUVILLE, R. SAMADFAM;
Charles River Labs. Montreal, Senneville, QC, Canada

Abstract: The atypical centrally acting analgesic tramadol is used for a variety of chronic pain conditions including chronic osteoarthritic (OA) joint and musculoskeletal pain. Tramadol is known to act through its weak opioid and monoaminergic mechanisms, and fewer side effects are reported than with traditional opioids. In the present study, we examined if efficacy of tramadol is maintained in the mono sodium iodoacetate (MIA)-induced OA joint pain model in rat when used over a longer duration, specifically in the NSAID-refractory late phase of the model. Joint pain was induced in rats by a single intra-articular injection of MIA (3 mg) into the right knee joint. Weight bearing deficit of the MIA-injected limb was then measured as an indication of joint pain using the Automated Dynamic Weight Bearing (ADWB) system. Tramadol was administered orally at 60 mg/kg in two different dosing protocols. In the first protocol, rats received tramadol twice daily continuously from Day 14 to Day 28 post model induction which is considered as the late phase of the MIA model. In the second protocol,

tramadol was administered only before each ADWB test (3 dosing over 2 days). Weight bearing assessments post tramadol dosing were performed on Days 15, 18, 21 and 28. ADWB data were analyzed off-line using the BioSeb software. A single intra-articular injection of MIA caused a significant reduction in weight bearing by the ipsilateral limb indicating presence of joint pain. The window of weight bearing deficit in the MIA rats was maintained during the assessment period of Day 14 to 28. In the first protocol when tramadol was continuously dosed from Day 14 to 28, moderate and significant relief of joint pain was observed on Day 15 only. Analgesic effects then gradually decreased over time and no significant effects were observed on Days 18, 21 and 28. In the second protocol, we wanted to examine whether loss of efficacy of tramadol was due to an apparent tolerance associated with the continuous dosing regimen, therefore effects of tramadol were assessed following dosing only before each ADWB test occasion. In this second protocol, tramadol produced moderate and significant effects on Day 15, and some minor but statistically significant effect was also observed on Day 18 while no effects were seen on Days 21 and 28. Overall, both dosing regimen of tramadol were not able to significantly change the MIA late phase pain response. This might be mainly due to the model's inherent characteristics of gradual joint deterioration and nature of pain in this late phase. These results also suggest that a minor role of tolerance by tramadol may also contribute to the efficacy loss.

Title: Role of 5-HT_{2A} receptor in potentiation of oxycodone antinociception

Authors: S. SIERRA[1], X. CUNO LAVILLA[1], D. STEVENS[2], K. CONTRERAS[2], M. DAMAJ[2], W. DEWEY[2], J. GONZALEZ-MAESO[1];
[1]Dept. of Physiol. and Biophysics, [2]Dept. of Pharmacol. & Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Although opioid analgesics can rapidly relieve pain, their chronic use presents serious side effects including opioid overdose and addiction. Serotonin receptors, including the 5-HT_{2A}R, have been involved in a number of processes related to nociception. However, the antinociceptive effects induced by 5-HT_{2A}R receptor ligands and the neural circuits related to 5-HT_{2A}R-dependent pain management remain largely unexplored. Here we characterized the

neuroanatomical localization of 5-HT_{2A}R in the tail-flick reflex (TFR) circuit, and tested the effects of the 5-HT_{2A}R antagonist volinanserin (or M100,907) on antinociceptive, exploratory and rewarding behavioral phenotypes induced by the μ-opioid receptor agonist oxycodone. To do so, we first performed immunostaining in mouse dorsal root ganglion (DRG) and lumbar spinal cord. Hot water immersion test was carried out in adult C57BL/6 male mice. Animals were pretreated (i.p.) with volinanserin (0.03, 0.06 or 0.125 mg/kg), or vehicle, after which animals received cumulative doses (p.o.) of the μ-opioid receptor agonist oxycodone (0.25 to 32.0 mg) or the CB_1R/CB_2R agonist CP55,490, or vehicle. For locomotor activity and conditioned place preference (CPP) tests, mice were pretreated with volinanserin after which animals received a single dose of oxycodone. Our immunostaining experiments show that 5-HT_{2A}R is present in the DRG and ventral horn neurons of the spinal cord. Behavior assays suggest that volinanserin increases the antinociceptive effects of oxycodone, but not of CP55,490 in male mice. Additionally, volinanserin significantly decreases the hyperlocomotor activity induced by oxycodone whereas in the CPP test this 5-HT_{2A}R antagonist does not potentiate rewarding effects of oxycodone. Overall, these results suggest that 5-HT_{2A}R antagonism represents a novel and highly selective opioid-sparing pharmacological tool to reduce nociception in mice.

Title: Sex differences in THC-induced recovery of activity in rats with hindpaw inflammation

Authors: A. WILSON-POE, ***A. A. BARADAR**, J. STICKNEY, M. M. MORGAN; Washington State Univ. Vancouver, Vancouver, WA

Abstract: The current opioid abuse crisis highlights the need for alternative pain medications. Cannabis has been proposed as a less addictive pain treatment, but cannabis is composed of many psychoactive substances and the effects on different pain conditions are not clear. Tetrahydrocannabinol (THC), the primary psychotropic substance in cannabis, has been shown to inhibit inflammatory pain in laboratory animals, but the high doses used in previous studies (e.g., 3.2 mg/kg) impair motor function thereby confounding assessment of nociception. The objective of the present study was to determine the ability of low doses of THC to restore

activity depressed by persistent inflammatory pain. Male and female Long-Evans rats were housed individually in a cage with a running wheel. Baseline activity was assessed on the seventh day in this cage. Hindpaw inflammation was induced immediately before the dark phase on Day 8 by injecting Complete Freund's Adjuvant (CFA) into the right hindpaw. Rats were injected with vehicle or THC (0.32, 0.56, or 1.0 mg/kg, s.c.) 48 hours after CFA injection. Administration of CFA into the hindpaw caused an almost complete depression of wheel running in both male and female rats. THC administration 48 hours later caused a transient recovery of wheel running that differed in female and male rats. In female rats, all three doses of THC caused a recovery in wheel running that exceeded baseline running and lasted approximately 1 hour. The lowest THC dose (0.32 mg/kg) caused the greatest recovery in wheel running. THC had almost no effect in male rats, although administration of the highest THC dose (1 mg/kg) caused a slight increase in wheel running (40% of baseline running levels). These data confirm in Long-Evans rats our previous data showing CFA-induced depression of wheel running in Sprague Dawley rats (Kandasamy et al., 2016). These data also confirm previous reports of greater antinociceptive effects of THC in female compared to male rats (Craft et al., 2012), but at much lower doses. THC-induced recovery of wheel running reveals that low doses of THC can produce antinociception in the absence of disruptive side effects.

Title: Dexpramipexole blocks $Na_v1.8$ sodium channels and affords analgesia in multiple nociceptive and neuropathic pain models

Authors: *M. URRU[1], M. MUZZI[1], E. COPPI[2], G. RANIERI[1], D. BUONVICINO[1], E. CAMAIONI[3], A. PUGLIESE[2], B. S. TANAKA[4], M. ESTACION[4], S. G. WAXMAN[4], S. D. DIB-HAJJ[4], A. CHIARUGI[1];

Abstract: Pain control is a vast, unmet medical need with a high societal cost impact. Current treatments (opioids, NSAIDs, antidepressants or anticonvulsants) are frequently inadequate or associated with adverse side effects. Voltage-gated sodium channels (Na_v) are crucial mediators of nociceptive transmission. Among these channels, the $Na_v1.8$ isoform is predominantly expressed in dorsal root ganglion neurons (DRG), a critical hub of nociceptive transmission. Dexpramipexole (DEX) is the R-isomer of the antiparkinson drug pramipexole. DEX recently failed a large phase III study in ALS patients, however, shows a favorable safety profile. Prior work from our group shows that DEX reduces I_A K^+ currents in rat hippocampal neurons. Here, we investigated the effect of DEX on sodium currents (I_{Na}) in rodent DRG neurons, as well as on pain-related behavior in different experimental models.
Patch clamp experiments demonstrated that DEX inhibits I_{Na} currents in a reversible manner with a IC_{50} of 294.4 nM. Inhibition appears selective for the Nav1.8 isoform, being absent in Nav1.8-null DRG neurons. Accordingly, DEX affords analgesia in nociceptive (formalin, writhing, inflammatory) and neuropathic (oxaliplatin, nerve ligation, diabetes) when administered at clinically-consistent doses (3 or 10 mg/kg) by means of i.p., oral or topical routes.
In light of the good safety profile of DEX in humans, our data point to a realistic translational potential of DEX for the treatment of different pain disorders.

Title: Potent analgesic activity of the novel M1/M4-selective muscarinic agonist NSX-0527

Authors: *J. OCKULY, J. BECK, S. HANSON, M. HENDRICKSON;
NeuroSolis, Inc., Madison, WI

Abstract: Despite many years of reluctance, the “opioid epidemic” has lately risen to the level of a national emergency in the public’s awareness. Medical treatments for both acute and chronic pain have relied heavily on morphine and morphine derivatives for centuries, along with the tacit acknowledgement that these compounds have an extremely heavy potential for addiction and subsequent abuse. The neurological expiation of opiate addiction can be summarized briefly as a disinhibition of dopaminergic pathways within structures of the basal ganglia associated with reward-seeking behavior and emotion. Novel analgesic drugs that bypass the dopaminergic

system are in higher demand than ever before. Muscarinic agonists are a class of compounds demonstrating clear analgesic activity, likely acting via stimulation of GABAergic interneurones within the brain and spinal cord, but previous attempts to develop drug candidates (e.g. xanomeline) have been abandoned due to poor tolerability. The novel M1/M4-selective orthosteric muscarinic agonist NSX-0527 and close-in analogue NSX-0559 were evaluated to determine their feasibility as analgesic drug candidates. Both compounds show good bioavailability (~75%) and brain penetration (~60%) along with excellent metabolic stability. In the tail-flick assay, they were more potent than morphine and xanomeline at inhibiting a spinally-mediated reflex response to a painful stimulus. Additionally, NSX-0559 was shown to have no activity at dopaminergic receptors - in fact, its efficacy is exclusively limited to muscarinic receptors, making potential side-effects predictable and manageable. In summary, NSX-0527 and NSX-0559 represent potential first-in-class antinociceptive treatments that are efficacious, well tolerated, and critically lack the capacity for addiction and abuse.

Title: Non-viral delivery of OPRM1 gene and F2RL1 RNAi for oral cancer pain

Authors: ***K. INOUE**[1], N. H. TU[1], J. DOLAN[2], K. IMAMURA[4], S. YAMANO[3], B. L. SCHMIDT[1];
[1]Bluestone Ctr. for Clin. Res., [3]Dept. of Prosthodontics, [2]New York University, Col. of Dent., New York, NY; [4]Dept. of Periodontology, Tokyo Dent. Col., Tokyo, Japan

Abstract: Oral cancer patients often suffer from severe function-induced pain during eating, drinking and speaking. Quality of life is severely degraded in these patients. The intensity and prevalence of pain is generally higher in patients with oral cancer than in patients with other

types of cancer. We seek to eliminate oral cancer pain by reversing epigenetic changes with gene therapy. Our work will set the stage for a new class of drugs that selectively disrupt nociceptive signaling with limited side effects. Viral vector-based treatment of cancer pain has been evaluated in preclinical studies but is plagued by problems with immune response, limited DNA carrying capacity, and high cost. Synthetic, non-viral vectors might preclude these obstacles. To improve non-viral gene transfer efficiency, we developed a novel non-viral hybrid vector - a cell-permeable peptide combined with a cationic lipids.
OPRM1 gene encodes the μ-opioid receptor and is methylated and transcriptionally silenced in human oral squamous cell carcinoma. F2RL1 gene encodes protease-activated receptor 2 (PAR2). PAR2 belongs to the G-protein-coupled receptor family and is expressed in many cancer types. PAR2 is associated with tumor progression, production of pro-tumor cytokines and pain. The aim of this study was to attenuate oral cancer pain with OPRM1 gene and F2RL1 RNAi delivered with a non-viral vector.
We evaluated the efficacy of non-viral gene therapy (F2RL1 and RNAi) in an oral cancer mouse model generated with the carcinogen 4-NQO. We employed a dolognawmeter assay as well as hind paw withdrawal and thermal hyperalgesia assays to determine whether the gene therapy, (OPRM1 gene expression and F2RL1 gene suppression) produced anti-nociceptive effects. Our *in vitro* work revealed that F2RL1 was knocked down in HSC-3 cells and that mouse TG cells decreased F2RL1 gene expression. Cell proliferation of HSC-3 cells was also inhibited. Our *in vivo* work revealed that the mice with tongue tumors treated with F2RL1 RNAi exhibited decreased gnaw time in the dolognawmeter compared to random RNAi (indicating less nociception after treatment). In addition, mice treated with F2RL1 RNAi with and without OPRM1 gene exhibited higher mechanical and thermal thresholds.
We infer from our findings that non-viral delivery of the OPRM1 gene and F2RL1 RNAi targeted to the cancer microenvironment produce an analgesic effect. Accordingly, we assert that non-viral gene delivery holds potential for cancer pain treatment.

Title: Prevention of opioid-self administration by agmatine-based analogues

Authors: *C. PETERSON[1], K. PFLEPSEN[1], K. KITTO[1], G. L. WILCOX[2], C. A. FAIRBANKS[3];
[1]Univ. of Minnesota, Minneapolis, MN; [2]Dept Neurosci, Pharmacol, Dermatol, Univ. Minnesota Med. Sch., Minneapolis, MN; [3]Depts Pharmaceut, Pharmacol & Neurosci, Univ. Minnesota, Minneapolis, MN

Abstract: B**ackground:** Chronic pain is a broadly experienced, debilitating condition that is a heightened health concern due to the concurrent pain and opioid epidemics. The currently available options for the treatment and management of chronic pain, opioids, are associated with risk of conversion to addiction and diversion from patients for whom use is intended. To this end, we have studied inhibition of the glutamatergic system, shown to play a central role in opioid addiction, to inhibit the development of opioid-seeking behavior in a rodent model of drug-seeking behavior. A decarboxylated form of L-arginine, agmatine, is able to prevent the development of fentanyl-seeking behavior in a model of mouse self-administration likely through its role as an N-methyl-D-aspartate antagonist. However, agmatine has shown limited penetration through the blood brain barrier (BBB) and a short systemic half-life, necessitating the need for central delivery. We have designed a strategically-substituted agmatine compound with the goal of improving its penetration through the BBB and increasing its half-life following systemic delivery in order to make it a more viable potential therapeutic for the treatment of opioid use disorders (OUD). **Methods: Prevention of Opioid Self-Administration** Mice (F, 21-30g) were given access to operant chambers and allowed to press either for oral oxycodone reward or an inactive control. Daily, the mice were given either a pre-treatment of a strategically-substituted agmatine (SSA) compound or vehicle control, i.p.. Daily lever-pressing was recorded as an indication of drug-seeking behavior. Additionally, this same cohort was allowed to lever press for food pellet reward following conclusion of oxycodone reinforcement. Area under the curve (AUC) was compared between SSA pre-treated and vehicle pre-treated groups.
Results: Pre-treatment with the strategically-substituted agmatine compound significantly decreased oxycodone seeking behavior, but had no impact on food-maintained responding. Additionally, the strategically-substituted agmatine compound showed no impact on motor coordination or cardiovascular function.
Conclusion: These data indicate that a strategically-substituted agmatine compound is capable of significantly reducing opioid-seeking behavior with a wide therapeutic window, avoiding the motor impairment and cardiovascular impairment typical of drugs of this class. Our future work includes optimization of dosing regimen as well as modeling the prevention of opioid relapse.

Title: Virtual embodiment treats chronic pain and improves function

Authors: A. F. ALVAREZ, J. PETROS, L. NGUYEN, *M. S. TRUJILLO;
Karuna Labs, San Francisco, CA

Abstract: Chronic pain is a major healthcare burden and is associated with depression, anxiety, functional impairment, and a significant burden on quality of life and productivity. Persistent pain is difficult to treat, and opioids are commonly prescribed despite the potential for misuse, abuse, and accidental overdose. There is an apparent need for non-addictive, non-invasive, non-pharmacological treatments for chronic pain. Rapid advancements in virtual reality (VR) technology has led to innovative therapeutic approaches for treating ailments such as anxiety, phobias, and post-traumatic stress disorder. VR has also been demonstrated to provide powerful analgesic effects and may be an effective tool for treating chronic pain. At Karuna Labs, we have developed a novel VR platform that combines virtual embodiment therapy (VET™) with graded motor imagery techniques to treat chronic pain. In virtual embodiment, the user experience can be manipulated and adjusted to modify how users interact with a virtual environment. Mirroring of movement where a contralateral limb is shown moving in VR space and augmentation where movement is overstated or understated are used to re-normalize maladaptive associations between movement and pain. A feasibility study on 24 chronic pain patients demonstrated that VET™ significantly reduced the intensity of perceived pain (as measured by paired t-test ($P < 0.05$) on subjective pain questionnaires) and patients who rated their pain as most severe saw the greatest improvement. Furthermore, this study demonstrated that VET™ has significant positive effects on alleviating pain as measured by a modified visual analog scale (paired t-test before and after each session ($P < 0.001$)). The current study expanded preliminary results to assess the ability of VET™ to treat generalized shoulder pain. We measured functional progress using a novel kinematic analysis tool that extracted features from movement within VET™ and tracked progress over the course of 8 sessions of VET™. This study demonstrated the potential of Karuna VET™ to serve as a digital function rehabilitation program that compliments current standards of care in treating chronic pain and improving function.

Abstract: Development of effective non-opioid therapeutics tailored to specific chronic pain syndromes is sorely needed. Our recent microchip gene expression profile identified upregulated cholecystokinin B (CCK-B) receptor in trigeminal ganglia (TG) as one suitable target among many others. Thus, the CCK-B receptor is an ideal candidate to impact both nociceptive and limbic components of *chronic* pain. More importantly, its inhibition can reverse opiate tolerance. Based on the literature and the gene expression changes over time, the CCK-B receptor is implicated as one of the persisting functional targets suitable for development of therapeutics to inhibit *chronic* pain- and anxiety-related behaviors. Here we describe the isolation and characterization of a panel of CCK-B receptor specific single-chain fragment variable (scFv) antibodies using ribosome display technology. Furthermore, we demonstrate *in vivo* efficacy of our antibodies in a relevant model of established neuropathic pain. The CCK-B receptor scFv antibody administered 3 weeks after trigeminal nerve constriction model induction effectively reduced CCKB receptor RNA, as well as pain, anxiety, and depression related behaviors. This is the first example, to date, of scFv antibodies that can block the CCK-B receptor directly with high potency and specificity. This highlights the exciting potential therapeutic opportunity of a brain penetrant antibody for blocking this G protein coupled type of receptor.

Title: Antiallodynic effects of abobotulinumtoxinA (Dysport) in a rat model of MRMT-1-induced bone cancer pain

Authors: V. MAFFRE[1], C. FAVRE-GUILMARD[2], ***M. KALINICHEV**[2], Y. DARBAKY[1], L. DIOP[1];
[1]ANS Biotech, Riom, France; [2]Ipsen, Les Ulis, France

Abstract: A significant proportion of patients with advanced breast, prostate or lung cancer develop skeletal metastasis and suffer from bone cancer pain. The MRMT-1 mammary carcinoma model of bone cancer in rats mimics aspects of the clinical pathogenesis and symptoms, including chronic pain and can be used for evaluation of the efficacy of novel analgesic medication (Medhurst et al. 2002). There is growing clinical and preclinical evidence that in addition to well-characterized muscle-relaxant properties, AbobotulinumtoxinA (AboBoNT-A; Dysport) can reduce different types of pain. The objective of this study was to assess the antiallodynic effect of intra-plantar administrations of AboBoNT-A in the model of MRMT-1-induced bone cancer pain in rats. **Methods:** Adult, male, Sprague-Dawley rats were anesthetized before receiving inoculation of 3.10^4 MRMT-1 mammary carcinoma cells into the medullary cavity of the tibial bone or receiving a sham-operation. On day 11 after cancer cell inoculation, animals received an acute, intraplantar administration of AboBoNT-A (10, 20, 40 U/kg) or vehicle (saline; n=10/group). The tactile sensitivity of both hind paws was measured on day 11 before AboBoNT-A treatment (Baseline) and on days 14, 18 and 21 post inoculation corresponding to days 3, 7 and 10 post-Dysport injection using electronic Von Frey test. **Results:** MRMT-1 cancer cells induced, from 11 days to 21 days after inoculation into the medullary cavity of the tibia, a reduced and stable paw withdrawal threshold in the vehicle-treated group. A single intraplantar administration of AboBoNT-A (5, 10, 20 and 40 U/kg) produces, in a dose and time-related manner, an antiallodynic effect on MRMT-1-induced mechanical hypersensitivity. Maximum effect was observed with the dose of 40 U/kg (32% to 40%, $p<0.001$) while the lowest doses of 5 and 10 U/kg did not induce any significant effect. Control paw withdrawal thresholds and body weights were not impacted by AboBoNT-A injection. **Conclusions:** AboBoNT-A reduces mechanical allodynia induced by MRMT-1 cells in a bone cancer pain model in rats. These results suggest a possible effective and long-lasting reduction in chronic pain associated with metastatic bone cancer in humans.

Title: Influence of strategically substituted agmatines on opioid-induced neuroplasticity

Authors: *B. M. CLEMENTS[1], C. D. PETERSON[2], K. F. KITTO[2], G. L. WILCOX[3], C. A. FAIRBANKS[4];
[1]Dept. of Pharmaceutics, [2]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]Dept. of Neuroscience, Pharmacology, Dermatol., Univ. Minnesota Med. Sch., Minneapolis, MN; [4]Dept. of Pharmaceutics, Neuroscience, Pharmacol., Univ. Minnesota, Minneapolis, MN

Abstract: In the face of the dual crises of chronic pain and opioid addiction, therapies remain to be developed to effectively treat opioid-induced neuroplasticity. Decades of work has supported the use of N-methyl-D-aspartate (NMDA) receptor and nitric oxide synthase (NOS) inhibitors to treat opioid tolerance and aspects of the addictive state, but adverse effects have limited clinical development. Recent work has shown that agmatine acts to reduce these maladaptive neuroplasticities without negative sides effects by acting specifically on NMDA receptors containing GluN2B subunits. Systemic agmatine, though, has been limited due to low blood-brain barrier permeability, necessitating high doses, and a short plasma half-life. To combat these issues, we have generated strategically substituted agmatines (SSAs) to increase distribution to the CNS and increase exposure to the drug. Previous work with these SSAs have shown benefit over agmatine as a treatment for chronic pain with no cardiovascular or motor deficits. Our objective is to confirm the influence of the SSAs on opioid-induced neuroplasticity, as seen with agmatine, by assessing opioid tolerance and comparing that response to the pharmacokinetics. Chronic Morphine Induced Analgesic Tolerance (52.5°C warm water tail flick assay): Mice were treated every 12 hours for 3 days with SSA1 (10 nmol, i.t.)/morphine sulfate (10 nmol, i.t.), SSA1/vehicle, morphine sulfate/vehicle, or vehicle/vehicle. Before the treatment. Mice were tested for thermal tail-flick latency prior to the start of treatment. Increasing doses of morphine were given centrally 24 hours after the final dose to assess tolerance. Dose response analysis showed morphine tolerance in morphine/vehicle group, but tolerance was not present in

SSA1/morphine group. Mice were then treated under the same research paradigm receiving systemic SSA1 (10 mg/kg, i.v.) against central morphine. Dose response analysis following induction of analgesic tolerance in systemic SSA1 animals shows similar behavior to central SSA1. Pharmacokinetics of SSA1 and the Conversion to Agmatine: Mice were injected with SSA1 (100 mg/kg, i.v.) or agmatine (100 mg/kg, i.v.) over a 4-hour time course. Serum and spinal cords were collected and tested for agmatine content using HPLC-UV/Vis. The change in agmatine following injection shows that SSA-1 drives higher plasma presence of agmatine, longer elimination half-life, and increased agmatine exposure in the CNS.
These data suggest that SSA-1 acts to reduce opioid-induced neuroplasticity, specifically as a function of opioid tolerance, potentially due to increased agmatine exposure in the CNS following SSA1 treatment.

Title: Non-opioid analgesics to treat chronic pain through the cannabinoid-binding site in glycine receptors

Authors: *J. CAPOROSO[1], M. WELLS[1], L. JIANG[1], M. MOSES[2], K. KOPER[2], Q. CHEN[1], P. TANG[1,3,4], Y. XU[1,4,5,6];
[1]Anesthesiol., [2]Neurosci., [3]Computat. and Systems Biol., [4]Parmacology and Chem. Biol., [5]Structural Biol., [6]Physics and Astronomy, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Marijuana's analgesic action has been linked to allosteric positive modulation of glycine receptors (GlyRs) by Δ9-tetrahydrocannabinol (THC), a major psychoactive component in cannabis. GlyRs are the predominant inhibitory ligand-gated ion channels that mediate the nociceptive signals in the central nervous system, and the glycinergic mechanism of analgesia is independent of other undesirable psychoactive effects of THC. Therefore, the discovery and development of compounds that selectively bind GlyRs will likely produce analgesia without negative psychoactive effects. Top-ranked compounds from computational screening that were predicted to bind to the THC site in α3GlyR were previously validated using *in vitro* electrophysiology. The compound with the highest potency and selectivity (MJPY1) was used as

a lead scaffold to generate analogs for *in vivo* characterization of the analgesic effects against neuropathic pain in rodents using the Hargreaves, von Frey, and Thermal Place Preference tests. Peripheral neuropathy was induced in Sprague-Dawley rats by a chronic constriction injury to the sciatic nerve and analgesia was assessed after a 10-day healing period to minimize inflammatory surgical pain and maximize neuropathic pain. Intraperitoneal administration of MJPY analogs produced analgesia against neuropathic pain as early as 30 minutes post injection and lasted for at least 2 hours against both thermal and mechanical stimuli. In conclusion, we have discovered a novel class of analgesics for neuropathic pain that act at the THC-binding site in α3GlyR. More extensive testing is currently underway to fully characterize the structure-activity relationship and to optimize their pharmaceutical properties and analgesic effects. The analgesic action of these novel compounds may have a significant impact on chronic pain management and help curb the use of popular analgesics that have dangerous addictive and abuse potential.

Abstract: The P2X purinoceptor 4 (P2X4) plays a crucial role in signaling leading to chronic inflammatory and neuropathic pains, thus, the P2X4 receptor provides a new potential therapeutic target for their treatment. We have generated a panel of mouse single-chain fragment variable-antibodies (scFvs) recognizing extracellular peptide of P2X4 using cell-free ribosome display, to reduce pain signaling by neurons. A mouse scFv library was generated, and ribosome display was applied for anti-P2X4 scFv recombinant antibody selection. After three rounds of bio-panning, we isolated a panel of recombinant antibodies followed by ELISA, cross reactivity analysis, western blotting and immunofluorescence staining, anti-P2X4 scFv clones with high

specificity and affinity were successfully selected. The efficacy of this therapeutic will be further evaluated using established capsaicin-induced or formalin-induced mouse inflammatory pain models.

Title: Sphingosine-1-phosphate type 1 receptors in the central nervous system contribute to the antinociceptive effects of FTY720 (fingolimod) in a mouse model of nerve injury-induced neuropathy

Authors: *D. E. SELLEY[1], G. DONVITO[1], V. D. MCLANE[1], S. SPIEGEL[2], K. F. HAUSER[1], A. H. LICHTMAN[1], L. J. SIM-SELLEY[1];
[1]Dept. of Pharmacol. & Toxicology, [2]Dept. of Biochem. & Mol. Biol., Virginia Commonwealth Univ., Richmond, VA

Abstract: Modulation of the sphingosine-1-phosphate (S1P) system regulates nociception in models of acute and chronic pain. FTY720 (fingolimod) produces antinociception in multiple neuropathic pain models. FTY720 is phosphorylated *in vivo* to an agonist/functional antagonist (FTY720-phosphate) of multiple S1P receptor types, including the $S1P_1$ receptor (S1PR1). The present study assessed the role S1PR1 in the CNS in the antinociceptive effect of FTY720 in male mice with chronic constriction injury (CCI) of the sciatic nerve. S1PR1 was conditionally knocked out (cKO) in neurons, astrocytes and oligodendrocytes in the CNS using the nestin promoter to express cre recombinase in S1PR1-floxed mice (NC-S1PR1 cKO). S1PR1 activity was assessed in control (S1PR1-floxed) and NC-S1PR1 cKO mice using [^{35}S]GTPγS binding stimulated by S1P or the S1PR1 selective agonist SEW2871 in the spinal cord and multiple brain regions. Results showed ≥ 85% reduction in maximal [^{35}S]GTPγS stimulation by S1P and near-complete reduction in stimulation by SEW2871 in the spinal cord and all gray matter regions examined in the brain, suggesting that: 1) S1PR1 was deleted in NC-S1PR1 cKO mice and 2) the vast majority of S1P-stimulated [^{35}S]GTPγS binding was mediated by S1PR1 in the CNS of control mice. Control and NC-S1PR1 cKO mice then received CCI or sham surgery. After one week, mice were administered daily injections (i.p.) of vehicle or FTY720 (0.1 mg/kg) for 14 days. Mechanical hypersensitivity was assessed with Von Frey filaments 1 h after injections on

days 1, 7 and 14. NC-mediated cKO of S1PR1 did not affect baseline sensitivity in mice with sham surgery nor did it affect CCI-induced mechanical hypersensitivity. Repeated daily administration of FTY720 produced time-dependent reversal of hypersensitivity in CCI mice, which was significant at day 1 and maximal by day 14. Interestingly, FTY720 also significantly reversed CCI-induced hypersensitivity in NC-S1PR1 cKO mice, but the magnitude of reversal was reduced (by ~65% on day 14) compared to control mice. These results indicate that S1PR1 expression in the CNS: 1) is not required for development of CCI-induced mechanical hypersensitivity and 2) plays a major but not exclusive role in FTY720-mediated reversal of CCI-induced hypersensitivity.

Title: Wiring specificity for output generation in the neocortex

Authors: *J. M. GUEST, A. BAST, M. SEETHARAMA, M. OBERLAENDER;
Max Planck Group: In Silico Brain Sci., Ctr. of Advanced European Studies and Res., Bonn, Germany

Abstract: Underlying structural and functional determinants that contribute to output generation in the neocortex during sensory information processing mostly remains unknown. It is thought that the primary source of output generation and thus the terminal point of sensory information processing in the neocortex are the pyramidal tract neurons (PTs). We have recently discovered that PTs have morphological and functional properties that reflect their respective sub-cortical target areas, indicating PTs receive inputs from different neuronal populations and or receive synaptic inputs at different dendritic compartments in a manner that reflects the subcortical targets. To test this hypothesis, we use a multidisciplinary approach that combines *in vivo* electrophysiological recordings with virus mediated optogenetic input mapping, anatomical reconstructions and biophysical modeling. Our results indicate a preference for thalamic input near to the location of the apical dendrite primary bifurcation of PTs and that the location of where the primary bifurcation occurs may be related to the PTs sub-cortical target. These results will then be used to constrain a biophysical model of a single PT within a realistic anatomical cortical reference frame to systematically characterize synaptic input integration that can give rise to long-range target related output patterns.

Abstract: Principles that shape the complicated synaptic wiring patterns of the neocortex remain unknown. This knowledge is, however, essential for understanding how higher functions, such as sensory perception, are implemented within the mammalian brain. Here, we describe synapse formation mechanisms mathematically, and show how to link the theories' predictions with empirical connectivity measurements. We use the approach to elucidate the degree to which proximity between neuronal structures determines connectivity - a controversial topic for decades. We find that proximity-based wiring patterns are consistent with the available empirical data at subcellular, cellular and network levels. Proximity-based wiring will hence conceal connections that reflect activity-dependent synapse formation processes. Our approach disentangles these different mechanistic origins of wiring, a necessity for identifying structural correlates of sensory experience, learning or memory.

Title: Depth-specific relationships between the molecular identity, intrinsic physiology and morphology of inhibitory interneurons in the rat neocortex

Authors: *F. YANEZ[1], D. UDVARY[1], J. M. GUEST[1], B. SAKMANN[2], D. FELDMEYER[3], M. OBERLAENDER[1];
[1]Max Planck Group: In Silico Brain Sci., Ctr. of Advanced European Studies and Res., Bonn, Germany; [2]Emeritus Group: Cortical Column In Silico, Max Planck Inst. of Neurobio., Martinsried, Germany; [3]Inst. of Neurosci. and Medicine, INM-10, Res. Ctr. Juelich, Juelich, Germany

Abstract: Inhibitory interneurons (INs) are commonly grouped into cell types based on their molecular identity, intrinsic physiology and/or axon morphology. Here, we systematically assess the relationships between these three classification criteria as a function of cortical depth in the vibrissal-related part of rat primary somatosensory cortex (i.e., barrel cortex). First, we determine the number and distribution of parvalbumin-, somatostatin- and calretinin-expressing INs throughout the entire barrel cortex. The data provides quantitative estimates at 50 micron resolution of the relative abundance of each of these molecularly defined IN classes across the cortical depth. Second, we objectively classify more than 300 *in vitro* recorded INs into physiological cell types based on their spiking patterns in response to somatic current injections (e.g., fast-spiking vs. non fast-spiking). The neurons are recorded across the entire cortical depth of the barrel cortex, and labeled with biocytin, which allows reconstructing their dendrite and axon morphology, as well as determining their respective somatic depth locations. Third, based on the axonal reconstructions, we objectively classify the neurons into morphological cell types (e.g., basket vs. Martinotti cells). For a subset of the recorded/reconstructed neurons, we additionally determine their respective molecular identity. We compare the relative abundances across the cortical depth of molecularly defined IN classes, with those determined by physiological and/or morphological properties. Our results provide quantitative insight into the relationships between the three main criteria that are currently used to classify INs, and reveal the degree to which somatic depth location in combination with molecular identity is predictive of an IN's physiological and/or morphological cell type, and vice versa.

Title: Cell type-specific structure and *in vivo* function of excitatory neurons in rat vibrissal motor cortex

Authors: *R. T. NARAYANAN, M. SEETHARAMA, J. M GUEST, A. JAVADOVA, M. OBERLAENDER;
Caesar, In Silico Brain Sci., Bonn, Germany

Abstract: Functional studies show that whisker stimulation evokes responses in both vibrissal somatosensory cortex (vS1) and vibrissal motor cortex (vM1). Conversely, multiple studies indicate stimulation of vS1 and vM1 both evokes whisker movements. Whereas the structure of vS1 has been described, very little is known about vM1. Here, we describe the location and extension of rat vM1 area by injecting trans-synaptic rabies virus onto the intrinsic muscles of the rat whiskers. We found that both vS1 and vM1 are located equal synaptic distance from the whisker muscle. Using cell-attached recording and biocytin labeling *in vivo*, we recorded electrophysiological properties and subsequently reconstructed dendrite-axon morphologies of neurons of vM1. The classification of neurons revealed that vM1 is composed of similar canonical cell types as vS1. However, the morphological properties of cell types are specific to the cortical area that they are located in. We conclude there are substantial similarities between these two cortices, indicating that both follow similar organizational principles.

Title: Electrophysiological characterization of sensorimotor cortex neurons projecting to mesencephalic nuclei

Authors: *V. LOPEZ-VIRGEN, R. OLIVARES-MORENO, G. ROJAS-PILONI;
Inst. de Neurobiologia, UNAM, Queretaro, Mexico

Abstract: Layer 5 pyramidal tract neurons (PTN) arecanonical elements of the cerebral cortex. PTN are the main excitatory output to subcortical structures like striatum, superior culliculus, pons, red nucleus and spinal cord, among others. Nevertheless, little is known about the electrophysiological characteristics expressing the diversity of theseprojection neurons. The aim of the present work is to distinguish the electrophysiological characteristics *in vivo* of the thick-tufted layer 5 pyramidal neurons of the sensorimotor cortex projecting to tectum, red nucleus (RN) and pons.Twenty wild-type C57BL/6 mice adults were anesthetized with isofluorane in oxygen (2-3%).A small craniotomy were made to insert a stimulation electrode in RN, pons or tectum. Foryuxtacellular recordings *in vivo* in layer 5 a cranial window was made in sensorimotor cortex (2.46 mm to -0.80 mm, and 0.5 to 0.7 relative to bregma).In order to identify the different projection neurons, the antidromic responses and collision test was analyzed. The animals were perfused and 100-µm coronal sections were obtained, mounted and marked with NIssl staining to confirm the stimulation electrode location. We found that the differentprojection PTN differs in theirspiking patterns, frequency, and sensory responses according the subcortical projection.Thesedifferences in electrophysiological parameters suggest that the PTN projectingsubcortically functionally segregated.

Abstract: Inhibitory interneurons in the neocortex, show a vast diversity in their morphological and electrophysiological properties. However, how such diversity on the single cellular level extends to both the sensory-evoked and the ongoing activity of these cells is still to be known in the deep layers, given their difficult accessibility and limits of current imaging techniques. Here we reconstruct the complete axon and dendrite morphology of cell attached in-vivo recorded inhibitory neurons in layer 5 of the rat barrel cortex, we also characterize the inhibitory neurons in term of their molecular identity, the degree of their primary thalamocortical inputs and spiking activity. Our data will provide a quantitative assessment of the relationship between the thalamocortical input, dendrite/axon morphologies and molecular identity with the in-vivo activity of these neurons. This research will aid to generate a more comprehensive cellular characterization and provide necessary information for future understanding of the microcircuits architecture of the neocortex.

Title: Synaptic properties can dominate cortical output computations

Authors: *A. BAST[1], R. EGGER[2], M. OBERLAENDER[1];
[1]In Silico Brain Sci., Ctr. of Advanced European Studies and Res., Bonn, Germany; [2]Neurosci. Inst., NYU Sch. of Med., New York, NY

Abstract: Cortical output mainly originates from pyramidal tract neurons (PTs). The determinants of spike generation in PTs are complex, as they receive input from local and far away neuron populations, have extensive dendritic trees and express a plethora of active conductances. The interplay between these components as well as their importance for the overall computation that PTs perform remains poorly understood. Here, we characterize excitatory and inhibitory spatiotemporal synaptic input patterns, for which this computation is

mainly determined by synaptic properties and can be described analytically. We show, that such input patterns are present during the onset of sensory stimuli in vivo, allowing to predict the responses of PTs with high temporal accuracy. This explicit analytical description of a cortical computation can be a starting point to investigate which information is encoded in the so far enigmatic responses of PTs.

Title: Reconstruction of whisker-related neuronal networks throughout the rat brain

Authors: *A. MAHARJAN, J. M. GUEST, M. M. SEETHARAMA, M. OBERLAENDER;
In Silico Brain Sci., Ctr. of Advanced European Studies and Res., Bonn, Germany

Abstract: Rodents actively move their facial whiskers to explore their environment. The whisker system is thus a common model system to investigate principles of sensory information processing, mechanisms that underlie motor control, and for studying interactions between sensory and motor pathways. Recent studies have provided detailed insight into the central pattern generator pathways that drive rhythmic whisker movements (whisking) at the level of the brain stem. Furthermore, accumulating evidence suggests that disjoint cortical feedback pathways from both primary motor and somatosensory areas to a variety of brain stem structures may play a crucial role in whisker motor control. Here, we provide a quantitative account of the structural organization of these brain-wide whisker-related pathways in the rat. We inject replication competent rabies virus into a single intrinsic whisker muscle. The virus labels synaptically connected neurons via retrograde trans-synaptic spread. At first order spread, the virus labels motoneurons that innervate the infected muscle. Subsequently, at second order, the virus labels neurons that are presynaptic to these motoneurons. We quantify the distribution of rabies-labeled neurons throughout the rat brain for several experiments that reflect second, third and fourth order transsynaptic spread. We show that the injections provide consistent results across experiments, and which are in line with those reported previously using conventional neuroanatomical tracers. We find that sensory- and motor-related brain areas, both in the neocortex and brainstem, can contribute equally to whisker muscle control (i.e., in terms of the number of neurons). Moreover, we find that motor-related areas are typically labeled in both hemispheres of the brain at the same order of transsynaptic spread, whereas sensory-related areas appear to be more unilaterally connected to the muscle. Our data will aid future studies to better interpret functional measurements during whisker-based behaviors.

Title: An approach towards visualizing airflow around animal faces and whiskers

Authors: ***T. L. JANSSEN**[1], J. M. THOMAS[2], M. J. HARTMANN[1], V. GOPAL[2]; [1]Northwestern Univ., Evanston, IL; [2]Elmhurst Col., Elmhurst, IL

Abstract: We describe an apparatus to track airflow around animal faces, with a particular focus on the nose, snout, and whiskers. Using neutrally buoyant bubbles as tracer particles, we are able to visualize the airflow around a 3D printed, biologically accurate model of a rat head. The system allows us to characterize how the rat's facial features affect the flow profile for various orientations of the head (both yaw and pitch). The present work describes the velocity field around the rat head in 2D planes for a flow that is steady in the mean. Unlike traditional particle image velocimetry (PIV) methods, our method does not require high-speed video, but rather makes use of low frame-rate videos. A custom tracking algorithm detects bubble tracks in each frame and uses these tracks to extract flow parameters. An extension of this work is being used to understand sensing for various flow regimes involving upwind bluffs. We anticipate that quantification of the effects of head orientation on flow around the rodent head will lead to a better understanding of how rodents orient their whiskers to optimize sensing in various flow profiles. We discuss how an extension of these results may aid in quantifying flow profiles for other animals.

Title: A robotic pinniped: Using biomimetic robotic whiskers to sense fluid flow

Authors: *H. M. EMNETT[1], K. J. KLECZKA[1,2], T. L. JANSSEN[1], M. J. Z. HARTMANN[1,2]; [1]Mechanical Engin., [2]Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: Many pinnipeds use their whiskers as a primary sensing modality when hunting. The whiskers bend and vibrate in response to the different flow patterns left by the pinnipeds' prey. In the present work, we describe the design of a biomimetic, robotic pinniped that can be used to sense flow underwater. The components of the system are plastic whiskers, artificial sensing "follicles," and a morphologically-accurate 3D printed head. Because no sensing occurs along the length of a real pinniped whisker, the artificial whiskers can be made out of plastic, with an artificial robotic follicle serving as a sensor at each whisker base. The plastic was carefully chosen to have material properties similar to that of a real pinniped whisker and can be fabricated to have the same geometry as whiskers found on either a sea lion or a harbor seal. The artificial follicle, located at the base of each whisker, is built to measure the specific mechanical signals most important for sensing flow. The whiskers, with their sensing follicles, are mounted to a 3D printed model of either a seal or sea lion head. These heads are based on 3D scans of real animals and the locations of the whisker basepoints match those on the real animal. We then use this robotic pinniped to analyze how different flow patterns affect the signals at the base of the whiskers, and thus how an animal might use these varying signals during active hunting. In the future, we anticipate using this apparatus as a method to determine which information is the most salient during wake tracking.

Title: Animals can use optogenetic-induced brain modulations as a conditioned stimulus, regardless of the cell type, type of modulations (activation or inhibition), and brain region opto-stimulated

Authors: *J. LUIS-ISLAS[1], G. B. FLORAN[1], R. GUTIERREZ[2];
[1]Physiology, Biophysical and Neurosciences, CINVESTAV, Mexico city, Mexico; [2]Pharmacol., CINVESTAV - IPN, Mexico City, Mexico

Abstract: Brain manipulations (e.g., optogenetic) have been used to perturb brain activity to evaluate their necessity of a behavior. Nevertheless, these Brain perturbations can generate interoceptive cues that can be used to guide behavior. Most studies have a focus on the somatosensory cortex (S1). However, we reason that any brain region will be able to generate interoceptive cues. We hypothesize that pairing an arbitrary optogenetic stimulation, regardless of the brain region, with a relevant behavioral event, will induce plasticity on brain circuits associating to that event, such as now the opto-stimulation will be able to drive behavior. To test this idea, first, we used the Thy1-ChR2 mice to photoactivate either cortical pyramidal neurons from layer V (in the prefrontal cortex, PFC) or its fibers to the nucleus accumbens shell (NAcSh). Thy1-ChR2 mice were trained in a two sipper sucrose alternating task, where -in order to receive two drops of sucrose- they had to alternate between two opposite left and right sippers (Phase 1). Additional licks in the rewarded sipper will no longer release more sucrose until mice licked the opposite sipper. In half of the trials, when the subject heads halfway toward the opposite port, a 1 s train of photostimulation (20Hz) + a tone were delivered, mice use these cues to change its direction and return to the previously rewarded port to be rewarded again with sucrose. If they continued and licked the opposite sipper, mice were punished (with 2 airpuffs). After learning, the tone was removed, and phase 2 begins: the subjects had to predict punishment only using photostimulation. We found that transgenic mice can avoid punishment, by only using the photostimulation cue (tone off). The same task was also developed with VGAT-ChR2 mice (ChR2 in GABAergic neurons), with fiber in PFC or thalamic reticular nucleus (TRN) or with Ires-Cre mice (ChR2 or ArchT in GABAergic neurons of lateral hypothalamus) showing similar results. Thus, optogenetic stimulation can be a predictive signal of an outcome, regardless of its original function. Finally, we tested if subjects can learn different rules by discriminating between 2 photostimulation frequencies (i.e., 20 Hz had to lick in a right port, 10 Hz had to do at opposite). We found that subjects can perform above 85% of correct trials. In conclusion, we demonstrate that arbitrary optogenetic stimulation evokes brain modulation and animals can use it as an interoceptive cue (conditioned stimulus), regardless the region, type of modulation (activation or inhibition) or frequency. This work paves the way to investigate how artificial network's modulations can be perceived for animals and how they can report them

Title: A 3D model for precise registration of neuronal morphologies

Authors: *M. M. SEETHARAMA, R. NARAYANAN, J. M. GUEST, M. OBERLAENDER;
Caesar, Bonn, Germany

Abstract: Delineating the structural organization of any brain region of interest often involves reconstructing and analyzing neuronal morphologies from that region. Since only a handful of neurons can be reconstructed per animal, it becomes essential to have a standardized 3D model into which anatomical data from different animals can be precisely registered. Such a model will account for not only the inter animal variability but also the variability across experimental conditions.
Here, we present such a standardized 3D model for rat vibrissal motor cortex, along with the precision involved in registering morphologies into the standard model. Registered neuronal morphologies can be readily compared with one another and hence can be accurately assigned to their respective morphological cell types.

Title: Swimming alters dynamics of lateral line afference in larval zebrafish

Authors: *D. A. SKANDALIS, E. T. LUNSFORD, J. C. LIAO;
Whitney Lab. for Marine Biosci., Univ. of Florida, St Augustine, FL

Abstract: Corollary discharge to sensory organs suppresses afference when the organism's own actions might overwhelm the sensory system. In fish, the lateral line detects water perturbations that might emanate from important extrinsic sources (exafference), but could also result from swimming (reafferance). Reafference is thought to be minimized by hindbrain cholinergic efferent neurons which project to the lateral line and reduce the probability of afferent spikes, though the effect of endogenous levels of efferent activity during swimming on afferent spiking dynamics has not been directly assessed. If the corollary discharge to the lateral line operates similarly to that in other organisms, fish may maintain generally high levels of sensitivity except while swimming, potentially resulting in insensitivity to critical exafferent stimuli. We recorded extracellular spontaneous and mechanically evoked afferent spike rates during fictive swimming of larval zebrafish (*Danio rerio*, n=20) while alternating 1 s of posterior lateral line neuromast stimulation (frequencies 5, 20, or 40 Hz) with 2 s off. Afferents responded most strongly to the first stimulus, after which the probability of an afferent response significantly decreased. Following stimulation, afferents displayed a refractory period proportional in duration to the stimulation frequency. Spontaneous and evoked spike rates decreased during swim bouts as predicted, but were not completely suppressed. We also found that this response persisted after the end of the swim in a post-swim refractory period. Despite the decreased evoked spike probability while swimming, the vector strength increased, indicating greater fidelity of spike timing to the original stimulus. This opposite relationship of spike probability and vector strength suggests that although information volume may decrease during the swim, information content may increase. Taken together, these results show that the corollary discharge does not completely suppress afference during the swim to render the fish insensitive. Rather, the lateral line maintains sensitivity to a degree dependent on the timing of exafferent and reafferent stimuli during or after the swim bout. We propose that such time dependence may be a general feature of hair cell systems and their regulation, such as in the inner ear and vestibular systems.

Title: Inhibitory control of sparse odor-coding in an insect olfactory-circuit

Authors: *S. RAY, Z. N. ALDWORTH, M. A. STOPFER;
NICHD, NIH, Bethesda, MD

Abstract: In the olfactory systems of insects and mammals, olfactory receptor neurons respond to a broad range of odors with vigorous spiking, but higher order neurons respond to odors much more sparsely and selectively. This transformation of the neural code for odors is mediated by feedback inhibition. The locust has been a good model system to study this process. In this animal, a single Giant GABAergic Neuron (GGN) is known to receive excitatory input from all higher order olfactory neurons known as Kenyon Cells (KCs), and, in turn, to inhibit every KC. Thus, GGN's membrane potential reflects the spiking response of the entire KC population. To better understand the role of feedback inhibition in olfactory coding, we built a detailed computational model of the olfactory circuit of the locust including a biophysically detailed GGN, all 50,000 KCs, and their inputs from the 830 projection neurons (PNs) that stand between the receptor neurons and the KCs. Our GGN model showed that, despite the neuron's large size and nonspiking nature, it is capable of transmitting electrical signals from its input region to its distant output branches to inhibit all KCs. Simulations of our model further showed that feedback inhibition from GGN greatly sparsens the firing of the KC population, while allowing a given KC to respond to a larger range of inputs from PNs. Based on parameters from our own experiments and the existing literature, we simulated the network model with various connectivity schemes and PN activity patterns with the goal of reproducing both realistic sparse spiking in KCs and realistic odor-evoked sustained depolarization of GGN. We found this required two things: (1) the synapses connecting GGN to KC must be diverse in strength, resulting in a mixture of weak and strong inhibition; and (2) different subsets of PNs must become active at different times during odor stimulation. Our model also predicted that the spike rates of a small portion of KCs should be unusually high. We confirmed this prediction with patch clamp recordings of many KCs made in vivo. Finally, our in vivo recordings showed that some odors hyperpolarized GGN. An identified neuron, IG, is known to inhibit (and receive inhibition from) GGN, but simply adding this connectivity to our model could not realistically reproduce GGN's hyperpolarization. Our analysis suggests an additional unknown neural pathway must exist to drive IG's activity. Thus, our work reveals a complex, well-regulated network of excitation and inhibition, and a new olfactory pathway, to transform neural codes for odors in the brain.

Title: Odor valence encoding in the antennal lobe and its behavioral correlates

Authors: *R. CHANDAK[1], M. TRANER[3], B. RAMAN[2];
[1]Biomed. Engin., Washington Univ. In St. Louis, St Louis, MO; [2]Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO; [3]Biomed. Engin., Washington Univ. in St. Louis, St Louis, MO

Abstract: The olfactory system receives a plethora of volatile stimuli inputs from an organism's surroundings. Predicting and understanding how neural activities encode the overall preference to olfactory stimuli, or valences, which guide primal behaviors such as fleeing away from a predator or towards food, are open challenges in systems neuroscience. In this study, we used the locust (*Schistocerca americana*) olfactory system to examine this issue. We began by examining innate preferences of locusts to an exhaustive panel of odorants comprising putative appetitive and aversive stimuli. By assaying the palp-opening responses of locusts using a simple binary metric - open or closed palp position, we ascertained whether or not individual locusts preferred an odorant. Combining information across a collection of locusts, we were able to calculate a preference index for each odorant in our panel. We also quantified this distribution for each sex separately to investigate any differences in valences arising due to gender differences. In addition, we studied the acquired behavior preferences of locusts using an appetitive conditioning assay. For this, we used odors with widely different preference indices to study whether a potential distinction exists between appetitive and aversive stimuli in their efficacy to induce associative learning. Our results indicate that starved locusts could be conditioned to associate an odor with a food reward only when the odorant was innately attractive. Aversive odors were not learnable. Surprisingly, reinforcing the offset responses of aversive odorants induced cross-learning for attractants in some cases. To understand the neural distinction between odorants with distinct overall valences, we are examining neural responses from excitatory projection neurons (PNs) in the locust antennal lobe that receive inputs directly from receptor neurons in the antenna. We will also study if local field potential oscillations observed in higher olfactory centers vary systematically with odor valence. In sum, we hope to understand how orthogonal behaviors (i.e., attraction and repulsion) are encoded in the antennal lobe and if neural responses can predict the valence and learnability of an odor.

Title: Concentration-dependent switch in neural ensembles in the locust antennal lobe

Authors: *S. NIZAMPATNAM, D. SAHA, B. RAMAN;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Identifying the intensity of a stimulus is an essential task for most sensory systems. While it is important to encode the identity of a stimulus invariant with respect to intensity, we sought to examine whether and when this invariance breaks down in an invertebrate model of the olfactory system. Increasing concentration of stimulus has been shown to activate additional, low-sensitive sensory neurons. As a result, the overall combination of neurons activated is thought to vary subtly with increasing intensity. This simple mechanism would allow subtle variations in the ensemble responses with stimulus intensity while allowing the odor-evoked responses to still cluster predominantly based on stimulus identity (Stopfer et al., 2003). We extended these earlier studies by examining how responses in the second-order projection neurons and local neurons in the antennal lobe, which directly receives input from sensory neurons, vary over a wide range of stimulus intensity (over 4 log units of dilution). Consistent with other reports in fruit flies (Olsen et al., 2010), our results also indicate that the local neuron responses scale linearly with concentrations to possibly facilitate gain-control computation in the antennal lobe. However, the projection neurons responses were altered in a non-linear manner. Most projection neurons that were activated at lower intensities were suppressed at higher intensities. As a result, at very different concentrations, we expect the ensemble neural responses evoked by the same stimulus became more distinct than neural activity encoding different odorants. This is currently being systematically investigated. Whether such drastic switch in ensemble projection neuron responses with intensity is observed for most odorants, and whether such ensemble responses changes correlate with variations in the behavioral responses to the same stimulus is also being currently explored.

Title: Cell type specific mechanisms for spike frequency modulation in the insects olfactory system

Authors: J. E. RADERMACHER, J. M. KLUSSMANN, D. FUSCA, S. CORNELIUSSEN, *P. KLOPPENBURG;
Biocenter, CECAD, Univ. of Cologne, Cologne, Germany

Abstract: In the insect olfactory system peripheral input from olfactory receptor neurons is strongly processed in the antennal lobe, the functional equivalent of the vertebrate olfactory bulb. Signal processing in the antennal lobe is accomplished by a highly interconnected network of local interneurons and projection (output) neurons. These interactions structure olfactory representation and ultimately shape the tuning profile of the projection (output) neurons. Here we analyzed intrinsic electrophysiological properties of cholinergic uniglomerular projection neurons and GABAergic local interneurons in the antennal lobe of the cockroach *Periplaneta americana*. While both neuron types are essential for odor processing in the antennal lobe, they have very different physiological tasks requiring specific physiological and morphological neuronal phenotypes. Local interneurons form synaptic connections exclusively in the antennal lobe and provide interactions between the glomerular pathways. While uniglomerular projection neurons also contribute to olfactory information processing within the antennal lobe, a main task of projection neurons is the transfer of preprocessed odor information from the antennal lobe to higher order centers in the protocerebrum. This study assessed whether and how the different tasks in odor information processing are reflected in the physiological phenotypes of these neurons. To this end we measured active and passive cellular parameters based on responses to defined current- and voltage clamp protocols of neurons that were pharmacologically isolated from synaptic input. We found significant cell-type-specific differences, with GABAergic local interneurons showing strong postinhibitory rebound after hyperpolarization, while uPNs showed spike frequency acceleration during sustained depolarization. The postinhibitory rebound of type I LNs was mediated by low voltage activated Ca^{2+} currents, whereas the spike frequency acceleration of uPNs was mediated by a combined effect of an inactivating voltage dependent K^+ current (I_A) and activation of calcium-activated non-specific cation current I_{CAN}.

Title: Mapping the Aedes aegypti antennal lobes

Authors: *S. SHANKAR, C. J. MCMENIMAN;
Johns Hopkins Univ., Baltimore, MD

Abstract: The antennal lobes (ALs) are the primary olfactory centre of the brain of the yellow fever mosquito, *Aedes aegypti*. In mosquitoes, the ALs mediate processing of a diversity of volatile odorants that drive innate behaviors such as host seeking, egg laying and foraging. Anatomically, the ALs are composed of functional units of neuropil known as glomeruli. An individual glomerulus is the point at which the axonal projections of olfactory sensory neurons expressing a single type of chemoreceptor, or complement of chemoreceptors converge and synapse with the dendritic arbors of projection neurons and local interneurons. Previous studies on the *Ae. aegypti* ALs, have reported between 35 and 49-50 glomeruli arranged around a non-glomerular core of mechanosensory neuropil known as the Johnston's Organ Centre. Here, we re-investigated the AL neuroanatomy of this mosquito species using improved labelling and imaging techniques. We present 3D models based on manual image segmentation and reconstruction of the left and right ALs from 10 male and 10 female mosquito brains. We observe that the AL is entirely composed of 77-80 olfactory glomeruli, and based on depth and spatial position, along the anterior-posterior, ventral-dorsal and medial-lateral axes, we classify 13 glomerular spatial groups in the male and female ALs. In our model, 70 individual glomeruli were spatially invariant and could be identified in at least 80% of all AL reconstructions, while the remaining glomeruli were classified as spatially variant, possibly reflecting morphological distortions in neuroanatomy as a result of *in vitro* dissection, fixation and imaging. Although we did not identify any sexually dimorphic glomeruli in the *Ae. aegypti* ALs, we found overall that the volume of the female antennal lobe, was approximately 1.5 times larger that of the male mosquitoes. We also present detailed two-dimensional maps, of representative male and female ALs, in which individual glomeruli were assigned a name based on spatial group and depth. Furthermore, using the binary QF2-QUAS binary expression system, we trace the neuronal projections of three classes of chemosensory neurons, to find non-overlapping subsets of 62 *Orco*, 14 *Ir8a and* 1 *GR1* positive glomeruli in each AL. These studies describe a revised model of the *Aedes aegypti* ALs. The high-resolution anatomical map presented here will serve as a useful reference for future functional imaging studies that aim to identify glomeruli activated by human odors to decode the molecular and cellular basis of mosquito attraction to humans.

Title: Sensitivity, specificity, and plasticity in the honeybee antennal lobe

Authors: *S. HANEY[1], H. LEI[2], B. H. SMITH[2], M. BAZHENOV[1];
[1]UCSD, La Jolla, CA; [2]Arizona State Univ., Tempe, AZ

Abstract: Sensing the environment involves both detection and categorization of stimuli. Olfactory systems need high sensitivity to quickly detect new and potentially important odors, but also need to be capable of classifying odors into categories to judge an appropriate response. However, these goals can be in conflict. While increasing sensitivity can be achieved by producing a large spiking response, excessive activity can produce a low signal to noise ratio and even saturate decoding circuits leading to poor categorization. We have shown that the honey bee can modulate which end of this spectrum it operates on depending on experience and plasticity. Previously, we have found that repeated and unrewarded exposure to a single odor sensitizes bees to all other odors, an effect termed novelty detection. This change is evident through an increased spike count and behavioral modification in response to the novel odors. Our computational modeling revealed that the novelty detection effect can be mediated by plastic disinhibition of the local inhibitory networks in the bee antennal lobe (AL). In this new work, we show that with increased sensitivity to the novel odors comes decreased specificity about each new odor identity. Specifically, we found that novelty detection mechanism: 1) decreases the overall impact of the local inhibitory networks; 2) decreases oscillatory synchrony; 3) decreases discriminability between two novel odors but increases discriminability between novel and familiar odors. Our study predicts that the honey bee brain can modulate AL inhibitory circuits locally in accordance with the current importance of the stimuli. Thus, pervasive but unrewarded odors give little response but are well characterized whereas novel but potentially interesting odors elicit large responses but initially are poorly characterized. This allows for a plasticity-, experience-, and odor-dependent manner of valuing two fundamental conflicting sensory goals: sensitivity and specificity.

Title: Electrophysiological examination of neurons in the palp olfactory pathway of locusts

Authors: *Z. N. ALDWORTH[1], M. A. STOPFER[2];
[1]NIH-NICHD, Bethesda, MD; [2]NICHD, NIH, Bethesda, MD

Abstract: Insects have proven to be a valuable model for studying the chemical senses, from sensory detection through behavior. An important question how neural circuits combine olfactory and gustatory cues. While the mushroom body is a candidate site for the combination of odor and taste information, the routes by which these modalities are combined remains unclear (Scott 2018). Most previous research has examined the olfactory pathway from the antenna to the primary calyces of the mushroom body, which play important roles in associative learning. However, another pathway that may allow olfactory and gustatory information to combine begins at the palps. The palps are composed of two pair of antenna-like organs near the mouthparts of insects which are used for feeding and food selection (Blaney & Chapman, 1970). In locusts, the tips of the palps are covered with several hundred contact chemosensilla, along with a small number of odor-detecting sensilla basiconica (Blaney, 1977). Each olfactory sensillum is innervated by 10-15 olfactory receptor neurons, which send their projections through the suboesophogeal ganglion to a region below the antennal lobe called the Lobus Glomerulatus (LG, Ignell et al, 2000). Olfactory information originating in the palp is kept segregated from antennal information through this first layer of processing (Dippel et al, 2016). From the LG, olfactory information ascends to the lateral horn and accessory calyx of the mushroom body, which are also the primary targets of gustatory information ascending along the tritocerebral tract (Frambach & Schürman, 2004). Convergence of gustatory and olfactory information in the accessory calyx potentially provides a location in the mushroom body potentially important for multimodal integration and associative learning.
To examine the suitability of the palp-accessory calyx pathway to serve as the substrate for combining olfactory and gustatory modalities, we make intracellular recordings from PNs receiving input in the LG and extracellular recordings from the palps and lateral horn. These recordings are made in combination with stimulation using both odorants and tastants, allowing us to test consecutive stages along the pathway for responsiveness to both stimulus modalities.

Title: Chronic exposure to La_2O_3 nanoparticles impairs honeybee's olfactory learning ability by damaging nervous system

Authors: *Y. LIU[1,2], Y. ZHANG[1], L. YIN[1];
[1]Inst. of Apicultural Research, CAAS, Beijing, China; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Nanoparticles (NPs) are increasingly used in industrial, agricultural and biological processes. However, little is known about the potential effects of nanoparticles on honey. In this study, we orally treated Apis *mellifera* L.with a set of concentrations of La_2O_3 (1, 10, 100, 1000 ppm) to test and determine their effect on survival, feeding rate and learning and memory behaviors, and further analyzed the neuronal apoptosis, synaptic units in the mushroom bodies and expression of selected memory or stress-related genes.
The results show that survival rates and feeding rates decreased in bees fed sugar syrup containing La_2O_3. Learning behavior was significant impaired by La_2O_3, while memory was not affected. La_2O_3 of 1ppm can induce nerve cell apoptosis in the brain of honeybees. We also found that the synaptic units density in the calyces of mushroom decreased after exposed to La_2O_3. Furthermore, memory-related genes expression were downregulated, stress-related genes expression were upregulated. Here, we provide evidence that nanoparticle La_2O_3 damages nervous system and thus impairs the olfactory learning ability.

Title: Effects of odor exposure on peripheral and central olfactory processing in *Drosophila*

Authors: *Z. GUGEL[1], E. J. HONG[2];
[2]Div. of Biol. & Biol. Engin., [1]Caltech, Pasadena, CA

Abstract: Plasticity is widely studied across different sensory systems and behavioral paradigms. Previous work in *Drosophila* olfaction has uncovered potential changes in odor preference and behaviors such as walking after chronic odor exposure. The synaptic and circuit mechanisms underlying these changes are unknown. Specifically, it is unclear if odor exposure alters odorant detection and coding at the level of olfactory neurons (ORNs) and antennal lobe projection neurons (PNs). Here, we perform a detailed characterization of the synaptic and cellular effects following chronic odor exposure. We exposed flies for two days to odorants known to selectively activate a single ORN type. PN odor responses were measured using patch-clamp electrophysiology following rearing. We find that odor exposure increases DL5 PN spike rates to low odor concentrations compared to paraffin-oil exposed flies. Surprisingly, we see evidence that other PNs have a heightened sensitivity after indirect rearing, which may be a result of a broad increase in lateral excitation across the antennal lobe. When we chronically reared flies to target another glomerulus, VM7, we find an increase in odor-evoked depolarization but no change in PN spike rates in the directly reared glomerulus. This result suggests that the effects of rearing are odor-dependent. To determine whether PN responses are a result of a change in input, we measured ORN spike rates and find no difference in paraffin and odor-reared responses. Next, we measured ORN-PN synaptic strength using a novel optogenetic technique to selectively recruit unitary EPSCs (uEPSCs) in PNs. The size of the uEPSCs was not different across the conditions, suggesting that the effects of PN sensitivity cannot be explained by a change in synaptic strength. Lastly, current injection reveals that directly reared PNs show heightened spike rates, suggesting that direct rearing may alter PN excitability.

Abstract: In insects, volatile chemical cues are received in the insect antenna where combinations of olfactory receptor neurons (ORNs) transduce these chemical signals into electrical signals and transmit them to downstream antennal lobe. In the fruit fly antennal lobe, the ORN signals are then relayed to at least two distinct populations of projection neurons: glutamatergic, uni-glomerular projection neurons (ePNs) and GABAergic, multiglomerular projection neurons (iPNs). How are the sensory input from ORNs transformed by these two distinct sub-populations of neurons within a single neural circuit? To understand this, using a custom-build light-sheet imaging setup, we monitored odor-evoked neural responses in transgenic flies expressing genetically encoded calcium indicators (GCaMP6f) in any one of these neural populations. We obtained 3D volumetric data with high spatial and temporal resolution. Neural activities in different neural compartments, such as dendritic processes (in the antennal lobe) and axonal projections (in the lateral horn) of ePNs and iPNs were monitored simultaneously. The three neural populations exhibited distinct tuning and temporal dynamics. We found the ePN projections to the lateral horn (LH) were functionally clustered, and that the response tuning between neighboring clusters appeared to be gradual (i.e. nearby lateral horn regions received functionally similar ePN inputs). On the other hand, the distribution of functional clusters in the calyx were not tightly clustered in space and seemed to be more dispersed. These results, while consistent with the recently published anatomical EM studies, reveal how sensory inputs from a single upstream neural network may be arranged topographically or non-topographically in distinct downstream targets. Further, we found that the information content varied as a function of time. Consistent with prior result in zebra fish, our preliminary results indicate that after odor onset, calcium signals in ePN and iPN axonal terminals were not odor specific but these coarse representations were refined over time to become more odor-specific. Interestingly, in many flies, after termination of odor stimulus, another bout of responses (i.e. OFF responses) were observed that activated ensembles of regions that were not activated during odor presentation. In sum, our data obtained with high temporal resolution, allowed us to examine how response dynamics may play an important in the fruit fly olfactory system.

Title: Octopaminergic neurons have multiple targets in *Drosophila* larval mushroom body calyx and regulate behavioral odor discrimination

Authors: *L. M. MASUDA-NAKAGAWA, A. D. MCLACHLAN, J. H. WONG, B. A. WAN, M. MONTAGNESE, S. ZHANG;
Dept. of Genet., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Behavior depends on discrimination of selective sensory representations. These are modified dynamically by changes in behavioral state, facilitating context-dependent selection of behavior. These are mediated by brain signals carried by noradrenergic input in mammals, or octopamine (OA) in insects. To understand the circuit mechanisms of this signaling, we characterized the function of two OA neurons, in the input region to the memory center, the mushroom body calyx, in larval *Drosophila*. Here they target multiple neurons, including olfactory projection neurons (PNs), the inhibitory neuron APL, a pair of extrinsic output neurons, but relatively few mushroom body intrinsic neurons, Kenyon cells. The OA receptor Oamb, a *Drosophila* alpha-1-adrenergic receptor ortholog, localized to PN terminals, and optogenetic activation of OA neurons both potentiated PN activity, and compromised odor discrimination behavior. Our results suggest that OA neurons gate odor signals for sensory processing via extrinsic inputs at the input to the olfactory learning circuit.

Title: Beyond sensory representations: Primary olfactory cortex reflects non-olfactory task-related variables

Authors: N. FEDERMAN, S. A. ROMANO, M. AMIGO DURAN, ***A. MARIN-BURGIN**; IBioBA-Conicet-Max Planck partner Inst., Buenos Aires, Argentina

Abstract: Sensory representations are typically thought as neuronal activity patterns that encode physical attributes of the outside world. However, increasing evidence is showing that as animals learn the association between a sensory stimulus and its behavioral relevance, stimulus representation in sensory cortical areas can change. Moreover, internal state as well as animal movements related to a particular task have been shown to modulate cortical activity. To study the dynamics of sensory cortex representations as behavior evolves, we developed a spatial context-olfactory task in which mice learn that an odor is rewarded when presented in a specific spatial context. We measured the activity of piriform cortex (PC) neurons in head-fixed mice running in a virtual reality environment. We find neurons not only responding to odors, but also to visual contexts and to water reward, indicating that the PC encodes information about relevant aspects of the task. Moreover, by analyzing the population activity dynamics using Principal Components Analysis (PCA), we find different population trajectories evolving through time that can discriminate aspects of different trial types. We then further dissected the contribution of different sensory and non-sensory variables to the modulation of PC activity at the level of individual trials, using a statistical approach based on Generalized Linear Models (GLMs). Our results show that, after animals have learned the context-odor-reward association, animal position in the virtual environment is a spatial element of the task that has considerable weight on PC responses. Furthermore, we found that variables related to both sensory and non-sensory aspects of the task (e.g., odor, context, reward, licking, sniffing rate and running speed) differently modulate PC activity, suggesting that the PC may use information from other brain areas to adapt odor processing depending on experience and behavior.

Title: Calretinin expressing interneurons are increased in olfaction and aggression related brain regions in forebrain specific-connective tissue growth factor knockout mice

Authors: *H.-C. CHANG[1], L.-J. LEE[1,2,3];
[1]Grad. Inst. of Anat. and Cell Biol., [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Connective tissue growth factor (CTGF) is essential in the development of the connective tissue. In the nervous system, CTGF is expressed in some distinct areas, such as the olfactory bulb and cortical subplate; however its function is still largely unknown. In order to elucidate the role of CTGF in the nervous system, *Emx1-Cre* driven forebrain-specific *Ctgf* knockout (Fb*Ctgf* KO) mice were generated. The expression of CTGF in the brain, including the olfactory bulb, is completely removed in the KO mice. Fb*Ctgf* KO mice showed exaggerated aggressive behaviors and greater c-fos expression in the medial amygdala (MeA). The aggressive behaviors in Fb*Ctgf* KO mice might be associated with increased calretinin (CR)-positive cells in the glomeruli of the olfactory bulb. In the present study, we examined the density of CR-positive cells in olfaction and aggression-related brain regions, including the anterior olfactory nucleus (AON), orbitofrontal cortex (OFC) and MeA. Compared with control mice, the numbers of CR-positive cells increased significantly in the AON and OFC of the Fb*Ctgf* KO mice; whereas in the MeA, the densities of CR-positive neurons were comparable between control and mutant mice. The density of CR-positive cells was also increased in the barrel cortex in Fb*Ctgf* KO mice, suggesting that the number of cortical CR-expressing neuron could be regulated by the presence of CTGF in the cortex. Increased CR-positive cells in the OFC might reduce the suppressive effect of OFC to the MeA thus enhance the aggressive performance in Fb*Ctgf* KO mice.

Abstract: The piriform cortex (PC) is a key sub-region of the olfactory cortex involved in olfactory processing and memory coding, it also implicated in various neurological and psychiatric disorders such as epilepsy, Alzheimer's disease and autism spectrum disorder. The PC is commonly divided into the anterior (APC) and posterior (PPC) parts, the APC and PPC differ markedly in their anatomical structures and physiological functions. However, the afferent connections of the two PC subdivisions, especially in a cell-type-specific manner remain poorly understood. Here, we mapped the whole-brain afferent inputs to the two main cell types (glutamatergic excitatory pyramidal neurons and GABAergic inhibitory interneurons) within the APC and PPC by adeno-associated virus and rabies virus-mediated cell-type-specific retrograde trans-synaptic tracing system. We found that excitatory and inhibitory neurons in both PC subdivisions receive similar afferent inputs dominantly from the olfactory areas, isocortex, hippocampal formation, cerebral nuclei and brain stem. Furthermore, we discovered that the input distributions are distinct between the two PC subdivisions. The APC preferentially innervated by some subregions of the olfactory areas and isocortex for both two types of neurons, supporting the function of the APC in encoding information about odor structures and odor associated contextual cues or values; whereas the inputs from hippocampal formation and amygdala were higher for the PPC, implying the function of the PPC in experience and emotion dependent information processing. Overall, our results expand our knowledge of the cell-type-specific afferent innervation of different PC subdivisions and provide a structural architecture for revealing the diverse function of the PC.

Title: Computational characterization of feedforward inhibitory neurons of anterior piriform cortex

Authors: *F. CAVARRETTA[1,2], T. A. CLELAND[2], C. LINSTER[1];
[1]Neurobio. and Behavior, [2]Psychology, Cornell Univ., Ithaca, NY

Abstract: The anterior piriform cortex (aPC) is an allocortex that integrates afferent inputs from the olfactory bulb (OB) with olfactory and non-olfactory information received from other brain regions. The axons of aPC pyramidal neurons extensively innervate the OB as well as other brain areas, providing feedback as well as feedforward processing.
In previous work, we modeled the biophysical properties of semilunar (SL) and superficial pyramidal (SP) cells, two classes of principal neurons in the aPC, along with their afferent and associative connections. Here we propose detailed models of two classes of aPC feedforward inhibitory neurons, horizontal (HZ) and neurogliaform (NG) cells, both of which are located in layer Ia, as well as bitufted (BT) cells, which are located in layer II. These interneurons have different intrinsic membrane and morphological properties and display distinct firing patterns. Based on the diverse data-dependent constraints imposed on these models, we propose that synaptic inhibition from HZ and NG cells is branch-specific on SP apical dendrites, as previously reported, but targets SL apical dendrites nonspecifically. Moreover, by assessing the outcomes of various HZ and NG connectivity profiles on balanced feedforward inhibition and the afferent fiber excitation of SLs and SP cells, we further suggest that HZ cells preferentially inhibit SL cells, whereas NG cells inhibit both SL and SP cells. Finally, again constrained by experimental data, we model the afferent fiber connectivity onto BT cells, and assess the hypothesis that the BT odor response is also driven by SLs. For each of these interneuron classes, we illustrate their specific dynamic effects on SL and SP responses, providing insight into the distinct functional roles of each interneuron class.

Title: Age-dependent increase of bouton-like structures in the mouse lateral olfactory tract

Authors: T. SATO[1], F. M. SEIBT[1], R. HOMMA[1], F. IMAMURA[2], ***S. NAGAYAMA**[1];
[1]McGovern Med. Sch. at UTHealth, Houston, TX; [2]Pharmacol., Pennsylvania State Univ. Col. of Med., Hershey, PA

Abstract: Olfactory information is transferred from the olfactory bulb to the olfactory cortex through the long axons of mitral and tufted cells whose axonal shafts are myelinated and bundled in the lateral olfactory tract (LOT). Here, we found previously unknown bouton-like structures along the mitral/tufted cells axons in the LOT. These structures were consistently observed regardless of the neurolabeling techniques, such as adeno-associated virus injection, electroporation labeling, or transgenic mouse lines. Protocadherin21(Pcdh21)-Brainbow mice generated by crossing Pcdh21-Cre (Cre expressing in mitral/tufted cells) mice with cre-inducible Brainbow mice allow us to observe a large population of axons as well as to identify each axonal structure. Using this transgenic mouse line, we evaluated the development of the bouton-like structure. Interestingly, these bouton-like structures were not detected in young (1-month old) mice but appeared in mice older than 3-month old. The number and size of the bouton-like structures increased in an age-dependent manner up to 6 months. After the 6 months, the amount of bouton-like structures did not increase although their size kept increasing. Surprisingly, these structures were not immunopositive to SV2, a marker for synaptic vesicle. In addition, these structures did not show calcium transient induced by the electrical stimulation of LOT in an acute slice preparation in which the LOT structure were almost intact. Therefore, these structures would not be canonical presynaptic sites, in which calcium is used for vesicle release. Moreover, our immunohistochemical analyses found that some of the bouton-like structures expressed the mitochondria marker, Tom20, and the autophagy marker, p62. These data suggest that the bouton-like structures in the LOT would rather be structures reflecting the change of internal metabolic conditions associated with aging.

Title: Neural circuit mechanisms of information routing in the mouse olfactory cortex

Authors: *S. DASTE[1], S. REZAEI-MAZINANI[2], W. A. MENA OROSTICA[2], A. FLEISCHMANN[1];
[1]Neurosci. and the Robert J. and Nancy D. Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [2]Ctr. for Interdisciplinary Res. in Biol. (CIRB) and CNRS UMR 7241 and INSERM U1050, Collège de France, Paris, France

Abstract: The Piriform Cortex (PCx), part of the mammalian olfactory system, encodes information about olfactory stimuli and odor memories. Piriform neurons project broadly to multiple target areas, including the Lateral Enthorinal Cortex (LEC), Cortical Amygdala (CoA), and the medial Prefrontal Cortex (mPFC). However, whether odor information is selectively transmitted to different target areas or broadly transmitted everywhere is poorly understood. Moreover, it is also unknown how information routing is shaped by learning and experience. Here we address these questions by recording neuronal activity in the PCx of awake behaving mice using GRIN lens technology and two-photon microscopy. We monitor the activity of a specific subset of PCx neurons by labelling neurons based on their projection targets using retrogradely transported AAVs. We chronically record the activity of up to 300 PCx neurons, and we can determine their odor-evoked population response properties under passive odor presentation and during appetitive learning. We will present preliminary data characterizing the response properties of piriform projecting neurons to LEC, CoA, mPFC and we will test our hypothesis that learning and experience reshape piriform response by recruiting relevant subsets based on context and valence. Together, our experiments will provide new insights into how olfactory information from piriform is broadcasted to targeted areas and how it is shaped by experience.

Title: The role of olfactory landmarks in place cell formation and navigation

Authors: *W. FISCHLER[1], N. R. JOSHI[3], L. J. KITCH[4], M. J. SCHNITZER[5], L. ABBOTT[2], R. AXEL[1];
[1]ZMBBI, [2]Neurosci., Columbia Univ., New York, NY; [3]Dept. of Cell Biol., Harvard Med. Sch., Boston, MA; [4]Stanford Univ., Stanford, CA; [5]Depts. Biol. & Applied Physics, Stanford Univ. Dept. of Biol., Stanford, CA

Abstract: A cognitive spatial map in the hippocampus combines internal information generated by an animal's movement in space (path integration) with sensory information from external landmarks. We have examined the convergence of external olfactory cues with internal self-

motion information to determine how mice represent, recognize, and employ olfactory landmarks to estimate their location relative to a reward site. We recorded the activity of GCaMP6f expressing neurons in the CA1 region of the hippocampus with a micro-endoscope while mice learned an odor guided virtual navigation task. Head-fixed mice were required to run on a featureless rotating ball in total darkness to reach a water reward located a virtual linear distance of 4 meters from the starting point. After 1-2 weeks of training without odor cues, 5.8% of the imaged neurons exhibited the properties of place cells. The number of place cells was maximal at the starting location and decreased exponentially with distance along the track. In the absence of odor cues the mice decreased their running speed and initiated anticipatory licking after traveling about 2m along the 4m track.
The mice then performed the task for 4 days with odor cues at 1m and 3m, and we observed a 6-fold increase in the number of place cells. In trials with either limonene or pinene 35% of recorded cells were classified as place cells. The animals suppressed licking and maintained high running speeds for ~3.5m of travel, licking ~0.5m before the goal location. The increase in place cell numbers occurred at all locations but was particularly pronounced at 1m and 3m, the locations of odor cues with the number of place cells decreasing exponentially as a function of distance from the cue. The place cell representations differed on limonene and pinene trials, demonstrating remapping.
Examining the emergence of place cells during training allowed us to observe the convergence of path integration with olfactory cues to establish spatial landmarks. Over the 4 days of training the number of place cells steadily increased. Place cells first emerged at the location of the 1m odor cue and as more place cells formed in the region between 1m and 3m, we observed the generation of an additional peak in place cell density at 3m. The emergence of place cells at the 3m odor cue coincided with the improvement in behavior. The topology of the hippocampal map, represented by population state trajectories, evolved to represent both the sensory and spatial structure of the environment. These results are consistent with a transformation of the internal representation of odor cues into distinct odor landmarks that serve to guide navigational behavior.

Title: Three-dimensional reconstruction of the layers of the main olfactory bulb and hippocampus proper in the allen mouse brain common coordinate framework

Authors: *Q. WANG, J. ROYALL, M. NAEEMI, K. HIROKAWA, L. NG, H. ZENG, J. A. HARRIS;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The main olfactory bulb and hippocampus proper in the mouse brain have multi-layered cellular architectures, and play crucial roles in olfaction, and in spatial navigation, learning and memory, respectively. In widely used 2D mouse brain atlases (Dong, 2018; Paxinos and Franklin, 2012), these layers were delineated based on cytoarchitecture and chemoarchitecture. However, in 3D atlases based on MRI images (Kjonigsen et al., 2014), transformation from 2D to 3D (Hjornevik et al., 2007), or our serial 2 photon tomography average template with multimodal references (Allen Mouse Brain Common Coordinate Framework, version 3, CCFv3), these layers were not three-dimensionally reconstructed. Since individual layers contain different cell types and efferent and afferent connections, it is important to reconstruct these layers in 3D for better understanding the functions of the two structures. The layers of the main olfactory bulb and hippocampus proper can be revealed with multimodal reference datasets, including cytoarchitecture, myeloarchitecture, genoarchitecture, chemoarchitecture and connectivity. To reconstruct these layers in CCFv3, we curated multimodal reference datasets from the Allen Institute portal (brain-map.org) in addition to the average template in which different layers of the main olfactory bulb and hippocampus proper have distinct brightness. By overlaying these references to the average template, we confirmed that the distinct bands of brightness in the average template correspond to specific layers of the two structures, and manually reconstructed these layers in 3D space, pixel by pixel, with 3D drawing software ITK-SNAP. In this study, we reconstructed 5 layers in the main olfactory bulb and CA3, and 4 layers in CA1 and CA2. In total, we added 14 3D reconstructed volumes into CCFv3, making 670 total structures in the final product. By adding new 3D volumes into CCFv3, we also demonstrate the flexibility of CCFv3 which can be improved periodically with additional data and updated knowledge. This improvement is critical for the detail and accuracy of neuroanatomical structures in CCFv3. Therefore, the newly updated CCFv3 will provide wider applications as a standard 3D digital mouse brain atlas for integrating, analyzing, visualizing, and modeling multimodal large-scale datasets generated from the Allen Institute for Brain Science and across the neuroscience community.

Title: A molecular atlas of cortical chemosensation

Authors: *J. R. HOWE, VI[1], C. L. CHAN[2], D. LEE[2], C. M. ROOT[2];
[1]Neurosci. Grad. Program, [2]Biol. Sci., UCSD, La Jolla, CA

Abstract: The paleocortex is an evolutionarily ancient, highly distinct region of the brain, with a unique three-layered structure and a wide range of functions centered on olfaction. One such region, the posterolateral cortical amygdala (plCoA), has recently been shown to assign innate emotional valence to certain odors, a dense connectivity to subcortical structures associated with the assigned valence, and a rostrocaudal valence topography. However, nearly nothing is currently known about the molecular features of any of the plCoA's constituent cells, preventing genetic access and drastically constraining the range of research that can be done in the region. Here, we performed droplet single-cell RNA sequencing on the paleocortical plCoA and the neocortical gustatory cortex (GC), a chemosensory region with a rostrocaudal taste topography, to create transcriptomic profiles of tens of thousands of individual cells, revealing dozens of classes of novel cell types and their relationships in these cortices. We have isolated cells based on their cortical layer, sex, and rostrocaudal coordinates, allowing identification of layer-specific, sex-specific, and topographic features among subpopulations of cells in the plCoA and GC. We also compare shared and distinct features between transcriptomes of cells in the plCoA and GC, illuminating the molecular relationship between these two regions in particular and the two cortical structures in general. In these experiments, we have identified molecular features of paleocortical structure, as well as created a resource that will greatly expedite genetic access to GC and plCoA subpopulations, accelerating future research into cortical chemosensation.

Title: Towards characterizing brain-wide neural circuitry dynamics underlying chemosensory avoidance in larval zebrafish

Authors: *K. SY, D. CHAN, H. LAI, Z. LI, J. CHOI, V. MOK, H. KO;
The Chinese Univ. of Hong Kong, Hong Kong, China

Abstract: Chemicals provide important environmental cues to guide animal behavior. While bilateral olfactory input is required for several animal species for optimizing odor navigation, the underlying circuit mediating bilateral integration of chemosensory information remains poorly understood. We employ larval zebrafish to study the bilateral integration of chemical signals upon encountering cadaverine, a diamine molecule released by decaying flesh, that drives chemosensory guided behaviour. In a customized arena where fluidic streams are spatially defined by laminar flow, we observed that 5 - 7 dpf freely swimming zebrafish larvae actively avoid the cadaverine-containing stream by increasing turn angles of subsequent swim bouts. Such behaviour necessitates bilateral olfactory input, as unilateral ablation of olfactory placode largely compromised the avoidance. Further on, we have built an integrated microfluidics - light sheet imaging platform for precise chemical stimulation while performing simultaneous neural activity and behavioural imaging, to characterize the brain-wide circuitry mediating the sensorimotor transformation.

Title: Unstable odor responses in piriform cortex

Authors: *C. E. SCHOONOVER[1], A. P. FINK[2], R. AXEL[3];
[2]Neurosci., [3]ZMBBI, [1]Columbia Univ., New York, NY

Abstract: The tuning properties of sensory neocortices are stably maintained over long periods in spite of continuous dendritic spine turnover. We have measured the stability of odor representations in piriform cortex (PCx), a three-layered paleocortical structure. In order to observe stimulus responses separated by long intervals, we developed an electrophysiological recording strategy that supports observation of a fixed population of single units for up to one month. In animals presented odorants at weekly intervals we find that representations are unstable; a linear classifier trained to classify responses to a panel of odorants recorded on day 1 performs nearly at chance one month later. However, we observe long term stability if odorants are presented at daily intervals. This stability depends on regular exposure: if daily odorant presentation is halted, representations become unstable once again. These results contrast with the stability of representations in sensory neocortices, even when stimulus presentation is infrequent. We hypothesize that this distinction reflects differences in circuit architecture between neocortex and paleocortex. Neocortex receives patterned thalamic input and exhibits local horizontal connectivity. This organization permits loss and restoration of similarly tuned synapses, ensuring the stability of sensory tuning. In contrast, PCx is characterized by unstructured innervation from olfactory bulb and distributed horizontal connections. Synaptic turnover in PCx is therefore likely to result in instability in stimulus representations, presenting a problem for the maintenance of learned behaviors elicited by odors. Our observations suggest that if PCx encodes odor identity, these representations must be transmitted to a more stable repository of odor information. Alternatively, PCx may not encode odor identity and instead may function in more transient processes of sensory recognition and learning.

Title: Normative modeling of sensory network dynamics for stimulus tracking

Authors: *S. MALLIK[1], D. SAHA[2], B. RAMAN[2], S. CHING[1];
[1]Electrical and Systems Engin., [2]Biomed. Engin., Washington Univ. In St. Louis, St Louis, MO

Abstract: We consider the question of how early sensory networks enable the detection and tracking of sensory stimuli in a combinatorial coding space. We do this through a normative, optimization-based framework wherein sensory networks provide input to a downstream latent decoder. Specifically, our model for sensory tracking uses the notion of a detection space where high dimensional stimuli are mapped via a dynamical, linear decoder onto lower dimensional, mutually orthogonal axes corresponding to different stimulus identities. The normative objective of the sensory network is to provide an activity to the decoder in a way that achieves high-fidelity trajectories (i.e., sensory decoding/tracking) in an efficient manner. It turns out that the optimal encoding strategy achieves this objective when sensory neurons respond to a stimulus onset by emitting a phasic transient followed by persistent tonic excitation. Upon withdrawal of a stimulus, the decoded latent state returns to its equilibrium following another short burst of phasic activity. Further, these optimal sensory responses are generated through a network with architecture and dynamics that are commensurate with known combinatorial coding systems, such as olfaction. Indeed, the synthesized network is highly compatible with that which is observed in the olfactory network of locusts. Interrogating the modeled network makes several predictions about tradeoffs in the speed and accuracy of sensory detection, as well as responses to stimulus mixtures.

Abstract: Olfaction is important for human cognition, but the anatomy of the human olfactory system is poorly understood. Diffusion magnetic resonance imaging (dMRI) is an attractive method for characterizing the fiber pathways that connect olfactory regions, but these areas are often obscured by blurring and imaging artifacts, due to their close proximity to the sinuses. Typical tensor models used to model white matter structure are also incapable of characterizing curving and crossing fibers within a single voxel. In this project, we addressed these shortcomings and designed a dMRI protocol for visualizing olfactory system structure. Subjects (n=5, 4 female) participated in olfactory threshold, odor discrimination, and odor identification tasks. We then collected dMRI and anatomical scans. Subjects wore 3D-milled head cases, matched to the scanner coil and to each subject's face and head, preventing motion during scanning and improving image quality. We collected dMRI scans with 1.5 mm isotropic resolution, b = 1000 s/mm^2, and 90 diffusion directions. We used a WIP (Siemens work in progress) multi-shot echo planar imaging sequence to reduce blurring and image artifacts. We also collected a 1.0 mm resolution whole brain T1-weighted anatomical scan, and a 0.5 mm resolution T2-weighted scan covering the ventral-anterior portion of the brain, including the orbitofrontal cortex and olfactory bulbs. Anatomical images were used to locate olfactory regions of interest, which were used as seeding regions for generating tractography models. We fit a constrained spherical deconvolution model from MRtrix2 to the dMRI data, capable of characterizing crossing and curving fibers within single voxels.Tractography data seeded from the olfactory bulb show the lateral olfactory tracts. Tracts were observed passing between piriform cortex seeds and orbitofrontal cortex, anterior cingulate cortex, fornix, mediodorsal thalamus, amygdala, hippocampus, entorhinal cortex, insula, and occipital cortex. Future analyses will determine microstructure properties for white matter voxels in the identified pathways, including fractional anisotropy, an indirect measure of white matter integrity, and relate them to measures of olfactory perception.

Title: Satiety alters sensitivity: Effects of food intake on olfactory processing in humans

Authors: *L. K. SHANAHAN[1], T. KAHNT[1,2];
[1]Neurol., Northwestern Univ., Chicago, IL; [2]Psychology, Northwestern Univ., Evanston, IL

Abstract: Odors serve as important cues for guiding food search and intake. Some previous work has demonstrated that olfactory sensitivity is enhanced in the hunger state when compared to the sated state, which could facilitate food search when nutrients are needed most. However, there are conflicting reports in the literature, and the neural mechanisms underlying these changes are not well understood. Here, we designed a novel paradigm to measure sensitivity to food odors. Human subjects performed a binary choice task where they smelled odor mixtures containing food and non-food components (e.g., pizza and pine), and indicated the component they perceived as dominant in the mixture. To compare behavior across hungry and sated states, subjects completed this task before and after a food odor-matched meal (e.g., pizza). Preliminary behavioral findings suggest that subjects are less likely to identify the food component as dominant in the mixture in the sated state, specifically for the mixture containing the matched food odor. By using functional magnetic resonance imaging (fMRI), we can study the neural correlates underpinning this shift in choice behavior. More specifically, we can gain insight into whether state-dependent changes in odor perception are driven by bottom-up or top-down influences. Our work will promote a richer understanding of the relationship between food intake and odor perception, which may have implications for eating disorders and obesity.

Title: Resting state fMRI study of the olfactory region in autism

Authors: *M. L. LAWRENCE, T. IKUTA;
Univ. of Mississippi, Oxford, MS

Abstract: Olfactory dysfunction has been found in many neurological and psychiatric disorders such as Schizophrenia, Alzheimer's disease, and Parkinson's disease. Autism Spectrum Disorder (ASD) has also been found to involve olfactory dysfunctions. However, the olfactory system in ASD has rarely been studied despite that the olfactory system may uniquely reveal underlying conditions. In this study, we aimed to examine the olfactory regions of the brain to elucidate the other parts of the brain that are differently connected to the olfactory regions in ASD. Using resting state fMRI data from Autism Brain Imaging Data Exchange (ABIDE), we analyzed the functional connectivity of the olfactory regions in 60 individuals with ASD and 60 without ASD.

Whole brain functional connectivity of the four olfactory regions (Olfactory Bulb, Olfactory Tract, Anterior Piriform Cortex, and Posterior Piriform cortex) was independently tested to test the group differences. While three other regions did not show a statistically significant difference between two groups in their connectivity to the rest of the brain, the APC showed lower connectivity to the ventromedial PFC (vmPFC) in the ASD group compared to the typically developing group. The vmPFC has been shown to be responsible for self-related processing and values in decision making. Consistent with previous findings, our results suggest that the olfactory processing and decision making is not well communicated. It is implicated that odor information is not well registered to the processes of decision making.

Title: Primacy model and the evolution of the olfactory receptor repertoire

Authors: H. GIAFFAR[1], D. RINBERG[2], ***A. KOULAKOV**[3];
[1]Cold Spring Harbor Laboratory, Watson Sch. of Biol. Sci., Cold Spring Harbor, NY; [2]Neurosci. Inst., New York Univ., New York, NY; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Understanding sensory processing relies on establishing a consistent relationship between the stimulus space, its neural representation, and perceptual quality. In olfaction, the difficulty in establishing these links lies partly in the complexity of the underlying odor input space and perceptual responses. Based on the recently proposed primacy code for concentration invariant odor identity representation and a few simple assumptions, we have developed a theoretical framework for mapping the odor input space to the response properties of olfactory receptors. We analyze a geometrical structure containing odor representations in a multidimensional space of receptor affinities and describe its low dimensional implementation, the primacy hull. We suggest statistical tests that can be used to detect correlations in receptor-ligand activity or olfactory connectivity data consistent with a primacy hull. We further discuss implications for the structure of feedforward connectivity in the early olfactory network.

Title: A physicochemical model of odor sampling

Authors: *T. A. CLELAND[1], M. E. GRONOWITZ[2], A. LIU[2];
[1]Psychology, [2]Computer Sci., Cornell Univ., Ithaca, NY

Abstract: To date, efforts to describe olfactory physicochemical sampling have been heuristic. The primary strategy has been to compose lists of many physicochemical properties, or molecular descriptors, of various odorous molecules and cross-reference these lists with perceptual or physiological datasets. While these approaches offer some predictive utility, they are not ultimately generative. For example, they cannot be used to explain the perceptual decomposition of odor mixtures, nor to study how the same physicochemical odor scene will be differently sampled by the noses of different animal species (potentially resulting in different profiles of similarity). We here present a general physicochemical sampling model based on established pharmacological laws in which arbitrary combinations of odorant ligands and receptors can be constructed and their individual and collective effects on the resulting odor

representation studied. Receptors occupy regions of a physicochemical quality space, or Q-space; this space maps the strength and efficacy of ligand-receptor interactions and enables recognition of the physical similarities among chemical species that are likely to be reflected in overlapping receptor interactions. Odors may comprise one or many ligands in characteristic concentration ratios; each ligand exhibits receptor-specific affinities and efficacies. Ligands interacting with common receptors compete with one another for dwell time; these competitive interactions appropriately simulate the degeneracy that fundamentally defines the capacities and limitations of odorant sampling. The outcome of these competing interactions is expressed as a pattern of receptor activation levels, thereafter mapped to glomerular presynaptic activation levels based on the convergence of sensory neuron axons. The metric of greatest interest is the perceptual discrimination sensitivity, a measure of how effectively the olfactory system at this level is able to recognize a small change in the physicochemical quality of a stimulus. This model captures the effects of changing the numbers and selectivities of receptors, the effects of increased numbers of ligands (eventually yielding "olfactory white"), the benefits of antagonist ligands, and the modest reduction in discrimination exhibited by transgenic mice in which olfactory sensory neuron targeting of glomeruli has been disrupted.

Abstract: Introduction: Oliviero et al. (2011) reported that 10 min of transcranial static magnetic field stimulation (tSMS) using a strongly powered cylindrical neodymium, iron and boron (NdFeB) magnet can reduce the amplitude of motor evoked potentials (MEPs), Since then, tSMS is getting a lot of attention as a new non-invasive brain stimulation (NIBS) techniques next to conventional methods, such as rTMS and tDCS. Further, we showed that tSMS over S1 decreases the amplitude of the N20 component of somatosensory evoked potentials (SEPs) following median nerve stimulation (Kirimoto et al., 2014), tSMS over M1 reduces the N33 component of SEPs (Kirimoto et al., 2016), and modulate cortical nociceptive processing (Kirimoto et al., 2018), similar to other NIBS techniques.
Objective: This study aimed to investigate the possibility of non-invasive modulation of visual spatial cognition by the application of tSMS over the parietal association cortex or temporal lobe in healthy humans.
Methods: Subjects performed a visuo-spatial task requiring judgements about the symmetry of prebisected lines. Visual stimuli consisted of symmetrically or asymmetrically transected lines, tachystoscopically presented for 150 ms on a computer-monitor. Performance was examined before immediately after, and 10 min after tSMS of 20 min. We used a cylindrical NdFeB neodymium magnet (diameter, 50 mm; height, 30 mm) with a surface magnetic flux density of 534 mT, maximum energy density of 49 MGOe, and a nominal strength of 862 N for tSMS. An NdFeB magnet or a non-magnetic stainless cylinder (for sham stimulation) was settled on the scalp over the right parietal association cortex (P4) or temporal lobe (C6) of 16 subjects for periods of 20 min.
Results: 9 of 16 subjects misjudged prebisected lines by consistently underestimating the length of the right-side segment (that is by judging lines to be exactly prebisected when the bisection mark was actually located to the left of the true midpoint, or by judging segment longer when lines were exactly bisected). In these subjects who showed leftward bias, scores of tasks were significantly improved at tSMS over C6 as compared to tSMS over C4 and sham stimulation conditions. In the right-biased group, no intervention effects ware observed for stimulation under any condition.
Conclusions: The main result of the present study is that transient inhibition of right temporal lobe, induced by tSMS, improves the visual spatial cognition, as tested with a line's length judgement task.

Title: fMRI guided electrophysiology of spatial attention shifts in the macaque superior parietal lobule

Authors: *M. DE VITIS[1,2,3], P. F. BALAN[1,3], C. GALLETTI[2], P. FATTORI[2], R. VOGELS[1,3], W. VANDUFFEL[1,3,4,5];

Abstract: We continuously shift our attention between items in the visual environment, and this represents a fundamental process for guiding goal-directed behavior. Visual spatial attention improves behavioral performance by allowing subjects to focus on the most relevant information in complex scenes and suppress irrelevant signals. Several human fMRI and TMS studies showed the involvement of superior parietal lobule (SPL) in covert shifts of attention. Despite hints from monkey electrophysiology (Galletti et al., 2010) and fMRI (Caspari et al., 2015), still little is known about the underlying neuronal mechanisms. Guided by monkey fMRI maps, we recorded single and multi-unit activity from shift-selective regions in medial SPL (parietal areas V6/V6A) using laminar probes.
Our covert selective spatial attention paradigm was highly similar to that of human (Molenberghs et al., 2007) and monkey (Caspari et al., 2015) fMRI experiments, and allowed us to dissociate attentional shift and stay, and motor events (used to probe the allocation of attention). Stimuli consisted of 2 pairs of yoked shapes, each containing a relevant and irrelevant stimulus (one located in the center of the receptive field (RF), and the other diametrically opposed). The display always contained one of the two pairs. A replacement of the first stimulus pair by the second could induce a spatial attention shift when the relevant stimulus position changed to the opposite visual hemifield (shift event). Alternatively, when the relevant stimulus of the new pair appeared at the same position as the relevant stimulus of the preceding pair this corresponded to a stay event. The allocation of attention was probed behaviorally by dimming events (50% of the trials) of the relevant/irrelevant stimuli, separated in time from the shift/stay events.
We recorded activity from 192 multi-unit sites in areas V6/V6Av of one rhesus monkey. We found that the average population activity of all recorded neurons was higher for shift than stay events (Wilcoxon test, $p<0.05$, FDR corrected) when the direction of the shifts pointed towards the RF. Conversely, when shifts pointed to the opposite direction, the activity for stay events was higher in early and late stages of the attention period (Wilcoxon test, $p<0.05$, FDR corrected). Shift-selective population activity peaked around 40-60 ms after event onset, when 66.7% of cells showed significant shift-selective activity (contrast shift vs. stay, Wilcoxon test, $p=10^{-5}$).

Consistent with the human and monkey fMRI data, these results show a strong correlate of shifting covert spatial attention at neuronal level within parietal areas V6/V6A in the absence of overt behavior.

Title: Isolating subcomponents of the N2pc: item-, feature-, and space-based selection

Authors: *M. V. BARTSCH[1], H. STRUMPF[2], C. TEICHMANN[2], M. A. SCHOENFELD[2,1,3], J.-M. HOPF[2,1];
[1]Leibniz Inst. for Neurobio., Magdeburg, Germany; [2]Univ. of Magdeburg, Magdeburg, Germany; [3]Kliniken Schmieder Heidelberg, Heidelberg, Germany

Abstract: The N2pc is a well-known component of the event-related brain response, widely used to investigate the allocation of attention during visual search. Visual search, however, involves a number of attentional selection processes, including feature-based attention (feature guidance), shifts of spatial attention, and target discrimination. The separate contribution of those subprocesses to the N2pc is often not acknowledged, and currently not well understood. Here, we report data from two ERP experiments aiming at clarifying the specific contribution of feature-, space- and item selection to the N2pc response. To this end, we recorded event-related potentials (ERPs) in human observers when performing two experiments employing different versions of a cued visual search task. Experiment 1 (23 subjects) was setup to isolate spatial shift of attention by comparing tasks where subjects either searched for a color-defined target across the whole visual field (VF) versus within a pre-defined VF. Experiment 2 (22 subjects) assessed the contribution of feature-based attention by comparing the selection of a color-defined target in a pre-defined VF with the selection of the same target at a pre-defined spatial location independent of its color. We find that, while all experimental conditions elicit robust N2pc effects, variations of amplitude and time course of the ERP response revealed a sequence of attentional subprocesses. Specifically, feature-attention was found to be reflected by early portions of the N2pc, while later portions index processes of target discrimination. Intermediate portions following feature-attention reflect shifts of attention. Taken together, the results

emphasize that the N2pc should be conceived of as a multi-component process that can be decomposed in feature, space and item selection processes.

Title: Isolating attentional modulation in superior colliculus associated with behavioral sensitivity, decision criterion and motor preparation

Authors: *S. GHOSH, J. H. R. MAUNSELL;
Dept. of Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Like those in visual cerebral cortex, neurons in the superior colliculus (SC) of monkeys are strongly modulated by attention. It has been a point of contention whether attention-related enhancement of neuronal activity in the SC is associated with selective increase in behavioral *d'* in neurons' receptive field or is instead associated with animals' response bias, which can be closely linked with motor planning. We trained rhesus monkeys in a novel visual orientation-change detection task that precisely dissociates perceptual sensitivity (*d'*), decision criterion and motor planning by presenting choice targets spatially orthogonal to the attended locations. Monkeys' attentional performance (*d'*) and decision criterion at the neuron's receptive-field location were independently controlled, and sequentially switched between high and low levels within short blocks of trials by adjusting relative reward probabilities associated with stimuli in the left and right visual hemifields. Multiple SC neurons were recorded simultaneously while the animal did the task. Results from two animals showed that SC neurons increased their rate of firing when behavioral selectivity (*d'*) increased at their receptive-field location. This attentional modulation was stronger for visuomotor neurons compared to purely visual neurons, and was negligible in motor neurons. Unlike selective *d'*, change in decision criterion had no effect on spiking of these same SC neurons. These results confirmed that SC neurons contribute selectively to specific attentional states, and increased attentional performance can enhance spiking of SC neurons independent of decision criterion or motor planning towards the receptive field.This behavioral task has special significance for isolating distinct behavioral components associated with attention states in brain areas that respond to motor actions.

Title: Properties of saccade vergence eye movements in athletes

Authors: *Y. YOSHIMURA[1], T. KIZUKA[2], K. MATSUDA[3], S. ONO[2];
[2]Hlth. and Sport Sci., [1]Univ. of Tsukuba, Ibaraki, Japan; [3]Human Informatics Res. Inst., AIST, Ibaraki, Japan

Abstract: It is well known that saccades are one of the eye movements to capture moving objects accurately with eyes. Saccades are rapid eye movements that shift the line of sight between successive points of fixation. For saccades in the two dimensions (2D) that are smaller than about 20 degrees, there is a linear relationship between peak velocity and amplitude. Saccades above 20 degrees, peak velocity shows a progressive increment with asymptotic values of about 500 degrees per second. The relationship between peak velocity and amplitude over a very wide range of saccades is called “main sequence”. Most of the previous studies dealing with saccades have reported saccades in the 2D. Although there are several studies have reported about saccades in the depth, it is still uncertain about the main sequence of saccade-vergence eye movements. Eye movements in the depth are called vergence eye movements. Vergence eye movements are disconjugate eye movements opposed to saccades in the 2D which are conjugate eye movements. Therefore, the purpose of this study was to clarify the properties of the main sequence of saccade-vergence eye movements in athletes. The subjects were college students belonging to college sports teams. The subjects were seated in front of stationary visual targets, which were 14 mm diameter balls positioned at different vergence angles (i.e. 2, 5, 10, 20 degrees). The subjects gazed at each target in order from nearest to farthest and vice versa. Ten repeated trials were conducted at each distance. Eye position was detected by the eye tracking system based on corneal reflections. The results showed that peak eye velocity of saccades in the depth task was slower than 2 dimensional saccades. Regarding the vergence eye movements, peak eye velocity of the convergence eye movement was larger than divergence. Furthermore, each subject showed different properties of the main sequence of saccade-vergence eye movements. These results could be associated with the different ability of depth perception in space.

Title: Visual awareness modulates visuospatial attention

Authors: *A. I. WILTERSON, N. KIM, C. KEMPER, M. S. A. GRAZIANO;
Princeton Univ., Princeton, NJ

Abstract: The discovery that attention to a stimulus and awareness of a stimulus are separable is arguably one of the most crucial experimental findings in the study of awareness. However, though separable, the two processes may still influence each other, and the nature of that interaction remains unresolved. The goal of the present five experiments was to examine how awareness influences attention. We measured two aspects of attention at three levels of awareness. Human subjects performed a visual attention task in which a cue affected subjects' attention, as measured by their reactions to a subsequent target. The task measured both exogenous attention drawn to the location of the cue, and endogenous attention directed to a location predicted by the cue. Awareness was tested at three levels. First, subjects were aware of all relevant aspects of the task. Second, subjects were visually aware of all stimuli, but unaware of the predictive contingencies between the cue and target. Third, subjects were unaware of the contingencies and also visually unaware of the cue. The results showed that all aspects of attention measured here were possible under all awareness conditions. Removing awareness of the cue-target contingencies had little effect on the present measures of attention. Removing awareness of the cue also left exogenous and even endogenous aspects of attention present, but endogenous attention was slower to develop. The results suggest that awareness and attention interact, but that awareness plays a modulatory rather than a necessary role.

Title: Multifaceted visual search reveals separate cortical subsystems for different aspects of the task

Authors: *S. SLIVKOFF[1], L. WEHBE[2,1], J. GALLANT[1];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Carnegie Mellon, Pittsburgh, PA

Abstract: Introduction: Previous studies show that the attention state of the brain affects its representation of visual features (Cukur et al. 2013, Harel et al. 2014, Baldauf et al. 2014). However, these studies only probed a limited stimulus set or a limited number of attention states. This makes it difficult to determine whether their results generalize to new conditions or if they are only relevant to the conditions examined. These previous studies were also unable to fully establish how their results might be affected by behavioral factors such as task difficulty and target detection.
Methods: We use functional magnetic resonance imaging (fMRI) to investigate the interaction between visual search and the representation of various task-relevant features in human cerebral cortex. For this we created a naturalistic visual search experiment with 14 distinct search conditions, controlling for potentially confounding factors such as target detection. This complex experimental design was optimized using mixed integer linear programming. We used voxelwise encoding models to characterize how cortical activity (as measured by the blood oxygen level-dependent signal) is affected by various experimental factors including the search target, stimulus content, target detection. We used separate datasets for training and testing in order to control for over-fitting, estimate prediction accuracy, and test generalization.
Results: We find that stimulus content, search target, target detection, and trial difficulty each elicit distinct spatial distributions of cortical activity. Each of these experimental factors predicts brain activity in different subregions within occipital, intraparietal, and prefrontal cortices. We also observe large differences in magnitude and spatial distribution of cortical activity associated with different search targets. In particular we find large differences in the spatial distribution of regions engaged by high-level semantic targets and low-level color targets. These effects are found in each individual subject, not merely at the group level.
Conclusion: We used a large number of distinct search conditions in order to characterize how attention interacts with a variety of experimental factors including search target, stimulus

content, target detection, and task difficulty. By characterizing all of these factors simultaneously within a cross-validated model, we were able to disentangle the effects of each factor and reveal that each predicts activity in a distinct set of cortical areas.

Title: Top-down retinotopic coordination of cortical state across V1, V4 and FEF of the Macaque

Authors: *J. VAN KEMPEN[1], M. BOYD[1], M. A. GIESELMANN[1], N. A. STEINMETZ[2], T. MOORE[3], T. A. ENGEL[4], A. THIELE[1];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Biol. Structure, Univ. of Washington, Seattle, WA; [3]Neurobio., Howard Hughes Med. Inst. - Stanford Univ., Stanford, CA; [4]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Spontaneous activity fluctuations are ubiquitous in cortex. The strength and coordination of these fluctuations between neuronal populations are affected by cortical state, and they reflect changes to neural excitability which influence sensory processing and behaviour. Recent evidence (Engel et al., 2016) revealed that fluctuations in cortical state, previously presumed to occur synchronously across the entire cortex, are modulated locally by spatial top-down attention in V4. Global cortical states can thus be coordinated by cognitive demands and operate on a local scale. Such local, attention-related state changes also occur within primary visual cortex (V1), and they co-occur between V1 and V4 (Program No. 145.12, SFN 2018). Here we investigate whether the coordination of cortical state is mediated in a top-down, bottom-up, or globally coordinated manner.
We recorded simultaneously from V1 and V4 using 16-contact laminar electrodes in 3 Macaque monkeys performing a selective attention task. In a different data set, we recorded simultaneously from 16-contact laminar electrodes in V4 and single or 16-contact electrodes in FEF. We used a Hidden Markov Model (HMM) to characterize On-Off dynamics in multi-unit activity, and investigated the effects of these dynamics on activity within and across areas.
As reported previously, cortical states are correlated between V1 and V4. State transitions in

either area are preceded and followed by activity changes in the other area. Although coordination of state changes is not deterministic, on average, state transitions in V4 precede state transitions in V1, suggesting that V4 activity-changes drive cortical state changes in V1. Similarly, we found that FEF firing rate changes precede cortical state transitions in V4. Together these results suggest that On-Off transitions traverse along the cortical hierarchy in a top-down manner.
Fitting a 4-state HMM to V1 and V4, in which either or both areas could be in an Off or On state, revealed that, when both areas were in an Off state, it was more likely for V4 than V1 to transition to an On state. Moreover, when both areas were in an On state, it was more likely for V4 than V1 to transition to an Off state. Critically, behavioural performance increased from when both areas were Off, through V1 On - V4 Off, through V1 Off - V4 On, to V1 and V4 On. Thus, cortical state is coordinated across retinotopic locations in a feedback manner, whereby FEF activity changes precede state transitions in V4, and V4 state transitions precede V1 state transitions.

Title: Linking noise correlations to spatiotemporal population dynamics and network structure

Authors: *Y. SHI[1], N. A. STEINMETZ[2], T. MOORE[3], K. BOAHEN[4], T. A. ENGEL[1]; [1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Biol. Structure, Univ. of Washington, Seattle, WA; [3]Neurobio., Howard Hughes Med. Inst. - Stanford Univ., Stanford, CA; [4]Dept. of Electrical Engin., Stanford Univ., Stanford, CA

Abstract: Co-fluctuations of neural activity are generally characterized as correlations between pairs of neurons, termed noise correlations. Noise correlations depend on anatomical dimensions, such as cortical layer and lateral distance, and they are also dynamically influenced by behavioral states, in particular, during spatial attention. Specifically, recordings from laterally separated neurons in superficial layers find a robust reduction of noise correlations during attention [1]. On the other hand, recordings from neurons in different layers of the same column find that changes of noise correlations differ across layers and overall are small compared to lateral noise-correlation changes [2]. Evidently, these varying patterns of noise correlations echo

the wide-scale population activity, but the dynamics of population-wide fluctuations and their relationship to the underlying circuitry remain unknown.
Here we present a theory which relates noise correlations to spatiotemporal dynamics of population activity and the network structure. The theory integrates vast data on noise correlations with our recent discovery that population activity in single columns spontaneously transitions between synchronous phases of vigorous (On) and faint (Off) spiking [3]. We develop a rate network model of cortical columns, which replicates cortical On-Off dynamics. Each unit in the network represents one layer—superficial or deep—of a single column. Units are connected laterally to their neighbors within the same layer, which correlates On-Off dynamics across columns. To test the theory, we analyze linear microelectrode array recordings of spiking activity from all layers of the primate area V4 during an attention task.
First, at the scale of single columns, the theory accurately predicts the broad distribution of attention-related changes of noise-correlations in our laminar recordings, indicating that they largely arise from the On-Off dynamics. Second, the network model mechanistically explains differences in attention-related changes of noise-correlations at different lateral distances. Finally, the theory accounts for differential modulation of noise correlations during spatial attention in superficial and deep layers. Our work provides a unifying framework that links network mechanisms shaping noise correlations to dynamics of population activity and underlying cortical circuit structure.

Title: Effects of local and global attention states on mouse superior colliculus activity during a visuospatial selection task

Authors: *S. E. BROOKE, E. G. MCBRIDE, E. M. CALLAWAY;
Salk Inst., La Jolla, CA

Abstract: Visuospatial attention allows one to ignore vast amounts of irrelevant stimuli by enhancing the information in an important space of the visual field. Its neural correlates and its behavioral output have been studied in detail in cortex, but complementary substrates including the superior colliculus (SC) are less well studied, particularly in mice. We utilize a mouse spatial selection task in which the probability that a subtle stimulus change, whose detection is required to receive a water reward, is much higher (80%) in one side of the visual field than in the unlikely (20%) side (McBride, Lee & Callaway 2019). Under these circumstances, these "80/20" mice learn to ignore one location and selectively attend to the other. In contrast, "50/50" mice train with equal probability in either location and therefore perform equally in response to changes in either location. The task consists of 3 epochs: 1) a bilateral visual stimulus that corresponds to trial onset, 2) a variable delay period, and 3) a unilateral change in stimulus contrast that corresponds to the response window. Using this paradigm, we have previously made bilateral electrophysiological recordings in the primary visual cortex (V1) using 64 channel silicone laminar probes. Results demonstrate performance-related selective changes in local field potentials, noise correlations, and spiking activity in 80/20 mice, and global changes in 50/50 mice. This task therefore allows measurements of the neural correlates of spatial selection and can potentially be used to investigate underlying mechanisms as well as substrates that control spatial selection. Here, we use the same behavioral paradigm to investigate task-related activity during selective and global brain states while recording from SC. We find that SC activity in response to the visual stimulus at trial onset is much greater in the superficial layers of the likely hemisphere, even though that stimulus is identical in both visual fields. This suggests that SC on the "likely" side is primed to respond more strongly. In contrast, we find that following the stimulus change there is more activity on correct than incorrect trials. This effect is bilateral even though the stimulus change is unilateral. This activity is consistent with transfer of bilateral cortical activity (observed in our prior studies) being transferred to the SC and then being used to generate the motor response. Planned experiments that will allow SC to be optogenetically inactivated during specific epochs of this task are expected to allow the roles of the SC in attentional control, visual stimulus detection and motor responses to be separated.

Title: Humans can attend to complex latent image dimensions

Authors: *H. SCOTT[1], A. SNYDER[1,2,3], I. FRUEND[4,5,6];
[1]Brain and Cognitive Sci., [2]Neurosci., [3]Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY;
[4]Dept. for Psychology, [5]Ctr. for Vision Res., [6]Vision: Sci. to Application, York Univ., Toronto, ON, Canada

Abstract: The visual system needs to compress the massive amount of information in the natural world into a more tractable form. One method to accomplish this is to represent regularities within the high dimensional data by a small number of latent variables. This method of removing redundancies in the input has successfully explained a number of physiological properties of biological sensory systems. In a similar fashion, a type of artificial neural network called Generative Adversarial Nets (GAN) are trained to reproduce realistic looking images from a lower-dimensional input, and so provide a possible candidate for a low dimensional latent representation of natural images. If the brain uses latent variables similar to those learned by a GAN to efficiently represent natural images, then people should be able to attend to changes along such dimensions. In this experiment, subjects watched movies that consisted of sequences of images created by moving along regular paths through a GAN's latent space. We hypothesized that people are sensitive to changes in the GAN's latent space, and can attend to specific latent dimensions. We found that human observers were not only able to detect changes in the complex high-dimensional feature dynamics of these movies, but they are able to selectively attend to high-probability changes at the cost of detecting fewer low-probability ones. This is despite being unable to verbalize their strategy in simple terms of typical feature descriptors such as color, motion, or shape. This supports the idea that the GAN's latent dimensions are--to some extent--matched to the latent dimensions used by the human visual system.

Title: Attention modulation of visual responses in cortical area V4 is cell-class and layer specific

Authors: X. WANG, A. S. NANDY, *M. P. JADI;
Yale Univ., New Haven, CT

Abstract: Perception is mediated by the concerted activity of a variety of neuronal cell classes that are embedded in the layered architecture of the sensory cortex. Attention is a critical component of perception, improving our ability to detect and discriminate task-relevant signals. To uncover the neural mechanisms of attention, it is therefore critical to understand how the activity of different cell classes is modulated by the deployment of attention. Here we analyzed cortical layer-specific neuronal responses from area V4 as monkeys performed an attention-demanding orientation change detection task. We used unsupervised machine learning techniques to identify cell classes based on either electrophysiological or functional properties. We found evidence of cell-class and layer-specific patterns of attention modulation in area V4. Visual responses show qualitatively different modulation patterns for the same cell class in different layers. Sensitivity to visual stimuli is also qualitatively different across cell classes and layers. This heterogeneity of attention-mediated information processing implies different functional modules that provide a neurobiological foundation for the normalization model of attention. Our findings also suggest that the normalization mechanism of attention is not homogenous across cortical layers.

Title: Rapid learning of a fixation-based visual selective attention task and its effects on V1 firing rates

Authors: *J. R. DOWDALL, M. L. SCHOLVINCK, Y. ZHANG, A. PETER, J. VEZOLI, P. FRIES;
Ernst Struengmann Inst. (ESI), Frankfurt, Germany

Abstract: Behaviorally relevant information receives preferential processing through mechanisms of selective attention. In the lab, visual selective attention is typically studied with tasks requiring subjects to maintain fixation and deploy attention to a peripheral stimulus. Under natural conditions, primates typically direct their gaze to the attended stimulus. Therefore, we hypothesized that attention is intrinsically biased to the fixated stimulus. We trained several macaques (Macaca mulatta) in two versions of a change detection task, utilizing two simultaneously presented stimuli that extended from the fovea into the periphery. The stimuli were either photos of natural objects (e.g., fruits, leaves) or artificial shapes. At the fovea, the

two stimuli overlapped such that their depth ordering determined which stimulus was fixated. Stimulus changes were small local hue changes, appearing at random times and random positions within the peripheral portion of the stimuli. Four macaques learned task 1: They maintained fixation until a change occurred on either one of the two stimuli (equally probable), and were rewarded for saccading to the change. Subsequently, these macaques, and two macaques naïve to task 1, were trained in task 2. In task 2, they maintained fixation until two simultaneous changes appeared (one on each object), but were only rewarded for saccading to the change on the fixated object. All but one of the macaques (i.e., 5/6) learned task 2 within 14 training days (criterion: >80% correct; training of the remaining macaque ended for other reasons). This included two animals that had no prior experience with an attentional cue nor with distractor suppression. We recorded multi-unit activity (MUA) from area V1 in two macaques during stable performance in task 1, as well as the learning period and stable performance in task 2. In task 1, the MUA response was transiently enhanced around 200 ms post-stimulus onset for the fixated compared to the un-fixated stimulus. In task 2, this transient enhancement was followed by sustained enhancement. These results suggest that attention is initially biased toward the fixated stimulus - even when both stimuli are equally behaviorally relevant. Thus, if both stimuli are behaviorally relevant (task 1), this effect is transient. If only one stimulus is behaviorally relevant (task 2), the effect is sustained. This bias toward the fixated stimulus may explain the rapid cue learning. In summary, this fixation-based attention task offers a more ecologically appropriate attention task that macaques learn quickly, which reduces training time and provides a means to investigate the interplay between attention and learning.

Title: Dynamic neural reconstructions of attended object features using EEG

Authors: *J. CHEN, M. D. STARKS, J. D. GOLOMB;
Ohio State Univ., Columbus, OH

Abstract: We live in a dynamic world and our environment contains far more stimuli than our brain can process at one time. Visual attention allows us to select relevant information and ignore irrelevant information. It is critical to understand how visual attention helps us process selective

feature information. Recently, fMRI has been widely used to reconstruct object features by applying inverted encoding models (e.g. Sprague & Serences, 2015). However, investigating the dynamics of cognitive processes, like neural mechanisms of attentional selection, requires more temporally sensitive methods. Here, we presented a series of studies using human electroencephalography (EEG) and steady-state visual evoked potential (SSVEP) to dynamically track attended object features. In one task, two gratings were shown on the screen, and subjects were asked to covertly attend to one of them and detect subtle orientation changes. The two gratings flickered at the same frequency but had different orientations. We were able to successfully reconstruct the attended orientation through time. Importantly, we reconstructed the attended orientation without including any location information in the model, using the EEG signal from all posterior electrodes. As trials increased in time, there appeared to be a better reconstruction of the attended grating's orientation. We also observed weaker reconstructions of the unattended grating's orientation. Moreover, the quality of the attended item's reconstruction appeared to be anti-correlated with the quality of the unattended item's reconstruction, perhaps indicative of an oscillation in attention with a limited attentional resource pool. Interestingly, topographic activity maps revealed no obvious lateralization between hemispheres as a function of whether the left or right item was attended. This lack of lateralization may indicate that activity in this context may be reflective of feature-content and not feature-location. These results illustrate the potential of using EEG to provide noninvasive neural measurements of attended feature representations. This could be particularly useful when studying the temporal dynamics of cognitive processes such as attention switching.

Title: The effect of visual attention on the responses of dorsal lateral prefrontal cortex neurons in virtual environments

Authors: *B. W. CORRIGAN[1], R. A. GULLI[2], M. ROUSSY[1], R. LUNA[1], A. J. SACHS[3], J. C. MARTINEZ-TRUJILLO[4];

Univ., London, ON, Canada; [3]The Ottawa Hosp., Ottawa, ON, Canada; [4]Dept. of Physiol. and Pharmacol. and Psychiatry, Brain and Mind Institute, Univ. of Western On, London, ON, Canada

Abstract: While there has been significant research on the effects of covert attention on the responses of neurons in the lateral prefrontal cortex of macaques, there has been less exploration of the effects of overt attention. This is particularly important during natural behavior, when animals tend to foveate the objects of interest. To address this issue we implanted two male macaca mulatta with two 96-channel Utah arrays (Blackrock microsystems, Utah) on the dorsal and ventral aspects of the left principal sulcus, just anterior to the arcuate, in areas 8a and 9/46. We had them navigate a virtual maze and perform an associative memory task. In a given block, there would be two objects presented at a certain position on the maze, the target object was indicated by the maze wall texture (e.g., wood walls means the target is the orange object and steel walls means it is the purple object). Each object location (left or right of the corridor) could vary from trial to trial. Because we wanted to look at the effect of feature-based attention during overt attention, we looked at the first fixations on an object after appearance when it was the target and when it was not. We recorded from 139 neurons in monkey T and 381 in monkey B. We examined the responses of neurons during overt attention: when the object is being foveated. We conducted a two way ANOVA on foveations to a specific object, with factors of position (left or right of the subject) and whether it was the target or the distracter. Monkey T had a significant main effect for position in 31% of neurons, a main effect of target in 17% and an interaction in 17%. Monkey B had a significant main effect for position in 35% of neurons, a main effect of target in 39% and an interaction in 21%.
These results show that the responses of lateral prefrontal cortex neurons are modulated by the behaviorally relevance of the object that is overtly attended. They also show that this effect is shaped by the position of the object in the environment. Further analyses aim at disentangling the role of these and other factors on the responses of single LPFC neurons and the entire population.

Title: Multivariate analysis of electrophysiological signals reveals task-dependent attentional modulation of shape and surface features

Authors: *N. LEE, L. GUO, A. NESTOR, M. NIEMEIER;
Univ. of Toronto, Toronto, ON, Canada

Abstract: It has been shown that attention to features such as motion, colour or contours acts upon early stages of processing to aid perception throughout the visual field. Further, this feature-based attention appears to work along parallel, additive channels if more than one feature is attended. We have continued to find additive effects of attention in a difficult object perception task that necessitated perceptual integration and decisional processes, suggesting that attention may be applied to whole objects and therefore, later stages of perception. To elucidate the time course of attention to object features, we recorded EEG from 64 scalp electrodes from human participants while they viewed and interacted with real objects. Objects were one of two shapes and surface features, respectively. Between two experiments we tested two categories of surface features: in Experiment 1, we investigated newly formed colour-weight associations such that objects of one colour were heavier than a second colour. In Experiment 2, we used wood and steel object, that is, surface textures that have a well-learned association with weight. To manipulate attention to features, participants either grasped and lifted the objects or touched the object with their knuckle, thus making features more or less task-relevant. We then compared the spatiotemporal EEG patterns between pairs of conditions via Mahalanobis distance to generate representational dissimilarity matrices (RDMs) at each time point. In both experiments, expected shape, colour and action RDM models significantly predicted actual RDMs. Moreover, models built from a priori hypotheses of colour and shape representation interactions with action uniquely explained variance as early as 100 ms after stimulus presentation. Taken together, this suggests that task-related attention modulates representation at intermediate latencies.

Title: Behavioral and neuronal effects of large-scale bilateral optogenetic inactivation of the lateral prefrontal cortex during feature attention and working memory

Authors: *D. MENDOZA-HALLIDAY[1], H. XU[1], F. AZEVEDO[2], R. DESIMONE[3];
[1]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [2]Harvard Med. Sch., Cambridge, MA;
[3]MIT, McGovern Inst. Brain Res., Cambridge, MA

Abstract: The lateral prefrontal cortex (LPFC) has been implicated in visual feature attention and working memory. However, demonstrating a causal role of LPFC in these cognitive functions requires temporally-specific inactivation of LFPC activity, which is a major challenge. Here we devised a method for large-scale bilateral optogenetic inactivation of LPFC in macaque monkeys. The animals performed a task requiring them to maintain in working memory the direction of motion of a sample full-screen random-dot surface and, after a 3.2 s delay period, attend to one of two overlapping, oppositely-moving, full-screen test random dot surface (a sample-matching target and an oppositely moving distractor) in order to report the occurrence of a small patch of speeding dots in the target surface. Large-scale bilateral LPFC optogenetic inactivation was accomplished by replacing the native dura with a transparent artificial dura over the lateral prefrontal cortex in each hemisphere and performing ~170 injections of the inhibitory opsin *Jaws* covering a surface area of ~50 mm^2 per hemisphere. Each LPFC was optogenetically stimulated with a high-power 635 nm laser 18 mm above the cortical surface in half of the trials, specifically during the target/distractor presentation. We found that bilateral LPFC optogenetic inactivation caused a remarkable deficit in task performance compared to trials with no inactivation. A decrease in task performance also occurred when optogenetic stimulation was delivered during the delay period, although this effect was less pronounced. Moreover, LPFC inactivation modulated neuronal responses to the test stimuli in several direction-selective areas along the dorsal visual pathway, far from the optogenetically-stimulated regions. Taken together, our results suggest that LPFC plays a causal role in visual feature attention and working memory, and that such role may involve the top-down modulation of activity in visual cortical neurons.

Title: Holographic imprinting of novelty detection

Authors: *Y. SHYMKIV[1], S. BAIR[1], J. P. HAMM[2], R. YUSTE[1];
[1]Columbia Univ., New York, NY; [2]Georgia State Univ., Atlanta, GA

Abstract: Perception of sensory information by the brain is highly dependent on the information context, where responses to the most informative, or “novel”, stimuli are selectively amplified. Deficits of novelty detection appear in patients with schizophrenia, suggesting its high importance for normal information processing and cognitive function. Here we use two-photon calcium imaging in awake mice undergoing the “oddball” paradigm and learn the neural activity structure encoding informational context in visual and auditory cortices. Analysis of trial to trial and averaged stimulus evoked responses reveals a low dimensional organization, consisting of independent, contextually selective subpopulations of neurons (“ensembles”). One major ensemble includes cells selectively responding to stimuli that are novel, i.e. novelty detectors, number of which increases from primary to secondary sensory cortex. Imaging in schizophrenia mouse models revealed that the low dimensional context specific structure is disorganized in disease. Further we use two-photon holographic stimulation along with go/no-go deviance detection behavioral readout to assess the functional importance and stability of novelty detection ensembles. We optically manipulate the low dimensional activity patterns in the primary sensory cortex in conjunction with the oddball paradigm to imprint an altered context specific activity and behavioral response. Furthermore, with optical imprinting in in schizophrenia mice we attempt to enhance the deviance detection behavior aiming at improving the functional phenotype of the disease.

Title: Attention maintains the neural-representational structure of primary visual cortex across the cortical hierarchy

Authors: *J. CHUNG, D.-J. YI;
Yonsei Univ., Seoul, Korea, Republic of

Abstract: Attention enhances the neural activity of task-relevant stimulus in sensory processing. Moreover, attention sharpens the neural population coding of attended features in sensory regions. But, attentional modulations on neural population coding across the cortical hierarchy still remains unclear. Here, we investigated attentional modulation on neural representational structure of visual stimulus across the cortical hierarchy. We used the working memory task fMRI from Human Connectome Project (HCP) dataset. The task tested n-back working memory

using within-category objects from four categories. Working memory is conceptualized as internally oriented attention, thus we compared characteristics of the structure between 0- and 2-back working memory conditions to investigate the attentional modulation. We specified cortical regions of interest from primary visual to prefrontal cortex participating in visual working memory process by using the general linear model analysis. We constructed inter-stimulus neural representational distance (IS-RD) matrix by calculating 1-Pearson correlations between multi-voxel fMRI activity patterns of all stimulus pairs in each cortical region. We separated IS-RD matrix into within- (task relevant) and cross-category (task irrelevant) parts. Based on the matrix, we measured two characteristics of the neural representational structure of visual stimulus. We calculated mean IS-RD to estimate the size, and inter-regional similarity of IS-RD matrices between primary visual cortex and the other regions to estimate the shape similarity across the cortical hierarchy. We assumed that primary visual cortex, which is at the lowest cortical hierarchy, represents the most primitive shape of visual stimulus in neural representational space most directly reflecting inter-stimulus distance in the physical space. We found that mean within-category IS-RD is increased in all regions. Mean cross-category IS-RD is rather decreased in the primary visual cortex and prefrontal regions, but only increased in the middle temporal region. We next found that Inter-regional IS-RD similarity is decreased along with the cortical hierarchy. All regions showed increased inter-regional similarities of within-category IS-RD matrix during 2-back. Interestingly, parietal and frontal regions also showed increased similarities of cross-category IS-RD matrix during 2-back. These results indicate that the attention modulates the size of task-relevant and -irrelevant neural representational structures in the opposite direction, while modulates the shape in the same direction to be similar with that of the primary visual cortex.

Title: Incongruency between visual saliency and task-based relevance: Effect on intraparietal sulcus and inferior parietal lobule

Authors: T. JAMOULLE[1], P. DUPONT[2], *R. R. VANDENBERGHE[3];
[1]KU Leuven, Leuven, Belgium; [2]Lab. for Cognitive Neurol., KU LEUVEN, Leuven, Belgium; [3]Univ. Hosp Gasthuisberg, Leuven, Belgium

Abstract: The balance between exogenous capture and endogenous selection is a central theme in attention research. If stimulus saliency is aligned with a subject's attentional priorities, selection will be facilitated. In case of a misalignment, endogenous selection may be compromised (automaticity of attentional capture). Here we distinguished between task-congruent vs -incongruent saliency. We predicted that early saliency effects in posterior IPS would be independent of task congruency and that task incongruency would activate middle IPS and the endogenous control network.
16 healthy subjects participated in a change detection task. Eight stimuli (letters and numbers, size 0.75°) were presented on an imaginary circle at 3.5° eccentricity followed by a mask (combined duration of array + mask = 500ms). Depending on the run, the array contained two letters and six numbers, or inversely, and subjects were instructed to attend to the two letters or the two numbers, respectively. Following the mask and a delay (100 ms), a central probe stimulus (500 ms) was presented and subjects had to indicate by key press whether the probe matched one of the two targets. There were three conditions: [no-saliency] all stimuli were either red or blue; [saliency-congruent] the two targets were of one color and the distracters of the other color; [saliency-incongruent] two of the distracters were of one color and the remaining stimuli of the other. Gaze fixation was monitored with EyeLink 1000 Plus. Based on a prior behavioral session, the array durations were adapted to match performance between conditions, while the total duration of array plus mask was held constant. Significance was set at voxel-level $p<0.001$ and corrected $p<0.05$ at the cluster-level (voxel size = 3 x 3 x 3 mm).
Saliency minus no-saliency conditions revealed activation in the right IPL (x = 48, y = -45, z = 46, Z = 3.95, k = 48, p=0.006). This was mainly driven by the 'saliency-congruent minus no-saliency' contrast (x = 42, y = -57, z = 37, Z = 4.41, k = 72, $p<0.001$). In the saliency-incongruent minus -congruent condition, activity was bilaterally increased in the posterior IPS (L: x = -24, y = -72, z = 34, , Z = 4.19, k = 308, $p<0.001$; R: x = 33, y = -78, z = 31, Z = 3.96, k = 110, $p<0.001$), the middle IPS (x = 15, y = -51, z = 55, Z = 4.18, k = 135, $p<0.001$) and the upper premotor cortex (x = -30, y = -6, z = 49, Z = 3.86, k = 47, p=0.008). The saliency-congruent minus -incongruent condition did not yield a significant effect
To conclude, saliency incongruency enhances activity in posterior IPS as well as in regions involved in endogenous control.

Title: A stable population code for attention in prefrontal cortex drives a dynamic code in visual cortex

Authors: A. C. SNYDER[1], B. M. YU[2], *M. A. SMITH[3];
[1]Univ. of Rochester, Rochester, NY; [2]Carnegie Mellon Univ., Pittsburgh, PA; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We recently found (Snyder et al., 2018, Nat. Comm.) that the population pattern of attention-related activity modulation in visual area V4 when visual stimuli are present substantially differs from when visual stimuli are absent but anticipated. Thus, the population code for attention in V4 is dynamic and context-dependent. This is sensible for a sensory population, for which read-out of cognitive factors (such as attention) should remain separable from stimulus-related signals until stimuli are actually processed. The question naturally arises whether the top-down attention signal from executive control areas is likewise dynamic, or rather is a stable code that impacts V4 differentially depending on the ongoing sensory context. We reasoned a stable executive code would support more reliable behavior than a dynamic code, which may be less robust to perturbation. To test this, we simultaneously recorded neural populations in V4 and dorsolateral prefrontal cortex (PFC; a known node in the endogenous attention network) in the same hemifield in two rhesus macaque monkeys while they performed a covert visual spatial attention task. Whereas the attention code in V4 differed substantially in the absence versus presence of visual stimuli, we found the attention code in PFC to be highly consistent across time and stimulus contexts. Moreover, the stability of this code had important functional consequences: stable PFC attention states predicted stronger attention signals in V4 at later time points, and also accounted for considerable variation in the animals' target-detection performance on a trial-by-trial basis. This shows a stable attention code in PFC drives the dynamic attention code in V4, and is important for reliable task performance.

Title: Attentional bias is mediated by oscillatory communication between PFC and V4

Authors: *B. SAHOO[1], A. C. SNYDER[1,2,3];
[1]Brain and Cognitive Sci., [2]Neurosci., [3]Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY

Abstract: Long range brain-wide coordination is essential for goal-directed behavior. In the context of selective attention, this network has been well characterized. Although attention has been mostly studied in the context where it is successfully deployed in the task, it would be crucial to understand what are the potential network level alterations where attentional control is faltered. For this, we investigated the coordination between PFC, which is an integral part of the attentional network, and a more sensory encoding area of the brain i.e. V4, during false alarms. We recorded local field potentials simultaneously from V4 and PFC with 96-channel Utah arrays in the same hemisphere of two adult male rhesus macaques performing a delayed non-match to sample task. The emerging view is that selective attention is non-stationary and nearly rhythmic in a theta frequency range i.e. 4-8 Hz. Also, oscillations in the alpha band have been shown to be a hallmark of attention. We estimated the strength of communication between V4 and PFC in these frequency bands using Canonical Coherence Analysis. We found that in correct-rejection trials the strength of communication between V4 and PFC in theta band is higher in the peri-stimulus period when the RF was attended compared to when it was ignored, whereas the opposite was true for the alpha band. During false alarms, we observed an increase in V4 and PFC communication in the theta and lower alpha band in the pre-stimulus period when the RF was attended compared to when it was ignored. Also, the V4 and PFC communication was higher in the theta and lower alpha band during false alarms compared to correct rejections. We present our evidence in a framework where false-alarms are caused by an unwarranted increase in top-down bias and that this bias manifests as coordination with PFC in the theta band.

Title: Feature based attention modulates BOLD signals of parvocellular layers in human lateral geniculate nucleus

Authors: W. LIN, ***P. ZHANG**;
Inst. of Biophysics, CAS, Beijing, China

Abstract: Attention can be directed to non-spatial features such as orientation, color or direction of motion. The lateral geniculate nucleus (LGN) is the earliest stage of the visual pathway where magno- and parvo-cellular visual processing remain clearly segregated. Cells in the dorsal parvocellular (P) layers of the LGN encode color information and spatial details, while magnocellular (M) cells in the ventral layers are highly sensitive to achromatic contrast and motion. Previous studies showed that activities of the LGN can be strongly modulated by spatial attention. Although there have been found M,P and K stream-specific feedback connections from deep layers of V1 to the LGN, whether feature-based attention can selectively modulate layer-specific activities of the LGN has not been clearly demonstrated. Using high-resolution fMRI at 7T and carefully designed functional localizer stimuli to isolate the magno- and parvo-cellular layer activities of the human LGN, we investigated the modulation of layer-specific activities of the LGN by feature-based attention. For the functional localizer, the P biased stimulus was a low spatial frequency (0.375 cpd), high contrast isoluminant red and green concentric ring grating, expanding or constricting at low speed (0.5 Hz). The M biased stimulus was a low luminance contrast (30%), low spatial frequency radial grating (4 spokes), rotating at high speed (15 Hz). During the feature-based attention task, the chromatic concentric ring and the luminance defined radial gratings were superimposed on one another at the same spatial location. Subjects were asked to either pay attention to the chromatic grating to detect occasional color contrast changes, or to the luminance defined motion to detect speed changes. Color and motion tasks were performed in alternation with a central fixation task. For each subject (n=9), a small cluster of voxels selectively biased to the P stimulus can be clearly identified in the dorsal lateral part of the LGN, consistent with the anatomical location of parvocellular layers. The fMRI signals of the parvocellularlayerswere significantly stronger when subjects attended to color contrast than to motion speed. The entire LGN also showed stronger activity when subjects attended to the stimulus than to the fixation, suggesting a modulation effect of spatial attention. Similar spatial and feature based attention effect were also found in cortical area hV4.These results clearly demonstrate that feature-based attention can selectively modulate parvocellular layer activities of the human LGN, the earliest stage of feature selective processing in visual hierarchy.

Title: Frequency-specific effects of directed attention on the gating of somatosensory responses

Authors: *A. I. WIESMAN, T. W. WILSON;
Neurolog. Sci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Sensory gating (SG) is the process in which population neural responses to similar stimuli are reduced when presented in succession. SG is thought to represent the functional gating of primary sensory inputs that are at least partially redundant in nature, which would spare shared neural resources from processing less salient stimulus features. Traditionally, SG has been considered “pre-attentive,” but very little is known about the effects of attentional state on this process. In this study, we investigate the impact of directed attention on SG in the somatosensory system using high density magnetoencephalography (MEG). Healthy young adults (n = 26) performed a novel multisensory paired-pulse oddball paradigm, in which attention was directed towards or away from paired-pulse stimulation of the left median nerve. The temporal, spectral, and spatial properties of oscillatory neural responses to the paired-pulse stimuli were quantified using advanced source imaging and virtual sensor analyses, and tested for interactions between attentional state and SG. Expectedly, we found that three stereotyped somatosensory oscillatory responses were significantly gated on the second stimulation: an early broadband response (10 - 70 Hz), and later alpha (8 - 14 Hz) and beta (20 - 26 Hz) responses. SG of these responses was significantly altered when attention was directed away from the somatosensory stimuli, and this reduction was stronger within the frequency bands commonly associated with attention and somatosensory processing (i.e., alpha and beta). These findings highlight the dynamic effects of attentional modulation on somatosensory processing, and suggest that, although SG might be pre-attentive, it is not attention-invariant. This is particularly important, as a number of SG studies in neurologic and psychiatric populations have demonstrated aberrant SG without controlling for attention. Many of these same populations have been found to exhibit attentional deficits, and so controlling for the effects of attentional state on SG is essential.

Title: In through the out door: Inactivation of primate superior colliculus alters spatial preferences of neurons in the caudate nucleus

Authors: *J. P. HERMAN[1], F. ARCIZET[2], R. J. KRAUZLIS[1];
[1]Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD; [2]Visual Information Processing, Inst. De La Vision, Paris, France

Abstract: Neuronal activity in the head of the caudate nucleus (CDh) is strongly influenced by the behavioral relevance and spatial location of visual stimuli. The prevailing view is that descending inputs to CDh provide information to distinguish relevant from irrelevant stimuli; this signal is then transmitted to the superior colliculus (SC) via the substantia nigra as inhibition which suppresses saccades to irrelevant visual field locations. In contrast to this implicitly feedforward and serial circuit, with caudate as input and SC as output, anatomy suggests that the SC is also the source of input signals for the caudate, forming a possible recurrent subcortical circuit. Specifically, we hypothesized that this recurrent loop might link the spatial preferences observed in both the SC and CDh for behaviorally relevant visual stimuli. To test this, we recorded extracellular activity from populations of CDh neurons before and during unilateral muscimol inactivation of SC while monkeys performed a covert spatial attention task. During inactivation, many fewer caudate neurons showed a significant preference for the side of presentation of the spatial cue, compared to before inactivation (24 during vs. 51 before). The magnitude of cue-side preference was also significantly diminished during inactivation compared to before. Finally, we found that both the mean and the variance of pairwise spike-count correlations amongst caudate neurons were significantly reduced during inactivation. Importantly, these effects were only observed during unilateral inactivation of SC ipsilateral to the caudate neurons, not during contralateral inactivation. These findings are consistent with the interpretation that inactivation of the SC attenuates the influence of a shared input to CDh neurons. We conclude that SC neuronal activity facilitates transmission of spatially-specific visual information to neurons in the CDh. Considered together with the caudate's well-established influence on SC activity, our results provide evidence that a previously unappreciated subcortical loop is important for defining the location of behaviorally relevant visual information.

Title: The neurophysiological priming effect of vibro kinetic stimulation during a digital multisensory entertainment experience- A NeuroIS study

Authors: *J. BOASEN[1,2], F. GIROUX[1], M.-O. DUCHESNEAU[1], J.-F. MÉNARD[3], M. PAQUETTE[3], P.-M. LEGER[1];
[1]Tech3lab, HEC Montréal, Montréal, QC, Canada; [2]Hokkaido Univ., Sapporo, Japan; [3]D-Box Technologies Inc., Longueil, QC, Canada

Abstract: **Intro**: Vibro kinetic (VK) technology is advancing, and increasingly used to create multisensory entertainment experiences. A goal of Neuro-Information-Systems (NeuroIS) science is to ascertain the validity of this kind of VK application. Research has demonstrated that temporally coincident VK stimuli are crossmodally neuronally integrated, and can enhance processing associated with aural and visual sensory modalities. VK stimulation has furthermore been shown to have a priming effect on sensory processing, in which the theta-band is a key brain rhythm. However, evidence regarding the neurophysiological effects of VK stimulation during cinematic experiences is scant. Here, we addressed this shortcoming by using a VK enhanced chair in a multisensory cinematic viewing experience to test the extent to which VK stimulation primed downstream neurophysiological responses. We hypothesized that VK priming would enhance theta power in areas of the brain associated sensory integration processing. **Materials/Methods**: Electroencephalograms (EEG) (BrainVision, 32 ch.) were recorded on 20 middle-age opera aficionados while experiencing a high-definition digital reproduction of Act I of Bizet's Carmen. All subjects sat in a VK enhanced seat (D-Box). During seven selected scenes of the experience, 10 subjects received high fidelity VK (HFVK) stimulation in precise temporal synchrony with musical elements such as the rhythm and melody of the auditory stimuli. The envelopes of source EEG theta-band (5-7 Hz) activity were extracted from the first two minutes after the selected scenes. Theta power was then averaged over time and across epochs for each subject, and normalized based on average baseline theta power two minutes prior to commencement of the experience. Comparisons of source EEG activity were then made between subjects who did or did not receive HFVK stimulation. **Results/Discussion**: Although our analyses are ongoing, preliminary results indicate that the theta-band rhythm is a relevant neurophysiological target to examine the priming effect of HFVK stimulation on sensory integration processing during multisensory cinematic experiences. Further analyses will need to assess changes in theta responsiveness to specific audio/visual events during the experience. Ultimately, we expect these results to create a foundation of evidence in the NeuroIS literature that serves to guide the development of VK technology, and increase its effectiveness in the entertainment sector.

Title: Tech3lab adaptive systems group for the research and development of neuroadaptive information systems (neuroIS)

Authors: *A. J. KARRAN, S. SENECAL, T. DEMAZURE, A. SURI, E. FREVE-GUERIN, E. DE-CELLES, M. FREDETTE;
HEC Montreal, Montreal, QC, Canada

Abstract: We report progress from a program of research which aims to create frameworks and software artefacts for neuroadaptive information systems. The goal of these projects is to utilise measures of real-time user brain activity to adapt the information systems (IS) to augment user performance, automate elements of the system, share the burden of decision making, allowing greater task flexibility for users. The first project combined neuroscience, design science and IS to create a passive brain-computer (BCI) interface artefact capable of augmenting the ability of a user to self-modulate sustained attention using a real-time biofeedback mechanism. Users performed an ecologically valid IS task that involved the simulated management of a supply chain. The task involved monitoring an information dashboard for long periods, followed by brief periods in which supply decisions are made. Three groups, control, threshold and continuous utilised the IS, receiving none, level dependent and continuous feedback respectively from the system. A between groups analysis showed a decrease in on-task error for the continuous group. Additional analysis via GLM and wavelet coherence analysis and showed significant differences in brain activity between the groups. The results revealed that neuroadaptive systems have the potential to increase task performance and decrease on-task error, by allowing IS users to self-modulate their level of sustained attention to better meet task demands. The second project aims to develop a reactive BCI as a neuro-adaptive system that adapts components of an IS based on the cognitive load of the user. The artefact operates as a recommender system that supports decision-making through the classification of cognitive load and the dynamic allocation of the information displayed on a web interface. For interface and UX designers, this artefact may present a new and innovative means to configure the right balance of information presented on an interface.
The goal of the final project is to create onboard vehicular IS driven by the classification of cognitive workload and decisions involving risk using a combination of psychophysiological and telemetric data and machine learning methods. We aim to create a multimodal classification model of “decisions involving risk”, and then apply the model to automatically classify those types of decision in both an automotive and aerospace context during simulated driving and

high-fidelity helicopter flight. Classifications will also be integrated into post-flight debriefing processes to highlight problematic manoeuvres, allowing instructors to better train pilots. We look forward to receiving feedback.

Title: An ERP approach to measuring mind wandering during learning multimedia use

Authors: *C. CONRAD[1], A. J. NEWMAN[2];
[2]Psychology & Neurosci., [1]Dalhousie Univ., Halifax, NS, Canada

Abstract: Interactive learning multimedia are employed in many different contexts, ranging from public education to corporate training. Though their low marginal costs make them efficient education tools, there is growing recognition that learning multimedia tools are yet to live up to their full potential, due to their inability to incorporate users' cognitive context. For instance, recent research in the role of mind wandering in the classroom suggests that students who report increased mind wandering observed reduced learning outcomes. By incorporating physiological user feedback from electroencephalography (EEG) that are correlated with mind wandering, learning multimedia tools might be improved. In this presentation we describe two studies which observed the P1-N1-P2 complex and P3 event related potential (ERP) responses elicited by auditory oddball stimuli that were played during online lecture videos. In the first experiment, 16 participants were recruited and asked to report when they experienced mind wandering by pressing a button. Amplitudes of responses to standard and oddball stimuli onset at 125 ms (P1), 225 ms (P2) and 275 ms (P3) were compared for periods 10 s before and after self-reported mind wandering events, using linear mixed effects analysis. Oddball amplitudes were significantly different from standard stimuli in the 10 seconds before a button press (when mind wandering was reported to occur) but not in the 10 seconds following (when people were back on task). In the second experiment, we attempted to replicate the observed results using a different reporting method in which participants (n=50) were prompted at pseudo-random intervals during a video to report the degree to which they are currently experiencing mind wandering. ERP responses from 10 seconds before prompts that resulted in high degrees of reported mind wandering were contrasted with 10 seconds before reports of high degrees of on-task thought. Component

amplitudes of responses to oddball stimuli onset at 75 ms (N1) and 125 ms (P2) were analyzed using linear mixed effects and found to be significantly different from standard stimuli when reporting on-task thought, but not when reporting mind wandering and no distinct P3 response was observed. These results suggest two distinct ERP correlates of mind wandering which might be used to passively measure the mind wandering state during learning multimedia use. Future work may yield further evidence to support the use of these correlates to validate the effect of various multimedia in preventing mind wandering or facilitating learning outcomes.

Title: Exploring the association between belief in misinformation and neural correlates of System 1: An EEG study

Authors: *M. MIRHOSEINI[1], S. BAKHTIARI[4], S. EARLY[2], N. E. SHAMY[1], G. CALIC[1], **K. HASSANEIN**[3];
[1]Information Systems, McMaster Univ., Hamilton, ON, Canada; [2]Information Systems, McMaster Univ., Burlington, ON, Canada; [3]McMaster Univ., Hamilton, ON, Canada; [4]Neurosci., McGill Univ., Montreal, QC, Canada

Abstract: Recent public discourse about the phenomenon of "fake news" has exposed the vulnerability of people to the widespread broadcast of misinformation on social media. Fake news is a type of misinformation that is presented as originating from reliable sources (Bronstein et al. 2018). Building upon dual system theories of cognition (Kahneman 2011), this research aims at predicting users' belief in misinformation based on the EEG measure of system 1. System1 is a fast, unconscious, and intuitive process that relies on long-term memory to retrieve similarity-based information and form an impression about a stimulus. On the other hand, system2 processing mode is a slow and conscious process, which is under our deliberate control and has much fewer cognitive resources than the associative mode (Evans 2014). System2 thinking is associated with frontal (Fz) theta rhythms (4-6 Hz) while system1 activities are correlated with increased parietal (Cpz) alpha (10-12 Hz) (Williams et al. 2019). 40 subjects (20 male and 20 female) participate in an experiment to 1) measure the neural correlates of system1 and system2 and 2) predict subjects' bias based on system 1 activations. Subjects are presented with 60 headlines, 20 of which are easy to identify as true or false (e.g., Democrats Criticize Trump's Border Policy). The remaining 40 headlines consist of more difficult to judge statements of which 50% are true, and 50% are false. Participants are asked to confirm or reject

the news headlines using two arrows of the keyboard. The news headlines are presented in a mimicked Facebook page similar to news shared on users' feed. EEG is being recorded from 20 electrodes using the Cognionics (Cognionics Inc., CA) quick-20 dry EEG headset. We then use a supervised machine learning technique (e.g. random forest) to predict subjects' bias using the EEG correlates of system1 and system2. Different EEG-based features that we expect to be informative for detecting correct/wrong subjects' decisions (different frequency bands and different brain lobes) will be fed to our machine learning method. The trained model selects a combination of EEG features that can best separate wrong and right trials. Within the selected EEG features by the model, we expect that higher system1 activation (Parietal Alpha) is associated with an increase in confirmation bias and belief in misinformation while more system 2 activities (Frontal Theta) results in more accurate identification of misinformation. This study advances our understanding of the neural correlates of the belief formation biases on social media.

Title: Short-term training with a mu-based brain-computer interface indicates enhancement of motor skills

Authors: A. INGRAHAM, ***A. B. RANDOLPH**;
Information Systems, Kennesaw State Univ., Kennesaw, GA

Abstract: Brain-computer interface (BCI) researchers have been using neural input devices for communication and control for almost three decades. More recently, the field has explored using BCIs for neuro-rehabilitation. Neuro-rehabilitation is an attempt to restore lost function due to a neurologic disability such as due to stroke. Unfortunately, only a small portion of stroke patients experience success in regaining lost motor function even with intensive rehabilitation. Hence, further exploration into various and complementary techniques for neuro-rehabilitation is still needed.
Here, we examined mental training using a mu-based BCI based on motor imagery for its ability to enhance motor skills in humans. We conducted a study of eighteen (10 male, 8 female)

healthy individuals aged 18 to 50 years-old who played a virtual match of tennis on the Nintendo Wii gaming platform at the start and end of a four-to-five day mental training period. Individuals used a mu-based BCI developed by the Wadsworth Center on the BCI2000 platform.
We conducted a paired t-test to determine if there was a significant difference in Wii scores before and after mental training with the mu-based BCI. The mean before playing the Wii was 78.71 while the mean after playing the Wii was 80.33. Because there was little variation between the two administrations, we concluded that although there is no statistically significant difference in the Wii scores before and after mental training, there is a practical difference; hence, we found there was a slight improvement in Wii scores after just three sessions of mental training. Although there was only a slight improvement in motor skills overall as measured based on play with a sports video game, there was a practical level of improvement observed which supports future research. Gameplay on the Wii console provides evidence that even short-term mental training with a BCI can help increase the proficiency and effectiveness of the brain and motor skills. This work contributes to the growing evidence that mental training with a BCI has both cognitive and physical benefits.

Title: Attentional habituation to non-essential computer notifications generalizes to security warnings: An fMRI study

Authors: *B. KIRWAN[1], B. ANDERSON[1], D. EARGLE[2], J. JENKINS[1], A. VANCE[3]; [1]Brigham Young Univ., Provo, UT; [2]Univ. of Colorado, Boulder, Boulder, CO; [3]Temple Univ., Philadelphia, PA

Abstract: Repeated exposures to a stimulus results in habituation of neural and behavioral responses to that stimulus. Habituation may also generalize to similar stimuli. Previous literature has shown that in the realm of computer security, habituation of neural responses within visual-attention networks accounts for much of the decreased behavioral responding to computer security warnings and that manipulations to security warnings that diminish habituation also improve security behaviors. While previous literature has focused on habituation to security warnings, little research has been done on habituation to the far more common non-security notifications. Here we examine the extent to which habituation to non-security notifications

generalizes to security warnings and the neural underpinnings of that generalization. In a series of experiments, participants performed an image categorization task and received frequent feedback notifications and computer security warnings. In a large online field experiment, we show that habituation to frequent non-security-related notifications does carry over to a one-time security warning. Generalization of habituation is manifest both in (1) decreased attention to warnings (as measured through behavioral indices such as mouse cursor tracking) and (2) lower warning adherence behavior. The carry-over effect, most importantly, is due to generalization, and not fatigue. The degree that generalization occurs depends on the similarity in look and feel between a notification and warning. In an fMRI experiment, we demonstrate habituation in visual-spatial attention networks to the frequent non-security notification that is distinct from fatigue. We further demonstrate generalization of habituation that is modulated by the similarity between notifications and warnings in terms of appearance and mode of interaction.

Title: Impact of extended training on vibrotactile feedback guided reaching

Authors: *V. SHAH[1,2], A. THOMAS[1], G. BALLARDINI[2], M. CASADIO[2], L. A. MROTEK[1], R. A. SCHEIDT[1,3,4];
[1]Biomed. Engin., Marquette Univ. and Med. Col. of Wisconsin, Milwaukee, WI; [2]Univ. of Genova, Genova, Italy; [3]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [4]Div. of Civil, Mechanical, and Manufacturing Innovation, Natl. Sci. Fndn., Alexandria, VA

Abstract: Our long-term goal is to enhance the planning and ongoing control of upper limb reaches through the integration of real-time vibrotactile cues. Previous studies using vibrotactile feedback (VTF) to enhance 2D targeted reaching found that the use of VTF initially requires involvement of significant cognitive resources. While short-term training (1 to 2 days) does improve target capture accuracy of VTF-guided reaches, movements do not reflect straight and

efficient point-to-point hand paths typical of visually-guided reaches. We hypothesized that long-term training with VTF would improve reaching in a way that reflects a normalization of movement kinematics and increased autonomy in the integration of VTF during reach planning and execution.
Four young participants with no known neurological impairment gave written consent to participate in 20 experimental sessions. Participants completed 5 session per week over 4 weeks. Four eccentric rotating mass motors were attached to the non-moving arm to create a VTF display that encoded information about the {X, Y} end effector's position of a custom-made 2D manipulandum grasped by the moving hand. During each session, participants performed targeted reaching under three different feedback conditions: visually-guided, VTF-guided, and no feedback. Participants were provided VTF-guided reach training for 30 mins during each session, for a total of 10 hrs of training. We analyzed target capture error, target capture time, and reach trajectory straightness prior to, during, and after training.
Repeated measures ANOVA found statistically significant differences in target capture error [$F_{(19,57)} = 5.20$, $p < 0.001$] and target capture time [$F_{(19,57)} = 5.38$, $p < 0.001$]. Post hoc, one-tailed paired samples t-test revealed that target capture error decreased significantly by 24.0% at the end of 5 hrs of VTF-guided reach training ($p < 0.05$) and by 37.4% after 10 hrs ($p < 0.05$). Target capture time decreased by 25.2% after 5 hrs of VTF-guided reach training and by 45.1% after 10 hrs ($p > 0.05$ in both cases). When VTF was first introduced, reach trajectories were decomposed into two sequential strokes performed parallel to the cardinal {X, Y} axes of the vibrotactile display; a measure of movement decomposition increased by 64.8%, on initial exposure compared to values from visually guided movements ($p < 0.05$). After 10 hrs of training, decomposition decreased to 37.4 % ($p > 0.05$, compared to baseline). These training related changes in reaching behavior indicate that 10 hrs of training with VTF advances users towards the autonomous use of supplemental VTF to guide smooth and efficient reaching in the absence of visual feedback.

Title: Musicians show better auditory and tactile identification of emotions in music

Authors: *A. SHARP[1], M.-S. HOUDE[1], B.-A. BACON[2], F. CHAMPOUX[1];
[1]Univ. De Montréal, Montréal, QC, Canada; [2]Carleton Univ., Ottawa, ON, Canada

Abstract: Musicians are better at processing sensory information and at integrating multisensory information in detection and discrimination tasks, but whether these enhanced abilities extend to more complex processes is still unknown. Emotional appeal is a crucial part of musical experience, but whether musicians can better identify emotions in music throughout different sensory modalities has yet to be determined. The goal of the present study was to investigate the auditory, tactile and audiotactile identification of emotions in musicians. Melodies expressing happiness, sadness, fear/threat, and peacefulness were played and participants had to rate each excerpt on a 10-point scale for each of the four emotions. Stimuli were presented through headphones and/or a glove with haptic audio exciters. The data suggest that musicians and control are comparable in the identification of the most basic (happiness and sadness) emotions. However, in the most difficult unisensory identification conditions (fear/threat and peacefulness), significant differences emerge between groups, suggesting that musical training enhances the identification of emotions, in both the auditory and tactile domains. These results support the hypothesis that musical training has an impact at all hierarchical levels of sensory and cognitive processing.

Title: Decoding melodic contours in early visual areas

Authors: J. HA[1], I. KIM[1], *W. SHIM[2];
[1]Ctr. For Neurosci. Imaging Research, IBS, Suwon, Korea, Republic of; [2]Biomed. Engin., Sungkyunkwan Univ., Suwon, Kyunggi-Do, Korea, Republic of

Abstract: Although primary sensory cortices have traditionally been considered to be unimodal, recent work has shown that multisensory processing also occurs in early modality-specific areas involved in primary sensory analysis. In particular, neuroanatomical studies on nonhuman primates and human neuroimaging studies found anatomical and functional connections between the auditory cortex and the anterior portion of the primary visual cortex (V1) retinotopically mapped to the peripheral visual field, which could support multisensory integration at early

stages of cortical processing. However, the extent to which auditory information can be processed in visual cortex, from low-level acoustic features to high-level abstract representations, remains unclear. In the current study, using fMRI and pattern classification methods, we investigate whether high-level auditory information that is metaphorically associated with visual properties, such as a melodic contour associated with visual motion, can be decoded in visual cortex in the absence of visual stimulation. While fixating at the center of the screen, participants either listened to an ascending or descending melody (auditory) or viewed random dots moving upward or downward in a circular annulus (visual) and monitored those stimuli for occasional changes in their directions. Shepard tones were used to create different melodic contours, which were perceived as infinitely ascending or descending in pitch. The direction of visually presented motion was successfully decoded in early and extrastriate visual areas (V1, V2, and V3). More interestingly, activities of the same visual areas were also predictive of the melodic contour with comparable accuracy. The decoding accuracy of the melodic contour was higher in the regions of visual cortex that correspond to the peripheral visual field compared to the regions mapped to the central visual field, whereas there was no significant difference between the central and peripheral visual regions for decoding visual motion. When the classifier was trained on the auditory data and tested on the visual data or vice versa, generalization performance was at chance level. Our results suggest that high-level auditory information that has an abstract association with visual properties, can be represented in visual cortex via cortical feedback facilitating multisensory integration in an abstract space, and this high-level auditory representation might not share a common neural code but is unique in nature.

Title: The neural basis of olfactory-trigeminal interaction

Authors: P. KARUNANAYAKA[1], L. JIAMING[2], Q. X. YANG[1], *K. SATHIAN[3];
[1]Ctr. for NMR Research, Dept. of Radiology, Penn State Col. of Med., Hershey, PA; [2]Drum Tower Hospital, Med. Sch. of Nanjing Univ., Nanjing, China; [3]Dept. of Neurol., Milton S. Hershey Med. Ctr. & Penn State COM, Hershey, PA

Abstract: Olfactory co-stimulation enhances the localization of chemosensory (Tremblay and Frasnelli, 2018, Chem Senses 43: 611-616) and somatosensory (Karunanayaka et al., 2018, bioRxiv, http://dx.doi.org/10.1101/519439) stimuli, both of which stimulate the trigeminal nerve.

The neural mechanisms of such olfactory-trigeminal interaction remain largely unknown. Here, we used functional magnetic resonance imaging (fMRI) to investigate the neural basis of enhanced sensitivity to intranasal somatosensory stimulation during olfactory co-stimulation. We hypothesized that olfactory-trigeminal integration is mediated by the primary olfactory cortex (POC). Fifteen healthy human subjects with normal olfactory function performed a localization task for weak air-puff stimuli in the presence or absence of the pure odorant, phenyl ethyl alcohol (PEA; rose odor). Consistent with the prior literature, PEA could not be localized to a nostril above chance. Yet, there was a significant improvement in the localization accuracy of weak, but not strong, air-puffs in the presence of PEA when both stimuli were delivered to the same nostril, but not to different nostrils. Correspondingly, bimodal stimulation with PEA and weak, but not strong, air-puffs enhanced activation, as measured by the blood oxygenation level-dependent (BOLD) signal, in the POC and superior temporal cortex (STC), compared to air-puffs alone. These behavioral and fMRI data follow the principle of inverse effectiveness, where multisensory integration is inversely related to stimulus strength. Activity in the POC and STC was also significantly correlated with the behavioral enhancement of weak air-puff localization by concomitant PEA. These data provide clear functional evidence for central integration of olfactory and trigeminal somatosensory inputs.

Title: Cross-modal suppression of auditory cortex by visual speech as a mechanism for audiovisual speech perception

Authors: *B. A. METZGER[1], E. A. NESBITT[1], J. F. MAGNOTTI[1], Z. WANG[2], P. J. KARAS[1], D. YOSHOR[1], M. S. BEAUCHAMP[1];
[1]Neurosurg., Baylor Col. of Med., Houston, TX; [2]Rice Univ., Houston, TX

Abstract: Humans perceive speech using visual info from the talker's mouth and auditory info from the talker's voice. For instance, viewing the talker's face enhances the intelligibility of noisy auditory speech. Key to this enhancement is the head start provided by vision, since most

speech is “mouth leading (ML)”, meaning that visual mouth movements begin before auditory vocalization. However, some speech (i.e. nasal consonant “m”) is “voice leading (VL)” with vocalization occurring before visible mouth movements. We constructed a model for audiovisual speech perception in which the early arrival of visual speech suppresses the representation of incompatible phonemes and enhances the representation of compatible phonemes in posterior superior temporal gyrus (pSTG), the cortical locus of speech perception (see Figure). Consistent with the model, a larger perceptual benefit of visual speech was observed for ML (28% accuracy increase) vs. VL words (4% increase). To examine the neural substrates of this benefit, we recorded from electrodes implanted on the pSTG of epileptic patients. Using broadband high-frequency activity (BHA) as a measure of neural activity, we observed smaller responses for AV *vs.* auditory-only ML words (34% difference, 118% increase from baseline *vs.* 152%) while VL words showed a smaller difference (5%, 129% *vs.* 134%). The model also predicts that any visual speech that precedes auditory speech should influence neural activity. To test this, we manipulated the timing of the visual relative to the audio component of naturally-spoken AV speech. ML stimuli were created by advancing the visual component by 300 ms. VL stimuli were created by delaying the visual component by 300 ms. Transformed ML speech should exhibit neural cross-modal suppression, while transformed VL speech should not. Consistent with this prediction, we observed smaller BHA responses for ML (116% increase from baseline) relative to VL speech (143% increase from baseline). Taken together, the data suggest cross-modal suppression of auditory cortex by visual speech plays a key role in AV speech perception.

Title: Assessing the contribution of visual speech features to audiovisual speech perception in noise

Authors: *A. E. O'SULLIVAN[1], A. R. NIDIFFER[2], E. C. LALOR[2,1];
[1]Trinity Col. Dublin, Dublin, Ireland; [2]Univ. of Rochester, Rochester, NY

Abstract: Seeing the face of the speaker you are listening to benefits speech intelligibility - particularly in noisy situations (Sumby and Pollack, 1954). The neural mechanisms underlying this improvement in intelligibility remains unclear. Behavioral studies have found that listeners predominantly gaze at the lips of the speaker when the acoustics are noisy (Vatikiotis-Bateson et al., 1998). The use of lip information under such conditions is not surprising since the lips convey general dynamic information (which is correlated with the acoustic envelope, Chandrasekaran et al., 2009), as well as detailed articulatory movements which convey complementary information (Campbell 2008). Neuroimaging work has also found an enhancement of lip processing regions in visual cortex when the acoustics are missing (Ozker et al., 2018). Together, this suggests that the lips are an important feature of visual speech which the brain exploits to assist speech processing. Research on how the rest of the facial features contributes to speech comprehension is less clear, particularly with respect to natural speech. It has been shown that other features of the face such as jaw, eye, and head movements contribute to speech comprehension (Jiang et al., 2002; Yehia et al., 2002; Munhall et al., 2004). Yet it remains unclear whether the information that confers the improved intelligibility of noisy audiovisual speech is shared between mouth movements and other dynamic facial features or whether they carry complementary information. Here we present an experiment where we have modulated the amount of facial information available to listeners as they listen to audiovisual speech in noise (-9 dB). In particular, we have tested the effects of degrading the information available from the lips on speech comprehension - while the rest of the facial information remains intact. As well as this, we have tested if degrading all of the information except the lips affects the multisensory benefit obtained for speech in noise. Our results show that the behavioral benefits of visual speech depend on access to both visual speech dynamics and articulatory information. These results extend our understanding of the contribution of visual speech features to audiovisual speech perception.

Title: Abcam monoclonal Egr-1 is an effective primary antibody replacement for Santa Cruz polyclonal Egr-1 in songbirds

Authors: E. N. SCULLY, J. M. SANCHEZ, *C. B. STURDY;
Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: The immediate early gene protein product ZENK (acronym zif268, Egr-1, NGFI-A, krox24) has been widely used in the songbird neurobiology research community, as well as other research areas interested in assessing learning and memory. In much of songbird research, ZENK is used to measure neural activation and identify the cellular and molecular substrates involved in the first stages of memory formation. Previous songbird research revealed that neurons in the auditory areas involved in auditory perception, mainly the caudomedial nidopallium (NCM) and caudomedial mesopallium (CMM), respond with high levels of ZENK protein expression in response to presentation of biologically-relevant auditory stimuli. Santa Cruz Egr-1 primary antibody has been widely used in the immunohistochemistry protocols for visualizing ZENK. However, Santa Cruz Biotechnology has discontinued production of Egr-1. Thus, the current study is focused on analyzing the effectiveness of alternative primary antibodies: Abcam polyclonal c-Fos, Abcam monoclonal Egr-1, and Proteintech polyclonal Egr-1. Abcam monoclonal Egr-1 succesfully labeled ZENK positive cells in the songbird NCM and CMM at a concentration of 1:2000 and 1:5000. Abcam polyclonal c-Fos also labeled cells in the auditory nuclei; however, this labeling was non-specific. Abcam monoclonal Egr-1 was found to have labeling at similar levels to previous studies using Santa Cruz polyclonal Egr-1 in NCM and CMM. Abcam was also found to specifically label only cells in the areas known to express ZENK, and not label cells in areas known not to express ZENK.

Title: Shape and texture detection using haptic sensation delivered through transcutaneous nerve stimulation

Authors: *L. VARGAS[1], Y. ZHU[3], H. HUANG[2], X. HU[4];
[1]NCSU/UNC Joint Dept. of Biomed. Engin., North Carolina State Univ. and Univ. of North Carolina-Chape, North Carolina State Univ. and Univ. of North Carolina-Chapel Hill, Chapel Hill, NC; [2]NCSU/UNC Joint Dept. of Biomed. Engin., North Carolina State Univ. and Univ. of North Carolina-Chapel Hill, Raleigh, NC; [3]Mechanical and Aerospace Engin., North Carolina State Univ., Raleigh, NC; [4]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Haptic perception is crucial for reducing the required cognitive burden and uncertainty that is currently existent during the open-loop control of many prosthesis and teleoperation devices. Using delivered haptic sensation to discriminate between different shapes, object locations, and textures allows for efficient and intuitive classification of a given interaction eliminating the need for high-level auditory or visual characterization. This study aimed to evaluate if percepts delivered using non-invasive transcutaneous nerve stimulation could feasibly be utilized to differentiate between object shape and location in hand along with various surface textures. Using a 2x8 electrode grid placed along the upper arm, charge-balanced bipolar stimulation is delivered to a pair of electrodes activating the median and ulnar nerves. Current sent to a select pair creates a specific electric field, which activates different portions of the sensory axon each of which innervate the hand at various locations. The encoding strategy implemented for object shape and location discrimination required the use of two electrodes pairs each of which corresponded to an elicited sensation in the median or ulnar portions of the hand. Based on the timing and the location of the individual perceptions, users were expected to determine the object's shape or location along a sensorized prosthesis. Alternatively, during surface texture trials, a single electrode pair was necessary as discrimination was encoded based on the frequency in which a change in sensation occurred as the prosthetic finger ran across surfaces with varying number of ridges. Subjects were able to discriminate object shape, object location, and surface texture with a success rate >85 percent. Our results demonstrated that transcutaneous nerve stimulation could be utilized to provide essential sensory information required to better interact with the world around us. The outcomes provide evidence of the efficacy of the current sensory feedback method and the strategies implemented to promote

increased intuitive interaction characterization and potentially improve user acceptance, control, and overall quality of life.

Title: Audio-visual interactions in the primary visual and auditory cortex

Authors: *A. M. WONG-KEE-YOU, S. NICHOLAS, A. LOTZE, H. SIMON, C. HOU; Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: The primary visual cortex is considered to play an active role in multisensory processing (e.g., Murray et al., 2016). This view is supported by human imaging studies demonstrating connectivity between the primary visual cortex and primary auditory cortex (Beer et al., 2011, 2013), and ERP studies reporting task related multisensory neural interactions over the posterior scalp (e.g., Molholm et al., 2004). In the current study, we aimed to further examine and identify audiovisual interactions across the primary visual and auditory cortex in humans, by using source-imaged steady-state visual/auditory evoked potentials. Visual (2 cpd gratings, on/off modulated at 6Hz) and auditory (440 Hz pure auditory tone, on/off modulated at 3.75Hz) stimuli were presented simultaneously or alone, and were tagged with distinct temporal frequencies. The responses associated with the individual visual and auditory stimulus (self-terms), and the interactions between both stimuli (intermodulation terms) were quantified in the frequency domain. Self-term responses revealed that both the primary visual (V1) and auditory (Brodmann areas 41 and 42) cortex respond to visual and auditory stimuli, whether they are presented simultaneously or presented alone. However, responses to the auditory stimuli were weaker than those to the visual stimuli. In addition to self-term responses, intermodulation responses were also observed in V1 and Brodmann areas 41 and 42, when the visual and auditory stimuli were presented simultaneously. Overall, our results support the view of connectivity between the primary visual and auditory cortex. Moreover, given that intermodulation responses are believed to represent non-linear integration of neural signals (Regan & Regan, 1988), our findings provide further evidence of multisensory interactions across the early visual and auditory cortex.

Title: Contribution of subjective body midline to estimating body orientation in space

Authors: K. TANI[1], *S. UEHARA[2], S. TANAKA[1];
[1]Lab. of Psychology, Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan; [2]Fujita Hlth. Univ., Toyoake, Japan

Abstract: The body midline forming a basis for the egocentric representation of an external object seems to contribute to the estimation of spatial orientation of the body in space. Given the fact that the body midline is erroneously perceived tilt when the body is tilted (e.g. Ceyte et al. 2007), the misperception of body midline during body tilt may influence the estimation of gravitational direction or body orientation. To elucidate this possibility, we conducted two human behavioral experiments. In the first experiment, 14 healthy subjects (7 females and 7 males, aged 21- 41 years) were asked to verbally report the subjective angle of body tilt relative to gravity (subjective body tilt; SBT), and to adjust a visual line with the perceived direction of gravity (subjective visual vertical; SVV) or body midline (subjective body longitudinal axis; SVBA) at upright, or the leftward or rightward tilt position. As a result, partial correlation analysis for each subject revealed the significant positive correlation [$p < 0.05$] between the SBT and SVBA angles among 13 subjects. On the other hand, the significant correlations between SVV and SVBA angles were found among only 3 subjects. To further investigate the causal relationship between SVBA and SBT, we manipulated SVBA by providing false feedback and evaluated its effect on SBT. We asked 9 subjects (3 females and 6 males, aged 21- 31 years) to answer the SBT angle, at the leftward or rightward tilt position, after they received the manipulated visual feedback for the SVBA angle. 2-way ANOVA (2 body angles × 3 feedback conditions) showed a significant main effect of feedback condition [$p = 0.01$], indicating that SBT was influenced by the manipulated direction of SVBA even when the body tilt angles were identical. These results suggest that the CNS would estimate the body orientation in space based on the internal body midline, as well as sensory signals such as vestibular or somatosensory inputs.

Title: Seeing a face in a crowd of emotional voices: Changes in perception and cortisol in response to emotional information across the senses

Authors: *S. C. IZEN[1], H. E. LAPP[1], D. A. HARRIS[2], R. G. HUNTER[1], V. M. CIARAMITARO[1];
[1]Psychology, Univ. of Massachusetts Boston, Boston, MA; [2]Epidemiology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: Correctly interpreting emotions is essential for social interaction. While emotional state can be expressed through several modalities (body posture or movements, body odor, touch, facial expression, or voice intonation), most research has focused on faces and emotional processing within one sensory modality or the transfer of processing from one modality to another. Less is known regarding how emotional processing interacts across the senses. Further, while one literature considers how emotional exposure yields a contrastive perceptual after-effect, another literature considers how emotional exposure induces mood changes. It is unclear if cortisol changes correlate better with perceptual or mood changes.
We examined if visual and auditory emotions of matched valence (congruent) conferred stronger perceptual and physiological effects compared to emotions of unmatched valence (incongruent). We quantified how exposure to angry faces and congruent versus incongruent sounds, altered perception, using a psychophysical adaptation paradigm, and how it altered a physiological proxy for stress or arousal, using salivary cortisol.
Methods: Adapting stimuli included 30 unique angry face images (NimStim database) gray-scaled to 50%. Test images included a subset of eight unique identities morphed along an angry to happy emotional continuum (neutral, 10%, 20%, 40%, and 80% happy and angry). Eighty-one participants (mean age=22.6) first judged 64 test faces as either happy or angry to obtain their baseline point of subjective equality (PSE), or unique neutral point. Next, after 3 minutes of exposure to either congruent (100% angry faces/negative sounds), incongruent (100% angry faces/positive sounds), visual only (100% angry faces), or auditory only (negative sounds) conditions, participants judged the test faces again. To determine the strength of interactions between seen and heard emotions, pre- and post-exposure to a given condition, we quantified changes in PSE and changes in salivary cortisol.
Results: While we found no significant perceptual advantage for congruent over incongruent emotions, effects on perception and cortisol were weakest for heard emotions. Furthermore, cortisol changes correlated significantly with perceptual changes, such that larger decreases in

cortisol post-exposure to negative emotions correlated with more positive perceptual after-effects.
Conclusions: Our results suggest that the more exposure to negative emotional information biases neutral faces to be perceived as happier, the greater the decrease in stress or arousal.

Title: Distinct light dependent human magnetoreception in geomagnetic food orientation

Authors: *K.-S. CHAE[1], S.-C. KIM[2], H.-J. KWON[1];
[1]Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Hankyong Natl. Univ., Anseong, Korea, Republic of

Abstract: It is well established that dozens of magnetoreceptive animals, from worms to mammals, use the Earth's magnetic field (geomagnetic field, GMF) to navigate short- or long-distance and modulate body alignment to fulfill biological needs, depending on species. For humans, it is largely thought that GMF cannot be sensed, even though some previous studies suggested that human may sense magnetic fields including the GMF. Very recently, using a self-rotatory chair experiment, we reported that human males can sense the GMF and use it to search for food direction in a blue light-dependent manner under starved condition. Here, we provide additional behavioral mechanistic evidence for human magnetoreception of the GMF. In a two-alternative forced choice paradigm, starved men showed a distinct light wavelength-dependent magnetic orientation, which may not be consistent with conventional role of light in magnetoreception. The exact reversal of the GMF resulted in orientation toward the magnetic north, indicating that orientation is mediated by axial direction but not polarity of magnetic field. The results confirm that humans can sense the GMF and use it for magnetic food orientation in a light- and inclination compass-dependent manner. Further, the results suggest that magnetite may not be involved in the observed human magnetoreception.

Title: Peripheral nerve stimulation is processed at a preconscious level

Authors: *N. CHOWDHURY, D. J. TYLER;
Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: Upper limb amputees rely on sight alone while using a prosthetic arm. While attempting to a grasp, they are guessing as to how much to close their hand on an object while not crushing it. This single sensory feedback bottlenecks the user's functional ability to purely focusing on the task at hand while using a device. This is one of the main contributing factors reported for why upper limb amputees abandon use of their prosthesis. Current literature suggests that haptic feedback diverts some of this visual effort to the tactile system, but the feedback becomes less effective the further from the hand it is implemented. Direct stimulation of the somatosensory cortex was used to fill this gap, but counterintuitively it has shown to provide information which is processed slower than visual feedback despite being perceived on the hand. This suggests that for tactile feedback to be used effectively, conscious perception may be less important than the preprocessing by subcortical areas. Our group's solution is to send stimuli through the peripheral nerves of the amputee's arm so that the signal is naturally directed by physiology to the correct areas of the brain before conscious perception occurs. In order to do this, we used an external stimulator to apply different intensities of tactile feedback to create an attentional blink task. By backmasking a threshold level stimulus with a medium intensity stimulus, we were able to shift the subject's conscious reaction back in time compared to when the masked stimulus had not occurred. This implies that the stimulus was used preconsciously to trigger a preplanned motor output. We also compared the reaction times due to stimulated tactile feedback with reaction times due to visual and vibrotactile feedback. Our results show that stimulated reaction times are consistent with tactile reactions times seen with able-bodied individuals and this once again confirms that the artificial tactile information is used similarly if not the same as for an able-bodied individual. These results taken together suggest peripheral nerve stimulation is used more intuitively than existing methods and could provide feedback resulting in intuitive control of a prosthesis.

Abstract: Synesthesia is a neurological condition in which people experience a sensory concatenation when exposed to a specific stimuli. For example, some people may hear colors. Past research has shown that synesthetes tend to exhibit more creativity through music, art, and verbal tasks. The present line of research investigates whether synesthetes elect to use differing levels of figurative language as compared to neurotypical participants. Participants completed three separate writing tasks (describing a childhood memory, writing a creative short story using three words, and describing a picture) which three coders rated for occurrence of figurative language. Figurative language was operationalized as language that is not interpreted in the literal sense, such as idioms, similes, and metaphors. Lexical choices were also measured. Preliminary data shows that synesthetes display different rates of figurative language in some but not all of the tasks, suggesting a correlation between synesthesia and creativity. Implications will be discussed.

Title: Human vibrotactile discrimination thresholds for sequential and simultaneous stimuli at four different locations on the body

Authors: *E. L. CORRIGAN[1], V. A. SHAH[1,2], A. THOMAS[1], J. MAJ[1], M. CASADIO[2], L. A. MROTEK[1], R. A. SCHEIDT[1,3,4];
[1]Biomed. Engin., Marquette Univ. and Med. Col. of Wisconsin, Milwaukee, WI; [2]Univ. of Genova, Genova, Italy; [3]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [4]Div. of Civil, Mechanical, and Manufacturing Innovation, Natl. Sci. Fndn., Alexandria, VA

Abstract: Body-machine interfaces (BMIs) can be used to enhance control of movement, whether of the body itself or of an external device. BMIs can be used by healthy individuals as well as patients (e.g. survivors of stroke), who may have better somatosensation at specific body locations. Vibrotactile feedback (VTF) is one mechanism that BMIs can use to augment intrinsic sensory information about the ongoing movement. We examined VTF perception at four body locations to determine suitable application sites for future multi-channel BMIs that use VTF cues to guide motion planning and control. Seventeen healthy adults (age 18-66 years) had a pair of small vibration motors affixed to the skin at each of four location pairs. The motors were placed on soft tissue on the right forearm (dermatome C7/T1), on both shoulders (dermatome C5), near the midline on the chest/back (dermatome T2), and on the medial and lateral sides of the right lower leg, just distal to the knee (dermatome L4/L5). Each pair of motors was spaced at least 8cm apart. The motors applied pairs of vibrotactile stimuli and participants verbally indicated (discriminated) which stimulus felt more intense, where greater intensity was defined as being greater in vibration frequency and/or amplitude. Each pair of stimuli included a standard (186 Hz; 750 ms duration) and a probe intensity (ranging from 100 Hz to 235 Hz; 750 ms). Standard and probe intensity pairs were presented sequentially or simultaneously. Stimuli order was counterbalanced across tactors and body locations. Probabilities that the probe felt more intense than the standard were computed and fit with a cumulative normal distribution function. The discrimination threshold was defined as one standard deviation of the underlying distribution. Two-way repeated measures ANOVA revealed that threshold magnitudes depend on both inter-stimulus timing ($F_{(1,48)} = 9.126$, $p = 0.004$) and locations ($F_{(3,48)} = 5.967$, $p = 0.002$).

Discrimination thresholds were best if stimuli were applied sequentially to the shoulders. Overall, discrimination thresholds were worst when stimuli were applied simultaneously to the chest. In this sample population, discrimination capability was impacted by location, and impacted by vibrotactile information timing. Thus, multiple body locations appear to be viable options for BMI applications. Future research will focus on vibrotactile discrimination capability in patient populations (i.e. survivors of stroke).

Title: Multisensory associative learning by classical conditioning of unique audiovisual stimulus combinations in the MEG

Authors: *T. R. SCHNEIDER[1], K. MÜSCH[2,1], A. K. ENGEL[1];
[1]Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Learning of new associations between sensory modalities can be beneficial, if the input of a single modality alone is not sufficiently predictive of upcoming events. The question how the brain resolves this crossmodal learning, i.e. the forming of new associations between sensory modalities, is not yet fully unraveled. We investigated crossmodal learning in a classical conditioning experiment in which only a combination of auditory and visual stimuli was sufficiently predictive of aversive unconditioned stimuli using magnetoencephalography (MEG). Simple auditory (sinusoidal tones) and visual stimuli (Gabor patches) served as conditioned stimuli (CS) and mildly aversive pain stimuli (electric stimulation of the finger tip) as unconditioned stimuli (UCS). Only unique audiovisual feature combinations (CS+) were predictive of UCS, while stimuli in each of the single modalities had no predictive value for UCS. Other unique audiovisual feature combinations (CS-) were predictive for the absence of UCS. We recorded neuronal activity in N=34 human participants (22 female, age range: 21-35 yrs.) using MEG during a crossmodal aversive conditioning paradigm. Pain thresholds were individually titrated and UCS were administered at 1.5 times the pain threshold. Participants rated the valence of CS and the expectancy of UCS revealing that new associations between

sensory modalities were learned and used for the prediction of UCS. Analysis of event-related fields revealed early differences between CS+ and CS- audiovisual stimulus combinations already between 60 to 120 ms following CS onset. Statistics were computed using cluster-based permutation tests. The results are interpreted as signs of early integration between sensory inputs and the formation of memory traces between sensory modalities.

Title: Impact of auditory cross modal plasticity on vision restoration

Authors: *T. G. MOWAD[1], A. E. WILLETT[2], A. DOUGAL[1], M. MAHMOUDIAN[1], M. DUONG[1], M. LIPIN[1], A. MAGUIRE[1], J. BENNETT[1], M. ASHTARI[1];

Abstract: In subjects with long-term visual deprivation, the visual cortex supports functions of other sensory inputs, a process known as the cross modal plasticity (CMP). The reorganization of the visual cortex during CMP has been considered as an impediment for vision restoration therapies. The goal of this study was to shed light on the largely unknown impact of this adaptive plasticity of the visual cortex on the success of vision restoration. Participants consisted of 8 LCA2 patients and 8 matched controls. The patients received retinal gene therapy (GT) in the left (n=7) or right (n=1) eye. All subjects underwent vision, auditory, and resting-state fMRI (rsfMRI); the patients received same tests 3 years after GT. fMRI tasks consisted of alternating active (30 s) and rest (15 s) blocks. Visual stimuli consisted of contrast-reversing checkerboards[1]. Auditory stimuli consisted of a random sequence of various tones. Auditory and visual stimulation were delivered using Resonance Technology Audio/Video apparatus[2]. Functional connectivity between the primary auditory (BA41) and the primary visual (BA17) areas were evaluated using the region of interest (ROI) based rsfMRI analysis. All fMRI analyses were performed in BrainVoyager20[3](BV). Statistical group comparisons were performed using fixed and random effect analysis as implemented in BV. Consistent with previous reports, the auditory stimuli activated the primary auditory and visual cortices in LCA2

patients, and rsfMRI showed a strong functional connectivity between BA41 and BA17 and vice versa in controls and LCA2 patients. Surprisingly, GT significantly enhanced auditory response in both auditory and visual cortices. Furthermore, GT significantly increased functional connectivity between BA41 and BA17 in LCA2 patients. Controls depicted similar activation patterns observed in LCA2 patients in and around the auditory cortex with no response in the primary visual cortex. After GT, the visual stimuli induced strong and widespread occipital lobe activations, thus demonstrating a significant improvement of the visual functions. The results indicate that primary visual cortex in LCA2 patients processes both visual and auditory stimuli 3 years after vision restoration. The enhanced auditory CMP activations after GT may stem from the increased functional connectivity between the BA41 and BA17 areas, supported by the rsfMRI results. In summary, our results are suggestive of the fact that the cross modal plasticity does not hinder the success of future retinal interventions to reinstate vision.

Title: Modulation of bistable visual perception by auditory stimuli in a multisensory environment with controlled attention

Authors: *G. BUCCI[1], M. CONCHA-MIRANDA[1], C. JOANA[2], P. MALDONADO[1]; [1]Neurosci., Univ. de Chile, Santiago, Chile; [2]Univ. of Louvain, Leuven, Belgium

Abstract: The integration of the multiple stimuli presented by the environment facilitates coherent perception and shapes our behavior. Understanding how the characteristics of stimuli influence sensory integration is important to understanding this phenomenon. Evidence has shown how one stimulus in one sensory modality can influence the perception of another stimulus in a different modality, especially when the latter stimulus is ambiguous and therefore difficult to perceive. However, it is not yet clear what characteristics a stimulus must present in order to allow the disambiguation in a different sensory modality and generate a perception that is coherent with the environment, especially in stimuli that present movement. We set out to investigate how the direction of a stimulus in one sensory modality could influence the perception of the direction of another one in a different sensory modality. For this, we observed whether the direction of a sound was able to generate a change in the visual perception of people. The subjects had to sit 70 centimeters from a screen in a totally dark room. On the screen, a bistable visual stimulus was presented with "structure from motion" movement. This bistable stimulus can be perceived in two possible ways: rotating to the right or to the left. Subjects had to respond each time they perceived a change in the direction of the stimulus. Simultaneously, the subjects heard a directional white noise (that could have a right or left direction). The direction of the sound was presented randomly. Changes in the level of arousal and attention evoked by auditory stimuli were controlled so that they could not explain the results. To date, 14 subjects have been recorded, 6 men and 8 women, with an average age of 27.57 years. We evaluated the effect of the direction of sound on the visual perception reported by the subjects. So far, no significant differences were observed between coherent audiovisual and incoherent audiovisual events. These results show that in the absence of significant changes in arousal, the direction of the sound does not affect the perceptual change of the subjects. This finding supports the hypothesis that a minimum level of attention is required for audiovisual sensory integration to occur.

Title: The contribution of consciousness in the multisensory integration of sound with a bistable visual stimulus

Authors: *S. VICENCIO[1,2,3], G. BUCCI[1,2,4], M. CONCHA-MIRANDA[1,2,4], N. SANTANDER[2], F. DANNEMANN[2], N. PONCE-ROBLES[2];

Abstract: The environment around us fills us with a multitude of sensory signals that differ in their physical nature and in the way they are processed by our senses and our brains. However, we do not perceive the objects of the world as a series of separate stimuli or as the mere sum of their sensory signals. The brain constructs a unique and coherent perception by integrating the different sources of information that come from our sensory pathways. This multisensory nature of our perception opens the question of how the various senses are integrated to form a single percept. In this regard, while there is evidence that conscious sensory processing is important for the integration of different sensory modalities, most of these studies have been conducted with brief or acute stimuli. In contrast, the role of consciousness on interactions that occur when sensory stimuli are coupled for a longer period of time has not been explored in detail. With this in mind, we set out to evaluate the effect of conscious perception on the sensory integration of moving and prolonged stimuli. We used a structure from motion stimulus, which consisted of moving dots that could be perceived either as a sphere turning to the left or to the right. This stimulus was paired with a battery of sounds that varied in direction (left or right) and intensity. The threshold at which subjects were able to differentiate a directional sound from a neutral one was evaluated, as well as the threshold at which they could correctly identify the orientation of that direction. With all of this, we analyzed the effect that the direction of conscious and subliminal sounds had on the direction of the visual stimulus reported by the subjects. We found that conscious directional sounds have a significant effect on the perception of the bistable visual stimulus, increasing the number of reports that are congruent with the direction of the auditory stimulus. On the other hand, we did not find this effect on subliminal directional sounds. These results show that in the absence of conscious perception, the direction of sound has no effect on the visual perception of subjects.

Title: Posterior superior temporal sulcus is involved in segregative and integrative cortical information processing underlying cross-modal perception, but not necessarily multisensory processing

Authors: *S. SINGH, A. MUKHERJEE, D. RAY, P. RAGHUNATHAN, A. BANERJEE;
Cognitive Brain Dynamics Lab., Natl. Brain Res. Ctr., Manesar, India

Abstract: In a naturalistic environment, brain is accustomed to integrate multiple sensory inputs into a coherent perceptual object. Over the years, the study of McGurk effect, a phenomenon in which visual stimulus shapes speech perception, provided insights on the multimodal integration in brain. However, an equivocal interpretation on its mechanism is still at large. Our study aims to reveal the role of posterior superior temporal sulcus (pSTS) during audiovisual (AV) illusory perception. A critical question is how does pSTS guide network modulations while processing for the sensory components of the signal? An associated question is, whether the role of pSTS extends beyond the sensory processing level to rather a representative of the cross-modal perceptual experience.
Forty-two healthy right-handed volunteers participated in the fMRI study, approved by the Institutional Human Ethics Committee of NBRC, India. Inside the scanner, AV stimuli were presented in a block design, comprising 28 activation blocks of 10 similar stimulus videos interspersed by rest blocks. There were 7 stimulus videos: 6 incongruent AV objects (/pa-/ka) corresponding to -300, -150, 0, 150, 300, and 450 ms audio signal lags, and 1 congruent AV object (/ta-/ta, or pure /ta). Participants reported their perceptual hearing experience of either /pa, /ta, or other during the presentation. Finally, 34 participants were categorized as McGurk perceivers based on the threshold that at least 60% of /ta being perceived in any lag condition. Cortical activation pattern and functional connectivity (FC) changes across AV lags, as well as across three other perceptual conditions, were analyzed among the McGurk perceivers. At group level, we then explored the interrelation between the changes in brain and the degree of illusory perceptual experience.
Illusory /ta perception was maximal during 0 lag, and it gradually decreased with more AV

separation. Cortical regions activated during different task conditions were also found to be very similar, however the degree of activation increased with decreasing AV separation as well as with increasing cross-modal /ta perception. We also observed more bilateral activation of cortical areas (including pSTS) at 0 and 150 ms AV lags. The degree of pSTS activity for large AV lags as well as the pure /ta condition were very similar. Further, seed-based FC analysis revealed that inferior frontal gyrus, precentral gyrus, pSTS, insular gyrus, and cingulate gyrus were crucial during AV illusory perception. Thus, pSTS region in both hemispheres played important role in segregative and integrative aspects of cortical information processing during McGurk illusory perception.

Title: Vestibular training promotes adaptation of the vestibular system in postural control among healthy adults

Authors: *K. O. APPIAH-KUBI[1], A. GALGON[2], R. TIERNEY[1], R. LAUER[1], W. WRIGHT[1]; [1]Temple Univ., Philadelphia, PA; [2]Univ. of the Sci., Philadelphia, PA

Abstract: **Purpose:** Postural stability depends on the integration of multisensory inputs to drive motor outputs. When visual and somatosensory input is available and reliable, this reduces the postural control system's reliance on the vestibular system. Despite this, vestibular loss can still cause severe postural dysfunction. One form of sensory training is vestibular adaptation/habituation achieved through rhythmic head-shaking activities. We hypothesized that the effect of a concurrent weight shifting and head-shake training will significantly alter the pattern of sensory weighting and vestibular role in maintaining postural stability as measured by vestibular reflexes (VOR, VCR and VSR).
Methods: Forty-two young healthy individuals (22 females; 23.0±3.5 years; 1.7±0.1 meters) were randomly assigned into four groups: 1) visual feedback weight shifting training (WST) coupled with an active rhythmic horizontal head-shake (HHS, n=11), 2) same WST with rhythmic vertical head-shake (VHS, n=10), 3) WST with no head-shake (NHS, n=11) and 4) no training/head-shake control (CTL, n=10) groups. Training was performed for 5 days/week for 20 minutes/session. Pre- and post- assessments were Sensory Organization Test (SOT), video head

impulse test (vHIT) and ramp perturbation trials. A between- and within-group repeated measures ANOVA was used to analyze the data. Alpha was set at $p<0.05$.
Results: Following training, the VOR gain showed a Group-by-Session effect, with HHS and VHS showing the biggest change (p=.040). The second ramp down perturbation trial showed a Group-by-Session effect in the COP sway area, especially in VHS (p=.004). The vestibular (head-shake) groups (HHS, VHS) also showed a faster automatic postural response (COP sway velocity, p=.010) during the ramp up trials. The medial gastrocnemius muscle showed reduced muscle activation in the SOT, with HHS showing the greatest change (p=.017). For the ramp up trials, medial gastrocnemius and rectus femoris showed significant changes in peak amplitudes, with decreased amplitude mainly for the vestibular groups ($p<0.05$). The SOT equilibrium, composite scores, sensory ratios and COP variables did not show significant changes ($p>0.05$).
Conclusion: Combined vestibular activation and WST show evidence of modifying vestibular responses in the vestibular groups. The change in VOR gain, postural control and muscle activation after training may be as a result of vestibular re-weighting via VOR, VCR or VSR adaptation and habituation. **Clinical relevance:** Findings may be used to guide the development of a vestibular rehabilitation intervention in populations with vestibular disorders.

Title: Memory consolidation and aesthetic judgments in sound-form symbolism (bouba-kiki)

Authors: V. RAMACHANDRAN, P. BHATTACHARYYA, Z. MARCUS, R. SEN, K. VON-KLEIST, *C. CHUNHARAS;
Psychology, UCSD, La Jolla, CA

Abstract: When naïve subjects are shown an amoeba shape and a jagged shape and asked, 'which of these is kiki and which is bouba', 95% pair the amoeba with bouba and the jagged shape with kiki. Despite the fact that neural populations activated by the shape (photons hitting the eye in parallel) are utterly different from sound-driven sequentially activated hair cells in the ear, the brain extracts the abstract property of sharpness or undulation in Fourier space.
When presented with a congruent sound-shape pair (e.g. amoeba(shape)=bouba(sound)) vs. incongruent sound-shape pair (amoeba=kiki), the former is remembered better. We showed participants a series of shapes paired with either congruent names or incongruent names, and after 10 minutes, asked them to pick the correct name for each shape from two name choices. In

the case of congruently named shapes (e.g. amoeba=bouba), they were asked to choose from two congruent names – one which was originally paired with that precise shape in the learning phase, and a second one (also congruent and bouba-like), which was presented with a different shape in the learning phase (e.g., when presented with an amoeba, they were asked to choose between "bouba" and "maluma"). The same procedure was used for incongruent name-shape pairs. Participants were better at remembering the correct name for congruent name-shape pairs than for incongruent name-shape pairs, even when they had to choose it over another equally congruent, but different name.
Attractive faces paired with unattractive names are less well remembered than those paired with attractive names. Likewise – words with mismatched colors (e.g., "red" printed in green ink) – even after being learned to criterion, may decay more readily than congruent ones (e.g. "red" printed in red ink).
We conclude: 1) Establishing congruence may continue into the consolidation period – not merely during acquisition. 2) Features that have an inherent affinity to be bound (amoeba+bouba), bind more strongly, persisting as a pair longer during the consolidation of memory (which involves not merely a stabilization of synapses, but editing, caricaturizing, binding, prioritizing etc.). 3) Even congruence derived from aesthetic judgment (e.g. pretty name+pretty face) might enhance memory consolidation. These observations have obvious implications for the emergence of language and the cognitive neural apparatus involved in consolidating memories.

Title: Effects of dominant eye and head direction on locomotion trajectory

Authors: ***H. JOO**[1], S. KIM[1,3], J.-K. RYU[2], K.-M. LEE[1,4];
[2]Inst. for Cognitive Sci., [1]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Neurosci. Res. Inst., Gachon Univ., Incheon, Korea, Republic of; [4]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Background
Self-orientation is the basis of human behaviors such as walking, grasping, and navigation, etc. To construct the relationship between the self and the surrounding environment, recognizing

self-orientation is required. Since human has limited cognitive resource capacity, aligning self-orientation to the so-called "cyclopean-eye" would take additional computational effort. Here, we hypothesized that self-orientation would follow the visual information of the dominant eye not the converged information of binocular vision.
Method
There were 9 conditions in total: three head rotation conditions(front, left, right) X three eye conditions(binocular, dominant eye, non-dominant eye). The dominant eye test was done prior to the experiment. Participants were asked to walk in a straight line ten times in each condition. To calculate the drifted walking tendency while walking under different conditions, participants wore a cap type motion tracker. There was no practice session before the test to prevent motor adaptation. The baseline was set by each participant's front head direction X binocular vision condition. The angle differences were analyzed, and the positive value means that the walking path was drifted to the direction of the dominant eye.
Result
In a binocular eye condition, we observed the tendency that walking path drifted to the direction of the head rotation. In dominant/non-dominant head rotation and eye conditions, the variance appeared smaller in the dominant head rotation and the dominant eye combination compared to the non-dominant head rotation and the non-dominant eye-condition. Analysis indicated that there was a significant main effect for head direction($F(2, 203)=13.173$, $p=.000$). There was no significant main effect for eye condition level($F(2, 203)=.385$, $p= .681$) and no significant interaction effect of head directions and eye conditions($F(2, 203)=2.175$, $p=.116$).
Conclusion
If self-orientation depends on the dominant eye's visual information, locomotion trajectory of the dominant eye condition will not differ from that of the binocular eye condition. In this study, however, we found only the head direction condition have significant effects on locomotion trajectory, and this is in line with our previous research. Thus, we can expect that there is an information processing mechanism to make a reference frame other than the visual information from the initial perceptual level.

Title: Functional connectivity between 'visual' and language areas in the blind predicts braille reading performance

Authors: *R. WANG[1], J. GONG[2], C. ZHAO[1], Y. XU[2], B. HONG[1];
[1]Dept. of Biomed. Engineering, Sch. of Medicine, Tsinghua Univ., Beijing, China; [2]Dept. of Information Art and Design, Tsinghua Univ., Beijing, China

Abstract: Prior studies have implicated activations in 'visual' cortex of the blind during language processing, including speech comprehension (Bedny, 2011; Röder, 2002) and verbal memory tasks (Amedi, 2003). It has been shown that blind subjects with higher activation in V1 perform better in verbal-memory tasks (Amedi, 2003). While there remains an outstanding question about how the functional connectivity between these 'visual' areas and language nodes contributes to linguistic behavior, which may help elucidate the reorganization of language network in the blind. With fMRI scan of 12 skilled blind Braille readers (mean age 22.55 years, 6 males) , we found that 'visual' areas including V1 and extrastriate cortex (V2) showed similar involvement to classic language areas including inferior frontal gyrus (IFG) and reading-specific visual word form area (VWFA) in the Braille reading task. We next analyzed resting-state functional connectivity (RSFC) to explore the altered neural network among these active nodes in the blind. Compared with the sighted group, the blind showed enhanced RSFC in left V2 - IFG (unpaired t-test, $P < 0.005$), left V2 - VWFA ($P < 0.05$) and left V1 - IFG ($P < 0.005$). We further investigated the correlation between RSFC and Braille reading performance. The left V2 - IFG and left V2 - VWFA connectivity strengths were positively correlated with the blind subject's Braille reading speed (character/per minute) respectively (left V2 - IFG: $P < 0.001$, $R^2 = 0.72$; left V2 - VWFA: $P < 0.05$, $R^2 = 0.42$). No such association with Braille reading performance was found in V1 connectivity. We postulated that with visual deprivation and Braille learning experience of the blind, additional language-sensitive neural connectivity developed to the left 'visual' area, especially lateral occipital region V2, which may explain the language-related brain activity of 'visual' areas in previous work. This study further revealed the causal role of extended language-related neural connectivity in 'visual' cortex in superior Braille reading performance of the blind.

Title: The causal role of the pSTS in auditory-visual speech integration: A voxel-based lesion-symptom mapping study

Authors: *O. G. WIESE[1], S. KAKAIZADA[3], C. VALDIVIA[3], S. HERVEY-JUMPER[4], D. BRANG[2];
[2]Psychology, [1]Univ. of Michigan, Ann Arbor, MI; [3]Neurosurg., [4]Univ. of California San Francisco, San Francisco, CA

Abstract: Auditory receptive speech abilities are important for social and emotional health in hearing individuals. However, the reliability of auditory signals varies widely in every-day settings (e.g., at a crowded party), requiring supplemental processes to enable accurate speech perception. The principle way this occurs is by auditory-visual (multisensory) compensatory mechanisms restoring auditory content using lipreading and other visual cues (i.e., speaker identity, rhythmic entrainment of visual speech, among others). Research suggests that the posterior region of the superior temporal sulcus (pSTS) is critical for multisensory compensatory mechanisms to modulate speech perception. Previous research using transcranial magnetic stimulation demonstrated that transient impairment of the left pSTS inhibited auditory-visual speech integration. However, a case study describing a patient five years after complete destruction of their left pSTS due to stroke reported intact auditory-visual integration using the McGurk effect. These discrepant results indicate that the case study was either a usual instance of the right pSTS supporting auditory-visual speech integration prior to the stroke, or, more likely, that functional reorganization due to neural plasticity allowed the individual to recover auditory-visual speech integration processes over the course of the five-year period. To discriminate between these possibilities, we examined auditory-visual speech integration abilities in patients with brain tumors in various locations. Specifically, we identified 8 patients with a tumor that extended into the left pSTS and 31 patients with tumors in other regions. Next, we compared these two groups' performance on a McGurk effect task to estimate their auditory-visual speech integration abilities. Preliminary results indicate that tumors located in the left pSTS are associated with significantly ($p<.05$) reduced strength of the McGurk effect, consistent with non-invasive data indicating the causal role of this structure in integrating auditory and visual speech information. Longitudinal tracking of these participants' behavioral performance will enable a better understanding of if (and when/how) compensatory structures re-enable auditory-visual speech integration processes.

Title: Motor interference in the rubber hand illusion correlates with the perception of the real hand disappearing

Authors: *A. T. READER, H. H. EHRSSON;
Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Background
A sense of ownership over the body arises through multisensory integration, whereby a combination of sensory cues provide a coherent experience of an owned body distinct from the world around us. However, our sense of body ownership is malleable, as shown by the rubber hand illusion (RHI): synchronous stroking of a fake hand and a participant's real hidden hand can induce a sense of ownership over the false limb, and cause the perceived position of the real hand to drift towards the fake one (proprioceptive drift). Some individuals also report a feeling of the real hand disappearing, which might reflect a feeling of disownership for the real hand.
It is still unclear if movement is reliant on a sense of ownership over our body, though the RHI may alter parietal-motor cortical connectivity and reduce corticospinal excitability. With this in mind, we examined if the RHI has functional consequences for basic movement.
Methods
We recruited 58 participants (mean age = 26.3 years, 29 female) who took part in two blocks (synchronous or asynchronous stroking of the real and false hand) of ten trials. The position of the right index finger was motion-tracked. In each trial stroking was performed for 30 seconds. After stroking, a tone signalled participants to rapidly abduct their index finger, providing measures of reaction time (RT), peak acceleration (PA), and peak velocity (PV). We also recorded proprioceptive drift and questionnaire statements (feelings of rubber hand ownership, real hand disappearance) for the synchronous and asynchronous conditions.
We predicted that, should the RHI alone interfere with movement, then RT would be greater in the synchronous than in the asynchronous condition, and PA and PV would be reduced. We also examined if specific components of the RHI (proprioceptive drift, sensations of rubber hand ownership and real hand disappearance) were correlated with changes in kinematic variables.
Results
Neither the RHI alone, nor proprioceptive drift or sensations of rubber hand ownership interfered convincingly with movement. However, individuals reporting a greater feeling of the real hand disappearing performed movements with smaller PA (r_τ=-.285, p=.004, BF_{10}=23.2) and PV (r_τ=-.270, p=.007, BF_{10}=13.7) following illusion induction. Though most participants did not affirm this feeling, the correlation was supported by effects observed in the subset (n=15) that did (BF_{10}>3).
Conclusion
Although it may not be an essential component of the RHI, a feeling of losing the real hand may have functional consequences for movement. This supports the idea that body ownership may mediate the capacity of the motor system for basic movement.

Title: Visual selection is influenced by natural auditory dynamics

Authors: ***M. K. SMITH**[1], M. GRABOWECKY[2], S. SUZUKI[2];
[1]Brain, Behavior and Cognition, [2]Psychology, Northwestern Univ., Evanston, IL

Abstract: We often find ourselves in environments containing multiple multisensory objects that vie for our attention. Our auditory system has the ability to play a crucial role in the visual selection process because it is good at rapidly identifying temporal regularities in our environment as well as detecting salient, transient events. The aim of this study was to investigate the role of dynamic auditory features in influencing visual selection. Participants engaged in a novel paradigm in which they experienced dynamic audiovisual combinations consisting of natural auditory soundscapes (nature, urban, and music) paired with visualizer displays containing distinct elements each of which represented the amplitude modulation changes of a given auditory frequency band as luminance changes. The visual elements were circles arranged in a 4x4 matrix. As the soundscape-visualizer combinations played, participants visually searched for a visual element that appeared to be an optimal match for what they heard at any point in time. By assigning the visual elements to correspond to dynamic changes within a particular frequency band, we probed whether specific frequency ranges provided useful information for visual selection. Across all auditory scenes we found a tendency for participants to fixate the visual elements that represented the auditory frequency bands with the highest pulse clarity ($t(50) = -4.14$, $p < 0.001$) rather than the visual elements representing the frequency bands with the highest intensity ($t(50) = 0.61$, $p = 0.54$). This result demonstrates that the auditory systems ability to identify the periodic dynamics in a chaotic signal can bias visual selection towards objects that may be plausible sources of those sounds.

Title: Integration of simultaneous artificial sensory percepts to identify prosthetic hand postures

Authors: *I. CUBEROVIC[1], J. L. SEGIL[3], E. L. GRACZYK[2], R. F. F. WEIR[3], D. J. TYLER[2]; [2]Biomed. Engin., [1]Case Western Reserve Univ., Cleveland, OH; [3]Univ. of Colorado Boulder, Boulder, CO

Abstract: Skilled prosthesis use requires both high degree-of-freedom control and sensory feedback. However, current prostheses do not restore somatosensation, forcing users to rely only on visual and auditory feedback to regulate movements. Prostheses are rarely used for complex motor tasks like tool manipulation, since these tasks divert attention away from the prosthetic device. Instead, they are adopted for supporting tasks, used passively, or not used. To provide sensory feedback to upper limb amputees, peripheral nerve interfaces are used to electrically activate the residual somatosensory nerves of the hand. In the intact system, multiple sources of sensory information are integrated to develop hand posture percepts. However, the extent to which prosthesis users can integrate patterns of artificial sensory information has not been studied. Here, we report on a case study of a person with transradial amputation.
We found that the participant was able to successfully integrate five simultaneous, electrically-evoked sensory percepts to identify prosthetic hand postures. He achieved 95.0% success in identifying 4 postures and 75.7% in identifying 7, significantly above chance ($p \leq 0.001$). Further, we studied how artificial somatosensation and the extant body schema are integrated in the decision-making process by varying the mapping between the prosthetic sensor and the location of the sensory percept. Two mappings were used across experimental conditions: 1) a congruent mapping (index finger sensor evokes perception on the index finger), and 2) an incongruent mapping (index finger sensor evokes perception on the ring finger). We found that the participant was able to learn postures more accurately ($p \leq 0.04$) and more quickly ($p \leq 0.022$) in the anatomically congruent condition. Further, we showed that his strategy in identifying postures and error types ($p \leq 0.011$) changed with mapping. Finally, we investigated how prior knowledge is applied in novel decision-making tasks by expanding the task to identifying seven

postures and found that he was only able to successfully generalize to novel postures in the anatomically congruent condition (p=0.018 and p=0.989, anatomically congruent and incongruent conditions, respectively).

Title: Stiffness-dependent sensory weighting of position and force feedback during pinching

Authors: *J. E. GEELEN[1,2], A. C. SCHOUTEN[1], N. F. RAMSEY[2], F. C. T. VAN DER HELM[1], W. MUGGE[1];
[1]BioMechanical Engin., Delft Univ. of Technol., Delft, Netherlands; [2]Brain Ctr. Rudolf Magnus, Univ. of Utrecht, Utrecht, Netherlands

Abstract: During daily activities, complex tasks such as opening a bottle, writing a note, and playing the piano reveal the dexterity and the high number of degrees of freedom of our fingers. When controlling finger movements, the central nervous system (CNS) has to cope with the redundancy of hand muscle activation and the uncertainty in the sensory feedback. The integration of multiple afferent inputs includes interrelations beyond the simple addition of inputs. Sensory weighting can be found within the proprioceptive system of the shoulder, more specifically between the two sensory modalities: muscle length and muscle force (Mugge et al. 2009). When pinching an object between two fingers, information from both proprioceptive modalities are related. Interactions with stiffer objects result in smaller position changes and higher force changes. Thus force feedback is expected to be dominant in that situation. We hypothesize that similar stiffness-dependent sensory weighting exists in object manipulation by the fingers.
This exploratory study investigates the weight adjustment of proprioceptive inputs by the CNS that facilitates optimal control of the fingers. A robotic manipulator was designed to provide an adjustable dynamic environment, a virtual spring, over a range of stiffnesses. The robot accurately measures the force and position of the tip of the fingers in a pinching motion. The subjects (n=10) were trained to blindly reproduce a force against the virtual spring. In regular trials, the fingertip position was linearly related to the applied force, and thus the weights were indistinguishable. The virtual spring dynamics were altered into a non-linear spring for some

trials, catch trials, revealing the sensory weighting. A maximum likelihood estimation model predicts the optimal integration of the proprioceptive sensory information and explains the sensory weighting in pinching. Future experiments that compare the brain activity patterns for distinct weightings of position and force during finger movements require knowledge about the stiffness level at the crossing point of these weights. With the current study, we provide the essential information to analyse the multisensory integration in the CNS during pinching.

Title: Short term monocular deprivation in adult humans influences multisensory interactions

Authors: *C. OPOKU-BAAH[1], J. E. OLSEN[2], B. HOU[2], M. T. WALLACE[3];
[1]Vanderbilt Brain Inst., [2]Neurosci. Dept., [3]Hearing and Speech Sci., Vanderbilt Univ., Nashville, TN

Abstract: Normal visual sensory experience plays a crucial role in the development of the visual and the multisensory systems. Even in the adult brain with limited plasticity, recent studies have shown that transient absence of visual input in one eye changes the dynamics of binocular rivalry to favor the deprived eye. This short-term experience-dependent plasticity is thought to likely reflect an upregulation of contrast-gain control mechanisms in the deprived eye. Here, we sought to extend this work into the multisensory (i.e., visual-auditory) arena, with the hypothesis that short term monocular deprivation will influence not only binocular interactions, but multisensory interactions as well. Participants were recruited to perform an audiovisual temporal numerosity judgment task using their deprived and non-deprived eyes in separate sessions. The sessions occurred before and after 90 minutes of monocular deprivation with an opaque eye patch. Each participant's pre and post deprivation results for the deprived and non-deprived eyes were obtained, analyzed and fit to a Bayesian Causal Inference (BCI) model with 9 parameters. Comparing the behavioral responses, we discovered that visual bias (which measures the influence of the more reliable modality (i.e. audition) on the perceived visual percept) tended to decrease for the deprived eye more than for the non-deprived eye. For the modeling results, two out of the nine parameters of the BCI model showed significant differences between the deprived

and non-deprived eye conditions. First, deprivation was found to decrease the variance (i.e., standard deviation) of the visual likelihoods of the deprived eye, demonstrating an improvement in visual sensory encoding. Second, after deprivation, the tendency to bind the audiovisual signals was reduced for the deprived eye but was increased for the non-deprived eye. Changes in visual likelihood and binding tendency were found to be strongly positively correlated, such that larger improvements in visual sensory encoding were associated with weaker binding tendency. Together, our findings support the hypothesis that short-term monocular deprivation can affect multisensory perceptual processes through a change in visual sensory encoding and the tendency to bind audiovisual signals. This indicates that changes in visual experience in the adult can influence the way the visual system interacts with other sensory modalities, and thus such changes in multisensory perception may contribute to the overall compensatory behaviors observed in patients with adult-onset visual deprivation.

Title: Audio-visual interactions during motion adaptation modulates the perceived duration of the motion aftereffect and the brain activity in hMT+

Authors: *M. PARK[1], C.-Y. KIM[2];
[1]Dept. of Psychology,, [2]Dept. of Psychology, Korea Univ., Seoul, Korea, Republic of

Abstract: The perceptual system forms a unified, coherent percept by integrating sensory inputs from multiple modalities each of which is processed through a distinct neural pathway. In our previous psychophysical study exploiting the motion aftereffect (MAE; an illusory motion caused by adaptation to physical motion), adaptation to visual motion accompanied by auditory motion with the congruent direction enhanced the intensity of the subsequent visual MAE, suggesting audio-visual interactions relatively early in the visual pathway. In the present study, we used functional magnetic resonance imaging (fMRI) to examine the neural mechanisms underlying such audiovisual congruence effect. Specifically, we focused on the motion sensitive area hMT+ since neural adaptation arising from direction-selective neurons in hMT+ has been considered as the neural basis of the MAE. During the 30-sec initial adaptation and the 12-sec top-up adaptation phases, MAE was induced by the 100%-coherence random-dot kinematograms (RDKs) moving either leftward or rightward. Leftward or rightward moving sound was

simulated by cross-fading the intensity of the white noise presented between binaural channels of noise-cancelling headphones. According to the audio-visual direction congruence, there were congruent and incongruent sound conditions along with stationary, and no-sound conditions. During the 4-sec test phase, participants reported the duration and the direction of the MAE experienced on a stationary RDK. Behavioral results from the three participants clearly replicated our previous findings that the duration of visual MAE was longer in the congruent condition and was shorter in the incongruent condition than in other conditions. fMRI results from the univariate analysis showed the greater activation in hMT+ in the congruent condition than in the incongruent condition, echoing the behavioral results. Results from the multivariate pattern analysis (MVPA) showed the difference in decoding accuracies between the congruent and incongruent conditions when a classifier discriminated the direction of the MAE after being trained to discriminate leftward versus rightward direction of physical motion. These results indicate that audio-visual interactions based on the direction congruence during adaptation lengthened the duration of the MAE, which was subserved by modulation of the intensity and the activity patterns of hMT+.

Title: Defining the time course of multisensory object processing: A three stage model

Authors: *T. VERCILLO[1], E. G. FREEDMAN[1], S. MOLHOLM[2], J. J. FOXE[1];
[1]Neurosci., Univ. of Rochester Sch. of Med., Rochester, NY; [2]Neuroscience/Pediatrics, Albert Einstein Col. of Med., Bronx, NY

Abstract: The majority of objects that we interact with in the natural environment are multisensory, stimulating multiple sense organs and leading to representations in a distributed sensory cortical network. Multisensory objects that are frequently encountered lead to strong associations across this network, with the end result perception of a unitary object. However, we know relatively little about the cortical processes sub-serving multisensory object formation and recognition. This is surprising given their relevance to learning to read (e.g., associating graphemes with phonemes) and to ubiquitous other tasks. To advance our understanding in this important domain, the present study investigated the brain processes affected by the learning and identification of novel visual-auditory objects. Thirty adults were remotely trained for a week to recognize, with ~100% accuracy, a novel class of multisensory objects (3D shapes paired to complex sounds), while data were live streamed to the lab via an Andriod device. High density

event related potentials (ERPs) were recorded to the unisensory (shapes or sounds only) and the multisensory (shapes and sounds) stimuli, before and after the intensive training. We differentiated multisensory effects by comparing individual ERPs to the multisensory versus the unisensory stimuli, and the summation of the unisensory responses. Moreover, we compared ERPs before and after training, to map the evolution of multisensory cortical responses between initial exposure to full consolidation (post-training) of these audiovisual pairings into a well-learned class of multisensory object. We report three major multisensory effects: 1) an early multisensory effect (<100 ms) within occipital scalp areas, triggered by the detection of simultaneous audiovisual signals and not related to multisensory learning; 2) an intermediate object-processing stage (100-200 ms), involving a larger cortical network, sensitive to the learned multisensory associations and 3) a late conceptual multisensory processing stage (>250 ms) that does not appear to be learning-specific. Results from this study provide support for multiple stages of processing of multisensory object learning and recognition, subserved by an extended network of cortical areas. This innovative work significantly contributes to our understanding of multisensory object representations, and could shed light on developmental learning disorders associated with multisensory integration.

Title: Characterizing auditory responses in human low-level visual cortex using ECoG

Authors: ***J. PLASS**[1], E. AHN[1], A. SHERMAN[2], V. TOWLE[3], W. STACEY[1], V. WASADE[4], J. TAO[3], S. WU[3], N. ISSA[3], M. GRABOWECKY[5], S. SUZUKI[5], D. BRANG[1];

Abstract: Sounds can facilitate the perception of simultaneous visual events. One mechanism thought to subserve these enhancements is crossmodal phase-resetting of subthreshold oscillations in low-level visual cortex. By placing visual cortex in a high-excitability state before visual input arrives, crossmodal phase-resetting is thought to enhance sensitivity for concurrent visual signals. Using intracranial electrocorticography (ECoG) in human epilepsy patients, we recently observed widespread auditory phase-resetting throughout visual cortex, including pericalcarine (putative V1/V2), lateral occipito-temporal (potentially V5/hMT+), inferior

occipito-temporal, and posterior parietal cortex. Here, we sought to further characterize the electrophysiological properties and stimulus selectivity of crossmodal responses in low-level (pericalcarine) visual cortex by analyzing additional indices of neural activity and responses to a wider variety of auditory stimuli. Consistent with research in non-human primates, pericalcarine electrodes exhibiting auditory phase-resetting demonstrated only weak or negligible neural firing, as indexed by high gamma (70-150 Hz) power. At lower frequencies (reflecting neural oscillatory activity), electrodes with the most pronounced phase-resetting effects (measured using inter-trial phase coherence; ITPC) exhibited increased power in the same frequency bands (theta/alpha), while electrodes with weaker ITPC exhibited broad power suppression. These results suggest that sounds primarily influence low-level visual cortex by modulating sub-threshold oscillations, potentially increasing theta/alpha power by synchronizing oscillations in targeted neural ensembles, while reducing neural variability overall. To characterize the stimulus selectivity of these responses, we examined whether they varied with the frequency (pure tones) or complexity of auditory stimuli. Crossmodal responses exhibited variable or no frequency preferences, and similar phase-resetting responses for pure tones, noise bursts, and speech. These results suggest that crossmodal responses in low-level visual cortex may primarily convey stimulus timing with minimal selectivity for stimulus content. Altogether, these results support the hypothesis that sounds enhance stimulus coding in low-level visual cortex by synchronizing subthreshold oscillations to the timing of auditory events.

Title: fMRI response to transcutaneous vagus nerve stimulation

Authors: *D. BORGMANN[1,3], B. KUZMANOVIC[1], L. RIGOUX[1], H. FENSELAU[2], M. TITTGEMEYER[1];
[1]Translational Neurocircuitry, [2]Synaptic Transmission in Energy Homeostasis, Max-Planck-Institute for Metabolism Res., Cologne, Germany; [3]Anat. II (Neuroanatomy), Univ. Hosp. of Cologne, Cologne, Germany

Abstract: Transcutaneous vagus nerve stimulation (tVNS) is known to have acute as well as long-term effects. The physiology of neither, however, is well understood. Classical block designs for the fMRI-analysis of acute brain activation in response to tVNS are difficult to

interpret due to time-varying effects of tVNS. Here, we used task-free functional MRI in humans to assess time-dependent effects of tVNS on brainstem neuronal responses. Specifically, we used a repeated- measures design with factors time (10 time points during a 7 minute stimulus- plus 3 minute post-stimulus interval), and group (sham vs. verum stimulation).
Activation of previously described downstream targets of vagal afferents like the dorso-vagal complex (DVC), parabrachial complex (PB) and substantia nigra (SN) showed significant (FEW brainstem cluster-level corrected under a cluster-defining threshold of $p < 0.001$) response to electrical stimulation in ROI-based analysis of the brainstem in 13 lean, healthy human subjects (8 females).
In the course of stimulation, we observed a linear increase in activation, which peaked during the 'off'-period after the 7 min stimulation phase, suggesting that carry over effects are particularly important when interpreting fMRI data with respect to the neurophysiology of tVNS.

Title: You or me? Defining the boundaries of self-other peripersonal space

Authors: *F. GARBARINI, C. FOSSATARO, M. GALIGANI, A. ROSSI SEBASTIANO, V. BRUNO, I. RONGA;
Univ. of Turin, Torino, Italy

Abstract: The concept of peripersonal space (PPS) captures the idea of a portion of space immediately surrounding the body (near space). Since the PPS representation is known to be highly plastic, changing with experience, here we asked whether it can be modulated by social-dependent contextual manipulations. In social contexts, the PPS can be defined as "my space" as opposed to "your space". Does the presence of someone else's hand modulate the boundaries of the self-related PPS? To answer this question, we capitalized on visuo-tactile multisensory integration, occurring when visual stimuli appear within the PPS boundary (i.e. close to the stimulated body district) and known to speed up the behavioural responses to tactile stimuli and to induce sub/super-additive responses in the neural activity (Visual Enhancement of Touch, VET). In two experiments, participants underwent a VET paradigm in which event-related

potentials (ERPs) and reaction times (RTs) to tactile stimuli were recorded. In both experiments, tactile (electrical) stimuli were delivered to the participants' hand, while visual stimuli (colored-led) could appear either near to the stimulated hand or far from it, at two different distances (i.e. 20 cm or 40 cm away from the stimulated hand). In the first experiment, we verified that, in both RTs and ERPs, significant differences between near and far conditions were found only when visual-stimuli in far position were coded as outside the PPS (40 cm away from the stimulated hand) and not when they were coded as inside (20 cm). In the second experiment, we demonstrated that, when another person's hand was present, so that the position far from the participant's hand was near to the co-experimenter's hand, visual-stimuli, previously coded as inside the PPS (at 20 cm), were coded as outside and significant differences between near and far conditions reappeared in both RTs and ERPs. Taken together, these findings show that the presence of someone else' body-parts reduces the self-related PPS boundary, within which integrated responses occur, and induces a social recoded of "my space" as "your space".

Title: The effect of free manipulation on bimanual integration in the haptic perception of the size of boxes and pliers

Authors: Q. XU[1,2], G. RISSO[1,2], ***G. BAUD-BOVY**[1,3];
[1]Inst. Italiano di Tecnologia, Genoa, Italy; [2]Univ. degli studi di Genova, Genoa, Italy; [3]Vita-Salute San Raffaele Univ., Milan, Italy

Abstract: Many circumstances in daily life require people to use both hands to manipulate objects and gather information about their shape. While historically most studies have focused on the integration of information from different sensory modalities, within-modality sensory integration and bimanual integration in particular raise similar questions about when the brain should or should not integrate information. Intriguingly, previous studies have shown little evidence that proprioceptive information from the two hands is integrated when apprehending the size or shape of objects. In the present study, we investigated the influence of lifting the object on bimanual integration. To that end, we measured how precisely people estimate the size of objects (wooden boxes, actuated apparatus with two movable flat surfaces and large-size

pliers) when using one hand or two hands with the object grounded or lifted. Results indicate that subjects are able to discriminate the size of complex tools such as pliers, and that lifting the object can improve size discrimination performance. We propose that the physical interaction between the two hands occurring during free manipulation enhances bimanual integration by strengthening the assumption that information is coming from the same object. However, no factor can single-handedly explain all the results. Like in other sensory integration studies, a mix of structural factors and cognitive factors such as the familiarity of the object appears to matter.

Abstract: As virtual reality head mounted display (VR-HMD) technology becomes more widely used in industry, research, and recreation, the oculomotor effects of continued use will become more prominent. This study aims to test the possible ocular effects caused by a new commercially available VR system. Participants were assigned to either a VR-training or real-world (RW) training condition. Researchers were trained to administer optometric tests by a licensed optometrist and measured vergence and accommodation facilities in both groups before and after a 30 minute session of dart throwing. Preliminary results indicate overall increase in the performance on the accommodation and vergence test, but no significant difference between the groups. This may show promising results to any individuals or organizations that would plan to implement VR in the future.

Title: Visual reorientation illusions on earth - Comparison of different assessment techniques

Authors: *N.-A. BURY, M. HUSSAIN, M. MCMANUS, L. R. HARRIS;
Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Human spatial orientation uses three reference frames: gravity, allocentric (orientation and relationships of visual objects and features) and egocentric (orientation of the body). Usually these frames are redundant; however, in unusual environmental conditions, such as in microgravity, they can become dissociated which can evoke Visual Reorientation Illusions (VRI) in which the interpretation of up can suddenly switch directions. Here we compare different assessment techniques for identifying VRIs evoked by altering the relationship between visual, gravity and body cues by means of the York tumbled room. Twenty-eight participants (12 female; 20.3 ± 2.6 yrs.) were positioned in two rooms with the identical interior layouts. One was normally oriented, the other was tilted 90° relative to gravity. Participants were blindfolded when entering either room and were guided to adopt the same orientation relative to the features of each room: upright in the normally-oriented room, supine in the tilted room. Participants were exposed to each room for 5s and 180s. Before, in between, and after these exposure periods, they donned a head mounted display in which they were immersed in a featureless virtual cubic room with six differently colored surfaces (randomly rotated for each trial) and identified the “ceiling” / “floor” (group A) or the surface “above” / “below” them (group B) by verbally indicating the appropriate colored surfaces. Afterwards they were asked whether they perceived a VRI during either exposure period. The rate of VRI reporting in the tumbled room (defined as when the visual frame dominated) depended on the identification technique used. VRIs were less likely to be reported using the cubic room technique compared to verbal report. Surprisingly, the shorter exposure period to the tumbled room led to >20% more VRI reports than the longer exposure. However, this was only the case for verbal reports. Use of different wording (ceiling/floor vs. above/below) evoked no difference in reports. We conclude that caution should be used when generalizing findings on VRI incidence when only a single identification technique is used. Longer exposure seemed to allow gravity to become more salient when deciding on the perceived direction of up.

Title: Inputs to neurons in layer 1 of mouse cerebral cortex

Authors: *E. LAI, G. W. ARBUTHNOTT;
OIST Grad. Univ., Okinawa, Japan

Abstract: In rodents, a major output from the basal ganglia arrives in layer 1 (L1) of frontal cortex. Neocortical L1, the most superficial layer of cerebral cortex, is composed of a small number of GABAergic interneurons and received massive excitatory input fibers from the ventromedial thalamus and other cortical and subcortical areas. Electrophysiological results have identified that L1 fibres from ventral motor thalamus have monosynaptic access to layer 5 cortical output (pyramidal tract, corticofugal or corticostriatal) and layer 6 corticothalamic output. Understanding the synaptic organization in L1 interneurons circuitry is vital for understanding the mechanism involved in regulating movement. For this study we have compared the postsynaptic responses in interneurons of L1 to optogenetic activation of both thalamocortical (thalamocortical pathway, TC) and contralateral cortical inputs (intratelencephalic tract, IT) using in vitro whole-cell patch-clamp recordings of motor cortex in C57BL/6J mice. We discovered that L1 interneurons received excitatory inputs from at least two set of input fibres. Interestingly, they evoked different paired-pulse response; TC afferent exhibited paired-pulse depression while IT input fibres evoked paired-pulse facilitation. Furthermore, many L1 interneurons have inhibitory responses - presumably from other interneurons within layer 1. In particular, L1 interneurons received proportionally more inhibitory signals after TC stimulation than after IT fibres. Such differences in the probability of finding inhibition strongly suggest that the two inputs control different numbers of interneurons, and so differently affect layer 1 actions. Based on our results, we hope that a study of this less populated area of cortex will illuminate the detailed interactions of motor thalamus with cortical areas involved in mechanisms of motor control. Increasing speculation about the role of cortex in Parkinson’s Disease symptoms -or even in the cause of the disease- make these experiments important for the understanding of the influence of basal ganglia on motor behavior.

Abstract: Short afferent inhibition (SAI) has been extensively studied to identify the experimental factors affecting the magnitude of the phenomenon, and to determine the underlying neural mechanisms. Current evidence indicates that sensory and motor pathways are involved in generating SAI, and that its modulation may depend on the inputs received via cholinergic neural activity to the GABAergic interneurons or pyramidal neurons. However, the correlation between cholinergic metabolism and SAI remains unclear. We aimed to identify the involvement of choline metabolism in SAI. We hypothesized that the involvement of the brain regions associated with choline metabolism is dependent on the stimulus paradigm of SAI, and that the choline metabolism in the primary somatosensory cortex (S1) and the striatum may be related to SAI with shorter and longer interstimulus interval (ISI). Sixteen right-handed, healthy adults participated in this study. On day 1, magnetic resonance spectroscopy (MRS) were conducted to evaluate the choline metabolism in the lower and upper part of the striatum, primary motor cortex (M1), and S1. Next, on day 2, SAIs were measured using a paired stimulation paradigm with electrical stimulation to the median nerve, and transcranial magnetic stimulation to the M1. According to the latency of the N20 component in somatosensory evoked potential, ISIs were set at N20 latency plus 2, 4, 6, 8, and 10 ms by each participant. Both MRS and SAI measurement were conducted between 0930 and 1200 h on different days. Pearson correlation analysis showed that SAI with an ISI of N20 plus 2 and 10 ms significantly correlated with choline concentration in S1 (r^2=0.256, p=0.04) and the lower part of the striatum (r^2=0.376, p=0.02), respectively. No other significant correlations between choline concentration and SAI were found. In line with our hypothesis, choline metabolism in S1 was involved in SAI with an ISI of N20 latency plus 2 ms. This supports previous studies indicating that S1 may modulate SAI with an ISI of N20 latency plus 2 ms, and identified the novel finding that higher choline concentration in S1 may be involved in lower SAI. Additionally, this is the first study to show

that choline metabolism in the striatum modulates SAI with an ISI of N20 latency plus 10 ms. This suggests that tonic cholinergic neural activity may modulate GABAergic neurons which inhibits the thalamo-cortical projection in the striatum, and which decreases SAI with an ISI of N20 latency plus 10 ms via the inhibited afferent input to M1. To conclude, SAI is modulated by distinct neural mechanisms that depend on ISI and choline metabolism in S1, and the striatum was involved in SAI with ISI of 2 ms and 10 ms.

Title: Crossed corticostriatal projections in the macaque brain

Authors: E. BORRA, ***G. LUPPINO**;
Dept. Med. and Surgery, Univ. of Parma, Parma, Italy

Abstract: Ipsilateral corticostriatal (CS) projections are the major source of input to the basal ganglia (BG) and it is largely agreed that different sets of functionally related cortical areas project to different parts of the striatum (striatal input channels), at the origin of largely segregated BG-thalamo-cortical loops. Indeed, we found that projections from inferior parietal, ventral premotor, and ventrolateral prefrontal areas involved in controlling goal-directed hand actions (lateral grasping network) overlap in two distinct putamen sectors and in one caudate sector, suggesting parallel BG processing and integration of different aspects of motor control. The striatum is also target of crossed projections from the contralateral hemisphere which have been so far somewhat neglected. In 2 macaques we analyzed the distribution of the direct and crossed CS projections based on 3 tracer injections placed at different dorso-ventral levels of the motor putamen and 1 in the mid-rostral caudate. In all cases, the labelling extensively and differentially involved mostly frontal motor (60-77% of ipsi + contra CS labeled cells), posterior parietal (8-18%) and cingulate areas (4-23%). The amount of labeling in the contralateral hemisphere largely varied according to the location of the injection site: quite low after the ventral putamen (5% of all CS labeled cells), higher after the middle putamen (14%), and even higher after the dorsalmost putamen and the caudate injection (23 and 29%, respectively). The distribution of the labeled cells in the contra- vs. the ipsilateral hemisphere showed clear

asymmetries. In some regions (e.g., parietal and ventral premotor cortex) the labeling in the contralateral hemisphere, compared to that in the ipsilateral one, was in all cases relatively scarce or almost negligible, whereas in other it was much richer. Indeed, in all cases, from 20 to 40% of area 24 (ipsi + contra) labeled cells was observed in the contralateral hemisphere; after the caudate injection 34% of area F3/SMA (ipsi + contra) labeled cells was observed in the contralateral hemisphere; after the dorsal putamen injection 36% of dorsal premotor area F2 (ipsi + contra) labeled cells was observed in the contralateral hemisphere. It is noteworthy that after the caudate injection, contralateral area F2 was the third strongest source of cortical input and after the dorsal putamen injection contralateral areas 24 and F1 (primary motor area) were the fourth and fifth strongest sources of cortical input, respectively. The present data provide evidence for potentially important contributions of crossed CS projections to information processing carried out in the macaque BG.

Title: Weight related sex differences in insular and striatal connectivity

Authors: *L. A. MAAYAN[1], A. LARR[2], P. REISS[3], M. J. HOPTMAN[4], J. NIERENBERG[2], K. HERNANDEZ[5], A. TIMKO[1], B. LEVENTHAL[6];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]NKI, Orangeburg, NY; [3]Univ. of Haifa, Haifa, Israel; [4]Schizophrenia Res., Nathan Kline Inst., Orangeburg, NY; [5]Duke Univ., Durham, NC; [6]UCSF, San Francisco, CA

Abstract: Neural processes regulating intake are finely tuned to maintain homeostasis; yet the mechanisms underlying dysfunction are not known. Previously we showed the relationship of BMI to functional connectivity between insula (Ins), inferior temporal gyrus and lingual gyrus as well as less robust findings of connectivity between nucleus accumbens (Nac) and sensorimotor strip. Here we delve further to examine sex differences in connectivity in relationship to BMI. 204 subjects completed study procedures after overnight fast. Weight and height were assessed with a detecto scale and stadiometer, and participants were given 15 minutes to consume a multi item meal followed by a 10 minute resting state fMRI on a Siemens Magnetom 3T scanner. Images were pre-processed and processed using AFNI and FSL commands. Functional connectivity was determined to seed regions of interest in Nucleus accumbens (Nac), Insula (Ins), Orbitofrontal cortex (OFC) and Inferior frontal gyrus (IFG). Results were analyzed for connectivity in relation to BMI across all subjects as well in contrast between sexes.

Results:
102 right handed adults had a normal distribution of BMI and are reported on in the following. When thresholded with threshold free cluster enhancement and regressed against BMI Left insula seed (LtINS) showed increased connectivity to right middle(17.9, 37.2, 14.8) and inferior temporal gyri (13.4, 45.4,11.9) and right insula seed (RtINS) to superior temporal gyrus (25.1,16, 22.3).
Males had increased connectivity between RtINS with right lingual gyrus (28.4,17.5,23.8) (threshold z=2.3 and p=.05 for this and following results) Females had decreased connectivity between Left Nac seed (LtNAC) and right pre and post central gyrus (18.9, 32.7, 47.1). LtINS had decreased connectivity with right middle and inferior temporal gyrus (14.7, 40.3, 14.6) and Left OFC seed (LOFC) showed increased connectivity with right insula and superior temporal gyrus (15.4, 43.5, 27.2).
Gender contrast
At higher BMI females had greater connectivity than males between LtNAC and left middle frontal gyrus (41.3, 57.3, 28.6) as well as between LOFC and a region including right inferior parietal lobe, superior temporal gyrus and insula (1.8, 30.4, 31.9).
Males had greater connectivity than females between right IFG seed and left superior frontal gyrus (30.5, 58.4, 23.9).
Conclusions
We found differences in reward sensitivity between sexes suggesting that decreased sensory connectivity to reward regions is more relevant to female than male BMI. Women and men also contrast in connectivity to insula suggesting that interoception may play a differential role in eating behavior between sexes.

Title: Electrical activity of the thalamic reticular nucleus is controlled in a differential way by the globus pallidus

Authors: *A. ALATORRE[1], A. OVIEDO-CHÁVEZ[1], J. R. MARTINEZ-ESCUDERO[2], E. QUEREJETA[1];

[1]Sección de Estudios de Posgrado e Investigación, Escuela Superior De Medicina, IPN, Mexico City, Mexico; [2]Escuela Superior de Medicina, IPN, Mexico City, Mexico

Abstract: The information that flows from different thalamic nuclei to the cerebral cortex (Ctx) is regulated by the electrical activity of the thalamic reticular nucleus (RTn) (Sherman et al, 1996). Through GABAergic projections, RTn neurons synchronize the overall electrical activity of thalamo-cortical (TC) neurons (Pinault, 2004). RTn receives glutamatergic afferents from layer six neurons of Ctx and TC collaterals. However, there is a GABAergic afferent pathway coming from the globus pallidus (external GP in primates) which effect in the electrical activity of RTn neurons have received scarce attention (Guillery et al, 2003). In the present work, we analyzed the electrical activity of RTn neurons in vivo in normal and lesioned ipsilateral GP Wistar rats by using unitary recordings. In normal conditions, we recorded two types of electrical behavior from the dorsal to the ventral pole in RTn: a tonic spiking and mixed spiking that consisted in a tonic firing alternating with burst activity. In lesioned rats the spontaneous frequency increased both tonic and mixed spiking (up to 3500%) as compared with normal rats (figures 1 and 2). Unlike that was observed in normal rats, we did not record mixed activity in the medial region of RTn; this fact allows us to arbitrarily divide the RTn into three regions: dorsal, medial and ventral pole. Mixed activity only was recorded in the dorsal and ventral pole. Burst index of the mixed neurons recorded in the ventral pole was similar as the mixed neurons recorded along the RTn in normal rats; BI in the neurons of the dorsal pole in lesioned rats was minor as compared with mixed neurons along the RTn in normal rats.
Our results showed that GP controls in differential ways different population of neurons in the RTn.

Title: Movement-related single unit activities in the external segment of the globus pallidus in a step-tracking movement task

Authors: *T. ISHIKAWA, S. KAKEI;
Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: The basal ganglia are considered to be one of the most important subcortical regions for motor control. In fact, distinctive types of movement disorders are observed in Parkinsonism and other abnormal conditions characterized by anatomic and biochemical changes in the basal ganglia. However, neural mechanism by which the basal ganglia contribute to control of voluntary movement is still controversial. We know little about functional role of individual nuclei in the basal ganglia in control of movements. To address this issue, we examined movement-related activities of neurons in the external segment of the globus pallidus (GPe) in a monkey performing a step-tracking wrist movement for eight directions and compared them with corresponding activities in the primary motor cortex in the same experiment. According to previous anatomical studies, neurons in GPe receive two distinct inputs originated from the motor cortex: an excitatory input via the subthalamic nucleus, and an inhibitory input via the putamen. We analyzed single unit activities of 81 GPe neurons with movement-related modulation in the movement task and obtained two major findings. First, we found that there are three types of neurons in terms of modulation changes of activity at movement onset. The first group of neurons (n=22, 27%) showed only excitation, while neurons in the second group (n=17, 21%) showed only suppression at movement onset. Forty-two neurons in the third group (52%) showed both excitation and suppression of activity depending on movement direction. In addition, 40 neurons out of 81 (49%) showed significant directional tuning at movement onset as often observed in neurons in motor cortices in the same experiment. These results suggest that the timing and balance of inputs from the subthalamic nucleus and the putamen to individual GPe neurons may dynamically change corresponding to kinematics of movement to perform or muscles to activate. Second, we performed a population analysis of movement-related GPe activities and found that excitatory modulation was dominant as a whole. Considering that excitation of GPe neurons is thought to have an excitatory effect on neurons in the thalamus by suppressing inhibitory neurons in the internal segment of the globus pallidus, movement-related activity in GPe appears to contribute to facilitation of cortical motor areas.

Title: Movement related oscillatory activities within corticobasal ganglia circuit predict motor performance

Authors: *J. CHOI[1], M. MALEKMOHAMMADI[1], S. NIKETEGHAD[2], N. POURATIAN[1]; [1]Neurosurg., [2]Bioengineering, Univ. of California, Los Angeles, CA

Abstract: Reaction time (RT) is one of the most important behavioral responses to evaluate the motor performance reflecting the overall efficacy of sensorimotor processing. In general, RT shows trial-by-trial variation, suggested to be modulated by the cortico-basal ganglia (BG) motor circuit. However, how the BG-cortical networks contribute to this RT variability remains underexplored. Here, we investigate the difference in the oscillatory activities within and between BG and motor cortex between fast and slow motor responses.We took advantage of deep brain stimulation (DBS) surgery to obtain invasive cortical and BG recordings during undergoing DBS lead implantation surgery. From 13 patients with idiopathic Parkinson's disease, we recorded local field potentials in sensorimotor cortical region and BG including subthalamic nucleus (STN) or globus pallidus internus (GPi) during a simple go task. We split all correct 'Go' trials into 3 groups based on the RT, which were 'fast', 'median', and 'slow' trials, and statically compared the movement-related changes in local and global BG-cortical oscillatory activities between 'fast' and 'slow' trials (by cluster-based permutation test). Additionally, the correlations between BG-cortical activities and RT were explored (by Spearman correlation). During the motor execution period, the slow trials showed significantly delayed event-related desynchronization (ERD) before the motor responses in motor cortex (M1) and STN in both low- and high-beta bands (13-20 and 20-30 Hz, respectively). Also, the slow trials showed significantly delayed event-related increases in M1 in broad gamma-band (70-200 Hz). Likewise, at the same period, the suppression of M1-GPi coherence in the whole beta band (13-30 Hz) was significantly delayed for the slow trials. Interestingly, during the motor preparation period, the motor cortical low-beta ERD was significantly stronger for the fast trials, and the magnitude of ERD was negatively correlated to RT.
Overall, our findings suggest that the modulation of the timing and magnitude of the oscillatory activities within BG-cortical circuit might subserve the dynamics of motor performance. Our study provides new insight in an electrophysiological role of BG-cortical circuit in motor control, particularly with respect to motor initiation.

Title: Preferential dopamine release in the caudolateral striatum from substantia nigra pars lateralis neurons receiving subthalamic nucleus input

Authors: *P. S. FREESTONE, K. L. TODD, J. LIPSKI;
Physiol., Univ. of Auckland, Auckland, New Zealand

Abstract: The subthalamic nucleus (STN) is unique being the only glutamatergic nucleus in the basal ganglia and also receiving direct cortical motor input forming the hyperdirect pathway. Recent anatomical and behavioural studies suggest that the STN exerts control over a subset of dopamine neurons in the substantia nigra pars lateralis (SNL) that preferentially project to the caudolateral region of the striatum, as opposed to the better studied substantia nigra pars compacta (SNC) to rostromedial striatum projection. Here, we applied electrochemical detection of electrically evoked dopamine release *in vivo* to better understand the role the STN has in modulating dopamine pathways in the basal ganglia. Experiments were conducted in anaesthetized (urethane; 1.4g/kg i.p) Wistar rats (~290g). Fast-scan cyclic voltammetry (FSCV) was used to measure evoked dopamine release in the rostromedial (centre) and caudolateral (tail) striatum. Dopamine release was evoked following electrical stimulation (300µA, 2ms, 60Hz, 2s, twisted-bipolar) of the STN, SNC and SNL. Modified controlled adsorption FSCV was used to accurately measure basal dopamine in both striatal regions. Electrical stimulation of the STN evoked significant dopamine release in the caudolateral striatum (53.4±13.9nM, n=5 hemispheres), but negligible release in the rostromedial striatum (17.4.±4.5nM, n=5). Conversely, stimulation of the SNC failed to evoke dopamine release in the caudolateral striatum (6.5±2.3nM, n=5), but evoked significant release in the rostromedial striatum (87.0±29.7nM, n=5). Importantly, stimulation of the SNL evoked the largest dopamine release in the caudolateral compared to rostromedial striatum (51.8±17.8nM vs 10.9±5.8nM, n=4) - this profile of response being comparable to that of stimulating the STN, suggesting a common pathway. Measurements of basal dopamine revealed a much lower level in the caudolateral striatum compared to the rostromedial striatum of the same hemisphere (255±30nM vs 416±33nM, n=12). These findings confirm that the caudolateral striatum receives greatest input from the SNL, and those neurons in turn are strongly innervated by glutamatergic input from the STN.

Title: Functional organization of basal ganglia thalamocortical projections

Authors: *A. D. LIEN, A. C. KREITZER;
Gladstone Inst. of Neurolog. Dis., San Francisco, CA

Abstract: Inhibitory basal ganglia outputs to the ventral anterior/ventral lateral (VA/VL) motor thalamus are thought to play an important role in motor behavior by influencing thalamic input to the cortex. A complete understanding of basal ganglia thalamocortical function requires knowledge of both the type of information being signalled by individual basal ganglia-recipient thalamus (BGThal) neurons during motor behavior and the cortical regions to which they convey this information. While primary sensory nuclei of the thalamus contain functional maps of sensory space that are recapitulated in their target cortical area through topographically organized thalamocortical projections, the functional organization of BGThal and its thalamocortical projections is poorly understood. We developed an optogenetic antidromic stimulation approach for mapping cortical projection targets of many simultaneously recorded BGThal thalamic neurons in head-fixed awake, behaving mice. We expressed ChR2 in VA/VL and transcranially photostimulated ChR2-expressing axons across an array of cortical locations covering the anterior half of the dorsal cortex (AP: -1 to 3 mm from bregma; ML: 0 to 3mm from midline) while recording single-unit spiking in VA/VL using silicon probes. For some units, photostimulation of cortical locations evoked reliable single spike responses with submillisecond jitter consistent with antidromic spike generation in distal axons. For each recorded unit we generated a cortical projection map based on the locations eliciting antidromic responses. Additionally, we used optogenetic basal ganglia indirect pathway stimulation, which should suppress BGThal firing, to identify the recorded neurons as basal ganglia-recipient. BGThal projections were found in almost all stimulated cortical locations and many individual projections were large, spanning several mm. To relate BGThal neuron cortical projection patterns to function, we obtained cortical projection maps of neurons recorded during locomotion while tracking limb position using high speed video and DeepLabCut. A subset of BGThal neurons fired preferentially at specific phases of the locomotor stride cycle. The projections of BGThal neurons that preferred the stance phase of the contralateral forelimb had more projections to posterior cortex while those preferring the swing phase tended to project more anteriorly. These results demonstrate that BGThal neurons encode highly specific information during movement that is conveyed to distinct cortical locations.

Title: Movement related activity in ventral pallidum and dopaminergic midbrain is gated by behavioral state

Authors: *R. CHEN, V. GADAGKAR, P. A. PUZEREY, J. H. GOLDBERG;
Cornell Univ., Ithaca, NY

Abstract: Dopamine (DA) neurons and their inputs from the ventral pallidum (VP) exhibit both reward and movement related firing, but it remains unknown if these signals can be gated by behavioral state. For example, movement-related dopamine signals have been observed in some studies but not others. One possibility is that some neurons are movement related and others are not. Another possibility is that a single neuron can be movement related under certain behavioral states but not others. We recorded single DA and VP neurons in birds transitioning between singing and non-singing states while monitoring body movement with microdrive-mounted accelerometers. The activity of many VP neurons was locked to body movements with millisecond timescale precision but only during non-singing states. During singing, these neurons switched off their tuning to movement and became instead precisely time-locked to specific song syllables. Similarly, many DA neurons exhibited phasic movement related activity but only during non-singing states; during singing these neurons lost their movement related signaling and instead encoded singing-related performance error. Changes in neuronal tuning could occur on 10 millisecond timescale at state boundaries. Our findings demonstrate that movement-related activity in single neurons can dramatically change with behavioral context.

Title: Functional innervation of the dorsal striatum by the rostral intralaminar thalamus

Authors: *K. K. COVER, G. W. BUNCE, B. N. MATHUR;
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The striatum mediates the selection of actions for reward acquisition through the dynamic activation of medium spiny output neurons (MSNs). Excitatory drive of MSNs is modulated by dopamine and acetylcholine. We recently elucidated a microcircuit by which glutamatergic projections arising from the rostral intralaminar nuclei of the thalamus (rILN) stably elicit striatal dopamine release through a striatal cholinergic interneuron intermediary to support action reinforcement. Unknown, however, is how this thalamostriatal projection directly influences direct versus indirect pathway MSNs to produce behavioral reinforcement. Here, we employ whole-cell patch clamp electrophysiology to interrogate the functional connectivity of rILN projections with MSN subpopulations in striatal slice. These results stand to inform how the rILN contributes to basal ganglia function and resulting behavior.

Title: A nano-to-milliscale imaging pipeline for detailing how multiple brain regions communicate with the striatum

Authors: *S. SHIGENO, V. SAMPATHKUMAR, R. VESCOVI, H. LI, A. J. MILLER, S. M. SHERMAN, N. B. KASTHURI;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: The striatal system has an essential role in action planning, reward learning, and goal-directed behaviors. A fundamental question in the striatum is understanding how varied brain regions, from cortex to thalamus, communicate with striatum. However, most studies that study long range connectivity in striatum focus on either looking at the coarse output of multiple brain regions at the macro level (e.g. MRI) or on the projections of individual neurons (e.g. Golgi or GFP like staining) without minimal context of the behavior of other brain regions. An ideal imaging pipeline would provide both: nanoscale information about the behavior of individual cell type labeled neurons and mesoscale information about long distance projections from many brain regions. In order to address this gap, we have developed a multimodal multiscale imaging pipeline using synchrotron X-ray microscopy and automated serial electron microscopy with

genetic labeling of specific cell types. We find interesting and contradictory results about the organization of long range projections in striatum. At the mesoscale, we image large volumes of striatum stained with a combined gold chloride myelin-specific staining and reduced osmium method with synchrotron source X-rays. We find evidence of 'crosstalk': smaller bundles of myelinated axons (MA) 'mix' and 'match' frequently across striatum, creating transitory macro bundles whose composition is constantly changing. At the nanoscale, we express an EM dense dye, APEX2, in layer 5 pyramidal neurons in M1, S1, and thalamus (pMO) and reconstruct labeled axons along with every individual MA in large volumes of white matter or spongy tracts in striatum. We find that axons from a specific cortical region spatially segregate within white matter bundles in striatum: clusters of 2-6 MA from a specific brain region remain more spatially proximate to each than to other brain regions. Thus we conclude that the 'logic' of long range connections from different brain regions in striatum is complicated with evidence of both global mixing between myelinated tracts and evidence of brain region specific segregation within individual tracts.

Abstract: The GPe, as part of the basal ganglia circuit, is critically involved in motor control. Alterations of GPe neuron activity are observed in both mouse models and human patients of Parkinson's disease (PD). Despite the clinical importance of the GPe, its neuronal composition remains elusive. Aside from $Foxp2^{+}$ neurons and $ChAT^{+}$ neurons that have been established as

unique neuron types, there is no consensus on the classification of GPe neurons. In this study, we leverage new mouse lines, viral tools, and molecular markers to better understand the molecular, anatomical, and intrinsic properties of the remaining GPe neurons. We found that Sox6 represents a novel, defining marker for GPe neuron subtypes. $Lhx6^+$ neurons that lack the expression of Sox6 were devoid of both parvalbumin and Npas1. This result confirms previous assertions of the existence of a unique $Lhx6^+$ GPe population. Furthermore, we identified the $Npas1^+$-$Nkx2.1^+$ population that lacks Foxp2 as a potentially distinct functional subclass. Both retrograde and anterograde tracing experiments revealed that $Npas1^+$-$Nkx2.1^+$ neurons represent the principal, non-cholinergic, cortically-projecting neurons; they project profusely in the frontal cortex and are part of a cortico-pallidal-cortical loop. Lastly, analysis of the spatial distribution and electrophysiological properties of a number of GPe neuron types further confirms the diversification of GPe subtypes. In summary, we provide improved descriptions of GPe neuron subtypes. By delineating different GPe neurons and their synaptic partners, our findings establish the circuit substrates that can be important for motor function and dysfunction. Our findings reconcile some of the discrepancies that arose from differences in techniques or the reliance on pre-existing tools.

Abstract: The GPe is a critical node within the basal ganglia circuit. Phasic changes in the activity of GPe neurons during movement and their alterations in Parkinson's disease suggest that the GPe is important in motor control. PV^+ neurons and $Npas1^+$ neurons are the two non-overlapping, principal neuron classes in the GPe. The distinct electrophysiological properties and axonal projection patterns suggest that these two neuron classes should serve different roles in regulating motor output. However, this idea has not been systematically tested. Here we demonstrate that PV^+ neurons and $Npas1^+$ neurons promote and suppress locomotion, respectively. Moreover, PV^+ neurons and $Npas1^+$ neurons are under different synaptic influence from the subthalamic nucleus (STN). Lastly, the selective weakening in the STN input to PV^+ neurons in chronic Parkinsonian mice reinforces the idea that the reciprocal GPe-STN loop plays key roles in disease symptomatology and thus provide the basis for future circuit-based therapies.

Title: Neuronal activity in the internal (GPi) and external globus pallidus (GPe) during proactive motor inhibition

Authors: F. HADJ-IDRIS, J. MUNUERA, I. AMEQRANE, M. ROUSTAN, M. GAY, C. KARACHI, *B. LAU;
Inst. du Cerveau et de la Moelle Épinière, Paris, France

Abstract: A crucial component of adaptive behavior is response inhibition, the capacity to refrain from reacting to external events or internal urges. In addition to reactive inhibition—initiated when specific stimuli are identified—responses can be inhibited proactively in the absence of explicit stimuli or triggered by particular contexts, acting to gate actions when fast or erroneous actions are highly undesirable. Cortico-basal ganglia interactions may be important for implementing proactive inhibition, and we recorded single neurons in the internal and external segments of the globus pallidus (GPi and GPi, respectively) while monkeys performed a behavioral task where we manipulated response uncertainty to change proactive inhibition.

Monkeys performed a Go/No-go task where the likelihood of No-go trials was centrally cued with visual stimuli that indicated either 0% or 50% likelihood of a No-go trial. Target location was randomly selected in the left or right hemifield with equal probability, and the visual target indicated whether the trial required a Go response. Analyses of reaction times, as well as commission and omission errors, indicated that monkeys proactively inhibited responses when faced with No-go uncertainty. We isolated single-unit activity from multi-channel single-unit recordings in the GPi and GPe. We used regression analyses to separate effects of movement from putative proactive inhibition and reward expectation. A significant proportion of neurons in both the GPi and the GPe responded in a manner consistent with encoding proactive inhibition, as well as encoding movement execution and movement direction. Neurons encoded proactive inhibition and movement direction with both positive and negative changes in relative activity in approximately equal proportions. We found that the fraction of neurons jointly encoding proactive inhibition and direction was close to that expected from independent coding of these two properties.

Title: Diminished dendritic excitability of indirect pathway striatal projection neurons in the Sapap3 knockout mouse model of compulsive behavior

Authors: *J. M. MALGADY[1], E. M. PRAGER[1], Z. B. HOBEL[1], Q. ZHANG[2], G. FENG[2], J. L. PLOTKIN[1];
[1]Dept. of Neurobio. & Behavior, Stony Brook Univ. Renaissance Sch. of Med., Stony Brook, NY; [2]McGovern Inst. for Brain Res. and Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The striatum is the main input nucleus of the basal ganglia and contains two distinct neuronal populations: direct pathway and indirect pathway spiny projection neurons (dSPNs and iSPNs). These neuronal populations act in parallel to regulate action selection, with dSPN activity predominantly leading to disinhibition of the thalamus and iSPN activity to inhibition of the thalamus. Under normal conditions, information flow through the striatum may be biased towards iSPNs since they are intrinsically more excitable than dSPNs. However, some circuit

models of compulsive behavior suggest that this bias may be reversed under pathological conditions. Furthermore, several studies have demonstrated pathway-specific corticostriatal synaptic dysfunction in mouse models of compulsive behavior, providing evidence for differences in dSPN vs iSPN activity in generating this pathological behavior. One such model is the Sapap3 knockout (KO) mouse. Sapap3 encodes for a scaffolding protein at glutamatergic synapses, is highly expressed in the striatum, and germ line deletion of Sapap3 leads to compulsive grooming. Using a cross between Sapap3 KO mice and a D2R (drd2-eGFP) reporter line (labeling iSPNs), we employed a combination of electrophysiology and 2-photon imaging in order to assess the dendritic excitability of iSPNs in the dorsal striatum, comparing Ca^{2+} transients at distal vs proximal dendrites in response to somatically-induced back-propagating action potentials (bAPs). Here we present evidence that somatically-generated action potentials propagate farther along iSPN dendrites of WT mice vs KO mice, suggesting that iSPN dendrites are intrinsically less excitable in Sapap3 KO mice. Preliminary data did not detect differences in measures of somatic excitability, such as rheobase or input resistance. Current experiments are ongoing to assess if there are parallel changes in dSPN excitability under the same pathological condition.

Title: Responses of substantia nigra pars reticulata neurons to direct and indirect pathway GABAergic projections depend on intracellular chloride dynamics:computational analysis based on mouse data

Authors: R. S. PHILLIPS, ***J. E. RUBIN**;
Dept. of Mathematics, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The substantia nigra pars reticulata (SNr) is the primary output nucleus of the rodent basal ganglia (BG) and receives converging $GABA_A$-receptor mediated synaptic inputs from the direct and indirect pathways. The resulting $GABA_A$ current (I_{GABA}) is typically considered to be inhibitory; however, it may also be shunting, excitatory, or biphasic with inhibitory-to-excitatory

responses mediated by intracellular chloride dynamics, which affect the $GABA_A$ reversal potential (E_{GABA}). Direct pathway projections synapse on the distal dendrites whereas indirect pathway projections form basket-like synapses around the somas of SNr neurons. Due to differences in compartment size and the distribution of the Cl extruder KCC2, dendritic and somatic compartments may have different susceptibilities to Cl accumulation and to breakdown of E_{GABA}. We predict that GABAergic signals to SNr will induce the range of atypical responses described above, depending on Cl extrusion capacity, compartment size and input properties. To investigate the contributions of the factors involved in shaping SNr responses to synaptic inputs, we constructed a novel data-driven conductance-based model of an SNr neuron that includes dendritic and somatic compartments. Our model recapitulates published data from experimental studies of short term plasticity in striatonigral and pallidonigral pathways. Moreover, simulations of our model show that $GABA_A$- and KCC2-mediated fluctuations in intracellular Cl can explain many aspects of the SNr spiking responses to GABAergic inputs from the direct and indirect pathways observed in data from the mouse. Finally, we also explore the predictions of our model relating to SNr activity patterns in functionally relevant settings involving inputs from both pathways, including decision-making tasks. Integration of $GABA_A$ receptor-mediated synaptic inputs to somatic and dendritic compartments is not unique to SNr neurons; thus, these results may have implications for other brain regions as well.

Title: Altered intrinsic electrophysiological properties of spiny projection neurons in LRRK2 mutant mice

Authors: ***H. XENIAS**[1], C. CHEN[2], S. KANG[2], S. CHERIAN[1], S. CHAN[1], L. PARISIADOU[2]; [1]Dept. of Physiol., [2]Dept. of Pharmacol., Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Missense mutations in leucine rich repeat kinase 2 (LRRK2) account for the most common genetic form of Parkinson's disease (PD). LRRK2 is highly expressed in spiny

projection neurons (SPNs) in the striatum. However, several aspects of LRRK2 function in the striatum remain elusive. As it is known that the firing of SPNs is altered in PD, we sought to examine if and how LRRK2 mutations affect the electrophysiological properties of SPNs and consequently impair motor output and learning. In particular, $LRRK2^{+/R1441C}$ represents one of the more common LRRK2 mutations with a genetic link to PD. We previously showed that $LRRK2^{+/R1441C}$ gives rise to pathological protein kinase A signaling in SPNs. Therefore, it is also possible that aberrant phosphoregulation and consequently altered channel protein trafficking and gating in $LRRK2^{+/R1441C}$ will result in altered intrinsic excitability of SPNs. This hypothesis was not previously tested in identified SPNs. In the present study, we examined the intrinsic and corticostriatal properties in $LRRK2^{+/R1441C}$ knock-in mice. Our data so far suggest altered responsiveness of SPNs to somatically-injected currents and an imbalance in the activity of dSPNs and iSPNs. We postulate that these alterations would also impair motor learning. The function and relevance of LRRK in motor learning and disease will be further discussed.

Abstract: The subthalamic nucleus (STN) which relays extensive inputs from a variety of cortical and subcortical structures serves as a convergence hub and a successful target for deep brain stimulation. However, there is little systematic investigation into fundamental characteristics including cellular and synaptic profiles as well as the functional anatomy. Indeed, the complexity of circuit organization in the STN, distinguished by its heterogeneous neuronal populations and the complex patterns of convergence and divergence which might occur at

individual cells, has long been underappreciated. In this study, we performed single-molecule *in situ* hybridization to detect the spatial distribution of major cell classes and further various neurotransmitter receptors in the STN. In addition, we developed a machine learning-based algorithm to analyze and integrate the expression patterns for multiple cell populations. Furthermore, using mammalian GFP reconstitution across synaptic partner (mGRASP) and electrophysiological recording, we characterized the basic neuronal properties of STN subpopulations such as synaptic connectivity and physiological features. Our results provide comprehensive distribution of diverse cell types of the STN and may enable cell type-specific functional studies to enhance our understanding of the basal ganglia circuitry.

Title: Motivation-related dopamine release in nucleus accumbens correlates with cholinergic interneuron activity

Authors: *A. MOHEBI[1], A. HAMID[2], J. D. BERKE[1];
[1]Neurol., UCSF, San Francisco, CA; [2]Dept. of Neurosci., HHMI and Brown Univ., Providence, RI

Abstract: The mesolimbic dopamine pathway (ventral tegmental area, VTA, to nucleus accumbens, NAc) is closely involved in both learning from rewards, and motivation to work for rewards. How dopamine release is regulated to achieve these distinct functions is not fully known. In a rat decision-making task we recently demonstrated that some NAc dopamine fluctuations reflect VTA firing, while others do not (Mohebi, Pettibone et al., *Nature* 2019). Consistent with prediction error coding, salient cues evoked transient spike bursts in optogenetically-identified VTA dopamine cells and a corresponding increase in NAc dopamine (measured with either fast-scan cyclic voltammetry or the optical sensor dLight1). However, NAc dopamine release also increased as rats approached rewards, without any increase in VTA dopamine cell spiking. We argued that this motivation-related aspect of NAc dopamine likely results from local control over release from dopamine terminals.
One potential mechanism of such local control involves cholinergic interneurons (CINs), which have previously been shown to be capable of evoking dopamine in brain slices. We have

therefore been examining whether NAc CINs contribute to motivation-related dopamine release in our behavioral task. We expressed the calcium indicator GCaMP6f in NAc ChAT+ neurons, and measured activity using fiber photometry (n=9 placements in 7 rats). We consistently observed that CIN activity rapidly ramps up during motivated approach, at the same time as dopamine increases. This supports the hypothesis that CINs drive motivation-related dopamine release independently from dopamine cell firing.

Title: Dorsolateral striatum regulates movement oppositely to dorsomedial striatum via complex striatopallidal subcircuitries

Authors: *Q. CUI[1], X. DU[1,2], V. LILASCHAROEN[3], A. PAMUKCU[1], D. GARCIA[1], B. BERCEAU[1], D. HONG[1], V. CHALASANI[1], B. LIM[3], S. CHAN[1];
[1]Physiol., Northwestern Univ., Chicago, IL; [2]Physiol., Qingdao Univ., Qingdao, China; [3]Biol. Sci., UCSD, La Jolla, CA

Abstract: The dorsal striatum can be subdivided into dorsomedial striatum (DMS) that regulates locomotion and initial motor learning and dorsolateral striatum (DLS) that modulates habitual behavior and gradual motor skill acquisition. It is established that activation of direct-pathway spiny projection neurons (dSPNs) and indirect-pathway spiny projection neurons (iSPNs) in the DMS promote and suppress movement, respectively. However, the roles of dSPNs and iSPNs in the DLS in relation to locomotion remain to be fully investigated. Despite the increasing evidence that suggest a dSPN projection to the external globus pallidus (GPe), the cellular target of this input has not been fully examined. To fill this knowledge gap, we utilized a combination of behavioral, electrophysiological, and anatomical techniques. We found that optogenetic activation of dSPNs and iSPNs in the DLS decreased and increased locomotion, respectively, directly opposite to the role of dSPNs and iSPNs in the DMS. By employing cell-specific retrograde labeling and *in situ* hybridization, we found that both the DMS and DLS organize with the GPe in a highly cell-specific manner. While dSPNs preferentially target Npas1+ GPe neurons, iSPNs preferentially innervate PV+ GPe neurons. Furthermore, functional studies using

ex vivo patch-clamp recordings with optogenetics confirmed this conclusion. In a chronic 6-OHDA lesioned mouse model of Parkinson's disease (PD), only the DLS dSPN-Npas1 input was strengthened. An increase in the number of synaptic contacts underlies this alteration. As Npas1+ GPe neurons preferentially inhibit iSPNs, we postulate that DLS dSPNs suppress locomotor behavior through disinhibition of DMS iSPNs activity, which mediate the "No-Go" pathway. The enhanced DLS dSPN-Npas1 input in 6-OHDA lesioned mice could be a mechanism that underlies the hypokinetic symptoms observed in PD patients.

Title: Proactive behavioral inhibition engages increase-type neurons in substantia nigra pars reticulata

Authors: *B.-M. GU, J. BERKE;
Dept. of Neurol., UCSF, San Francisco, CA

Abstract: The ability to inhibit actions is central to adaptive behavioral control. Behavioral inhibition can be "reactive" - e.g. aborting imminent actions in response to a Stop signal - or "proactive" - e.g. restraining actions in anticipation of a possible Stop signal. In an earlier series of rat Stop-signal electrophysiology studies we found that reactive inhibition involves a sequence of mechanisms within the basal ganglia. First, a very rapid "Pause" operates via the subthalamic nucleus, exciting the substantia nigra pars reticulata (SNr) to retard movement initiation (Schmidt et al. Nat Neuro 2013). Then, a slightly slower "Cancel" engages arkypallidal neurons of the globus pallidus (GP), inhibiting striatum to terminate movement preparation (Mallet et al. Neuron 2016). However, we did not address proactive inhibition, which has been hypothesized to involve the GP-SNr indirect pathway (Aron, Biol. Psych. 2011).
We modified our Stop-signal task to probe selective proactive inhibition in rats. Subjects were cued that a Stop signal either would not occur (0%), might occur after a Leftward instruction cue (50%-Left), or might occur after a Rightward instruction cue (50%-Right). Consistent with selective proactive inhibition, reaction times when no Stop signal occurred were slower, but only

for the direction for which a Stop signal was possible.
During this proactive task we recorded from the SNr (n=270 single-units from 35 sessions from 7 rats). The SNr has previously been shown to contain cells that decrease firing in association with movements, that promote movement onset by disinhibiting downstream structures, and also cells that increase with movements. We hypothesized that proactive inhibition would involve altered firing of decrease-type cells: either a higher initial firing rate (greater distance to "threshold") or a more gradual decrease in firing (slower movement towards threshold). Neither prediction proved correct. Instead, increase-type neurons showed higher firing rates when a Stop cue was anticipated. These results identify a new potential function for a poorly-understood basal ganglia cell class, and a new potential mechanism for behavioral control.

Title: Dopamine neurons multiplex components of goal-directed actions

Authors: Y. KREMER, ***J. FLAKOWSKI**, C. ROHNER, C. LUSCHER;
Univ. of Geneva, Geneva, Switzerland

Abstract: Does dopamine (DA) neuronal activity within the ventral tegmental area (VTA) in response to external cues or rewards represent a learning signal in freely moving animals? To find it out, we introduced a spatial task where the mice can trigger a reward-predicting cue by going to a specific location within an operant box. Simultaneous *in vivo* single-unit recordings revealed that a fraction of DA neurons exhibited activity that reflected various components of the goal-directed action (e.g. distance from location to reward, velocity and licking) along with phasic responses to cue and reward. Neuronal activity discriminated between rewarded and unrewarded trials, generating an error signal even in the absence of external cues in expert animals. Following a reversal protocol, mice readily learned to move to a different location, which became impossible if we jammed the internal error signal by optogenetic manipulations. We conclude that a multiplexed internal representation of the task determines the overall activity of VTA DA neurons, engaging a learning process that leads to the behavioral adaptations of goal-directed actions.

Title: Nucleus accumbens neuronal population dynamics during cocaine associated behaviors

Authors: *R. VAN ZESSEN[1], J. FLAKOWSKI[1], C. LUSCHER[1,2];
[1]Basic Neurosci., Univ. of Geneva, Geneva, Switzerland; [2]Dept. of Clin. Neurosciences, Geneva Univ. Hosp., Geneva, Switzerland

Abstract: Drugs of abuse initially increase Nucleus Accumbens (NAc) dopamine levels, leading to input-specific synaptic potentiation of afferents onto NAc spiny projection neurons (SPNs). However, how this affects activity dynamics of identified SPN subtypes remains elusive. The NAc mainly contains spiny projection neurons (SPNs) that are characterized by their expression of dopamine 1 receptors (D1R) or dopamine 2 receptors (D2R), and has been suggested to be involved in motivated behaviors. Here we use miniaturized endoscopic imaging techniques in mice to record calcium activity of D1R and D2R SPNs during cocaine exposure and cocaine-associated behaviors. D1R-cre and D2R-cre transgenic mice were injected with a cre-dependent GCaMP6f virus and a gradient-index lens was placed above the NAc. Calcium activity was then monitored in freely moving animals while they were repeatedly exposed to cocaine in an open field. Calcium and locomotion data were recorded and analysed. While both classes of neurons show divergent responses directly after cocaine exposure, we find that specific activity profiles become more prominent with repeated cocaine exposure and while animals are behaviorally sensitized to the effects of cocaine. Moreover we investigate how these activity profiles relate to self-paced movement-related activity, cocaine cue-related activity and spatial ensemble activity maps of identified NAc SPNs. Insights into the drug-related activity dynamics provides a foundation for understanding the circuit-level pathogenesis that leads to addiction.

Abstract: The dorsal striatum is critical for the control of behavior. Interneurons make up a small fraction of striatal cells, but are poised to play a major role in coordinating striatal output and function. However, the sparse distribution and heterogeneity of interneurons has made it difficult to assess their contributions to striatal network dynamics and behavior. We combined wide-field single cell calcium imaging with optogenetics to test the capacity of parvalbumin and cholinergic interneurons to affect MSN activity and influence the behavior of mice engaged in voluntarily locomotion. We found evidence that both interneurons subtypes have unique contributions to striatal network activity and dissociable roles in supporting movement. Parvalbumin neuron activity is coincident with motor initiation and facilitates movement by refining the activation of MSN networks responsible for movement execution. Cholinergic neurons are recruited throughout movement and show peak activity moments before reductions in motor output. These findings reveal that interneurons have the capacity to regulate broader striatal networks to facilitate distinct components of voluntary movement.

Title: Classification, characterization and connectivity of Chrna2-expressing striatal interneurons

Authors: *A. TOKARSKA, G. SILBERBERG;
Neurosci., Karolinska Inst., Stockholm, Sweden

Abstract: The striatum is composed almost entirely of GABAergic neurons, most of which are projection neurons: the medium spiny neurons (MSNs), which are strongly modulated by a small yet heterogeneous population of GABAergic interneurons. In addition to the previously described fast-spiking interneurons (FS) and low-threshold spiking cells (LTS), recent studies emphasize the significance of newly observed cell-types such as 5Ht3a-, NPY-, TH- expressing interneurons.
In this study, we used a newly generated transgenic mouse line that labels striatal interneurons expressing the gene coding for the α2 nicotine receptor subunit (Chrna2). Using ex vivo whole-cell recordings combined with optogenetics, we obtained a detailed characterization of the electrophysiological, morphological and synaptic properties of Chrna2 cells. Hierarchical clustering based on electrophysiological properties revealed the existence of three distinct subtypes of Chrna2 cells with strikingly different morphologies, suggesting possible different network functions. Based on the expression of molecular markers, connectivity, and nicotine sensitivity, type I consists of FS-like cells, while type II and type III form new populations. Chrna2 interneurons receive glutamatergic cortical inputs from motor cortex, mediated by both AMPA and NMDA glutamate receptors. Paired recordings from different subtypes of Chrna2 interneurons revealed differences in the dynamics and strength of cortical inputs in the respective subtypes. Surprisingly, striatal Chrna2 interneurons do not resemble Chrna2 interneurons form hippocampus (CA1) or neocortex (Chrna2+ Martinotti cells) in terms of their intrinsic properties or molecular markers.

Title: Presence and relevance of GIRK channel activity in parvalbumin interneurons in the mouse nucleus accumbens

Authors: *T. ROSE, E. MARRON, K. D. WICKMAN;
Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: The nucleus accumbens (NAc) integrates motivation with motor action, and its dysregulation has been linked to neuropsychiatric disorders. The NAc harbors diverse microcircuits that fine-tune output from medium spiny neurons (MSNs) to regulate behaviors related to reward and reinforcement. Despite comprising only 1-2% of NAc neurons, fast-spiking interneurons (FSIs) - often defined by parvalbumin (PV) expression - exert a powerful inhibitory influence over MSN output. FSI manipulations alter behavioral responding to drugs of abuse, and exposure to addictive drugs can alter FSI excitability. While NAc FSIs receive multiple excitatory inputs that influence addiction-related behaviors, less is known about the role of inhibitory inputs and relevant postsynaptic signaling pathways in these neurons. The goal of this exploratory study was to probe the presence and relevance of a common inhibitory G protein-dependent signaling mediator in NAc PV neurons. G protein-gated inwardly rectifying potassium/K+ (GIRK) channels mediate G protein-dependent postsynaptic inhibition throughout the nervous system, but are expressed at or below the level of detection in the NAc. Indeed, GIRK channel activity is not seen in the vast majority of NAc MSNs. Here, we show that the GABAB receptor agonist baclofen (200 mM) evokes a reliable inhibitory current (Vhold = -60 mV) in NAc PV neurons in slices from PV-tdTomato mice. The baclofen-induced current was accompanied by a decrease in input resistance and was blocked by 0.3 mM Ba2+, consistent with a GIRK-mediated response. Furthermore, ablation of the GIRK2 subunit using a viral CRISPR/Cas9 approach in PVCre(+):Cas9GFP(+) mice eliminated the baclofen-induced current in NAc PV neurons. To probe the relevance of GIRK-dependent signaling in NAc PV neurons to reward-related behavior, we are evaluating cocaine-induced locomotor activity in the CRISPR/Cas9 loss-of-function model, as well as a gain-of-function model involving the viral-mediated, Cre-dependent overexpression of GIRK2 in PVCre(+) mice. Male and female mice are being used in this study, with subjects aged 7 wk at the time of viral infusion surgery and 11-12 wk at the time of electrophysiological or behavioral analysis. Our preliminary data shows that strengthening of GIRK channel activity in NAc PV neurons enhances, while suppression of GIRK channel activity attenuates, the acute motor-stimulatory effect of cocaine. Thus, GIRK-dependent signaling in NAc PV neurons may contribute to behavioral sensitivity to cocaine in mice, and could be a promising target for therapeutic intervention in addiction.

Title: Dendrite specific inhibition facilitates rebound firing in SNc dopamine neurons

Authors: *R. C. EVANS[1], E. TWEDELL[1], Z. M. KHALIQ[2];
[1]NIH, Bethesda, MD; [2]NIH/NINDS, Bethesda, MD

Abstract: Dopamine neurons in the substantia nigra pars compacta (SNc) are often inhibited by aversive events. A subset of these neurons fire rebound bursts of action potentials or show rebound calcium activity following the aversive pause in activity. The functional circuit underlying both the aversive inhibition and the rebound bursting are currently unknown. Retrograde viral tracing studies have been used to generate a comprehensive list of inputs to dopaminergic neurons, revealing diverse inhibitory inputs from nearly all nuclei in the basal ganglia. However, the functional strength, specific receptors activated, and dendritic location of each input have not yet been tested. Here we use two-photon imaging and local optogenetic activation to functionally map the inhibitory inputs from basal ganglia nuclei onto dopamine neuron dendrites. We compare the strength and location of five (5) separate genetically-defined inhibitory subpopulations in the striatum (striosome and matrix), globus pallidus (Pvalb and Lhx6), and substantia nigra pars reticulata (SNr). We find that the striosomal inputs selectively inhibit the ventrally-projecting “SNr dendrite” of the dopamine neurons. Although isolated to the SNr dendrite, this connection exerts strong control over the entire cell, pausing action potentials and facilitating rebound firing. By contrast, activation of the Lhx6-positive inputs from the globus pallidus leads to inhibition of dopamine neurons at the soma and proximal dendrites, but does not result in rebound spiking. We find that striosomal input facilitates rebound firing because it activates GABA-B receptors, which strongly hyperpolarize the SNr dendrite. Because the globus pallidus inputs selectively activate GABA-A receptors, they pause firing through shunting inhibtion without recruiting rebound mechanisms (such as T-type calcium channels and the Ih current). Finally, we use a computational model in Genesis simulation software to show that dendrite-specific inhibition more effectively generates rebound action potentials than either somatic inhibition or broad inhibition of the entire dendritic arbor. Therefore, inhibition from striosomes onto SNc dopamine neurons is optimally placed to produce rebound firing.

Title: Direct axonal recordings identify a role of GABA-A receptors on subthreshold and suprathreshold control of axonal action potentials and dopamine release

Authors: *P. F. KRAMER, E. L. TWEDELL, Z. M. KHALIQ;
NIH/NINDS, Bethesda, MD

Abstract: Decades of electrophysiological research have examined the circuit and cellular-level mechanisms that control striatal dopamine release using methods like voltammetry and microdialysis. However, the indirect nature of these methods leaves open questions about the presence of axonal receptors and their influence over axonal excitability and ultimately dopamine release. Specifically, GABA-A receptors modulate transmitter release in some neurons, including potentially dopamine neurons, but the mechanisms of this modulation are varied and debated.To address this knowledge gap, we performed direct recordings from the cut ends of dopaminergic neuron axons, including from branching axons within the dorsal striatum. Our results provide definitive evidence for the existence of GABA-A receptor-mediated conductances. First, in contrast to their function at the soma, we found axonal GABA-A receptors were depolarizing. Perforated patch experiments showed that the chloride reversal potential was always depolarized (~-56 mV) relative to rest (~-68 mV). Second, activation of GABA-A receptors decreased the amplitude of a propagating action potential through shunting inhibition. In the dorsal striatum, calcium imaging experiments suggest that this shunting effect increases the probability of propagation failures. Third, we were surprised to see that electrical stimulation in the striatum resulted in a depolarizing, GABA-A mediated, post-synaptic potential (EPSP) in the axon. Finally, we found that diazepam, a broad-spectrum benzodiazepine, decreased the input resistance of striatal dopamine neuron axons, suggesting an underappreciated mechanism of action for these drugs.In conclusion, direct recordings from dopamine neuron axons demonstrate that GABA-A receptors are important modulators of axonal action potential propagation and dopamine release. In addition, these receptors are targets of benzodiazepines, as well as potentially other drugs that target GABA-A receptors like ethanol and barbiturates.

Title: Reversal potential of GABA-A synapses in neurons of basal ganglia receiving motor thalamus

Authors: *E. K. BICHLER, D. JAEGER;
Dept. Biol., Emory Univ., Atlanta, GA

Abstract: GABA-A receptors are chloride channels and therefore can have different reversal potentials in neurons with different internal chloride concentration due to differential function of chloride transporters. An interesting question is posed by the similarity of firing rates across cerebellar input and basal ganglia input receiving motor thalamus (CBMT and BGMT) in vivo, despite CBMT receiving excitatory cerebellar and BGMT receiving inhibitory basal ganglia input. One potential explanation of this difference could be regulation of the chloride reversal potential (E_{Cl}) to more positive values in BGMT, thus weakening the inhibitory effect of GABAergic input. For example, E_{Cl} was found to be -45 mV in thalamic reticular nucleus, which is more depolarized than -80 mV found in sensory thalamic nuclei. However, the chloride equilibrium potential has not been measured in BGMT neurons to date.
We used whole-cell gramicidin perforated patch-clamp recordings from BGMT neurons in adult mice to address this question. In one set of experiments, AAV-Syn-EF1a-DIO-hchR2-EYFP vector was injected into SNr in slc32 GAD-Cre mice. 14-18 weeks later, GABA-A-mediated IPSCs were evoked in BGMT neurons by 2ms light flashes using a 480 nm filter on an 120W X-Cite light source. In an additional data set GABA (100 μM) was directly puffed onto the cell bodies of neurons in the same anatomical location in motor thalamus via a glass pipette.
In order to isolate GABA-A signaling, excitatory synaptic transmission was blocked with DNQX and D-AP5, and GABA-B IPSCs were blocked with CGP 55845. GABA-A-induced membrane current was recorded at different holding potentials. A peak-current voltage relationship was plotted, and the x-intercept of the linear fit was taken as GABA-A reversal potential.
In our preliminary data set we find that the average chloride reversal potential was -71 mV (N=8) which would indicate a ~10 mV depolarizing shift compared to sensory thalamus.
We will further investigate if chloride equilibrium potential is yet more depolarized in 6-

hydroxydopamine- lesioned mice as a potential homeostatic adaptation due to increased nigral inhibitory input as posited by classic Parkinson's disease models.

Title: Top-down attentional modulation of steady-state somatosensory evoked potentials characterizing individual optimal attentional strategy for motor learning

Authors: *T. SAKURADA[1,2], K. NAGAI[1];
[1]Ritsumeikan Univ., Shiga, Japan; [2]Jichi Med. Univ., Tochigi, Japan

Abstract: Focus of attention is an influential factor for improving motor performance. Previous studies have found that directing attention to movement outcome (external focus; EF) results in greater improvement in motor performance than directing attention to body movement (internal focus; IF). On the other hand, we recently have found that the EF did not always lead to a better motor performance compared to the IF in both healthy and stroke populations. In a neuroimaging study, although we reported that the frontoparietal network is one of the neural bases of the individual optimal attentional strategy, it remains unclear whether sensory cortexes also associated with the individual differences. In this study, we aimed to explore the involvement of the early sensory cortexes for the individual optimal attentional strategy by recording steady-state somatosensory/visual evoked potentials (SSSEP/SSVEP). Firstly, twenty-five participants performed a visuomotor learning task with reaching movement under the IF and EF conditions. Fourteen participants showed higher motor learning effect in the EF condition (EF-dominant), whereas the others showed the opposite trend (IF-dominant). Subsequently, we recorded the SSSEP from the somatosensory cortex during presenting vibration stimuli on the fingertips (22 Hz and 25 Hz) and the SSVEP from the visual cortex during presenting flickering visual stimuli (12 Hz and 15 Hz). When the IF-dominant individuals actively directed their attention to vibration stimuli the amplitude of SSSEP markedly got stronger. On the other hand, the top-down attentional modulation of SSSEP amplitude was not observed in the EF-dominant individuals. Regarding the SSVEP amplitude, there was no difference in attentional modulation between IF- and EF-individuals. These results suggest that somatosensory cortex relates to the individual optimal attentional strategy. Furthermore, the top-down modulation of the SSSEP amplitude depending on the dominance of attentional strategy implies that the cognitive ability of attention control rather than response characteristic of sensory processing to focused stimuli characterize the individual attentional optimality.

Title: Visuomotor adaptation and retention during balance-challenged reaching and walking tasks

Authors: ***A. BAKKUM**, J. M. DONELAN, D. S. MARIGOLD;
Simon Fraser Univ., Burnaby, BC, Canada

Abstract: The ability to adapt to our surroundings and retain what is learned is essential for performing many daily activities. Studies on reaching adaptation demonstrate that learning two opposing mappings shortly after one another interferes with consolidation of the motor memory. However, most of these studies focus on isolated upper-limb movements while the participant is in a seated position and balance is not a major concern. Yet, balance challenges are inherent to everyday reaching and walking, where the ability to complete these tasks depends critically on the control of the whole body. Interestingly, learning during walking appears less susceptible to interference. Could the balance challenges encountered during more complex, whole-body movements, provide an explanation for the differences observed in motor learning? In this study, we test the hypothesis that challenging balance during standing-based reaching and walking tasks (i.e., whole-body movements) leads to better learning, reflected by greater retention. Four groups (n=12 each) adapted to a new visuomotor mapping induced by prism lenses while performing either a precision reaching or walking task, with or without a balance manipulation. In balance-challenged groups, participants performed the task with inflatable rubber hemispheres (radii: 8.5cm) attached to the soles of their shoes to reduce the control afforded by shifting the center of pressure under the base of support. This manipulation challenged balance, reflected by increased effort (muscle activity: reaching, p=2.22e-6; walking, p=0.003), instability (trunk acceleration variability: reaching, p=0.0007; walking, p=4.81e-6), and motor variability (end-point error variability: reaching, p=0.008; walking, p=9.31e-6). Across all groups, the balance-challenged walking group demonstrated the greatest effort, instability, and motor variability. All groups adapted to the new mapping with similar adaptation rates. To assess retention, participants repeated the adaptation protocol one week later. Neither reaching group showed significant retention of the mapping. However, both walking groups showed retention (balance-unchallenged, p=4.51e-5; balance-challenged, p=0.001). Additionally, the walking balance-

challenged group showed greater retention (Retention Index, p=0.025). Overall, our results support the idea that challenging walking balance enhances visuomotor retention.

Title: Does factorization facilitate reward-based motor learning?

Authors: *K. VAN DER KOOIJ[1], N. M. VAN MASTRIGT[2], J. B. SMEETS[3];
[1]Vrije Univ. Amsterdam, The Netherlands, Amsterdam, Netherlands; [2]Human Movement Sci., Vrije Univ., Amsterdam, Netherlands; [3]Human Movement Sci., Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: In reward-based motor learning, errors can be reduced by varying the motor output and repeating successes. When multiple factors may underlie success (reward), it is unknown how we link success to these factors. Here, we ask whether a single factor is learned more rapidly when the total number of factors is restricted and further test whether learning of two factors is facilitated by practicing the them sequentially. Participants performed a novel 3D drawing task in which they viewed a virtual slanted line and were asked to copy this line with movement of a controller. Performance feedback was limited to binary reward (success) information. Two factors could contribute to reward: vertical slant and length of the drawn line. We based the feedback either on a single factor or on the combination of the two factors. A ‘slant first’ group first received feedback on slant, then on length and finished with combined feedback, a ‘length first’ group first received feedback on length, then on slant and finished with combined feedback, and a ‘combined’ group received feedback on the combined error in all learning blocks. Results show that learning of a single factor (slant or length) was not facilitated by restricting the total number of factors. Consistently, learning of the two factors was not facilitated by practicing them sequentially. This suggests that the nervous system can explore and exploit two parameters in parallel.

Title: Strategic compensation in mirror-reversal adaptation tasks

Authors: *S. A. WILTERSON, J. A. TAYLOR;
Psychology, Princeton Univ., Princeton, NJ

Abstract: Re-aiming strategies appear to dominate learning for visuomotor adaptation tasks (Taylor et al., 2014) and we have recently observed that strategies can take on different forms depending on task conditions (McDougle and Taylor 2019). When there are only a few training targets (low set size) participants preferentially employ a discrete or rule-based strategy. This type of strategy may involve holding a stimulus-response pairing in working memory. However, when there are many training targets (high set size), participants employ a parametric or algorithmic strategy such as performing a mental rotation. We recently found that strategies also account for the lion's share of learning in a mirror-reversal task, but that the particular form of strategy employed by participants is unclear. Participants may preferentially use a discrete strategy, such as flipping across the y-axis, or a parametric strategy, such as mentally rotating or scanning from the target to the solution. It is also possible that participants must combine both strategies, such as flipping and rotating sequentially. Our first experiment systematically varied both horizontal distance and angular perturbation size to expose constraints on strategy use in the mirror-reversal task. Surprisingly, reaction time was constant across all imposed perturbations. This suggests that participants are employing a discrete strategy to solve the mirror reversal. We further investigated this possibility with a 2 (set-size: 2 vs 12 targets) x 2 (perturbation-type: rotation vs mirror) design. Under visuomotor rotation, we replicated the set-size findings of McDougle and Taylor, 2019, demonstrating a discrete strategy with low set-sizes and a parametric strategy with high set-sizes. Reaction times were significantly faster under mirror reversal than under either visuomotor rotation condition. Additionally, there was only a slight difference in mirror reversal reaction times under different set sizes, echoing Hick's Law as opposed to a difference in strategy. These findings suggest that strategy use in mirror-reversal tasks is closer to a discrete strategy which holds stimulus-response pairings in working memory. We conclude that strategies appear to dominate learning in both visuomotor rotation and mirror-reversal tasks, and that the form of the strategy differs depending on the particular task demands with important implications for how motor learning proceeds.

Title: Lateralization in motor learning of a *de novo* shuffleboard task

Authors: *J. YUK[1], J. B. DINGWELL[1], J. P. CUSUMANO[2], R. L. SAINBURG[1]; [1]Kinesiology, Pennsylvania State Univ., University Park, PA; [2]Dept. of Engin. Sci. & Mechanics, Penn State Univ., University Park, PA

Abstract: We have previously proposed a hypothesis of motor lateralization that attributes predictive control of limb trajectory to the dominant hemisphere and control of limb impedance to the non-dominant hemisphere. This model is supported by studies demonstrating sensorimotor adaptation during visuomotor rotations in patients with focal cortical lesions. However, it is not known whether specialization of the dominant system will also be reflected in learning of a de novo task. We now ask whether lateralization of motor learning will occur during learning of a task that requires predictive control of hand trajectory. In our de novo task, participants hit a virtual puck from a central location toward a 180° arc located 35 cm from the initial puck position. Participants were free to start each trial anywhere behind a horizontal line located 10 cm posterior to the puck. Hand velocity was transferred to the puck at impact depending on the location of impact, and the magnitude and direction of the hand velocity vector. Thus, accurate performance required coordinated control of hand velocity and impact location. Six right-handed young adults performed the task with both arms: 3 with their dominant arm first and 3 with their non-dominant arm first. Both arms showed similar adaptation early (fast) learning phase. However, over the slow, asymptotic phase of learning, the dominant arm continued to improve performance, while the non-dominant arm did not. Interestingly, variance in hand start positions was higher for the dominant arm earlier in learning. We propose the dominant hemisphere-limb system developed a model of control through exploration of state space early in learning that was more extensive than that learned by the non-dominant hemisphere. As a result, the dominant arm showed a greater reduction in error throughout the slow phase of learning. We suggest this asymmetry in learning a de novo task reflects dominant hemisphere specialization for predictive control of trajectory.

Title: Learning and retrieving motor memories depending on gaze-reach coordination

Authors: *N. ABEKAWA, H. GOMI;
NTT Communication Sci. Labs., Kanagawa, Japan

Abstract: We can learn and execute multiple motor skills that are engaged in different behavioral contexts. To facilitate learning, each context should have linkage with different internal states that are inherently represented in sensorimotor processing (e.g. Howard et al., 2013). Meanwhile, it is known that the brain computes the spatial coordination between gaze and reaching target in motor planning (Buneo et al. 2002). Additionally, an fMRI study (Prado et al., 2005) showed neural activities in different cortical area for hand-reaching to foveal and peripheral targets. These reports can raise an advanced hypothesis that leaning of multiple motor skills is facilitated when each memory is linked with different gaze-reach coordination. We tested this hypothesis using learning paradigm including visuomotor rotation (Exp.1), force-field perturbation (Exp.2), and learning generalization (Exp.3). In Exps. 1 and 2, participants reached a target while looking at the target (Foveal reach: FOV) or at elsewhere (Peripheral reach: PER). We applied visuomotor rotations (Exp.1) or velocity-dependent forces (Exp.2). The direction of perturbation (CW or CCW) varied randomly across trials, but was individually coupled with FOV or PER. In both Exps., we found decrease in reaching error with training, and clear aftereffects for both FOV and PER. The results suggest that the brain can form and retrieve distinct internal models of kinematic and dynamic control that are linked to the different gaze-reach coordination. In Exp.3, we examined generalization of learning in visuomotor rotation across different gaze-reach coordination. We found that after participants completed learning in PER, adaptation gain was maintained in reaching to the target in the same visual field as in learning trials, whereas it was partially generalized for reaching to foveal target and opposite visual field. Unlike learning in PER, generalization pattern of learning in FOV highly depended on reaching directions. For reaching along sagittal axis, learning was fully generalized to every gaze location we tested, but for reaching in oblique axis, learning gain decreased as the gaze location separated from adapted one. Our findings indicate that different gaze-reach coordination forms partially separated representation in motor learning even if the location of reaching target is same across conditions. Several generalization patterns also suggest different learning mechanisms depending on gaze-reach coordination and reaching directions. Taken together, our

data give a new insight into the sensorimotor representation of gaze-reach coordination, which essentially contribute to motor learning.

Title: Learning and generalization of complex visuomotor priors are context specific

Authors: *C. L. HEWITSON, M. J. CROSSLEY, D. M. KAPLAN;
Cognitive Sci., Macquarie Univ., Sydney, Australia

Abstract: Visuomotor adaptation tasks perturb the relationship between motor commands and their visual consequences. Humans can reliably learn to compensate for this type of perturbation by implicitly re-tuning their motor system. However, there is an apparent paradox in the literature regarding when the sign of the perturbation is randomly changed from trial to trial (e.g., leftward shift vs rightward shift). According to a simple state-space model, which is consistent with a large body of empirical data, this paradigm should prevent any appreciable re-tuning of the motor system since adaptation to leftward perturbations will be cancelled by adaptation to rightward perturbations on average. However, some work suggests that, at least in versions of this paradigm, humans can adapt to complex probability distributions of visuomotor perturbations including bimodal distributions with oppositely signed peaks (Körding and Wolpert, 2004). Although there is an apparent tension between these two results, drawing strong conclusions of any type is currently limited by the paucity of data bearing on this issue. To begin to address this, we investigated adaptation to a bimodal visuomotor prior with oppositely signed peaks and then tested generalization of this learning to novel reach directions. Our preliminary results indicate that initial learning does in fact occur and that this learning generalizes as two distinct unimodal distributions, selected according to movement context. Specifically, the positively signed component of the imposed bimodal distribution generalizes to rightward target directions, while the negatively signed component generalizes to leftward target directions. These findings raise important questions for conventional and Bayesian models of sensorimotor learning. They also suggest that the brain might employ distinct processes for visuomotor learning when operating in probabilistic versus non-probabilistic regimes.

Title: Holding the arm still through integration of cortical commands

Authors: *S. T. ALBERT[1], A. M. HADJIOSIF[2], J. JANG[1], A. J. ZIMNIK[4], M. M. CHURCHLAND[5], J. W. KRAKAUER[3], R. SHADMEHR[6];
[1]Biomed. Engin., Johns Hopkins Sch. of Med., Baltimore, MD; [2]Neurology, Neurosci., [3]Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Neurosci., [5]Neurosci., Columbia Univ., New York, NY; [6]Dept Biomed. Eng, Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD

Abstract: “Posture [accompanies] movement like a shadow.” - Sir Charles Sherrington. In other words, every movement ends in a period of stillness. When we make a reaching movement, it is thought that a cortical system produces motor commands that move our arm towards a desired goal. Curiously, when the motor cortex is transiently inhibited mid-movement, the arm maintains its current position, rather than falling to the side under the weight of gravity (Guo et al., eLife, 2015). How does the brain maintain the position of the arm despite inactivity in the motor cortex?Current models of reaching assume that to maintain a posture, the cortex translates the sensory location of a target into a set of motor commands that hold the arm in place. Here we consider a different possibility; perhaps the motor commands that hold the arm still are produced by a different, potentially subcortical, system whose output depends on the sequence of motor commands that the cortex produced in order to move the arm. Notably, the oculomotor system is designed in this way; the gaze-holding system uses distinct “move” and “hold” controllers that are serially linked. The hold circuitry resides in brainstem structures that mathematically integrate the commands that moved the eyes. Might the brain use a similar process of neural integration in the control of reaching?To test this hypothesis, we performed point-to-point reaching experiments in humans (n=246) and non-human primates (n=2). We found a clear relationship between the motor commands that held the arm, and those that moved the arm: irrespective of reach direction, reach duration, and reach endpoint, holding motor commands

were proportional to the time-integral of the reaching motor commands that preceded them. This relationship was causal; when we imposed changes on the reach commands with force field perturbations, what followed were precise alterations in the hold commands. Finally, we found that following damage to the corticospinal tract, the reach commands were severely impaired, but the holding system continued to faithfully integrate the now imperfect reach commands.Together, these findings suggest that the eye and the arm may share a common design principle of control: moving and holding use different neural circuits, but are causally linked to one another through a neural integrator. In this way, the way we hold still does not directly depend on the location of the target, but rather the integral of the commands that moved our body towards that target.

Title: Anterograde interference develops from a transient reduction in error sensitivity

Abstract: When we experience an error during a movement, we adapt our future movements to improve our accuracy. The strength and duration of these motor adaptations provide insight into the mechanisms underlying memory formation in the brain. A memory is thought to be consolidated when it is no longer susceptible to interference from new information. Here we

aimed to track the time course of motor memory formation using anterograde interference as a marker for stabilization.Anterograde interference refers to an impairment in learning in Environment B after prior exposure to Environment A, where A and B are dissimilar perturbations. When A and B are experienced in close succession, consolidation of the A memory occludes the ability of the nervous system to adapt to the B perturbation. The dissipation of anterograde interference may signal the progress of consolidation.In order to monitor the duration of anterograde interference, we varied the time interval elapsed between adaptation to opposing rotations from 5 min through 24 hr (n=93 total participants). We fit a state-space model of error-based learning to differentiate between potential sources of interference: a lingering bias of performance towards the original A perturbation, an increase in the rate of memory decay, or a decrease in the sensitivity to error.We found that prior learning affected two specific parameters of our learning model: the initial bias of learning towards the memory of A, and the sensitivity to error in the B period. The initial bias in learning was strong, and persisted even if perturbations were separated by 24 hours. On the other hand, error sensitivity was reduced at 5 min and 1 hr but returned to control levels by 6 hours. Our findings suggest that anterograde interference is caused by a transient reduction in the sensitivity to error that recovers within a relatively short time window. Our work provides insight into the timeline of memory stabilization.

Title: Exposing chronic, severe/moderate stroke survivors to startle during reach training improves voluntary reaching distance, final position error, and muscle activity

Authors: *M. RAHIMI, C. F. HONEYCUTT;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: StartReact (SR), startle-evoked-movement, has recently been posed as a potential therapeutic target for individuals with stroke. SR elicited reaching and hand movements in individuals with stroke show improvements compared to voluntary in terms of muscle activity onset, amplitude, and coordination patterns (Honeycutt & Perreault, 2012; Honeycutt, Tresch & Perreault, 2015). Still, SR evokes functionally inappropriate flexion movements that increases with impairment (Honeycutt & Perreault, 2014). Furthermore, Choundhury et al., 2019 suggest

that SR may increase spasticity because stimulation of the reticulospinal tract.
Still, none of these concerns have been evaluated directly because to-date no laboratory has evaluated the impact of SR on voluntary reaching movements in individuals with stroke. The objective of this study was to evaluate the impact of a single session of SR on voluntary reaching in individuals with severe/moderate stroke. Optimistically, we hypothesized that a single session of training with SR would improve the voluntary movements in terms of final accuracy, total displacement, and max muscle activity.
Eleven individuals with severe/moderate impairment (UEFM: 8-41/66; Modified Ashworth: 0-4/4) resulting from a stroke participated. Subjects reached to 3 targets. A loud, startling stimulus was applied during 33% of trials. The first 10 voluntary (no startle) and the last 10 voluntary trials were compared. We found that voluntary reaching displacement, final accuracy, onset latency, and max muscle activity were all improved. Specifically, an increase in reaching displacement ($\Delta = 1.18$ cm, all: $P < 0.0003$) and decrease in final error ($\Delta = 0.83$ cm, all: $P < 0.013$). Faster muscle onsets in all muscles (average $\Delta = 77$ ms, all: $P < 0.017$) and larger max muscle activity in 73% of muscles (average $\Delta = 0.11$ mV, all: $P < 0.05$) was found.
In conclusion, a single session of reach training with SR enhanced voluntary movement in individuals with severe/moderate stroke. Moreover, the size of the improvement is notable. A recent review of task-specific training, shows a maximum of 11.1 % improvement in reaching distances, (Rensink, Schuurmans, Lindeman, & Hafsteinsdóttir, 2009) while we found a 15.8+/-4.5 %. While this study supports the further evaluation of SR as a therapeutic target, future studies should more carefully evaluate spasticity specifically as well as perform appropriate controls to ensure all effects are attributable to SR.

Title: Delineating the neural basis of flexible versus rigid skills

Authors: *S. KONDAPAVULUR, S. M. LEMKE, K. GANGULY;
Univ. of California, San Francisco, San Francisco, CA

Abstract: The rodent reach-to-grasp task of retrieving single pellets is often used to assess skilled upper limb movements. With motor skill acquisition and consolidation, execution becomes smooth, fast, and stereotyped - this is known to be paralleled by increased coordinated neural activity between primary motor cortex (M1) and dorsolateral striatum (DLS). We were interested in testing whether the motor skill typically achieved in this task is "flexible", i.e. can adapt to changes in task parameters, or is "rigid", i.e. a habitual action that may have to be unlearned in order to adapt to changes.
We specifically trained rats to reach to one location (Position A), until a fast, consistent, and accurate skill level was achieved. We then switched the pellet location to Position B, and observed whether the rats reached toward Position A (i.e. rigid skill state) or more toward Position B (i.e. flexible skill state). We then continued this training towards Position B over multiple days. We also recorded neural activity (both single unit activity and local field potential) from M1 and DLS over this period. Additionally, we inactivated DLS during the initial transition from Position A to Position B to assess if DLS may play a causal role in transitioning between positions.
We found that training rats to reach to a single location promoted rigid skill learning. When the pellet was initially switched to Position B, the rats primarily reached to Position A during the first session; with subsequent training to Position B, we observed more correct reaches to this location. Interestingly, M1 and DLS activity evolved during the transition from a rigid to flexible skill state. M1-DLS coordination was high during the rigid skill baseline of reaching towards Position A; however, this coordination was not present in the initial switch reach session with attempts towards Position B. With further training to Position B, M1-DLS coordination re-emerged. These results suggest that M1-DLS coordination reflects stereotypy of a learned movement and may reflect a rigid skilled state. Future work will determine how M1-DLS coordination can support multiple consolidated skilled states.

Title: Greater neural responses to others' errors is associated with motor learning by observing

Authors: *H. R. MCGREGOR[1], E.-M. REUTER[2], P. L. GRIBBLE[3], T. J. CARROLL[4];
[1]Univ. of Florida, Gainesville, FL; [2]Sch. of Human Movement and Nutr. Sci., Univ. of Queensland, Brisbane, Australia; [3]Brain and Mind Inst., Western University, Canada, London, ON, Canada; [4]Sch. of Human Movement and Nutr. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: While many of our motor skills are acquired through physical practice, we can also learn how to make movements by observing others. For example, individuals can learn how to reach in novel dynamic environments ('force fields', FF) by observing the movements of a tutor. Behavioural research suggests that observing a tutor's kinematic errors drives motor learning by observing. Here we used electroencephalograpy (EEG) to investigate if subjects' neural responses to observed errors relate to their observation-related gains in motor performance. Healthy subjects (n=40) held the handle of a vBot robotic manipulandum, and were instructed to perform straight reaching movements to visual targets in the horizontal plane. In a baseline condition, all subjects performed reaches in a 'null field' in which the robot did not apply forces to the hand. We then recorded EEG activity while subjects observed either a learning video (n=20) or a control video (n=20). The learning video showed a tutor adapting his reaches to a counterclockwise velocity-dependent force field (CCW FF). The control video showed a tutor performing reaches in an unlearnable FF environment in which the direction of the FF varied randomly from trial to trial. Subjects then performed reaches in a CCW FF as a behavioural assessment of learning achieved from observation. We found that subjects who had observed the learning video exhibited superior performance when they subsequently performed reaches in the CCW FF compared to subjects who did not observe learning in the control video. We used EEG data collected during observation to estimate subjects' neural responses to errors committed by the tutor. We extracted event-related potentials time-locked to the tutor's peak kinematic error on a trial by trial basis, and assessed the error-related negativity (ERN) component. For both groups, the amplitude of the ERN scaled with the magnitude of errors observed in the video. However, for the learning video group only, those subjects who exhibited greater neural responses when observing small errors were those who learned more from observation. This suggests that greater sensitivity to small errors committed by the tutor during learning was associated with increased observation-related gains in motor performance.

Title: Generalizing movement patterns following shoulder fixation

Authors: *R. S. MAEDA[1], J. ZDYBAL[2], P. L. GRIBBLE[4], A. PRUSZYNSKI[3];
[1]Brain and Mind Inst., [3]Physiol. and Pharmacol., [2]Western Univ., London, ON, Canada; [4]Brain and Mind Inst., Western University, Canada, London, ON, Canada

Abstract: A common goal of motor learning is generalizing newly learned movement patterns beyond the training context. Here we tested whether learning a new physical property of the arm during self-initiated reaching generalizes to new arm configurations. Seventy human participants (38 females) performed a single-joint elbow reaching task and/or countered mechanical perturbations that created pure elbow motion using a robotic exoskeleton (KINARM, BKIN Tech). This robot permits shoulder and elbow rotation in the horizontal plane. Participants first performed single-joint elbow reaching with the shoulder joint either free to rotate or locked by the robotic manipulandum. With the shoulder free, we found activation of shoulder extensor muscles for pure elbow extension trials, as required to counter the interaction torques that arise at the shoulder due to forearm rotation. After locking the shoulder joint, we found a substantial reduction in shoulder muscle activity over many trials. This reduction is appropriate because locking the shoulder joint cancels the interaction torques and thus removes the need to activate shoulder muscles. In our first three experiments, we tested whether this reduction generalizes when reaching is self-initiated in (1) a different initial shoulder orientation, (2) a different initial elbow orientation and (3) for different reach distance/speed. If the nervous system attributes this learning as a novel an internal model of the arm's dynamics, then generalization should be broad regardless of joint orientation, and speed/distances. We found robust generalization across initial shoulder orientation and reach distance/speed but not for initial elbow orientation. In our fourth experiment, we tested whether generalization is also transferred to feedback control by applying mechanical perturbations and observing reflex responses in a distinct shoulder orientation. We found robust transfer to feedback control. Thus, the nervous system learns a coordination pattern following shoulder fixation rather than a general model of the altered limb dynamics.

Title: Characterizing *de novo* learning of continuous motor skill

Authors: *C. S. YANG[1], N. J. COWAN[2], A. M. HAITH[3];
[1]Dept. of Neurosci., [2]Dept. of Mechanical Engin., [3]Dept. of Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: In order to perform new motor tasks, humans must learn to generate novel patterns of movement. It has been hypothesized that humans possess at least two motor learning mechanisms: 1) adaptation: adjustment of an existing motor skill, and 2) de novo learning: generating a new motor skill from scratch. Although both of these mechanisms are ethologically important, recent work has shown that the scope of behavioral change that can occur via adaptation is rather limited, and we believe many real-world skills, like riding a bike or playing the piano, must be learned de novo. However, we currently have a poor understanding of how real-world skills are learned because relatively few studies have examined de novo learning. To this end, we investigated the properties of motor controllers acquired through de novo learning. Healthy human participants learned to control a cursor under a challenging bimanual hand-to-cursor mapping, which we have previously established is learned de novo. We assessed how well participants learned the mapping by having them track a target moving in a sum-of-sinusoids trajectory, analyzing their behavior using a frequency-domain system identification approach. Participants reached asymptotic performance within 4 days of practice (as measured by the gain and phase of their frequency responses), reaching a plateau which was slightly poorer than that of baseline behavior. By measuring how the frequency responses of their tracking behavior improved, we could subsequently model how the control architecture of the sensorimotor system evolved with practice. We believe this work helps us to understand learning at the level of continuous control and is critical to deciphering how complex real-world skills are learned.

Title: Time course of the long latency feedback response during short term motor adaptation

Authors: *S. K. COLTMAN, P. L. GRIBBLE;
Univ. of Western Ontario, London, ON, Canada

Abstract: The ability to adapt voluntary movements is essential for maintaining accurate performance. We can study motor adaptation in the laboratory by testing how human subjects adapt reaching movements of the arm to externally imposed force perturbations. It has been proposed that reaching toward a target uses a motor command generator, forward modelling that predicts the dynamics of the limb and updating of the initial commands using reliable feedback that is available during and after a movement. An underlying assumption of this framework is that feedback gains should depend on the dynamics of the task. Previous work has suggested that as participants learn to produce the appropriate motor commands to predictively compensate for a force field, they show an increase in the feedback gains associated with externally imposed force perturbations of the arm. Participants grasped the handle of a robotic manipulandum and performed reaches to a virtual visual target while the hand/arm were occluded. During reaching to a target 45° left of centre, we introduced an abrupt counter-clockwise velocity-dependent force field during a block of trials. As participants adapted their reaching movements to counter the force field we randomly interspersed mechanical probe trials designed to stretch the triceps muscle and elicit the long-latency feedback response. Short-term motor adaptation is believed to be supported by two separate processes, each with distinct timescales that operate simultaneously. Characteristically, the fast process learns quickly, but has poor retention; while the slow process has better retention but learns more slowly. We aimed to explore whether the feedback response changed in a parallel fashion to the voluntary system during the course of learning or whether it's time course was distinct. This will inform a deeper understanding of whether these two systems share the same underlying learning process(es) (i.e., fast and/or slow) or whether they rely on dissociable processes. Based on previous work suggesting that the feedback gains are greater in the early stages of learning a new task, and that with practice we learn to reduce our errors, improve our accuracy, become less variable, and develop smooth, effortless performance, we predicted that the time course of the long-latency feedback response will mirror the fast process.

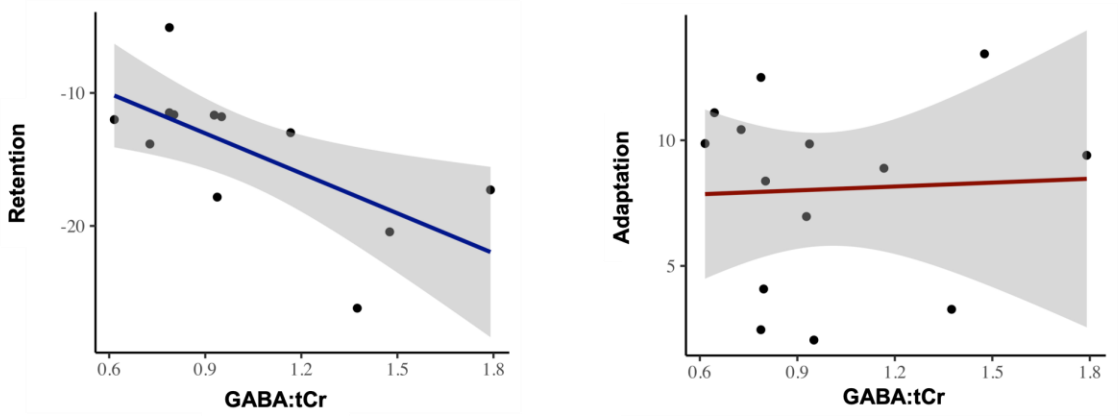
Title: Motor cortex neurotransmitters predict retention, but not adaptation

Authors: *C. R. NETTEKOVEN[1], S. BRADY[1], J. LEVENSTEIN[1], U. EMIR[2], N. JENKINSON[3], C. J. STAGG[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Purdue Univ., West Lafayette, IN; [3]Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Neurotransmitter concentrations in human primary motor cortex (M1) relate to learning of motor skills. For example, decreases in M1 gamma-aminobutyric acid (GABA), as assessed by magnetic resonance spectroscopy (MRS) have been observed during learning of model-free tasks. However, it is not clear if similar changes are seen during learning of model-based tasks, where learning would be expected to occur outside M1, but retention is thought to be M1-dependent.
Methods:
Using a within-subject design (N=15 healthy participants) MRS data (7T) were acquired from the left M1 during the performance of a visuo-motor adaptation task using a hand-held joystick. During one session (adaptation session) visual feedback was rotated, and participants adapted their movements to the perturbed feedback. This was followed by a washout period (no offset), which allows to quantify the retention of the compensatory movement. During the other session (control session) no rotation was imposed.
Analysis:
Task performance was quantified using a model-free approach (mean error). To predict task performance (adaptation or retention) from metabolite concentrations, a regression analysis was performed.
Results:
As hypothesised, M1 GABA at baseline ($GABA_{Baseline}$) significantly predicted retention ($F_{1,11}$=-8.51, p=0.01), but not adaptation ($F_{1,12}$=0.03, p=0.87); participants with higher $GABA_{Baseline}$ retained more compensatory movement. M1 glutamate at baseline ($Glu_{Baseline}$) also predicted retention ($F_{1,11}$=10.47, p=0.01). Follow-up analysis showed that $GABA_{Baseline}$ and $Glu_{Baseline}$ were highly correlated (r_{14}=0.72, p=0.01) and suggested that the relationship with retention was driven by the shared variance of GABA and Glutamate. As expected, $GABA_{Baseline}$ did not correlate with retention (r_{11}=-0.25, p = 0.38) or adaptation (r_{11}=-0.22, p=0.51) in the control session.
In summary, we provide evidence that inter-individual differences in performance on a model-based motor task can be predicted from magnetic resonance spectroscopy-assessed neurochemical concentration levels in M1.



LEFT. Retention. GABA at baseline significantly predicts retention ($F(1,11) = 8.51$; $p = 0.01$).
RIGHT. Adaptation. GABA at baseline does not predict adaptation ($F(1,12) = 0.03$; $p = 0.87$).
As expected, GABA showed no relationship with retention ($r(11) = -0.25$, $p = 0.38$) or adaptation ($r(11) = -0.22$, $p = 0.51$) in the control session.

Title: Neuroanatomical correlates of motor learning and visuospatial processes in cognitively-intact older adults

Authors: *J. LINGO VANGILDER[1], M. C. FITZHUGH[2], C. ROGALSKY[2], S. Y. SCHAEFER[1];
[1]Sch. of Biol. and Hlth. Systems Engin., [2]Speech and Hearing Sci., Arizona State Univ., Tempe, AZ

Abstract: We have recently shown that by testing older adults' visuospatial function, we can predict their motor learning capacity. In fact, our studies show that older adults with above-normal visuospatial scores retained up to four times as much skill as those with below-normal visuospatial scores, regardless of baseline upper extremity motor function, age, and other impairments in language, attention, or delayed memory. We hypothesize that visuospatial tests

have predictive value because they probe the health of critical neural structures for motor skill learning. Classic neuropsychological studies have long supported the role of parietal cortex in visuospatial function and more recent neuroimaging studies have shown that the structural integrity of white matter tracts between parietal and frontal cortices are related to various visuospatial abilities. More specifically, our preliminary data suggest that the right superior longitudinal fasciculus (SLF), a frontoparietal white matter tract, may be a candidate neural pathway for predicting visuospatial function in older adults and for explaining our previous behavioral findings. Thus, the purpose of this ongoing study is to address the gap in knowledge of the relationship between right SLF structure and motor learning ability. Cognitively-intact older adults (n=10, age>65) completed a baseline trial and 50 training trials on an upper extremity motor task using their nondominant hand, and were retested one week later to quantify the amount of motor skill learned and retained over a one-week period. Participants also underwent diffusion tensor magnetic resonance imaging to quantify right SLF fractional anisotropy (FA), a measure of white matter structural integrity. Results indicate that right SLF FA positively correlated with motor learning ability (R^2=0.34, p=0.079), where higher right SLF FA values predict better one-week motor learning. These preliminary data serve as proof-of-concept and support our hypothesis that motor learning processes may be integrated in the right SLF, and that SLF integrity may mediate the relationship between visuospatial test scores and motor learning outcomes. Moreover, results of this study suggest that paper-and-pencil visuospatial tests currently used in clinical settings could be used as a cost-effective proxy for neuroimaging, particularly in cases of contraindication or lack of imaging resources.

UKE, Hamburg, Germany; [4]INECO, Buenos Aires, Argentina; [5]Clin. Neuroscience, Univ. of Geneva Med. Sch., Geneva, Switzerland

Abstract: *Background and purpose:* Healthy aging entails changes in cognitive and motor function. Motor training can improve motor function in older adults, but learning is diminished in comparison to that observed in younger individuals. The origin of this impaired learning, e.g., speed, dexterity, brain plasticity or a combination of them remains to be singled out. The present study aims to detect differences in strategy in the execution of a motor task (i.e. chunking strategies) between young and older adults in order to identify underlying mechanisms and plausible targets for interventional strategies to improve motor learning in older adults.
Methods: 50 healthy participants from three different age groups (young [18-30 yo], middle-aged [50-65 yo] and old [>65 yo]) were trained in a finger sequence-tapping task over the course of five consecutive days. Data-driven computational methods were applied to detect motor deployment strategies (i.e. chunking) to determine whether there was a set of motor strategies characteristic to each age group.
Results: There were no differences in the execution error rates between groups. Still, mean classification accuracies of up-to 0.86 (F-score) were achieved when predicting young and old aged subjects from the chunking patterns generated on day 1. The middle-aged group could not be predicted effectively.
Conclusion: Young and old adults approach new tasks through markedly different motor strategies in the execution of sequential motor tasks, which might explain performance differences at a behavioral level. One of these different strategies is related to the evolution of chunking patterns of motor sequences during the learning process.

Title: Conscious aiming strategies override implicit adaptation to opposing visuomotor perturbations

Authors: *M. N. AYALA[1], D. Y. HENRIQUES[2];
[1]York Univ., Toronto, ON, Canada; [2]Dept Kinesiol & Hlth. Sci., York Univ., North York, ON, Canada

Abstract: The ability to switch between different tools accurately and efficiently is a remarkable human feat afforded by a flexible and adaptive motor system. This is readily examined in dual adaptation paradigms, where the motor system is challenged to perform under switching, opposing visuomotor perturbations. Typically, dual adaptation doesn't proceed unless each mapping is trained in association with a predictive cue. In the first part of these experiments, we examined the efficacy of multiple cues in facilitating dual visuomotor adaptation including active follow-through movements, passive follow-through movements, active three-part lead-in movements, and a static visual control cue. In the final intervention, we gave participants a dual aiming strategy to dissociate the subcomponents of dual adaptation. This was motivated by recent advances revealing that adaptation can be characterized by at least two qualitatively different mechanisms: (1) an explicit process which arises due to the implementation of conscious aiming strategies, and (2) an implicit, unaware process, thought to reflect adaptation of internal models in the cerebellum. However, the extent by which dual adaptation is governed by a conscious, explicit process has yet to be investigated. To this end, we instructed an Explicit-Instruction group with a compensatory strategy about the perturbations (30° CW or 30° CCW rotations) and their relationships to each context (visual cues), and compared their performance to a No-Instruction group. Following perturbed training, participants were asked to either use or ignore the strategy as they reached without visual feedback. This Process Dissociation Procedure teased apart the implicit and explicit contributions to dual adaptation. First, we found that active movement sequences tend to facilitate dual learning but passive movement consequences do not. In the active movement experiments where dual learning was elicited, we found significant implicit and explicit reach aftereffects in the expected directions. Furthermore, static visual cues didn't elicit dual adaptation, but those in the Explicit-Instruction group were able to compensate by implementing aiming strategies. Critically, we found no implicit contributions, but an effect of instruction, suggesting that explicit aiming strategies inhibit implicit mechanisms in dual adaptation. Thus, by implementing conscious strategies, dual adaptation can be easily facilitated even when learning would not occur otherwise.

Title: Distance control and proprioceptive localization of lower limb in patients with cerebellar disease

Authors: *Y.-G. SONG[1], S. CHEON[2], C.-H. LIM[2];
[1]Marine Sports, Pukyong Natl. Univ., Busan, Korea, Republic of; [2]Korea Univ., Seoul, Korea, Republic of

Abstract: The accurate movement control and proprioceptive localization depends on our innate knowledge of limb state (i.e., proprioception, specifically limb position sense). The aim of this study was to investigate the effect of distance control and proprioceptive localization of lower limb in patients with cerebellar disease during different task conditions. Twelve patients with cerebellar disease (CD) and age- and sex-matched 12 normal controls participated in the study. Both groups practiced (i.e., 5 trial for each condition) reaching to the targets with their right lower limb presented at three distance conditions (5, 10, 15cm) while sitting. Kinematic data were measured to determine scaling of movement accuracy (i.e., error of distance and absolute distance error) from start to target position. The results demonstrated that error of distance and absolute distance error of CD patients were higher than normal controls. In particular, this difference was greater at 5cm than at 10cm and 15cm. Taken together, the results suggest that CD patients have deficit to distance control and proprioceptive localization during lower limb movement.

Title: Desensitization upon relearning for implicit sensorimotor adaptation

Authors: *G. AVRAHAM[1,2], D. E. PARVIN[1,2], H. E. KIM[3], J. R. MOREHEAD[4], R. B. IVRY[1,2];
[1]Dept. of Psychology, [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Dept. of Physical Therapy, Univ. of Delaware, Newark, DE; [4]Sch. of Engin. and Applied Sci., Harvard Univ., Cambridge, MA

Abstract: The motor system has an impressive ability to adapt to sudden environmental changes, and to quickly readjust when the changes are transient. If similar perturbations are re-

encountered, the learning is faster, a phenomenon known as savings. The lion's share of this effect is explained by the recall of an explicit aiming strategy (Haith *et al.*, 2015; Morehead *et al*., 2015), but it is possible that an implicit process also contributes to savings. We test this hypothesis using clamped visual feedback, in which a cursor follows an invariant path away from the target, independent of the hand path. This method was shown to induce implicit adaptation: Unaware reaching deviates to the opposite direction (Morehead *et al.*, 2017).
In Experiment 1, participants (n=16) reached to 8 targets located within a single quadrant. Exposure to 2° clamp offset over 80 cycles caused implicit adaptation. After a 10 cycles washout with veridical feedback, the clamp was re-introduced. Interestingly, early relearning was 49% faster, but the asymptote was 23% smaller, suggesting that the overall relearning decreased. The faster early relearning may reflect an implicit process that was not fully washed out by the short veridical feedback session. To address this possibility, in Experiment 2 (n=16) we introduced an extended veridical feedback washout of 30 cycles. Early relearning was now 33% slower, corroborating its dependency on the washout duration.
Due to adaptation, participants experience errors during the early veridical feedback washout, which may cause awareness of the clamp effect on reach direction. Therefore, the weaker relearning could result from an explicit strategy to compensate for the hand deviation. In Experiment 3, participants first adapted to either 2° or 15° clamp (n=32) for 60 cycles. We then used a reversed clamp (-2°/-15°), maintaining this feedback until the median reach direction was smaller than 3° for 3 consecutive cycles, and then presented veridical feedback (50 cycles overall). Thus, we washed out implicit adaptation while eliminating the experience of adaptation-driven errors. When repeating the original clamp, we again saw decrements in both early rate (30%) and asymptote (9%) of relearning. In Experiment 4 (n=32), we found that these effects did not generalize to the opposite side of the workspace.
In conclusion, instead of savings, we saw decreased implicit adaptation upon re-exposure that is workspace-specific. Similar effects in rodents were attributed to transient depletion of plasticity in cerebellar synapses (Nguyen-Vu *et al.,* 2017). The effect may also reflect a habituation-like response to a persistent error.

Title: Deficits in motor learning of older adults is correlated to delays in the reticulospinal system

Authors: J. J. SCHREIBER[1], K. ELLIOTT[1], S. Y. SCHAEFER[2], ***C. F. HONEYCUTT**[1]; [2]SBHSE, [1]Arizona State Univ., Tempe, AZ

Abstract: Motor skill acquisition, the process by which individuals practice and consolidate movement to become faster, more accurate and efficient, declines with age (Gunning-Dixon, Head, Raz, Acker, & Williamson, 2002; King, 2016; Roig, Ritterband-Rosenbaum, Lundbye-Jensen, & Nielsen, 2014; Seidler, 2007). Initial skill acquisition is dominated by cortical structures; however as learning proceeds, literature from rodents and songbirds suggests that there is a transition away from cortical execution (Kawai et. al. 2015; Andalman & Fee, 2009; Desmurget & Turner, 2010; Quaglino & Quaglino, 2007; Walter et al., 2019). Recent evidence indicates that the reticulospinal system may play an important role in integration and retention of learned motor skills. Specifically, reticulospinal contributions are shown to increase over the course of a 10-day training regimen (Kirkpatrick et. al. 2015).
The brainstem has known age-rated deficits including cell shrinkage and death in rodents (Sabel and Stein 1981) and volume loss in humans (Luft et al. 1999; Lambert et al. 2013). Given the role of the reticulospinal system in skill acquisition and older adult's poor capacity to learn, it begs the question: are delays in the reticulospinal system contributing to older adult's poor capacity to learn? Our objective was to evaluate if delays in the reticulospinal system (measured via the startle reflex) are correlated to impairment of motor learning in older adults. We hypothesized that individuals with fast startle responses would show the most learning and retention while individuals with delayed startle responses would show the least. We indeed found that individuals with fast and intact startle responses have larger % improvement and % retention compared to individuals with delayed startle responses. Further, linear regression analysis indicated that startle onset latency exists within a continuum of learning outcomes suggesting that startle onset latency may be a sensitive measure to predict learning deficits. There exists no method to determine an individual's relative learning capacity. Thus, this result opens the possibility of startle, which is an easy and inexpensive behavioral measure, being used to predict learning deficits in older adults to facilitate better dosing during rehabilitation therapy.

Title: Comparing latencies of information processing supporting feedforward and feedback control of reaching

Authors: *K. KITA[1], C. YANG[2], Y. DU[1], A. M. HAITH[1];
[1]Neurol., Johns Hopkins Univ., Baltimore, MD; [2]Neurosci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Feedback responses to a mid-movement perturbation are initiated within around 100-150 ms. Preparation of feedforward movements has also been shown to occur within a similar time period. Furthermore, conflicting responses have been shown to emerge at different times for both feedforward and feedback. Feedforward and feedback control have, however, never been directly compared. Despite these compelling parallels, it remains unclear whether the time course for preparing a feedforward movement are the same, or whether preparation of feedforward movements might require additional processing stages. Here we directly compared the time course of information processing for feedforward and feedback responses both when acting under veridical feedback, and when acting under a mirror reversal. Human participants performed center-out reaching movements towards four equally-spaced targets at a distance of 10cm under two conditions: 1) a timed-response condition where participants were forced to respond at a range of preparation times (PTs) ranging from 100 to 600ms, 2) a target jump condition where participants initiated reaching to a target, but the target jumped 5cm orthogonally to the direction of movement. Condition 1 reveals the time course over which feedforward control is prepared, based on the minimum preparation time required to consistently generate accurate movements. Condition 2 reveals the latency at feedback responses are initiated to compensate for the target jump after participants were already moving. We found that target location was reflected in behavior at a similar latency in both conditions.Participants performed the same two conditions in an environment with mirror (up-down)-reversed visual feedback. When target processing required a movement orthogonal to the mirroring axis (i.e. up or down), both feedforward and feedback behavior exhibited two clear phases of behavior. In Condition 1, at low PTs, participants initiated movement towards the actual target location, but at longer PTs they were able to move their hand away from the target in order to bring the cursor to the target. In Condition 2, in response to target jumps upward or downward, participants initially pursued the target with their hand, but rapidly reversed their correction to move their hand away from the target, guiding the cursor to the target. The timescale of these events were broadly consistent across the two conditions. These results suggest that a single underlying process drives changes in feedforward and feedback control.

Title: Spiking neuron model of motor control with adaptation to visuomotor rotation

Authors: *N. VAIDYANATHAN, C. ELIASMITH;
Univ. of Waterloo, Waterloo, ON, Canada

Abstract: There are numerous behavioral and physiological studies that show how the brain compensates for uncertainties and unexpected changes in the sensory environment while still successfully perform motor tasks. To date, there have been a variety of phenomenological models proposed for explaining this sensory motor adaptation. But in order to relate the suggested control algorithms with their neural realizations, it is important to have biologically plausible mechanisms that capture both neural activities and the higher order behaviors that they give rise to. Here we extend a previous model, the Recurrent Error-driven Adaptive Control Hierarchy (REACH), that accounts for dynamic and kinematic adaptation, to also capture visuomotor adaptations. To demonstrate this behavior, we consider the conventional task of 'visuomotor rotation' using a two link arm in a planar reaching task. The model consists of anatomically organized structures including M1, PMd and cerebellum to incorporate different aspects of the behavior. The extended model has a multimodal Kalman filter to accomodate an internal model for dynamic prediction of limb states and sensory integration of vision and proprioception. A spike based algorithm is implemented to learn the visuomotor transformation. Replicating experiments in humans and non-human primates, the model is made to reach when given either abrupt or fast implicit rotations. We also use the model to explore multirate adaptations to further demonstrate classical characteristics such as savings and interference. While the proposed model is consistent with the experimental data of rapid adaptations, the model also exhibits spiking activity comparable to empirical data. A plausible and anatomically organized neuron model describing the adaptation to visuomotor rotations, and eventually to other visuomotor transformations, can provide insights and significantly improve our understanding of the motor system organization and function.

Title: Punishment, but not reward, impairs retention and decreases cortical feedback related potentials during motor learning

Authors: *C. M. HILL[1,2], M. STRINGER[3], D. E. WADDELL[3], A. J. DEL ARCO[2];
[1]KNPE, Northern Illinois Univ., Dekalb, IL; [2]Health, Exercise Sci. and Recreation Mgmt. (HESRM), The Univ. of Mississippi, Oxford, MS; [3]Biomed. Engin., Univ. of Mississippi, University, MS

Abstract: Reward and punishment have demonstrated dissociable effects on motor learning, with punishment enhancing the learning rate and reward increasing retention of the motor task. However, these findings have been primarily demonstrated at the level of behavior, and no study has presented the neural correlates. The aim of this research is to determine whether reward and punishment feedback produces a different cortical neural response associated with motor learning and retention. Participants were randomly placed into one of three groups [Reward (n=14), Punishment (n=14), Control (n=14)] and performed 680 trials of a visuomotor rotation task under five testing conditions [Baseline (80 trials), Adaptation (200 trials), No Vision (200 trials), Washout (100 trials), and Readaptation (100 trials)] with a Wacom pen and tablet. Adaptation (learning phase), No Vision (retention phase), and Readaptation featured an incongruent position between the cursor and the target, with the cursor trajectory rotated 30-degrees counterclockwise to the target, requiring the participant to adapt their movement to hit the target. After each trial, feedback based on error magnitude was provided during the learning phase in the form of a positive number (Reward), negative number (Punishment) or two vertical lines (Control). Positive and negative numbers represented a monetary gain and loss, respectively. EEG was recorded throughout all task conditions from 28 electrodes placed according to the 10-20 system. Reach angle and event-related potentials (ERPs) time locked to feedback presentation (Reward, Punishment or Control) were calculated for each participant during the learning and retention phases of the task. We found that all feedback groups displayed similar changes in reach angles throughout the learning phase of the task, suggesting reinforcement feedback does not alter task adaptation and performance. However, the Punishment group did not maintain the learned reach angle during the retention phase (13.28 ±3.11°), while Reward (19.65 ±0.59°) and Control (19.34 ±1.59°) groups preserved their performance ($F(2,39)=4.157$, $p=0.023$, RMANOVA). Moreover, punishment significantly decreased the peak amplitude of the feedback ERPs during the retention phase compared to the learning phase ($F(2,35)=3.361$, $p=0.009$, RMANOVA). ERP changes were not found in the

Reward and Control groups. We propose that punishment feedback does not adequately update the internal representation of the adaptive behavior necessary to retain the motor task.

Title: Improved motor timing enhances time perception

Authors: *J. GUO[1], Z. ZHANG[3], D. STERNAD[4], J.-H. SONG[1,2];
[1]Dept. of Cognitive, Linguistic & Psychological Sci., [2]Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [3]Dept. of Bioengineering, [4]Departments of Biology, Electrical & Computer Engineering, and Physics, Northeastern Univ., Boston, MA

Abstract: Previous studies demonstrated that motor timing and time perception share common mechanisms and brain processes. For instance, participants who displayed larger timing variability in single-finger rhythmic tapping also demonstrated lower acuity in time perception (Keele et al., 1985). However, these studies examined simple movements, i.e. finger or foot tapping, performed in an explicitly rhythmic fashion. It is unclear whether the inherent timing of more complex movements without explicit periodicity also affected time perception. Here, we examined whether practicing a sequence of controlled throwing movements enhances the sensitivity of time-interval discrimination and, if so, whether this enhanced sensitivity is selectively linked to the timing of the trained movement. In the experiment, participants (n = 14) practiced throwing a ball to hit a target in a virtual environment for 4 daily sessions. Over 4 days of throwing practice, participants stabilized the release time between the onset of the throwing movements and the ball release to approximately 300 ms. Following each throwing session, participants also performed a time-interval discrimination task, in which they reported which of the first standard (t = 300, 600, 1000, or 3000 ms in each block) or the second comparison ($t \pm \alpha t$) time-interval both marked by two auditory beeps was longer. We found that with throwing practice, they enhanced the sensitivity of time discrimination selectively for the interval of 300 ms close to the release time, but not for others. In addition, within individuals, the magnitude of motor timing improvement predicts the enhancement of time-interval discrimination. These results demonstrated that improvement of motor timing enhances the sensitivity of time perception, even for timing patterns inherent to a more complex motor task. We interpret these

finding that there is a shared temporal mechanism between perception and movement regardless of rhythmicity or complexity of the motor tasks.

Title: Cracking a whip: Motor control beyond reach?

Authors: ***A. KROTOV**[1], Z. ZHANG[4], M. RUSSO[2], N. HOGAN[5], D. STERNAD[3];
[1]Bioengineering, [2]Biol., [3]Biology, Electrical and Computer Engin. and Physics, Northeastern Univ., Boston, MA; [4]Neurosci., Columbia Univ., New York, NY; [5]Mechanical Engin. and Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Over the past decades, much of motor neuroscience research has focused on unconstrained reaching-like movements and summarized insights in descriptions of control and learning, including internal models and optimal feedback control strategies. However, this understanding of motor control is challenged when addressing more advanced tasks such as interacting with complex objects, i.e. objects that have internal dynamics. Using the extreme example of cracking a bullwhip, this study asked how humans manipulate the wave dynamics of the whip's infinite number of degrees of freedom. Prediction based on an internal model of this object would challenge even modern supercomputers. How do humans achieve their dexterity? To examine how humans learn to manipulate this complex object, the experimental study tested participants cracking a 1.8m-long bullwhip to hit a two-inch target at 2.2m distance with the tip of the whip. Two task variants were tested: hitting the target in a single-shot movement and hitting the target repeatedly using a rhythmic action to keep the whip in the air. We recruited one expert with 20 years of experience who performed one session of data collection. Fifteen novice participants practiced the task in 15 sessions over 5 weeks. The novices could view the expert performance as a model for their practice. Kinematics of subjects' torso, dominant arm, and the whip were measured with 3D motion capture. Ten markers attached to the whip were used to reconstruct this continuous object. Remarkably, analyses of the expert data revealed that variability over successive actions was smaller and the precision of hitting the target was higher

during continuous rhythmic movements. Principal component analysis of the seven markers on the whip revealed that variability decreased from the shoulder to the tip of the whip. Analysis of the novice participants' data showed that the error between the tip of the whip and the target decreased with practice, indicating skill learning. In addition, subjects were able to reduce the dimensionality of motions of their arm and torso and approach a reproducible near-planar motion of the whip. Maximum force and torque during each attempt decreased, leading to smoother whip movements. These trends were more pronounced when the task was performed rhythmically. Based on these first results, we suggest that subjects may represent this prodigiously complex dynamic object in terms of the primitive actions—rhythmic and discrete—they may use for interactive control. Faster learning with rhythmic performance may arise from the stability of the dynamic attractor that underlies rhythmic actions.

Title: Portable control system enables dexterous home use of an advanced bionic arm

Authors: *M. R. BRINTON[1], E. L. BARCIKOWSKI[5], T. S. DAVIS[2], J. A. GEORGE[1], M. D. PASKETT[1], D. J. WARREN[1], C. C. DUNCAN[3], D. T. HUTCHINSON[4], G. A. CLARK[1]; [1]Biomed. Engin., [2]Neurosurg., [3]Physical Med. and Rehabil., [4]Orthopaedics, Univ. of Utah, Salt Lake City, UT; [5]Ripple Neuro, Salt Lake City, UT

Abstract: We present advances in developing and implementing a portable bionic-arm system with intuitive, dexterous control of several degrees-of-freedom (DOFs) using electromyographic (EMG) recordings and naturalistic, high-resolution sensory feedback. A portable processor (Nomad; Ripple, LLC) records and down-selects from 496 differential EMG channels (from 32 single-ended electrodes); predicts user intent using a modified Kalman filter (George et al., SfN 2019); and controls an advanced six-DOF bionic arm (DEKA "LUKE" Arm). To train the modified Kalman filter (MKF), users simply press a button and the portable processor records EMG signals while the users mimic preprogrammed movements of the bionic arm with their phantom limb and residual forearm muscles. The MKF is trained and the user has full control of the bionic arm in less than 15 minutes. Previously trained algorithms can also be loaded for

immediate use. The portable system stores the arm's 6 position and 13 force sensor values (sampled at 33 Hz) for post-hoc analysis. This rich dataset allows us to understand how amputees use prosthetic arms for daily tasks specific to their circumstance and of their own choosing—unlike predefined generic tasks often performed in controlled laboratory settings. For example, analyses of these data can provide information about preferred grasps and their frequency and strength. An upper-limb amputee performed a preliminary, supervised take-home trial of the portable system to complete activities of daily living (ADLs) of his own choosing and in his own home (e.g., donning shoes, opening/locking doors, turning on faucet, playing with dog, taking out trash, opening refrigerator). The participant repeatedly expressed his surprise and pleasure with the portable system. While opening and locking a door, he exclaimed "I couldn't do that with my [commercial prosthetic arm], for sure!"; while opening refrigerator and cabinet doors he remarked, "I would have never thought that would happen!" and "That [task] was a little more precise than I thought I could do." Ongoing developments include incorporating biomimetic stimulation (for closed-loop sensorimotor control) via implanted Utah Slanted Electrode Arrays; more advanced control algorithms (e.g., convolutional neural network); and a user-friendly tablet-based interface to train and adjust the motor control and sensory feedback algorithms via the portable processor's Wi-Fi network. When complete, this portable bionic-arm system will enable us to explore the functional and psychological benefits associated with long-term, at-home use of sensorized and dexterous bionic arms.

Title: Shared controllers improve control and performance of upper-limb prostheses

Authors: T. C. HANSEN[1], H. DANTAS[2], J. A. GEORGE[1], G. A. CLARK[1], *D. J. WARREN[1], V. MATHEWS[2];
[1]Biomed. Engin., Univ. of Utah, Salt Lake City, UT; [2]Oregon State Univ., Corvallis, OR

Abstract: This work explores approaches to provide intuitive and reliable control of bionic arms via a shared control system that uses multiple control algorithms in parallel, where a linear combination of their outputs is the control signal. Using multiple algorithms could provide the benefits of each algorithm while reducing the disadvantages of each alone. This system could allow for self-aware bionic arms that assist the user in efficiently performing everyday tasks.
We present a shared controller consisting of two control algorithms: a Kalman filter (KF) movement intent decoder and a classifier decoder employing a multilayer perceptron (MLP). The KF decoder allows for proportional real-time adjustments but is more prone to unintended movements than the MLP decoder. Each decoder was trained on 32 channels of surface electromyography (EMG) data obtained non-invasively from three intact-arm subjects (one subject was an author). During testing trials, the subjects performed a target touching task in a virtual environment where they moved digits of a virtual hand to specific targets and held them there for as long as possible. The percent time in the target region (PTTR) was calculated for each trial. Each subject's data were analyzed separately, treating each trial as a separate observation.
Experiments using the KF-only decoder or the MLP-only decoder had a median PTTR of 17% and 16%, respectively. The median PTTR for shared control ranged from 21% to 68% (Fig. 1). The shared controller PTTR was significantly higher than either the KF or MLP decoders alone across all subjects (Conover-Iman, $p < 0.001$ and $p < 0.001$, respectively, corrected for multiple comparisons). Given the limited sample size of this preliminary data, we intend to perform testing in additional subjects.
Following these results, we have begun investigating a shared control system using a bionic hand with sensors on the fingertips that detect proximity to a nearby object and contact pressure. We propose using shared control between EMG-based and proximity/pressure-based controllers to assist in reaching for and grasping objects.

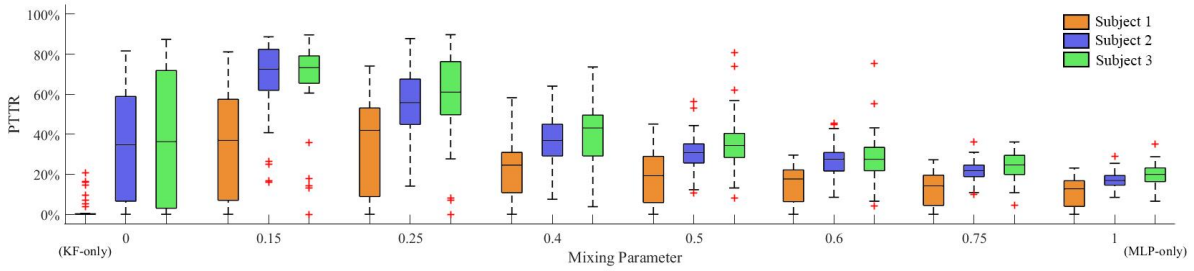

Fig. 1: Percentage Time in Target Region (PTTR) for a target touching task. Trials with KF-only control had a median PTTR of 17%, and trials with MLP-only control had a median PTTR of 16%. The shared controller with mixing parameter 0.15 (15% MLP and 85% KF) had the highest median PTTR at 68%, significantly outperforming the KF-only and MLP-only decoders across all subjects (Conover-Iman, $p < 0.001$ and $p < 0.001$, respectively for all subjects, corrected for multiple comparisions). Outliers outside upper or lower quartiles by ≥ 1.5 * IQR indicated with +

Abstract: Hand gestures offer a natural way for humans to control, interact with, and engage with intelligent systems and devices. Applications of hand gesture recognition range from providing touchless user interfaces for consumer electronics to enabling natural, dexterous control of robotic arms and rehabilitative prostheses. Because many of these applications require long-term, continuous use of the device, it is crucial for hand gesture recognition systems to be contained within small, wearable form factors.
Here, we present a wearable, wireless system for EMG-based gesture recognition that enables high-density EMG acquisition and signal processing, as well as completely on-board and online training, inference, and incremental updates using a hyperdimensional (HD) computing machine learning model. The system consists of a custom-designed, screen-printed 64-channel flexible electrode array that minimizes wiring and enhances comfort without sacrificing signal quality. The electrode array interfaces with a device featuring a custom-designed low-power integrated circuit used to sample and digitize EMG for processing in an on-board FPGA, where we have implemented an HD computing classification algorithm.
Signal properties change with sweating, fatigue, muscle contraction effort, and electrode displacement due to changing situational contexts such as limb and body position or device doffing and donning. These variations can cause significant degradations in classification accuracy, usually because a new situational context was not considered during model training. Therefore, it is particularly important to be able to train or update the classification model on-the-fly, which is implemented efficiently on the hardwareby leveraging HD computing. We

achieve above 95% accuracy in classifying 21 common finger gestures, with little accuracy degradation between different arm positions and wear sessions.

Title: A synergy-model-based regression for simultaneous, intuitive, proportional, high degree-of-freedom control in a prosthetic hand from chronically implanted EMG evaluated in virtual reality

Authors: *P. LUKYANENKO, H. DEWALD, J. LAMBRECHT, R. F. KIRSCH, D. J. TYLER, M. WILLIAMS;
Biomed. Engin., Case Western Reserve Univ., Cleveland, OH

Abstract: With the development of high degree-of-freedom (DoF) prosthetic hands, patients' need for improved prosthetic hand control has become clear. One drawback of current feedforward controllers is their dependence on a high volume of user data needed for controller training and the frequent need for recalibration. We have previously demonstrated an intuitive, proportional, simultaneous and regression-based controller in 3 DoF using a K-nearest-neighbor decoder which remained stable over several months when using chronically implanted EMG. To create a similar controller with the added capability of scaling to higher DoF without requiring a prohibitive volume of user data, we leveraged a muscle synergy framework. The muscle activity in training data creates basis vectors in EMG feature space based on underlying muscle synergies. During operation, the algorithm decomposes EMG patterns into linear combinations of learned muscle patterns. This process allows training on simple, isolated DoF activities to be composed into several degrees of freedom simultaneously, arbitrarily, and with user controlled rates of motion. All clinical trials were performed under IRB, FDA, and DoN HAARP approval. Two trans-radial amputee subjects were implanted with bipolar EMG electrodes with percutaneous indwelling leads. At the time of the study, one subject (S8) had 8 functioning

bipolar electrodes, and the other subject (S6) had six. To gather training data, a VR system was used to guide users through sample movements in three and four degrees of freedom. To evaluate controller performance, subjects were asked to match a comprehensive set of targets in VR with 3 and 4 DoF controllers, as well as with their intact limb. 80 targets were presented in batches of 16, with user-defined rest periods between targets and 30 second time limits.
Targets were generated in a quasi-random manner to evenly sample gross movements in 3 and 4 Dof. Metrics include time-to-target and path efficiency. EMG controllers were re-evaluated over a 6-month period without retraining to evaluate stability over time. In 3 DoF, S8 and S6 performance remained consistent over 6 months post-training. Time-to-match was between 50 and 100% higher than corresponding intact limb match times. In 4 DoF over 6 months post-training S8 performance trended towards improvement whereas S6's match rate decreased substantially. This deterioration is likely due to an insufficient number of EMG channels being used to move in a higher dimension space. These results indicate that a synergy-model-based-regression is a promising method for high degree of freedom prosthetic hand control, provided sufficient EMG channels.

Title: Combining data-driven and modeling-based approaches to improve myoelectric motor decoding

Authors: *R. M. HINSON, Jr[1], H. HUANG[2];

Abstract: The neural decoding of motor intent is a complex problem that is an active subject of research in rehabilitation fields. In particular, electromyography (EMG) is commonly used for the control of upper limb prosthetic devices by amputees because it is a readily accessible and rich source of neural information encoding motor commands. This technology has been widely applied using pattern recognition to map EMG activation patterns to multi-joint, physiologic motions for intuitive control. However, this approach only allows for a discrete set of motions to be generated by users. As a result, efforts to allow for continuous and simultaneous multi-joint

control have increased. These continuous mappings of EMG to motion have been implemented using machine learning-based techniques as well as musculoskeletal modeling-based approaches. In previous work, we implemented a generic (non-customized parameters) musculoskeletal model that multiple subjects used to control a virtual hand with no significant difference in performance compared to customized models. While transferable between users, this model was not optimized for each user. Therefore, in this study we aim to combine this generic musculoskeletal model with a data-driven model to improve performance while keeping the decoder transferable between users. We recorded motion capture data of 6 able-bodied subjects performing wrist flexion/extension and metacarpophalangeal (MCP) flexion/extension in cyclic and random motions in 9 different postures. This data was time-synced with surface EMG data from the extensor digitorum, flexor digitorum superficialis, extensor carpi radialis longus, and flexor carpi radialis muscles. An autoregressive kinematic model was trained using half the available data. The other half of the data were used for evaluation. This data-driven model was combined with the generic musculoskeletal model using an Unscented Kalman Filter. The data-driven model was used to predict the kinematics between timesteps while the musculoskeletal model used the EMG data for the update step. The results were compared to the musculoskeletal model alone. Preliminary results show no change in root mean square error (RMSE) or correlation (compared to kinematic data) for the wrist joint. However, significant ($p < 0.05$) decreases of 11.97%, 8.63%, and 6.81% in RMSE of MCP joint angle prediction were observed for isolated wrist, isolated MCP, and simultaneous joint motions, respectively. This demonstrates the potential benefits of this approach for motor decoding and prosthesis control, as it improves predictive accuracy while using generalizable approaches that don't require customization.

Title: Different motor unit recruitment pattern between peripheral nerve stimulation and motor point stimulation

Authors: *K. NAKAGAWA[1,2], K. L. FOK[1,3], K. MASANI[1,3];

Abstract: Neuromuscular electrical stimulation is widely used to induce muscle contractions in many clinical settings. Neuromuscular electrical stimulation can be delivered via peripheral nerve stimulation (PNS) and motor point stimulation (MPS). Although MPS is often used in clinical settings such as upper and lower limb rehabilitation, its neural mechanism is not completely understood. Here we investigated the recruitment pattern of the motor unit during MPS compared to PNS. Ten able-bodied individuals participated. We measured electromyograms of plantarflexor muscles and the ankle joint torque. Twitch contractions were induced through tibial nerve stimulation for PNS and motor point of soleus muscle for MPS. When the stimulation intensity was gradually increased from the sub-threshold to the maximum, M-wave, H-reflex, F-wave and twitch torque were identified. We analyzed the duration from torque onset to peak torque (time-to-peak) to investigate the recruitment order of motor unit. H-reflex and M-wave were identified in PNS, while MPS did not evoke H-reflex but M-wave and F-wave. When we focused on the stimulation intensities with which only H-reflex was induced in PNS, we found that time-to-peak was longer in PNS than MPS, and that time-to-peak in MPS increased with increasing stimulation intensity while time-to-peak in PNS did not change depending on the stimulation intensity. Since time-to-peak reflects the balance of fast and slow muscle fibers recruited, shorter/longer time-to-peak indicates that fast muscle fibers were recruited more/less. Thus, these results suggested that the recruitment pattern of motor unit is reverse of the size principle in MPS, while random in PNS.

Title: Compound muscles action potential (CMAP) as a new outcome measurement in SOD1 mouse model of ALS and oxaliplatin-induced polyneuropathy in mice

Authors: *R. O. PUSSINEN, T. BOLKVADZE, J. TOIVANEN, A.-M. KÄRKKÄINEN, M. DUDEK, D. MISZCZUK;

Abstract: A motor neuron can activate hundreds of muscle fibers in synchrony with one single action potential, and the resulting electric signal is detectable from the muscle itself by electromyography (EMG). When the appropriate nerve is stimulated electrically, the evoked responses can be measured with surface or needle electrodes at a distal muscle level. Compound Muscle Action Potential (CMAP) is the measure of the evoked potential. CMAP is a clinically relevant measure frequently utilized in research studies such as oxaliplatin induced

polyneuropathy and in monitoring of patients with neuromuscular disorders such as amyotrophic lateral sclerosis (ALS). Also, CMAP measurements correlate well with age, severity and clinical measures of function. Furthermore, CMAP is minimally invasive and allow assessment of function longitudinally in the same individual.
In the present study, CMAP was measured in SOD1 mice and age-matched non-transgenic control littermates weekly on 8-18 weeks of age in parallel with clinical score assessment. In oxaliplatin model, male C57BL/6J mice were dosed with six injections of 4.5 mg/kg oxaliplatin i.p. (at days: 0, 4, 8, 12, 16, 20) and CMAP as well as cool allodynia acetone test was measured on days -4, 22, 29, 36 and 43. In all experiments, CMAP was recorded under isoflurane anesthesia. The stimulation was done close the sciatic nerve at the proximal hind limb using 26 G monopolar stimulation needle. Recording was performed on the skin overlying the proximal portion of the gastrocnemius muscle of the hindlimb. The sciatic CMAP responses were obtained by stimulating the sciatic nerve with square-wave pulses of 0.1 ms duration and intensity ranging from 1-10 mA.
Our electrophysiological investigations show that oxaliplatin challenge resulted in deficits in temporal summation in motor units and therefore evoke motor weakness and/or coordination. Furthermore, the progressive decrease of CMAP amplitudes was observed in SOD1 mice. Current data supports the use of this electrophysiological technique in the preclinical research of neuromuscular function in phenotyping as well as in future efficacy studies for drug development.

Title: Electromyography device for effective communication in spastic cerebral disease

Authors: *G. LOPEZ-ARMAS, J. MARGAIN-MORENO, A. ARENAS-PEREZ, Y. NAVA-RAZO, D. GONZÁLEZ-MORALES;
Ctr. De Enseñanza Técnico Industrial, Guadalajara, Mexico

Abstract: Introduction: Spastic cerebral palsy is the most common type of cerebral palsy accompanied of cognitive impairment. Spasticity is a form of hypertonia, or increased muscle tone. This results in stiff muscles which can make movement difficult or even impossible. Therefore people may have difficulty moving from one position to another and controlling individual muscles or muscle groups needed for performing certain tasks like handling objects or

speaking due smaller muscles or muscle groups such as the tongue, facial muscles or vocal folds also are affected. In this work, we present a novel device that allow a direct communication that uses a signals from surface EMG to control a mobile application that allows the user with cerebral palsy to choose simple pictograms into a tablet through one muscle movement.
Methodology: The first stage consist an integrate instrument amplification and series of circuits that allow us to filter the signal in a range of 20 to 500 Hz, this stage is supplied by a 9 volt battery. In the stage of processing the signal, it an ADC included in a programed microcontroller. Each electrical pulse sends a command by serial communication to the mobile application. The application contains a bank of pictograms organized into the following categories: social, people, verbs, things, descriptive, places and micellanious. Each of the categories mentioned above is represented by basic colors that is used internationally. The developed application envioroment used is Ionic Framewok B4. This tool allows to create application on multiple plataforms (iOS, native Android, desktop and web as a progressive application) that can be updated and implemented with the server built into the cloud, focuses on the user experience with the interface and allows the user to navigate using the command received by serial communication, this system adapts to the cognitive abilities of the user, delimiting the number of words or phrases known by the user, as well as their mobility, since for its use It is only necessary to move a muscle voluntarily.
Results: We demonstrate the use of this device with 3 children with medical diagnostic of spastic cerebral palsy. We observe that users feels independence to communicate, which significantly improves their way of interacting with people and their quality of life.

Title: Development of a wearable sensor array for performing high-density electromyography in ambulatory subjects

Authors: *C. N. SCHOENEWALD[1], J. E. TING[2], D. SARMA[1], D. J. WEBER[3];
[1]Physical Med. and Rehabil., [2]Bioengineerng, [3]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Peripheral neuropathy (PN) and diabetic polyneuropathy (DPN) are examples of neurological complications which cause sensory and motor fiber impairments, as well as pain, often localized in the lower-limbs. Diagnosing early stage muscle pathophysiology in conditions such as these is routinely completed through surface electromyography (sEMG). While traditional bipolar sEMG provides limited coverage of muscle activity, a high-density array of electrodes, specifically designed to align with muscle fibers, can measure and map myoelectric signals propagating throughout the entirety of a muscle. Furthermore, recording with a high-density array allows for decomposition of the composite activity into signals from individual motor units. Untethered, high-density arrays of sensors for measuring volitional and stimulation-evoked muscle activity across an entire leg have the potential to provide novel insights into the post-impairment functional recruitment of muscles during ambulation. As a step in the development of a wearable tool, preliminary studies were performed in able-bodied subjects during cued ankle movements with a prototype 32-channel high-density myoelectric array (HDMA), oriented over the medial and lateral gastrocnemius muscles. To obtain ideal interelectrode distances (IEDs), physiological features such as density and direction of muscle fibers, as well as surface area and depth of muscles were analyzed. Myoelectric features such as root-mean-square, an indicator of the amplitude of activity, and the power spectral density of the signal, a representation of the frequency content, were also considered. An assessment of the similarity in features across electrode pairs in the array showed a decrease in high correlation values at a horizontal IED of 40mm and a vertical IED of 15 mm. These were determined to be maximal spacing for collection over the subset of muscles in the calf region. Wearable HDMAs may offer new insights into the the myoelectric dynamics and spatiotemporal features of musculoskeletal control.
