Abstract: A glycoprotein Reelin secreted into the extracellular matrix by Cajal-Retzius cells has been implicated in the control of neuronal migration and positioning during bran corticogenesis. In the present study, we observed in E12-16 brain of reelin-deficient reeler mouse that production of Tbr2-positive intermediate progenitor cells (IPCs) was suppressed in progenitor compartments (SVZ and IZ). In addition, expression of Ngn2 which directly activates Tbr2 expression was also delayed. Conversion from IPCs to Tbr1-positive postmitotic neurons in preplate is markedly decreased in reeler mice. We found that depression of p27kip1 protein, a CIP/Kip family, was observed in the in the preplate and cortical plate in reeler mice. In particular, cell culture study showed that depressed level of p27kip1 in reelin deficient condition was recovered by reelin treatment. Thus we suggest that reelin-induced p27kip1 pathway may be involved in neuronal differentiation of early-born neurons

Title: Compound screen on the proliferation and differentiation of neural progenitor cells

Authors: X. XIA, *S. T. WONG, D. GAO, X. XU, T. ZHOU;
Systems Med. and Bioengineering, Houston Methodist Res. Institute, Weill Cornell Med. Col., Houston, TX

Abstract: Neural progenitor (NP) cells are the multipotent cells that produce neurons and glial cells in the central nervous system, small molecule compounds promoting their proliferation and neuronal differentiation are of pivotal importance to regenerative medicine. We carried out a high-content screen to systematically characterize known bioactive compounds, on their effects on the self-renewing division, neuronal differentiation and dopaminergic neuronal differentiation of NP cells. The screen successfully identified major effective pharmacological classes, and allowed us to compare the pharmacological responsive profiles of several types of widely used NP cells. This study revealed the potential of several small molecule compounds for use in regenerative medicine or transplantation therapy. The screening result also provided insight into the signaling network regulating the neuronal differentiation of NP cells.

Title: Signaling through gp130 and Jak/Stat regulates the proliferation and neurogenic capacity of Müller glia-derived progenitor cells in the avian retina

Authors: *L. J. TODD, A. J. FISCHER;
The Ohio State Univ., Columbus, OH

Abstract: Müller glia can be stimulated to de-differentiate, proliferate and form Müller glia-derived progenitor cells (MGPCs) that are capable of regenerating retinal neurons. The capacity of MGPCs to regenerate retinal neurons varies considerably across vertebrates. The MGPCs in zebrafish retina are able to restore fully functional neurons after injury. By contrast, proliferating MGPCs can be formed in the retinas of birds and mammals, but these cells appear to be biased to form new glia or remain undifferentiated. Thus, one of the key hurdles to harnessing the

regenerative potential of MGPCs is to identify means to stimulate neurogenesis from these cells. In the zebrafish retina, several key cell-signaling pathways have been identified to drive the de-differentiation of mature Müller glia and formation of proliferating of MGPCs. One of these key cell-signaling pathways is the Jak-Stat-pathway. In the retinas of warm-blooded vertebrates, the Jak-Stat pathway is known to stimulate glial differentiation during development and induce gliotic phenotypes in mature glia. We investigated whether Jak-Stat signaling influences the reprogramming of Müller glia and neuronal differentiation of the progeny produced by MGPCs in the avian retina *in vivo*. We observed that pStat3 accumulates selectively in Muller glia in response to intraocular injections of CNTF, FGF2 and retinal damage. We found that inhibition of gp130 receptor, JAK2 kinase or Stat3 suppresses the formation of MGPCs in NMDA-damaged or FGF2-treated retinas. By comparison, activation of Jak-Stat signaling via intraocular injections of CNTF with FGF2 significantly increased numbers of proliferating MGPCs in the absence of retinal damage. Evidence is provided that inhibition of Jak-Stat signaling may impact the formation of MGPCs in the FGF2-treated retina through modulating activation of microglia. Importantly, when signaling through the gp130 co-receptor is inhibited after the proliferation of MGPCs, we found a significant increase in neuronal differentiation at the expense of glial differentiation. Inhibition of gp130 resulted in decreased mRNA levels of notch1, hes1 and hes5, components of the Notch-pathway which are known to inhibit neuronal differentiation. We conclude that Jak-Stat signaling plays important roles during the formation of proliferating MGPCs and differentiation of their progeny. We propose that that targeting gp130 co-receptor and the Jak-Stat pathway may be a means to increase the neurogenic capacity of MGPCs in higher vertebrates.

Title: Transcriptome analysis of neural progenitor cells and immature neurons in optic tectum of Xenopus laevis

Authors: *L.-C. HUANG[1], J. CORNELIUS[2], A. YERI[3], K. KUSUMI[2], K. VAN KEUREN-JENSEN[3], H. T. CLINE[1];
[1]Dorris Neurosci. Ctr., The Scripps Reearch Inst., La Jolla, CA; [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Neurogenomics Div., Translational Genomics Res. Inst., Phoenix, AZ

Abstract: In the developing optic tectum of Xenopus laevis, neural progenitor cells undergo symmetric proliferative division, asymmetric neurogenic division and direct neuronal differentiation (Bestman and Cline, 2012). To provide insights into mechanisms that govern progenitor cell self-renewal and neuronal differentiation, an unbiased analysis on the transcript profile of neural progenitor cells and immature neurons was conducted. The midbrain of stage 46 animals was electroporated with a plasmid from which turboGFP reporter expression was driven by sox2/oct4 enhancer and minimal FGF promoter. TurboGFP+ve neural progenitor cells were enriched from animals reared in dark for 24 hours after electroporation, while turboGFP+ve immature neurons were enriched from animals reared in enhanced visual stimulation for 24 hours (Sharma and Cline, 2010; Bestman et al., 2015). These GFP+ve cells were isolated, using Fluorescence-activated cell sorting (FACS), and their mRNA was amplified in order for their transcripts to be analyzed by RNA-seq. Transcriptome analyses revealed distinct gene expression profiles in neural progenitor cells and immature neurons. ~70% of the reads were aligned to the X. laevis genome scaffolds (Xenbase: genome scaffold assembly v7.1 with gff3 v1.6), which confirms the specificity of the RNA amplification protocol. Out of the aligned reads, ~31% were intergenic, and ~61% were mRNA, in average. Over 54,000 annotated genes in X. laevis genome, 724 and 783 of transcripts were differentially expressed between neural progenitor cells and immature neurons, using Tophat2 and STAR as the aligner, respectively. Of these differentially expressed transcripts, ~ 60% were up-regulated, and ~ 40% were down-regulated. Genes with differential expression were clustered into the following categories, based on their molecular function, using DAVID, a functional annotation tool: voltage-gated ion activity, calcium binding, protein serine/threonine kinase activity, extracellular matrix structure constituent, transcriptome co-factor activity, and endoribonuclease activity. Transcriptome analyses revealed the complexity of transcript profiles between neural progenitor cells and immature neurons. These studies enhance our understanding the molecular mechanisms that regulate the fate of neural progenitor cells differentiated into neurons.

Title: DLX transcriptional regulation of neural progenitor cell fate in the developing forebrain

Authors: ***S. JAPONI**[1], M. CASEY[1], J. ZAGOZEWSKI[1], D. D. EISENSTAT[2];
[1]Dept. of Med. Genet., [2]Dept. of Med. Genet. and Dep. of Pediatrics, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Introduction Differentiation of inhibitory interneurons from neural progenitors and their migration to appropriate regions in the forebrain contributes to maintaining the balance between excitation and inhibition crucial for proper neural function. Dlx homeobox genes encode transcription factors that specifically bind to homeodomain binding sites in regulatory regions and regulate target gene expression. In the Dlx1/2 double knockout (DKO) mouse, tangential migration of inhibitory interneurons from the ganglionic eminences to the neocortex is impaired. Disruption of signaling by the CXCR4 chemokine receptor results in improper migration of interneurons in the forebrain. We hypothesize that Dlx2 promotes interneuron differentiation and migration by activating Cxcr4 expression. Methods We have used chromatin immunoprecipitation (ChIP) of embryonic mouse forebrain (E13.5) using a specific antibody to DLX2 followed by PCR using oligonucleotide primers flanking candidate homeodomain binding TAAT/ATTA motifs. Targets are characterized using gel shift and reporter gene assays *in vitro* and validated by gene expression studies *in vivo* comparing wild-type and DKO forebrain tissues. Results ChIP-based PCR demonstrated that DLX2 binds to regions containing putative DLX2 binding sites upstream of the transcriptional start site of Cxcr4. Dlx2 significantly affected luciferase reporter gene expression *in vitro* when co-expressed with the regulatory regions of Cxcr4 occupied by DLX2 *in vivo*. Furthermore, gel shift assays revealed the critical sites on Cxcr4 necessary for DLX2 binding. Quantitative RT-PCR showed a decrease in transcript level of Cxcr4 in the Dlx1/2 DKO tissues compared to the WT supporting an activating role for DLX2 on Cxcr4 expression *in vivo*. Conclusions Our results support the hypothesis that DLX2 directly activates expression of Cxcr4, thereby contributing to the transcriptional regulation of differentiating and migrating interneurons in the developing forebrain. This proposed research study will contribute to the emerging evidence supporting a role for DLX transcription factors in maintaining the balance of excitation to inhibition during brain development.

Title: Positive feedback between RNA binding protein HuD and transcription factor SATB1 promotes neurogenesis

Authors: F. WANG[1], J. J. TIDEI[1], E. D. POLICH[1], Y. GAO[1], N. PERRONE-BIZZOZERO[2], W. GUO[3], *X. ZHAO[1];

Abstract: The mammalian ELAV-like protein HuD is a neuronal RNA-binding protein implicated in neuronal development, plasticity, and diseases. Although HuD has long been associated with neuronal development, the function of HuD in neural stem cell differentiation and the underlying mechanisms have gone largely unexplored. Here we show that HuD promotes neuronal differentiation of neural stem/progenitor cells (NSCs) in the adult subventricular zone by stabilizing the mRNA of special AT-rich DNA-binding protein 1 (SATB1), a critical transcriptional regulator in neurodevelopment. We find that SATB1 deficiency impairs the neuronal differentiation of NSCs, whereas SATB1 overexpression rescues the neuronal differentiation phenotypes resulting from HuD deficiency. Interestingly, we also discover that SATB1 is a transcriptional activator of HuD during NSC neuronal differentiation. In addition, we demonstrate that NeuroD1, a neuronal master regulator, is a direct downstream target of SATB1. Therefore, HuD and SATB1 form a positive regulatory loop that enhances NeuroD1 transcription and subsequent neuronal differentiation. Our results here reveal a novel positive

feedback network between an RNA-binding protein and a transcription factor, which plays critical regulatory roles in neurogenesis.

Title: Maternal high-fat diet alters neurogenesis in the embryonic mouse forebrain

Authors: ***M. NAMIHIRA**[1], M. YAMANO[2], K. HIRANO[1], M. I. OTSUKA[3], K. IGARASHI[3]; [1]Biomed. Res. Institute, AIST, Ibaraki, Japan; [2]Dept. of Comprehensive Rehabil., Osaka Prefecture Univ., Osaka, Japan; [3]Life Sci. Tokyo Advanced Res. center (L-StaR), Hoshi Univ. Sch. of Pharm. and Pharmaceut. Sci., Tokyo, Japan

Abstract: Epidemiological and animal studies have reported that maternal overconsumption of saturated fats during pregnancy influence on offspring health, ranging from metabolic to behavioral disorders. However, little is known about the influence of the maternal unbalanced diet on the development of embryonic brain including neurogenesis of neural stem cells. Here, we show that maternal high-fat diet (HFD) impact on epigenetic regulation of neural precursors and alter the differentiation of these cells in fetal cortex of mice. In late-gestational stage, embryonic cortex exposed maternal HFD exhibited the enhancement of neuronal production and hyper-acetylation of histone H3 lysine in neural precursors. The analysis of genome-wide gene expression by RNA-seq revealed that the expression of several genes involved in neuronal and glial differentiation of neural precursors were significantly altered in these embryonic cortex. We also found that Hippo pathway effector YAP was inactivated in the cortex. Furthermore, postnatal young male mice exposed maternal HFD display hyperactivity only at night. Taken together, these results suggest that an unbalanced diet during pregnancy alters the neurogenesis in embryonic forebrain through the epigenetic changes and the inactivation of Hippo pathway in neural precursors, and that it may be as a potent risk factor of neurodevelopmental disorder. Further analysis of the influence of maternal HFD on fetal brain development is currently underway.

Title: Perturbations of the albino mouse retinal pigment epithelium during retinal ganglion cell genesis

Authors: *L. IWAI, A. RAMOS, A. SCHALER, S. WEINREB, K. ROBINSON, R. BLAZESKI, C. A. MASON;
Pathology and Cell Biol, Columbia Univ., New York, NY

Abstract: During early eye development, the retinal pigment epithelium (RPE) is apposed to the neural retina. As the RPE acquires pigment, retinal ganglion cells (RGCs) are born and specified into the ipsilaterally- and contralaterally-projecting subpopulations. This divergent RGC projection is the basis for binocular vision. In mice, the ipsilateral projection arises from the ventrotemporal (VT) retina from embryonic ages (E) 13.5 and E15.5. Our previous studies identified genes that specify the two RGC subpopulations, e.g., Zic2 and EphB1 that regulate cell fate and projection of ipsilateral RGCs. In albino mammals, disruption of pigmentation in the RPE results in a reduced ipsilateral RGC projection. Our studies showed that in the albino mouse retina, the peak of RGC birth in the VT retina is delayed by about a day, resulting in fewer Zic2-positive RGCs that are born between E13 and E14, mirroring the reduction of ipsilateral RGCs. The RGCs that are born at E17.5, instead, express the contralateral RGC marker Islet2 (Bhansali et al., 2014). These data suggest that the timing of neurogenesis is linked to RGC subtype specification. To further probe how the RPE and the pigment pathway regulate RGC

neurogenesis and cell fate specification, we compared features of wild type RPE with albino RPE during embryonic development. First, using IHC, ISH and EM, we analyzed the morphological and cell biological features of albino and pigmented RPE at E13.5, 15.5 and 17.5. Cell shape, melanosome localization, and gap junction protein (Cx43) expression, localization and phosphorylation state are disrupted in the albino RPE. Second, we are identifying gene expression differences in albino and pigmented RPE at E13.5. Our microarray data analyzed by GSEA indicates that more genes are upregulated than those that are downregulated in albino RPE compared with pigmented RPE. Those genes that are enriched in albino retina include signaling, cytoskeleton, and cell junction/adhesion genes. Signaling genes more highly expressed in albino RPE compared with pigmented RPE are related to Wnts, BMPs, Hedgehog, and Notch. Our results suggest that perturbation of the cell biology of the albino RPE during RGC genesis may affect the integrity of the RPE and in turn, the transmission of factors affecting RGC specification. These studies should reveal how the RPE normally affects neural retinal development, and provide guidelines for directing stem cells into RGCs for replacement in injured or degenerating visual pathways.

Title: Role of GDNF/GFRα1 on neural stem cells development

Authors: *A. BONAFINA, P. FONTANET, D. IRALA, G. PARATCHA, M. LEDDA;
Div. of Mol. and Celular Neurosci., Inst. of Celular Biol. and Neurosciences, Buenos Aires City, Argentina

Abstract: The cerebral cortex is among the most complex of all biological structures and the major site of higher cognitive functions specific to our species. During its development, progenitors proliferate in the ventricular zone and then migrate into the cortical layers where they differentiate into specific cell types. This timed sequence of the developmental process is controlled by an intrinsic cellular program, as well as extrinsic environmental cues. Because impaired regulation of progenitors causes many developmental disorders, it is crucial to understand the mechanisms underlying the behavior of progenitors, including migration, proliferation, and differentiation. Glial cell line-derived neurotrophic factor (GDNF) was originally discovered because of its ability to promote the survival of ventral midbrain dopaminergic neurons. GDNF signals by binding to the glycosylphosphatidylinositol-anchored receptor GFRα1 in complex with the canonic receptor tyrosine kinase Ret or the neural cell adhesion molecule (NCAM). GDNF and its receptor GFRα1 have been reported to have an essential role in cell migration and differentiation in the peripheral and central nervous system. In particular, GDNF can stimulate migration of precursors of inhibitory interneurons in the rostral migratory stream, and the cerebral cortex. However the role of GDNF/ GFRα1 in the forebrain development is still unknown. In the present work, we set out to investigate new roles of GDNF in the developing nervous system. In particular, we analyzed the role of GDNF and its receptor GFRα1 in the development of cortical precursors. Our results indicate that GDNF and GFRα1 control the transition of neuronal glutamatergic progenitors from a proliferative state towards neuronal differentiation, in a Ret-independent manner. We show that GDNF is able to arrest the proliferation of cultured neuronal precursors induced by bFGF promoting neuronal morphological differentiation. The physiological relevance of this system in cell cycle arrest and differentiation of neuronal precursors is being elucidated in GFRα1-conditional mice.

Title: CLASP2 regulates symmetric divisions of neural progenitor cells in early brain development

Authors: *G. M. DILLON[1], W. TYLER[2], K. OMURO[1], T. F. HAYDAR[2], U. BEFFERT[1], A. HO[1];
[1]Biol., [2]Anat. and Neurobio., Boston Univ., Boston, MA

Abstract: Brain development requires the precise timing and control of progenitor cell divisions to produce neurons which migrate into the six major cell layers of the neocortex. Excitatory projection neurons arise from the proliferative epithelium lining the cerebral ventricles. Within this proliferative zone, post-mitotic neurons can be generated from both radial glial cells (apical progenitors) present at the ventricular zone and by intermediate progenitor cells (basal progenitors) found predominantly in the subventricular zone. During cell division, the mitotic spindle is a polarized, microtubule based structure that acts as a cellular scaffold to facilitate the proper segregation of genetic material. Previous evidence demonstrates that microtubule plus-end binding proteins (+TIPs) are essential factors in regulating orientation of the mitotic spindle through connections between the centrosome and kinetochore. In non-neuronal cells, CLIP-associating proteins (CLASPs) are +TIPs that have been shown to be enriched at both the centrosome and kinetochore during mitosis and play an important role in regulating spindle positioning, pole integrity, and chromosome alignment. However, little is known about the role of CLASPs during neural progenitor divisions of the developing forebrain. To determine whether brain-enriched CLASP2 is directly involved in the timing and control of neurogenesis, we performed *in utero* electroporation loss-of-function studies. We electroporated shRNA constructs of CLASP2 or scrambled control into the lateral ventricle of wild type mice at embryonic day 14.5 and analyzed brain sections 48 hours later. During this time, apical progenitors at the ventricle are transitioning from symmetric, self-renewing divisions to asymmetric divisions producing post-mitotic neurons and/or intermediate progenitor cells. We found that CLASP2 knockdown caused a specific increase in the Sox2-positive, apical progenitor population with no overall change in the Tbr2-positive, intermediate progenitor population. In addition, CLASP2 knockdown produced an increase in the percentage of cells expressing the cell cycle marker Ki67 suggesting that the increased apical progenitor population may be stuck in a proliferative state. These findings correlated with an increase in the angle of the mitotic spindle following CLASP2 knockdown. Overall, our results suggest that CLASP2 has a specific role in the transition of apical progenitor cells from symmetric to asymmetric divisions affecting the population of proliferative cells at the ventricle during early brain development.

Title: Different effects of bone morphogenetic receptor type 1 subunits in neural stem and progenitor cells

Authors: J. CHEN, H. NORTH, *C.-Y. PENG, J. A. KESSLER;
Neurol., Northwestern Univ., Chicago, IL

Abstract: Bone morphogenetic protein (BMP) regulates neural stem and progenitor cell maturation by signaling via its receptor subunits. BMP receptor complexes are composed of two BMP receptor II (BMPRII) subunits and two of either BMP receptor 1a (BMPR1a) or BMP receptor 1b (BMPR1b) subunits. Although BMPR1a and BMPR1b have been reported to have some overlapping functions, they appear to have divergent roles in the nervous system during development and post injury. Previous work in our lab have shown that ablation of β1-integrin in cultured neural stem cells (NSCs) results in increased BMPR1b and decreased BMPR1a recruitment to lipid rafts. Additionally, the levels of downstream BMP signaling targets phospho-P38 and phospho-SMAD1/5/8, along with Glial Fibrillary Acidic Protein (GFAP), increase in the absence of β1int. These findings suggest a potential increase in astrocytic cell fate as a result of BMPR1b signaling. *In vitro* overexpression of constitutive active and dominant negative forms of the BMPR1 receptors suggest that BMPR1b likely mediates astrocytic lineage commitment by NSCs, while BMPR1a inhibits NSC astrocytic differentiation. We hypothesize that BMPR1a and BMPR1b mediate different biologic effects on NSCs, such as quiescence or cell fate decisions, through different downstream transcriptional targets. These downstream targets are being analyzed via RNA deep sequencing.

Title: Retinal ganglion cell genesis and subtype determination in the binocular circuit

Authors: *F. MARCUCCI[1], Q. WANG[1], T. KUWAJIMA[1], C. SOARES[1], S. KHALID[1], M. ROSS[2], C. MASON[1];
[1]Pathology, Columbia Univ., New York, NY; [2]Brain & Mind Res. Inst., Weill Med. Col. of Cornell Univ., New York, NY

Abstract: The generation of multiple cell types from progenitor pools requires mechanisms to achieve specificity of cell fate. Previous studies in the cortex and spinal cord suggest that cell subtype specification is closely related to the time of neurogenesis. In animals with binocular vision, retinal ganglion cells (RGCs) are divided into two subclasses by their laterality of projection: ipsilateral RGCs arise exclusively from the ventrotemporal (VT) retina, and contralateral RGCs arise from all retinal regions and project to the opposite side of the brain. A balanced production of ipsilaterally and contralaterally projecting RGCs is essential for generating proper connectivity. Here we explore whether ipsi and contra RGCs can be distinguished by their time of birth. We also investigated the role of a cell cycle regulatory gene, Cyclin D2, in RGC generation and axon trajectory. By using EdU birthdating in combination with subtype-specific RGC markers, we find that of the RGCs that populate the retina at E15, ipsilateral RGCs are born between E13 and E14, whereas contralateral RGCs are continuously produced during a longer interval of time that starts at E11. Moreover contralaterally projecting RGCs arising from VT retina at later stages of development and usually considered “late-born”, appear to be generated from E13 to 15, earlier than previously thought. Cyclin D2 was identified as a VT enriched gene at E11-14 (Wang and Mason, unpublished). Several lines of evidence suggest that CyclinDs can act as regulators of signaling pathways for cell fate decisions. In mice lacking Cyclin D2, fewer Zic2+ (ipsi) RGCs are apparent at E15, resulting in a smaller ipsilateral RGC projection through the optic chiasm. No compensatory increase of “late-born” contralateral RGCs, as measured by Islet2 expression, is observed in Cyclin D2 mutants; analyses are ongoing with other contralateral RGC markers. Thus, Cyclin D2, as suggested in other brain regions, may affect the timing and therefore production of specific RGC subtypes. Cyclin D2 might modulate ipsilateral RGC neurogenesis by affecting timing of birth and/or cell cycle length. To investigate theses possibilities, we are performing birthdating and cell cycle measurements in mice that lack Cyclin D2. Together, these results implicate that specification of ipsi versus contra RGC cell fate

occurs through distinct mechanisms involving neurogenic timing, leading to the expression of factors differentially regulating the phenotype of each subpopulation.

Abstract: Radial glia-like neural stem cells (RGLs) are known to play a critical role in key functions for brain development such as extension of their processes to pia mater and guidance of new born neurons to the proper region in developing cortex. Despite their significant roles, regulatory mechanisms on RGLs are not well understood. We found that a Ca2+ activated chloride channel, anoctamin 1 (ANO1) is essential for the RGL function. ANO1 was highly expressed in RGLs of mouse embryonic brain. The presence of Ca2+-activated currents were confirmed in RGLs. More importantly, knockdown of ANO1 or ANO1 inhibitors suppressed the process extension and protrusion of RGLs. Furthermore, this phenotype was reversed by overexpression of ANO1. More importantly, abnormal processes in RGLs were found in embryonic brain of Ano1-deficient mice. The size of the embryonic brain was significantly reduced compared to those of wild-type mice. BDNF is known to be essential for neurite outgrowth in RGLs. Surprisingly, BDNF activated ANO1 in RGLs. Thus, we conclude that ANO1 mediates Ca2+ dependent process extension of RGLs during embryonic cortical development.

Title: Comparative analysis of cerebral cortical progenitor transcriptional heterogeneity at single-cell resolution

Authors: ***M. B. JOHNSON**[1], P. P. WANG[1], C. A. WALSH[1,2];
[1]Genet. & Genomics, [2]Howard Hughes Med. Inst., Boston Children's Hosp., Boston, MA

Abstract: The human cerebral cortex depends for its normal development and size on a precisely controlled balance between self-renewal and differentiation of diverse neural progenitor cells. Due to their abundance in fetal human cortex compared to other species, a morphologically distinct progenitor subtype called basal or outer radial glia (ORG) has been suggested to be crucial to the evolutionary expansion of the human cortex. However, little is yet known regarding how ORG are molecularly or functionally distinct from other progenitor subtypes. We first combined progenitor subtype-specific sorting with transcriptome-wide RNA sequencing to identify genes enriched in human ORG compared to classic ventricular radial glial cells, including several transcription factors downstream of the key proneural regulator neurogenin, as well as numerous previously uncharacterized, evolutionarily dynamic long noncoding RNAs. Next, we performed single-cell transcriptional profiling of progenitors from human, mouse, and ferret, a gyrencephalic carnivore with abundant ORG, and found that the heterogeneity of progenitor transcriptional states correlates with size and complexity of the mature cerebral cortex. We find that a key feature of the diversity of human cortical progenitors is more frequent co-expression of progenitor and proneural transcriptional programs, suggestive of increased proliferation and self-renewal of neuronal lineage-committed precursors, which may contribute to increased neuronal numbers and cortical size. Finally, we have investigated the function of

human ORG-enriched genes in progenitor proliferation and differentiation using the ferret as a model system. We find that activation of the neurogenin pathway in ferret ventricular radial glial cells initiates a human ORG-like transcriptional program, and drives delamination of progenitors from the ventricular surface, a key step in the formation of basal ORG. Altogether, these studies provide new insights into the molecular drivers of progenitor diversity in human cortex and suggest genetic mechanisms that may have contributed to the evolution of human cortical complexity.

Title: Embryonic ablation of HCN/h current impedes development of the cerebral cortex by affecting stem cell proliferation and differentiation

Authors: *A. SCHLUSCHE[1], S. VAY[2], I. JAKOVCEVSKI[1], M. SCHROETER[2], A. RUEGER[2], D. ISBRANDT[1];

Abstract: The development of the cerebral cortex is a complex process comprising cell division, differentiation, migration, axonal pathfinding, and synaptogenesis. Impairments in any of these steps may cause persistent structural and/or functional abnormalities. For all processes involved in cortical development the spontaneous activity including calcium waves in neurons and its precursor cells, mediated by intrinsic and extrinsic properties, is of great importance. The extrinsic properties mainly arise from stimulation of neurotransmitter receptors via synaptic or volume transmission, whereas the intrinsic biophysical properties of precursor cells and neurons are defined by their ion channel composition. The hyperpolarization-activated cyclic nucleotide-gated non-selective cation (HCN) channels mediating the h current (I_h) shape the biophysical properties of neurons throughout brain development. HCN channels consist of four subunits that

assemble into homo- or heteromeric tetramers. Our laboratory generated a transgenic mouse line expressing a dominant-negative HCN subunit (HCN-DN) that led to functional suppression of I_h independent of the endogenous subunit composition. By expressing the transgene under control of the EMX1 promoter I_h suppression starts at embryonal day 9.5 (E9.5) in a forebrain restricted manner. The functional ablation of I_h in early prenatal brain development resulted in a severe phenotype with pronounced microcephalus and reduced neonatal viability, but no alteration in cell proliferation or apoptosis at postnatal day 0 (P0) could be detected. *In utero* electroporation (IUE) of HCN-DN into the lateral ventricle performed at E15 and analyzed at E19 suggests no alteration in migration. To assess the impact of I_h blockade on differentiation *in vitro*, we pharmacologically blocked I_h using ZD7288 in rat cortical stem cells. The preliminary results show a decrease in proliferation and increased glial and reduced neuronal differentiation of stem cells upon I_h blockage. Our data support the hypothesis that I_h is an important intrinsic regulator of the proliferation and differentiation of neural progenitors, and that mutations in HCN channel genes could lead to severe brain malformations.

Title: The GFAP gene involvement in neural stem cell differentiation

Authors: S. GARCIA-LOPEZ[1,2], A. GUTIERREZ-SEIJO[1,3], A. NELKE[1,2], M. P. PEREIRA[1,2], *A. MARTINEZ-SERRANO[1,2];

Abstract: Introduction: Deep understanding of human neural stem cell (hNSC) biology is of primary interest to coax their potential into real cell replacement therapies. NSCs from several species, including humans, are limited in their proliferative capacity, entering senescence in

culture rather soon. In our lab this issue has been addressed by immortalizing the hNSC with the best immortalizing gene, viral myc (the p100gag-myc fusion protein between chicken myc and retrovial gag-pol). Still, another problem remains, the loss of their neurogenic potential with passaging. Previous work showed that this undesired drift could be overcome by the forced expression of Bcl-XL transgene. One of the consequences of the forced expression of Bcl-XL was a reduction of GFAP(+) cells during their differentiation, as determined by immunocytochemistry (ICC). Objective: The role of GFAP in hNSC differentiation has been largely underexplored. Based on previous studies, it can be postulated that the disruption of GFAP expression occurring during differentiation of hNSCs might reduce the potential for Glia generation, and, at the same time, enhance the Neurogenic potential. We examined this hypothesis in an *in vitro* model of immortalized hNSC. Methods & Results: Lentiviral particles encoding shRNAs targeting the GFAP gene have been used to silence protein expression will be monitored by WB and ICC. A MOI=5 was found to be enough to downregulate GFAP protein expression. In the differentiated hNSC samples we observed a significantly higher number of TH(+) cells (p-value < 0.05), indicating that the disruption of GFAP protein expression might promote acquisition of a neuronal fate. Conclusion: Present data on the silencing of GFAP gene expression allow to suggest that GFAP protein levels during hNSC differentiation play a role in neuronal commitment, differentiation or both.

Title: Histone demethylase LSD1 controls Notch signaling and GABAergic neuronal differentiation in human neural stem cell

Authors: *K. HIRANO, M. NAMIHIRA;
Biomed. research institute, AIST, Tsukuba-Shi, Japan

Abstract: Neural stem cells (NSCs) are defined as cells that posses the ability to self renew and to differentiate into three major cell types, neurons, astrosytes and oligodendrocytes of central nerves systems (CNS). The fate specification of NSCs in cortex of embryonic mouse brain is controlled by epigenetic modifications such as DNA methylations and histone modifications.

However, the role of epigenetic modification in fetal NSCs during the development of primate cerebral cortex, which possesses more elaborate structures and functions compared with those of rodent, remains largely unknown. To address this issue, we investigate the function of epigenetic factors in human NSCs (hNSCs) that were derived from cerebral cortex of fetus and are expanded continuously in monolayer culture. We found that the inhibitor for lysine specific demethylase 1 (LSD1), which is a histone demethylase of mono- and di-methylated lysine 4 and 9 on histone H3, suppressed the GABAergic neuronal differentiation of hNSC. Furthermore, LSD1 inhibitor also upregulated several genes, including HES5 and HEYL, which are target genes of Notch signaling, at initial stage of neuronal differentiation. These results implied that histone demethylation by LSD1 play an important role in the development of GABAergic neuron through the regulation of Notch signaling in hNSCs.

Title: Becoming a new neuron in the cerebral cortex

Authors: *S. GOVINDAN, L. TELLEY, K. DEVARAJU, D. JABAUDON;
Univ. of Geneve, Geneve, Switzerland

Abstract: The cerebral cortex is composed of distinct types of neurons that assemble into specific circuits during development. While much progress has been made in understanding the type-specific gene expression of these neurons once they reach the cortex, their early post-mitotic, pre-circuit biology remains largely unexplored. To investigate these primordial differentiation processes, we developed a novel technology which allows *in vivo* labelling of select time- and phase-locked cohorts of newborn neurons right from the time of mitotic division. Through the real-time resolution provided by this approach, we were able to longitudinally characterize cell-type specific primordial transcriptional activity as it was unfolding in nascent neurons in the crucial 12 hours following cytokinesis. Our results provide a

first insight into the type-specific incipient genetic programs that direct the initial steps of neuronal differentiation and shed light on the transcriptional dynamics underlying cellular diversity and plasticity in the developing mammalian neocortex.

Title: Rod-enriched miRNAs and their expression during Müller glia-derived progenitors acquisition of photoreceptor phenotype

Authors: *H. QUINTERO[1], A. I. GOMEZ-MONTALVO[2], M. LAMAS[1];
[2]Farmacobiologia, [1]CINVESTAV, Ciudad DE Mexico, Mexico

Abstract: During retinal development, retinal progenitors differentiate to give rise to six neuronal and one glial type. This process requires a fine modulation in gene expression to confer identity and specific functions to each cell. MicroRNAs have the ability to regulate hundreds of genes at posttranscriptional level, arising as great candidates of differentiation regulation. Previous reports have shown the expression patterns of retinal miRNAs, however, is still necessary to identify patterns of cell-specific miRNAs in order to gain better understanding on miRNA regulation in each retinal subpopulation. Here, we identify a subset of rod-enriched miRNAs, which may be implicated in the acquisition of rod phenotype. For this purpose, we FACS-isolated CD73-positive rods and by miRNA arrays, we analyzed their profile expression; afterwards, using qPCR, we validated a subset of miRNAs as rod-enriched. Subsequently, we analyzed the expression levels of those miRNAs in a differentiation protocol towards rod phenotype. We found a preferential expression of miR-183, 182, 124, 9*, 181c and 301b* in rods. When Müller glia-derived progenitors (MGDP) are committed to early neuronal phenotypes, there is a upregulation of miR-124 expression and these levels of expression are sustained during acquisition of rod-like phenotype and are accompanied with the upregulation of

mir-9* and 181c. This work makes a progress in the establishment of miRNA signature in rods and suggests an important role of miRNAs during MGDP acquisition of rod-like phenotype

Title: Genetic disruption of O-GlcNAcase results in impaired neurogenesis in the developing mouse brain

Authors: ***C. LEE**, Y. YANG, J.-H. HUR, E.-K. KIM, P.-G. SUH;
UNIST, Ulsan, Korea, Republic of

Abstract: The monosaccharide N-acetyl-D-glucosamine can be added to serine or threonine residues of nuclear and cytoplasmic proteins to form O-linked N-acetylglucosamine (O-GlcNAc) as a post-translational modification. The addition and removal of O-GlcNAc, a dynamic cycling process, are catalyzed by O-GlcNAc transferase (OGT) and O-GlcNAcase (OGA), respectively. Importantly, it has been shown that O-GlcNAc level is closely related to a diverse physiological function such as cell division, cell signaling, metabolism, and apoptosis. O-GlcNAc is abundant in the brain and O-GlcNAc cycling is crucial for normal brain functions as well as for the etiology of neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. However, the role of O-GlcNAc in the developing brain is not well known. To investigate the cellular and physiological roles of OGA associated with dysregulation of O-GlcNAcylation, we previously generated OGA homozygous null (OGA-/-) mice, which have constitutively elevated O-GlcNAc levels. Here we show that OGA gene was highly expressed in the ventricular zone (VZ) and subventricular zone (SVZ) of the developing brain. OGA-/- embryonic brain had a thinner cerebral cortex, most obvious in the cortical plate, and enlarged lateral ventricles. The number of dividing cells in the VZ was normal in the OGA-/- embryonic brain. OGA-/- mice exhibited reduced number of postmitotic neurons in the VZ of the ganglionic eminence whereas similar in the VZ of the dorsal pallium compared with WT. Together, these findings indicate that the absence of OGA leads to impaired neurogenesis in the developing brain in a region-specific manner.

Title: The exon junction complex controls embryonic neurogenesis through post-transcriptional gene regulation

Authors: *H. MAO[1], J. MCMAHON[2], E. MILLER[2], L.-J. PILAZ[2], D. SILVER[2];
[1]MGM, [2]Duke Univ., Durham, NC

Abstract: The cerebral cortex controls complex human traits such as memory and language. Neurons of the cerebral cortex are produced during embryonic neurogenesis. During this process, radial glia cells (RGCs) undergo self-renewal to expand their population and differentiation to produce neurons and intermediate progenitors (INPs), which also generate neurons. Disruption of embryonic neurogenesis underlies numerous neurodevelopmental disorders including microcephaly and autism. Therefore to understand the pathogenesis of these disorders it is critical to identify genes regulating neurogenesis. Our lab recently discovered that haploinsufficiency of either *Magoh* or *Rbm8a* causes microcephaly in mice. Both *Magoh* and *Rbm8a* mutants have defective RGC proliferation leading to fewer INPs and ectopic production of neurons that undergo extensive apoptosis. Magoh and Rbm8a form the exon junction complex (EJC) with Eif4a3. The EJC bind RNA and mediate RNA splicing, localization, translation, and non-sense mediated decay. Emerging evidence shows that mutations and copy number variations in EJC components are associated with human neurodevelopmental disorders. All EJC core components are highly expressed in the developing brain, indicating that these components may act together to regulate cortical development. To test this, we generated *Eif4a3* conditional mutants and found that haploinsufficiency of *Eif4a3* causes phenotypes similar to *Magoh* and *Rbm8a* mutants. Using deep RNA-sequencing of all three mutants, we identified overlapping RNA targets of the EJC, including transcription factors critical for cell fate determination, such as *Tbr2*. Using RNA immunoprecipitation (RIP) from embryonic cortices, we also discovered that core EJC components interact with RNA encoding critical neurogenesis genes. Our data argue that EJC components work together to regulate RGC proliferation and differentiation. Future proteomic, electroporation, and genomic experiments will further elucidate how EJC components impact brain development. Given the strong association of EJC mutations and human neurodevelopmental disorders, our studies are likely to be of clinical relevance.

Title: Newly identified developmental controls direct corticospinal motor neuron segmental targeting

Authors: ***V. V. SAHNI**[1], S. SHNIDER[2], J. SONG[2], J. MACKLIS[2];
[1]Stem Cell and Regenerative Biol., [2]Harvard Univ., Cambridge, MA

Abstract: In recent years, several key controls over specification and differentiation of neocortical projection neurons have been identified. These studies have focused on controls that specifically distinguish one subtype of neocortical projection neurons, e.g. corticospinal motor neurons (CSMN), from closely related corticothalamic projection neurons (CThPN) or intracortical callosal projection neurons (CPN). However, these broad subtypes of neurons exhibit known anatomical heterogeneity. For instance, CSMN somatotopically and precisely target specific segments along the rostrocaudal axis of the spinal cord, the molecular basis for which remains unknown. CSMN located rostro-laterally in the neocortex extend axons to proximal targets, such as the pons and medulla (i.e. hindbrain) and to the cervical cord (collectively "$CSMN_C$") and those located caudo-medially extend their axons more distally to the lumbar spinal cord ("$CSMN_L$"). We investigated the molecular determinants over CSMN segmental target specificity. We selectively isolated $CSMN_C$ and $CSMN_L$ at three critical developmental times, and identified differentially expressed genes between these two CSMN subpopulations during development. Using gain- and loss-of function analyses, we identified molecular controls that function to direct CSMN axon extension to appropriate levels of the spinal cord (short axon extension by $CSMN_C$ and long axon extension by $CSMN_L$). Interestingly, we find that some of these controls associate with subtype-specific forms of CSMN disease in humans. We focused our efforts on molecular controls specifically expressed by $CSMN_C$, since this population has undergone substantial expansion through evolution from rodents to primates

and humans, and potentially represents an evolutionarily "newer" CSMN sub-population. We identified a previously unstudied molecular control, that acts, at least in part, as a transcriptional regulator to suppress expression of $CSMN_L$ genes in $CSMN_C$, to limit their axon extension to the cervical cord. This provides a potential mechanism that might have allowed for the expansion of this subpopulation during evolution. Further, analysis of recently available transcriptome of the developing human brain indicates that its spatiotemporal expression is conserved in humans. Together, these newly identified controls constitute new, bi-directional mechanisms directing CSMN axonal targeting, and lay the foundation for more in-depth studies of mechanisms directing CSMN subtype-specification, as well as the development, regeneration, and evolution of precise corticospinal circuitry.

Title: D-serine accelerates neural stem cell differentiation and NMDA receptor expression

Authors: ***S. BARBATI**, L. LEONE, M. D'ASCENZO, A. MASTRODONATO, C. GRASSI; Univ. Cattolica, Med. Sch., Rome, Italy

Abstract: Adult hippocampal neurogenesis is a process generating new functional neurons from adult neural stem/precursor cells (NSCs) that has a critical role in memory formation and cognitive functions. It is currently accepted that a combination of neurogenic niche signals and cell intrinsic programs orchestrate the transition from undifferentiated NSC state to a progenitor cell committed to the neuronal fate. In particular, the neurogenic process depends on the expression of the basic helix-loop-helix (bHLH) transcription factors, finally resulting in the activation of a neuronal gene cascade. Compelling evidence shows that among the molecules released by the neurogenic niche, D-serine represents an important co-agonist of N-methyl-D-aspartate (NMDA) receptors whose activation has been shown to enhance NSC proliferation *in vitro* and adult neurogenesis *in vivo*. Moreover, abnormal levels of D-serine have been reported in aging and Alzheimer's disease, conditions in which dysregulation of glutamatergic system is associated with impaired neurogenesis. Here we investigated the effects of exogenous administration of D-serine on cultured adult hippocampal NSCs to identify the molecular mechanisms underlying its neurogenic effect. To this aim we performed real-time RT-PCR on

cellular extracts obtained from NSC cultured under both proliferative and differentiating conditions. Our findings demonstrated that addition of D-serine to the culture medium significantly increased the proliferation of undifferentiated NSCs and this effect was associated with a marked enhancement (+217% of control cells, $p<0.05$) of the pro-proliferative Hes1 gene expression. In differentiating NSCs cultured in the presence of D-serine expression of the determination gene Mash1 was higher than controls (+50%, $p<0.05$) and it reached a peak circa 24h earlier, thus suggesting early cell commitment to the neuronal fate. It has been recently demonstrated that activation of NMDA receptors increases proliferation and differentiation of NSCs (Joo et al., 2007). In light with this evidence we evaluated whether the addition of D-serine in NSC culture medium also affects the expression of NMDA receptor subunits. Our real time PCR data demonstrated an earlier and increased expression of the NR1, NR2A and NR2B subunits (+300%, +500%, +75% respectively, $p<0.05$) in differentiating NSCs cultured in the presence of D-serine. Collectively, these results suggest that D-serine positively modulates neurogenesis by accelerating NSC commitment to the neuronal phenotype and the expression of NMDA receptor subunits.

Title: Role of glial cell remodeling during peripheral nerve reorganization in *Drosophila*

Authors: A. SUBRAMANIAN[1], *J. J. FERNANDES[2];
[1]Biol., [2]Miami Univ., Oxford, OH

Abstract: Remodeling of the larval nervous system during development is necessary for the development of adult specific behaviors in the fruit-fly *Drosophila* melanogaster. During metamorphosis, five pairs of abdominal nerves fuse together to form a terminal nerve trunk (TNT) as they exit the CNS. The nerves later defasciculate from the TNT at appropriate segmental levels to innervate the body wall. Glial cells are likely to play a significant role in this process, as we have determined by following the remodeling of four ensheathing layers. The

most external layer, the neural lamella and the most internal wrapping glial layer are absent during the entire process of TNT formation. However, the two other glial layers- the perineural glia (PG) and the sub-perineural glia (SPG) persist during this process. Confocal microscopy analyses have been substantiated by transmission electron microscopy (TEM) to study the ultrastructural changes that take place during peripheral nerve reorganization. The present study focuses on the role of the PG and SPG glial layers in TNT formation. A three-fold increase in the glial population was observed during the first day of metamorphosis (25% of development), when 75% of the cells comprises of perineural glia. Induction of perineural glial cell death by targeting Diphtheria Toxin (DT), results in abnormal defasciculation patterns in 100% of animals (n=15). TEM studies are currently underway to identify the nature of ultrastructural changes in these mutants. Cells of the SPG layer will also be manipulated by targeting Diphtheria Toxin (DT), and the TNT will be examined using confocal analyses and TEM. The study of glial remodeling in *Drosophila* will lay the groundwork for future studies on the role of glia- neuron communication during TNT formation, and could lead to the establishment of a model system to study gliopathies.

Title: Cholinergic neuron systems indirectly impact the growth of young mice

Authors: ***H. ZHU**[1], Y. LU[2];
[1]Phisology, Huazhong Univ. of Sci. and Technol., Wuhan, China; [2]Pathophysiology, Tongji Med. Col., WUhan, China

Abstract: abstract:cholinergic neuron systems which regulate the acetylcholine signal underlies specific aspects of cognitive functions and behaviors, and involved in the pathophosiology of some neuropsychiatric disorders. We focused on the inducible cholinergic system inhibition model based on transgenic mice and a nobel phenomenon was observed during our previous experiments: intensively inhibited individual showed smaller quantity of weight growth ranged from induction period. So we accumulate abundant (n=396) data of induced transgenic model (inductive agent tamoxifen) and we first classifying the inhibition degree as control (without inhibition gene), slight(less than 30% cholinergic neuron inhibited), medial(30%--60%inhibited

), intensive(more than 60% inhibited). There exists no differences in weight growth between those groups except intensive group which in analogous original weight with other groups manifest remarkable lower weight growth compared with them. The phenomenon showed than there might be a indirect pathway of cholinergic system participated in the growth and development of mice which might be compensatory via other neuronal system when cholinergic system is partly restricted. Yet highly restriction to the function of cholinergic system would interfere with the weight growth of young mice which indicate that cholinergic system could indirectly impact the growth of young mice. Keywords: cholinergic system, tamoxifen, weight growth

Title: Shh and Wnt signaling in human fetal brain development

Authors: *F. MEMI, J. ORTEGA, N. ZECEVIC;
Neurosci., Uconn Hlth. Ctr., Farmington, CT

Abstract: The embryonic patterning and development of the CNS rely on the combinatorial effect of secreted factors, such as sonic hedgehog (Shh) and wingless (Wnt) that establish gene regulatory networks which in turn, will guide the basic developmental processes including cell proliferation and specification. These molecules display a distinct expression pattern; Wnts are expressed dorsally and guide the neuronal progenitors into glutamatergic fate whereas the ventrally secreted Shh specifies GABAergic inhibitory cell population. Thus, a fine co-ordination of Wnt and Shh signaling pathways is required for the proper development of the forebrain. Despite the importance of these molecules, little is known about their expression pattern during the human fetal brain development. A possible reason is the limited availability of human embryonic tissue and the difficulty to detect secreted factors by immunohistochemistry (IHC). Thus, we used *in situ* hybridization (ISH) to determine the spatiotemporal expression pattern of Shh and Wnts in a wide range of developmental stages of human fetal brain (15-24gw). Combining ISH with IHC, we identified the Shh and Wnt-expressing cells in the human

dorsal and ventral telencephalon. We also assessed the expression pattern of the major members of Shh and Wnt signaling, such as the receptors and the downstream effectors that lead to transcriptional activation. Interestingly, we detected differences between mouse and human that can be due to the species-specific cis-regulatory elements controlling gene expression. Evolutionary changes in cis-regulatory elements have been associated with the presence of a primate-specific interneuron progenitor pool in the cortical VZ/SVZ, which we previously showed, that can be modulated by Shh (Radonjic et al., 2014). Here, to study the role of Wnt signaling in the specification of human telencephalic progenitors, we performed pharmacological *in vitro* experiments in enriched radial glial cell (RGC) cultures isolated from fetal human dorsal and ventral brain. We studied the effects of Wnt agonist (CHIR99021) and antagonist (XAV939) on cell proliferation and differentiation of human RGCs and found that, in accordance with mouse studies, activation of Wnt signaling in human RGCs mainly promotes increased cell proliferation and induction of glutamatergic neurogenesis.

Title: Hyaluronic acid-based hydrogels designed to direct oligodendrocyte differentiation

Authors: ***S. K. SEIDLITS**, J. LIANG, A. EHSANIPOUR, C. M. WALTHERS; Bioengineering, UCLA, Los Angeles, CA

Abstract: Introduction: Many disorders of the central nervous system (CNS) cause extensive death of highly specialized cells, such as motor neurons and oligodendrocytes. Although neural stem/progenitor cells (NS/PCs) are capable of differentiating into these specialized cells, this process is inefficient and has failed to mediate substantial repair of CNS function. In order to effectively employ cell-based therapies clinically in the CNS, it is imperative to develop strategies to direct differentiation of large numbers of NS/PCs. NS/PCs can differentiate into neurons, astrocytes and oligodendrocytes; however, this work focuses on the process of oligodendrocyte lineage (OL) differentiation. We posit that coordination of extracellular matrix and growth factor cues is necessary for OL maturation. Thus, we have developed 3D, culture

microenvironments in which the combinatorial effects of soluble and substrate-mediated cues on OL differentiation can be evaluated independently and in combination. Materials and Methods: Sodium hyaluronate (~700 kDa) was modified with thiol groups and cross-linked with 20 kDa 4-arm PEG-maleimide. Cysteine-terminated, integrin-binding peptides were added to facilitate NS/PC attachment and differentiation. NS/PCs derived from human H9 embryonic stem cells were cultured in 3D, hyaluronic acid (HA) hydrogels for 3 weeks in media formulated for stem cell proliferation or OL differentiation. After 3 weeks, cell/hydrogel constructs were fixed and characterized by immunolabling of OL markers. Results and Discussion: After culturing for 3-weeks in 3D, HA hydrogels in differentiation media, NS/PCs showed increased expression in OL markers (NG2, PDGR-alpha, CNPase) and decreased expression of markers for pluripotency (nestin, Sox2) than those cultured on laminin-coated glass coverslips in otherwise identical conditions. Addition of differentiation promoting factors to the medium further enhanced this effect. Cells grown in HA hydrogels also expressed higher levels of the HA receptor CD44 than those grown on laminin-coated coverglasses. Finally, proliferation of NS/PCs embedded in HA hydrogels was dependent on the identity of adhesive peptides incorporated. Specifically, peptides containing the RGD binding motif increased proliferation. Conclusions: These novel hydrogels mimic the HA-rich, native spinal cord environment, can be easily modified with biomolecules, such as adhesive peptides, and provide a means for biocompatible, 3D culture. Results demonstrate that 3D culture of human NS/PCs in HA-based hydrogels increases efficiency of OL differentiation compared to standard, 2D cultures.

Title: Single-cell analysis reveals that endogenous retrotransposons generate somatic mosaicism in the neurons and non-neuronal cells

Authors: *J. A. ERWIN[1], A. C. M. PAQUOLA[1], T. SINGER[1], M. NOVOTNY[2], I. GALLINA[1], C. BUTCHER[1], J. R. HERDY[1], R. LASKEN[2], A. R. MUOTRI[3], F. GAGE[1]; [1]LOG-G, The Salk Inst. For Biol. Studies, La Jolla, CA; [2]J. Craig Venter Inst., La Jolla, CA; [3]Univ. of California San Diego, La Jolla, CA

Abstract: It has long been thought that neuronal genomes are invariable; however, recent studies have demonstrated that mobile elements actively retrotranspose during neurogenesis, thereby creating genomic diversity between neurons. In addition, mounting data demonstrate that mobile elements are misregulated in certain neurological disorders, including Rett syndrome and schizophrenia. The unique composition of genetic mosaicism present in the brain may contribute to disease and also the behavior differences observed between genetically identical organisms. Many questions remain regarding the regulation of retrotransposition, the full characterization of other mobile elements and the functional significance of retrotransposition during neurogenesis. Because each individual neuron has the potential to have a unique genome, single-cell approaches are essential to measure and observe this genomic diversity, which is obscured in bulk samples. I will present data using single-cell genome and transcriptome sequencing to characterize the nature and regulation of neuronal genome mosaicism. In order to address the question whether somatic retrotransposition occurs in other tissues and, more generally, how it impacts human development and function, we developed a targeted sequencing approach to identify Alu and L1 retrotransposition events in single cells and bulk tissues. We applied this method to cortex, hippocampus, heart and liver postmortem samples from four non-diseased young adults. We confirm that somatic L1 retrotransposition occurs in hippocampal neurons, and we also found evidence of somatic Alu retrotransposition in the liver as well as somatic L1 retrotransposition in non-neuronal cells in the cortex. We did not observe any cell-type specific difference in estimated rates of retrotransposition. These findings suggest that somatic retrotransposition is not restricted to neurons but occurs as part of the normal condition of human somatic cells. We also apply single-cell transcriptomic approaches to quantify the level of diversity present in cells with retrotransposition and identify regulators of somatic retrotransposition.

Title: Long non-coding RNA transcriptional mechanisms in GABAergic interneuron precursors

Authors: I. CAJIGAS[1], D. LEIB[1], J. COCHRANE[2], H. LUO[1], K. SWYTER[1], S. CHEN[1], J. YATES[3], R. KINGSTON[2], *J. D. KOHTZ[1];

Abstract: Transcription-regulating long non-coding RNAs (lncRNAs) have the potential to control site-specific gene expression of thousands of targets. Previously, we showed that *Evf2*, the first described ultraconserved lncRNA, increases association of transcription activators (DLX homeodomain proteins) to key DNA enhancers, but represses gene expression. Loss of Evf2 results in GABAergic interneuron defects, reducing GABAergic synaptic inhibition in the adult hippocampus. Here, mass spectrometry shows that the *Evf2*/DLX1 ribonucleoprotein (RNP) contains SWI/SNF related chromatin-remodelers, Brahma related gene 1 (BRG1, SMARCA4) and Brahma-associated factor (BAF170, SMARCC2) in developing forebrain. The importance of BRG1/RNA and BRG1/homeodomain interactions in neurodevelopmental disorders is underscored by the finding that mutations in Coffin Siris Syndrome, a human intellectual disability disorder, localize to the BRG1 RNA binding and DLX1 binding domains. *In vitro* studies show that both RNA/BRG1 binding and RNA inhibition of BRG1 ATPase/remodeling activity is promiscuous, suggesting that context is a critical factor in RNA-dependent chromatin remodeling inhibition. Together, these experiments support a model where RNAs convert an active enhancer to a repressed enhancer by directly inhibiting chromatin-remodeling activity, revealing a novel regulatory mechanism in GABAergic interneuron precursors.

Title: Dopaminergic neuronal differentiation modifies PrPC expression

Authors: ***M. H. LUZ**, M. A. P. DA SILVA, A. M. XAVIER, I. GLEZER, K. S. LEE; Bioquímica / Biologia Mol., Univ. Federal De São Paulo - UNIFESP, Sao Paulo, Brazil

Abstract: Cellular prion protein (PrP^C) is a glycosylphosphatidylinositol (GPI)-anchored membrane glycoprotein that plays several roles in cellular homeostasis and neuroprotection. However, its conformational change may lead to loss of function and accumulation of protein aggregates. It is plausible to speculate that the conformation of PrPC can be easily altered by reactive oxygen species (ROS) due to its high expression level and the presence of repetitive octapeptide sequences (PHGGGWGQ) which are enriched of amino acids that are more susceptible to oxidation. Thus, PrPC can neutralize ROS, but the modified PrPC would be degraded. ROS are produced as byproduct in several metabolic pathways. Oxidative metabolites can also be generated from autoxidation of dopamine (DA) or from enzymatic deamination. Therefore, our purpose was to characterize the PrP^C turnover during the N2a differentiation into dopaminergic neurons. The differentiation was effectively accomplished using 1 mM dibutyryl cAMP, which induced the expression of tyrosine hydroxilase (TH) and the production of DOPAC, a dopamine metabolite. Despite the effective differentiation, we could not observe enhanced production of ROS, which was assessed by DCFDA and CellRox. However, the differentiation reduced the level of total PrPC as well as the membrane fraction. This reduction was not triggered by increased degradation, indicating that the PrPC expression was down-regulated while TH expression was induced by dibutyryl cAMP. Knockdown of PrP^C by shRNA also increased TH levels. Our data suggest that PrP^C participates in regulation of TH expression as its suppressor.

Sch., Geneva, Switzerland; [5]Inst. of Physiol., Münster, Germany

Abstract: Accumulating evidence from work on ion-regulatory proteins (IRPs), such as ion transporters and carbonic anhydrases (CAs), show that they are of fundamental importance in a wide spectrum of molecular and cellular mechanisms controlling brain development, plasticity, and disease[1]. We have recently shown that the neuron-specific chloride transporter KCC2 is, in addition to its well-known role in chloride extrusion, a multifunctional protein which has an important structural factor in the generation of dendritic spines in cortical neurons[1,2]. The present work focuses on another neuron-specific IRP, CA isoform VII (CA VII) and demonstrates that in addition to its previously known role in neuronal pH regulation[3], and thereby in the modulation of ionic plasticity in GABAergic synapses, CA VII has a structural role via direct interaction with filamentous actin (F-actin). We have shown that mouse hippocampal neurons are endowed with two catalytically highly active cytosolic CA isoforms (VII and II) and that these isoforms are fully responsible for CA-dependent modulation of somatic and dendritic pH[3]. In the present study, the subcellular localization of CA VII and II was studied by overexpressing them in rat cortical neurons *in vitro* and *in vivo* and in cultured fibroblasts. In cell cultures, CA VII, but not CA II, showed strong co-localization with F-actin. Direct interaction of CA VII and actin was confirmed with actin pull-down assay. In cortical neurons, both in cultures and *in vivo*, CA VII localized strongly to dendritic spines. To address the CA VII-actin interaction we did molecular modelling and constructed CA VII mutants. We identified domains that were crucial for CA VII's interaction with F-actin and probably for its spine targeting. Spine density analysis of WT

and CA7 KO mouse cortical layer 2/3 neurons, performed as described before[2], showed increased spine number in the CA VII KO mice. Together with the distinctive over-expression phenotype of CA VII transfected neurons in WT mice, these results provide further support to a novel morphogenic role of CA VII in neurons. Title: Sumoylation of sigma-1 receptor chaperones at the nuclear pore complex may relate to a potential role of sigma-1 receptors in the nucleo-cytoplasmic transport of macromoleculars

Authors: *P.-T. LEE, T.-P. SU;
Cell. Pathobiology Section, Integrative Neurosci. Res. Br., IRP/NIDA/NIH, Baltimore, MD

Abstract: Sigma-1 receptors (Sig-1Rs) are ligand-regulated membrane proteins which function as molecular chaperones in the endoplasmic reticulum (ER) that plays important roles in the proper folding and quality control of proteins. Our recent works indicate that Sig-1Rs not only exist at the ER and plasma membrane but also exist in the nuclear envelope (NE). NE is a contiguous structure of the ER network that provides bidirectional nucleo-cytoplasmic transport of macromolecules through the nuclear pore complex (NPC). The NPC is comprised of multiple copies of 30 different proteins that facilitate transport of karyopherin-cargo complexes through the nuclear pore. We test the hypothesis that Sig-1Rs at the NE may at least in part associate with the NPC and thus participate in the functioning of NPC. We found that Sig-1Rs exist in the isolated fractions of NE and NPC by using nuclei sub-fractionation procedures. Sig-1Rs also

partly co-localize and interact with NPC as seen from the immunostaining and immunoprecipitation assays. Sig-1R depletion in HeLa cells slightly attenuates the nuclear import of the nuclear factor of activated T cell (NFAT), suggesting that Sig-1Rs are involved in the control of nuclear transport. The post-translational modifications (PTMs) of proteins may also occur as they are translocated between the cytoplasm and the nucleus. The modification includes SUMOylation which covalently adds small ubiquitin-related modifier (SUMO) to lysine residue of its substrates by an enzymatic cascade. It has been shown that SUMO-conjugating enzyme UBC9 as well as the de-SUMO enzyme sentrin-specific proteases (SENPs) is also localized in the cytoplasmic filaments of NPC and NE. The results from our immmunoprecipitation assay and *in vitro* pull-down assay revealed that Sig-1Rs interact with UBC9. Those results together suggest that Sig-1R may be modified by SUMO. To investigate the PTM of Sig-1R by SUMO, we generate recombinant glutathione S-transferase (GST)-tagged proteins including full-length and three truncated fragments of mouse Sig-1R. The *in vitro* SUMOylation assay revealed that full-length (amino acids 1 to 223) and truncated (amino acids 80 to 173) of recombinant Sig-1Rs can be conjugated by SUMO-1, which belongs to a subtype of SUMO family. In addition, mutation of the lysine residue of Sig-1R at amino acid 142 to arginine completely abolished the conjugation by SUMO-1 using either *in vivo* or *in vitro* SUMOylation assay. In this study, we demonstrated a novel PTM of Sig-1R chaperone that may occur at the NPC. Our results suggest that SUMOylation status of Sig-1R at the NPC may play potential roles in the nucleo-cytoplasmic transport of macromolecules.

Title: DNA polymerase β activity in neural progenitors is required for postmitotic neuronal survival in the developing cortex

Authors: K. ONISHI, N. SUGO, S. TOYODA, T. HIRAYAMA, T. YAGI, *N. YAMAMOTO; Osaka Univ, Grad Sch. Frontier Biosci, Suita, Osaka, Japan

Abstract: DNA repair is essential to maintain the genome stability in all cell types including neuronal cells. It has been demonstrated that lack of DNA polymerase β (Polβ), an enzyme of the base excision repair (BER) pathway, results in neuronal apoptosis in the developing cortex (Sugo et al., *EMBO J*, **19**, 1397-1402, 2000). However, how Polβ functions on cortical cells during development is totally unknown. We addressed this issue by investigating phenotypic differences between two distinct forebrain-specific Polβ conditional knockout mice, Emx1-CRE/Polβ$^{fl/fl}$ and Nex-CRE/Polβ$^{fl/fl}$ mice. In Emx1-CRE/Polβ$^{fl/fl}$ embryos, in which Polβ function is inactivated in all excitatory cortical cells including progenitor cells, the majority of cortical plate (CP) cells but not ventricular zone (VZ) cells showed cleaved caspase3-positive apoptosis in E14.5, similarly to the phenotype of Polβ$^{-/-}$ embryos. In Emx1-CRE/Polβ$^{fl/fl}$ embryos, γH2AX-foci immunopositivity was also increased in the majority of both CP and VZ cells, indicating the occurrence of DNA double-strand breaks (DSBs). In contrast, E14.5 Nex-CRE/Polβ$^{fl/fl}$ embryos, in which Polβ becomes inactivated after the final mitosis, showed such abnormalities in neither CP nor VZ cells. To further investigate the influence by the lack of the BER pathway, cultured Polβ-deficient cortical progenitors were treated with a base-damaging agent, methyl methanesulfornate. This treatment increased occurrence of not only DNA single-strand breaks but also DSBs during S phase. Taken together, our results suggest that Polβ contributes to neuronal survival in the developing cortex by reducing the catastrophic risk of conversion from a base damage into DSB in neural progenitors.

Title: Overexpression of human gata-1 and gata-2 interferes with spine formation and produces depressive behavior in rats

Authors: *S. KO, ESQ[1], M. CHOI[2], S. WANG[1], S. LEE[1], R. S. DUMAN[3], H. SON[2]; [1]Hanyang Univ., Seoul, Korea, Republic of; [2]Col. of Medicine, Hanyang Univ., Seoul, Korea, Republic of; [3]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Functional consequences to which vertebrate GATA transcription factors contribute in the adult brain remain largely an open question. The present study examines how human GATA-1 and GATA-2 (hGATA-1 and hGATA-2) are linked to neuronal differentiation and depressive behaviors in rats. We investigated the effects of adeno-associated viral expression of hGATA-1 and hGATA-2 (AAV-hGATA1 and AAV-hGATA2) in the dentate gyrus (DG) of the dorsal hippocampus on dendrite branching and spine number. We also examined the influence of AAV-hGATA1 and AAV-hGATA2 infusions into the dorsal hippocampus on rodent behavior in models of depression. Viral expression of hGATA-1 and hGATA-2 cDNA in rat hippocampal neurons impaired dendritic outgrowth and spine formation. Moreover, viral-mediated expression of hGATA-1 and hGATA-2 in the dorsal hippocampus caused depressive-like deficits in the forced swim test and learned helplessness models of depression, and decreased the expression of several synapse-related genes as well as spine number in hippocampal neurons. Conversely, shRNA knockdown of GATA-2 increased synapse-related gene expression, spine number, and dendrite branching. The results demonstrate that hGATA-1 and hGATA-2 expression in hippocampus is sufficient to cause depressive like behaviors that are associated with reduction in spine synapse density and expression of synapse- related genes.

Title: The Erk5 signaling cascade and its possible role in modulating nurr1 transcriptional activity in the mouse developing midbrain

Authors: *P. SACCHETTI[1], E. KARHAN[2], G. DOWNING[2], C. CONNELLY[1], Q. LI[3]; [1]Biol. Sci., [2]Master's Program in Neurosciences, Univ. of Hartford, West Hartford, CT; [3]Mount Holyoke Col., South Hadley, MA

Abstract: The nuclear receptor nurr1 (NRA4A2) is an essential player in the development and maintenance of gene expression in developing midbrain dopamine neurons and seems to confer neuroprotection to these neurons. Differently from other members of the nuclear receptor superfamily of transcription factors, nurr1 transcriptional activity does not seem to be under the control of a ligand. In addition, the quest for nurr1 modulators has provided no specific insights into the mechanisms governing the activation and inactivation of this important developmental transcription factor. However, the identification of regulators would be extremely useful to clarify the mechanisms by which nurr1 confers neuroprotection to dopamine neurons. The Extracellular Signal-Regulated Kinase 5 (Erk5) signaling pathway is implicated in neuronal differentiation and cell survival in response to environmental stressors in different cell types. Interestingly, Erk5 can interact and enhance the activity of nurr1 *in vitro*. However, no clear evidence exists of the presence of Erk5 in midbrain neurons. In the present study, we wanted to address the possible implication of the Erk5 signaling cascade in the development of midbrain dopamine neurons in mice. We have undertaken the systematic analysis of mRNA and protein expression of Erk5 and the main components of the signaling cascade in the midbrain during dopamine neuronal development. Preliminary data suggests that some components of the Erk5 signaling cascade are expressed during midbrain development. The goal is to determine if nurr1 and Erk5 are coexpressed in developing dopamine neurons to further explore the role of this signaling cascade in regulating nurr1 transcription activity and mediating neuroprotection.

Title: Role of reactive oxygen species and NADPH oxidases in the action of NMDA and high potassium in developing cerebellar granule neurons

Authors: *J. MORAN, M. OLGUIN-ALBUERNE, F. GOMEZ-FERNANDEZ, R. IBARRA-GARCIA PADILLA, S. GONZALEZ-MARTINEZ;
Natl. Univ. of Mexico, Apdo. Postal 70-253, Mexico

Abstract: Increasing evidence reveals a fundamental role of reactive oxygen species (ROS) in physiological and developmental processes. However, the mechanisms underlying such influence remain unclear. NADPH oxidases (NOX) are thought to be one of the main sources of these ROS, and the inhibition of NOX negatively affects neural differentiation, axon growth, and neurogenesis. On the other hand, in previous studies we demonstrated that depolarizing conditions (25 mM KCl, K25) and N-methyl-D-aspartate (NMDA) promote neuronal survival and maturation of cultured rat cerebellar granule neurons (CGN). It has also been shown that NMDA receptors are implicated in neuronal migration of CGN. Besides, it has been proposed that the activation of the NMDA receptor produces ROS from NOX2. Thus, all these evidences suggest that ROS and NOX may play an important role as mediators of some trophic conditions such as potassium depolarization and NMDA receptor activation during cerebellar development. In this work, we evaluated whether ROS and NOX are involved in the trophic actions of NMDA and K25 in CGN. In order to evaluate this possibility, we cultured CGN from 0 to 7 days *in vitro* (DIV) under physiologic concentrations of KCl (5 mM, K5) with or without 150 μM NMDA (NMDA) or depolarizing concentrations of KCl (25 mM, K25) that are believed to mimic the presynaptic trophic action on CGN. Cells were treated also with the antioxidants MnTMPyP and EuK-134, as well as the NOX inhibitors apocynin and AEBSF, and cell ROS levels, cell viability and neuronal migration were measured. Under these conditions, we observed that CGN cultured under all three conditions showed a marked increase in the ROS levels during 0-2 DIV, but from 3-5 DIV, CGN in K25 reduced ROS levels, while K5 and NMDA maintained a relatively high concentration of ROS. Under these conditions, K25 markedly reduced cell death that was observed at 3-7 DIV under K5 or NMDA conditions. Both, MnTMPyP and apocynin, reduced the effect of K25 on CGN survival. In addition, only NMDA significantly increased the rate of neuronal migration and all antioxidants and NOX inhibitors tested markedly reduced CGN migration. These results suggest that ROS could play a critical role in some developmental processes of CGN and that the trophic actions of potassium depolarization and NMDA receptor activation seem to be mediated by ROS probably produced by a NOX. At early times of development, the production of ROS seems to be critical for neuronal maturation. During a second stage of CGN development, ROS levels reach a low basal state to allow cell survival, otherwise this would lead to the activation of the programmed cell death

Title: Isoform specific regulation of GABAergic motor neuron development in *C. elegans*

Authors: *R. CAMPBELL[1], W. W. WALTHALL[2];
[2]Biol., [1]Georgia State Univ., Atlanta, GA

Abstract: The generation of complexity and diversity in the nervous system throughout evolution has been a fundamental area of research in neuroscience. It has been proposed that differences in gene regulation (epigenetic, transcriptional, post transcriptional, translational and post translational) could be responsible for the complexity and diversity in nervous systems. More recently evidence has shown that there is a trend in increased splice variants in the nervous system from reptiles to primates during development. Suggesting that splice variants may allow for increased complexity and diversity during evolution. However, due to the complexity of the nervous system, testing these hypotheses is difficult. Using the nematode, Caenorhabditis elegans, these hypotheses can be examined at a single neuron level. Previous studies have shown that evolutionarily conserved transcription factors are both necessary and sufficient for the post mitotic differentiation of different motor neurons. By examining the transcriptional regulation of one such factor, the COUP-TFII homolog, UNC-55, mechanisms of both differential transcription and isoform specific regulation of the expression of UNC-55 can be examined between motor neuron subtypes. Utilizing bioinformatics, putative transcription factor binding sites (cis sites) of the MEIS domain transcription factor, UNC-62 were found on the unc-55 promoter. Different classical mutant alleles and newly generated CRISPR/Cas9 alleles of UNC-62 repress, activate or have no effect on UNC-55::GFP expression. Dissection of the unc-55 promoter identified multiple regions that correlate with the UNC-62 mutant expression patterns. Using epistasis experiments, we found further evidence that different isoforms of UNC-62 work through different regions of the unc-55 promoter. Furthermore we provide evidence that the differentiation of GABAergic motor neurons is required in part by different UNC-62 isoforms in different sub classes. MEIS/UNC-62 and COUP-TFII/UNC-55 both appear to have conserved roles in development of the nervous system in other model systems. Thus, isoform specific regulation of gene expression and differentiation via conserved genes could provide a mechanism throughout evolution to generate diversity and complexity. Isoform specific transcriptional regulation of differentiating neurons is a relatively unexplored area of research.

Further research into this new exciting area could help to answer fundamental questions about evolution of the nervous system.

Title: Rainbow enhancer family for restrictive gene expression in the zebrafish green, red and blue cone photoreceptors

Authors: *X. WEI;
Univ. Pittsburgh, Pittsburgh, PA

Abstract: Specific interactions between cis- and trans-transcriptional regulatory factors underlie distinct gene expression profiles, which in turn dictate the morphogenesis and functionality of various cell types. It is, however, challenging to study such interactions because many regulatory factors are yet to be identified and because the principles that govern these interactions are complex and remain elusive. Here, we report the identification of three members of the rainbow enhancer family that control restrictive gene expression in the red, green, and blue (RGB) cone photoreceptors in the zebrafish retina: the enhancers of apicobasal polarity genes *ponli* and *crb2b* and the enhancer of an unknown gene. These rainbow enhancers share teleost-conserved sequence motifs that are critical for their RGB cone specific transcriptional regulation. We propose that a common or similar cis-regulatory mechanism(s) may underlie restrictive expression of a set of genes in RGB cones and consequently underlie proper RGB cone development and functions.

Title: Ketamine alters the expression of cytochrome p450 (cyp) genes in zebrafish larvae

Authors: *J. KANUNGO, B. L. ROBINSON, S. F. ALI, M. G. PAULE, M. DUMAS; Neurotoxicology, Natl. Ctr. For Toxicological Research/Food and Drug Admin., Jefferson, AR

Abstract: Ketamine, an antagonist of the N-methyl-d-aspartate (NMDA)-type glutamate receptors, is a pediatric anesthetic. Cytochrome P450 (CYP) mixed-function mono-oxygenase superfamily members include enzymes that not only metabolize endogenous molecules such as hormones, retinoids and lipids, but also biotransform xenobiotics. Deregulated activation/suppression of these CYP enzymes can cause physiological and developmental complications. Our studies show that ketamine causes developmental toxicity (neurotoxicity and cardiotoxicity) in zebrafish embryos. We have also shown that ketamine alters steroid hormone levels (endocrine disruption) and down-regulates CYP aromatase (CYP19A1a) gene expression in zebrafish larvae. In mammals, xenobiotics are known to induce the expression of their own metabolic enzymes. In this study, we explored whether ketamine alters the expression of its own metabolic enzyme CYP3A65 (zebrafish ortholog of the mammalian CYP3A4) gene in a dose-dependent manner in zebrafish larvae. Additionally, we also assessed ketamine-induced changes in the expression of *CYP1A*. CYP1A is induced by the carcinogenic polyaromatic hydrocarbons and halogenated aromatic hydrocarbons, compounds metabolically activated by this enzyme. Zebrafish larvae at three days post-fertilization (3 dpf) were exposed to ketamine for 24 h. Quantitative real-time reverse transcription polymerase chain reaction (qRT-PCR) analyses revealed that ketamine, at various concentrations (including doses equivalent to human sub-anesthetic and anesthetic doses), significantly induced CYP3A65 mRNA expression in a dose-dependent manner. In contrast, a sub-anesthetic dose of ketamine did not change CYP1A mRNA expression, whereas anesthetic doses significantly reduced its expression. These results, compliant with reported mammalian data, reinforce the suitability of modeling anesthetic-induced toxicity in zebrafish larvae *in vivo.*

Title: Role of CLN6 in neurite outgrowth and vesicle trafficking

Authors: *S. KOH[1], J. CAIN[1], H. MAGEE[1], K. WHITE[1], D. TIMM[1], K. HENSLEY[2], J. WEIMER[1];
[1]Sanford Hlth., Sioux Falls, SD; [2]The Univ. of TOLEDO, Toledo, OH

Abstract: Neurons become polarized as they develop specialized structures called axons and dendrites. These structures, or neurites, are made up of a network of microtubules which are used to transport cargo containing vesicles from the neuron soma. The cargo transported in these vesicles is necessary for the polarization and survival of the neuron. CRMP2 is a cytosolic phosphoprotein involved in the specification of neurites and regulates vesicular transport through an array of additional binding proteins. Disruption in CRMP2 signaling has been implicated in a host of neurological disorders, including variant late infantile neuronal ceroid lipofuscinoses (vLINCLs). vLINCL is a childhood neurodegenerative disease with age of onset between 2 and 6 years and results in seizures, motor dysfunction, retinopathy, and premature death. vLINCL results from mutations in *CLN6,* an ER-membrane and vesicular associated protein found to complex with CRMP2 and Kinesin light chain 4 (KLC4). We hypothesize that CLN6 forms a complex with CRMP2, a microtubule binding protein, and KLC4, a kinesin microtubule motor protein, to form the CCK complex which works to shuttle vesicular cargo along the network of microtubules in axons and dendrites. The trimeric CCK complex regulates initial neuronal outgrowth and delivery of vital cargo to the distal end of the growing neurite using CLN6 on an ER-derived vesicle, serving as a "molecular tag" for cargo transport. Our lab has shown that mutations in Cln6 can disrupt the formation of the CCK complex, affecting both neurite outgrowth and vesicular transport. To assess the role of Cln6 in neuritogenesis and vesicle transport, primary neuronal cultures were prepared from E15.5 timed pregnant wild type and *Cln6* mutant mice. Early neurite outgrowth was measured and the number of ER vesicles was counted in the presence and absence of Lanthionine ketimine *ethyl ester* (LKE), a molecule shown to stabilize CRMP2 interactions and promote neurite outgrowth. Live images were captured and the velocity of ER vesicles was measured. Disruption of the CCK complex in the *Cln6* mutant mice resulted in reduced initial neurite outgrowth, which was rescued with LKE

treatment. *Cln6* mice had fewer ER derived vesicles in their processes, which was also recovered with LKE treatment. Our findings suggest that mutations in Cln6 can alter the stability of the CCK complex, reducing the proper transport of ER-derived vesicles from the cell soma to the distal portion of the neuron and that treatment with CRMP2 stabilizing compounds are able to partially restore these defects in intracellular transport and may provide therapeutic benefit in vLINCL patients.

Title: Functional Maturation of neuronal networks *in vitro* is accelerated by combination of bioactive whey protein, natural bovine complex lipids and DHA

Authors: B. M. BADER[1], C. KUANG[2], C. EHNERT[1], K. JUEGELT[1], A. GRAMOWSKI-VOSS[1], Y. XIAO[2], R. MCMAHON[2], *O. H.-U. SCHROEDER[1], D. HONDMANN[3]; [1]NeuroProof GmbH, Rostock, Germany; [2]Mead Johnson Pediatric Nutr. Inst., Evansville, IL; [3]Mead Johnson Pediatric Nutr. Inst., Glenview, IL

Abstract: Optimal and adequate nutrition early in life is important for healthy growth and development. Especially brain development depends on supply of lipids and fatty acids. Studies have shown that Docosahexaenoic Acid (DHA), for example, plays an important role in infant brain development and it has been added to infant formula. It is of great interest to explore whether additional nutrients, in concert with DHA, are beneficial for the early brain development. In this context, we developed a brain-on-chip platform integrating multielectrode array (MEA) chips and neuronal tissue culture to dissect the nutritional impact on the neuronal network maturation, and asked whether the synergistically beneficial effects of nutritional combination of a bioactive whey protein (BWP), natural bovine complex lipids and DHA on neuronal maturation. Our newly developed "EARLY BRAIN DEVELOPMENT INDEX" is the measure for compound effects on early neuronal network maturation into complex neuronal circuits. We used primary neuronal cell cultures from mice (E15 cortex) which form actively communicating networks within a week when growing on micro electrode arrays (MEA). This spontaneous activity maintains for at least four weeks *in vitro*. We used the MEA technology

(Axion12 well MEAs, Maestro recording system, Axion Biosystems, Inc.) to record extra-cellular action potentials (i.e. spike trains) of single neurons of the network which were recorded at 7, 14, 21 and 28 days *in vitro*. These spike trains were analyzed by proprietary multi-parametric data analysis methods computing over 200 functional parameters describing the activity patterns for each recording day. This in-depth analysis allows following functional neuronal maturation from neurons of embryonic status to mature neuronal cells for 4 weeks *in vitro* and investigating of compound-induced effects on this maturation. The results show that combining DHA, BWP and natural bovine complex lipids together accelerates functional neuronal maturation above all other combinations and does not exhibit the late decline shown for the single components. In conclusion, natural bovine complex lipids as well as BWP in combination with DHA significantly accelerate functional neuronal maturation *in vitro*.

Title: Dmrt genes differentially participate in Cajal-Retzius cell development of the cerebral cortex

Authors: *T. KIKKAWA[1], N. SAKAYORI[3], H. YUUKI[1], Y. KATSUYAMA[2], N. OSUMI[1]; [1]Dept. of Developmental Neurosci., Tohoku Univ. Sch. of Med., Sendai, Miyagi, Japan; [2]Dept. of Organ Anat., Tohoku Univ. Sch. of Med., Sendai, Japan; [3]Dept. of Mol. Genet., Inst. of Biomed. Sciences, Fukushima Med. Univ., Fukushima, Japan

Abstract: For the development of the central nervous system, a large variety of neuronal cell types are needed to be generated at defined times and locations. Cajal-Retzius (CR) cells are the first neurons generated during corticogenesis and are essential pioneer neurons that control neuronal migration in the cortex. CR cells are derived from specific regions within the cortex, i.e., the pallial septum (PS), pallial-subpallial boundary (PSB), and cortical hem (CH). However, the molecular mechanism underlying the generation of CR cell subtype in distinct CR cell origins is poorly understood. We have previously shown that *Dmrta1* (*double-sex* and *mab-3* related transcription factor like family A1) is expressed in neural stem/progenitor cells in the neocortex and regulates proneural genes downstream of Pax6 (Kikkawa et al., 2013). In this study, we found that Dmrta1 was expressed in the PS, PSB, and a part of the CH, whereas Dmrt3 was strongly expressed in the CH. To reveal functions of *Dmrta1* and *Dmrt3* in the production of CR cells from distinct origins, we observed CR cells in *Dmrta1* and *Dmrt3* knockout (KO) mice (Konno et al., 2012). We found that *Dmrt3* ablation decreased the number of p73-positive CR cells derived from the CH compared with wild type (WT) mice, which may be reflection of the abnormal CH structure of *Dmrt3* KO mice. However, there were no differences between WT and *Dmrta1* KO mice in the numbers of p73-positive CR cells in the caudal cortex. These results suggest that *Dmrt3* is involved in the development of the CH-derived CR subtype. To further explore differential functions among Dmrt family members in CR cell development, we are currently analyzing the PS- and PSB-derived CR subtypes using *Dmrta1* and *Dmrt3* KO mice.

Title: Studying the function of human hippocampal neurons in a dish

Authors: *A. SARKAR, H. J. KIM, C. BARDY, A. MEI, R. JAPPELLI, F. H. GAGE;
Lab. of Genetics-Gage, The Salk Inst. For Biol. Studies, La Jolla, CA

Abstract: Hippocampus is the site of learning and memory in the brain and a growing body of evidences suggest some dysfunctions in hippocampal circuitry in the pathophysiology of many psychiatric and neurodegenerative diseases. More specifically, deficits in synaptic transmission in the hippocampal neurons have already been implicated in schizophrenia, major depression disorder and bipolar disorder. The availability of human ES and pluripotent stem cells (hPSCs) offers the opportunity to generate lineage-specific cells to investigate mechanisms of human diseases in brain regions such as the hippocampus. In this study, we investigated the development and functioning of a human neuronal circuitry *in vitro* consisting of hippocampal neurons derived from human ES cells. We utilized a two-step human stem cell based, directed differentiation protocol to generate hippocampal cultures. In the first step, we have used HuES6 cells to generate neuronal progenitor cells (NPC) with forebrain specific identities. In the second step, we further differentiated these NPCs to generate a neuronal culture enriched in mature hippocampal neurons. These neurons express appropriate cell fate and synaptic markers, and proved to be functionally active by the presence of mature spontaneous and evoked action potentials. We then used a microfluidic device based compartmentalized platform to study the synaptic connectivity between neurons. To identify the hippocampal neurons, we have also been able to utilize a promoter specific lentiviral reporter for live cell imaging. We demonstrated the establishment of functional neuronal network with time-lapse calcium imaging and extracellular electrophysiology recordings on these neurons at multiple time-points during differentiation. We demonstrate that this model recapitulates many of the features of hippocampal neuronal circuitry. The ability to mimic the developmental process of disease-relevant cell types in an *in vitro* setting is important for providing insights into the mechanisms of neurodevelopmental disorders. Furthermore, this lineage-specific model may provide important insights into the functioning of human hippocampal neurons from patients with various neurological disorders.

Title: Akirin2: A novel regulator of cortical development

Authors: P. J. BOSCH, L. C. FULLER, *J. A. WEINER;
Dept. of Biol., The Univ. of Iowa, Iowa City, IA

Abstract: Corticogenesis relies on proper temporal and spatial regulation of progenitor cell division to create a highly organized six-layer cortex. Premature differentiation of cells, disruption of cell cycle timing, excessive apoptosis, or incorrect migration signals can have devastating effects, resulting in a number of congenital disorders. Though genes encoding many key players in cortical development have been identified, our understanding remains incomplete. We found that Akirin2, a small nuclear protein with no known protein domains, DNA/RNA binding motifs or catalytic activity, is expressed in the embryonic telencephalon. Akirin2 has been reported to bind to 14-3-3 proteins, to regulate the NF-κB pathway, and to play roles in immune function, skeletal myogenesis, and meiosis. Little else is known, though Akirins have been postulated to control gene expression by acting as an interface between transcription factors and chromatin remodeling machinery. To study the role of Akirin2 in cortical development, we generated cortex-restricted knockout mice by crossing Emx1-Cre and floxed Akirin2 (Goto et al., Nature Immunol., 2008) lines. Most mutants do not survive past birth, and exhibit a massive reduction in cortex size, with very little dorsomedial telencephalon present. At embryonic day (E)12, when neuronal differentiation has just begun, the mutant telencephalon is already noticeably reduced in size. As the Emx1-Cre driver is active at E9, it appears that Akirin2 is required for the proliferation or survival of progenitors, or for prevention of premature neuronal differentiation. In support of this, we find disorganized and reduced EdU staining, following a 2 hour exposure, in the cortical ventricular zone of E12-14 mutants compared to controls. Interestingly, the Emx1-Cre transgene is also active in the limb epithelium, and we observe a soft-tissue syndactyly in Akirin2 mutant paws. Cleaved caspase-3 staining is decreased, and EdU staining is increased, in interdigital tissue at E13-14, implying that disrupted developmental apoptosis and/or proliferation leads to fusion of digits in Akirin2 mutants. We are currently analyzing cell-type specific markers during early corticogenesis and using a TdTomato Cre-reporter allele to directly visualize mutant progenitors and their behavior. We are also generating Akirin2/Bax double knockout mice to genetically block apoptosis and assess whether Akirin2 is required for survival of cortical progenitors. Elucidating Akirin2's mechanism of action will contribute to our overall understanding of cortical development and shed light on the cellular roles of this still-enigmatic protein.

Title: Imidazole-based small molecules that promote neurogenesis in pluripotent cells

Authors: *D. HALDER;
Dept. of Chemistry, Yonsei Univ., Ctr. For Biofunctional Molecules Res., Seoul, Korea, Republic of

Abstract: Imidazole-based small molecules that promote neurogenesis in pluripotent cells** *Debasish Halder, Jinhong Park, Wan Namkung and Injae Shin** **Abstract**: Several lines of evidence suggest that P19 cells are appropriate *in vitro* models for studies of neurogenesis. Herein we describe two small molecules termed neurodazine (Nz) and neurodazole (Nzl), which induce neuronal differentiation of P19 cells. Their ability to induce neurogenesis of P19 cells is comparable to that of retinoic acid. However, Nz and Nzl were found to be more selective neurogenesis inducers than retinoic acid owing to their unique ability to suppress astrocyte differentiation of P19 cells. Our results show that Nz and Nzl promote production of physiologically active neurons because P19 cell-derived neurons induced by these substances have functional glutamate responsiveness. The present study suggest that Nz and Nzl could serve as important tools to induce formation of specific populations of neuronal cell types from P19 cells as part of studies aimed at uncovering the molecular mechanisms that determine cell fate and developing new cell therapies. * Corresponding author e-mail: injae@yonsei.ac.kr ** This work was supported financially by grants from National Creative Research Initiative (2010-0018272, I.S.) and Basic Science Research programs (2012R1A1A1040142, N.W.) Title: Pten regulates amacrine cell number by reducing responsiveness to Tgfb negative feedback signaling

Authors: *N. TACHIBANA, R. CANTRUP, R. DIXIT, D. ZINYK, S. MCFARLANE, C. SCHUURMANS;
Univ. of Calgary, Calgary, AB, Canada

Abstract: The retina is comprised of one glial and six neuronal cell types that are all derived from a common pool of multipotent retinal progenitors during development. Generating proper numbers of each of these cell-types is essential to establish a functional neural network. Pten is a protein and lipid phosphatase that negatively regulates PI3K signaling and controls progenitor cell proliferation as well as cell differentiation in several cell lineages. Here we asked whether Pten plays a role in controlling cell proliferation and differentiation in the developing retina. To better understand how Pten might function in the developing retina, we first performed a detailed spatio and temporal analysis of its expression, comparing the distribution of Pten to that of phosphorylated, activated forms of Akt, which are reduced when Pten is active. We found a general trend towards higher pAkt levels over developmental time, with Pten and Akt expressed at low levels in retinal progenitors, and at higher levels in postmitotic retinal cells in the inner and ganglion cell layers. To assess Pten function, we generated a retinal-specific conditional knock-out. The loss of Pten resulted in a transient increase followed by a decrease in progenitor cell proliferation. Consequently, fewer amacrine cells and rod photoreceptors were produced. We further pursued Pten function in regulating amacrine cell production, demonstrating that Pten is not required in amacrine cells to regulate negative feedback signaling. Instead, we found that Pten is required in retinal progenitor cells, where it regulates pSmad2/3 levels and responsiveness to Tgfb2 negative feedback signaling. Taken together, this study has revealed that Pten is a key regulator of proliferation and differentiation in the retina, acting in part by controlling responsiveness to Tgfb2 negative feedback signaling.

Title: Comparative analysis of DNA methylation in saliva and brain of children with and without autism spectrum disorder (ASD)

Authors: *J. MARTINEZ[1], A. DELORA[1], F. MENNEN[2], J. A. STEPHEN[3], E. L. BEARER[1]; [1]Pathology, Univ. of New Mexico, Albuquerque, NM; [2]USC, Los Angeles, CA; [3]The Mind Res. Network, Albuquerque, NM

Abstract: Adverse childhood experience leads to adult mental and physical health problems. Our hypothesis is that these outcomes are in part due to epigenetic changes that alter patterns of expression in the brain and impact brain circuitry. Yet there are no existing biomarkers to witness these epigenetic events. Our over-arching goal is to discover and develop biomarkers to detect and measure such epigenetic changes. For epigenetic analysis, we focus on DNA methylation because basic science has developed the tools for detection and analysis, and because clinical studies of specific methylation sites correlate with emotional outcomes. DNA methylation is currently detected by three approaches: 1) bisulfite conversion and sequencing, with or without reduced representation; 2) Infinium HM450K BeadChip; and 3) Methyl binding domain (MBD) pulldown followed by sequence analysis of DNA fragments. For analysis of methylation events in the brain, we are limited to either peripheral tissue in the living subject or post-mortem brain. Hence correlation of peripheral methylation patterns with brain is a necessary step to identify biomarkers for diagnosis. Here we report whole genome methylation patterns in children with and without ASD, compare methods for analysis, and compare DNA methylation patterns in saliva with post-mortem brains. We found a subset of specific genes with significant changes in both brain and saliva compared to normal controls. These studies identified a subset of methylation sites in saliva that correlate with those brain in these children with ASD. We are now applying these techniques to children referred for therapy after documented maltreatment. As a first pass to determine chronic stress objectively, we measure hair cortisol, and for impact we analyze whole genome DNA methylation patterns. We expect that methylation patterns will be a useful biomarker to identify children at risk for future psychosocial disorders, facilitating earlier interventions than are now possible. Supported by NIMH R01MH087660 and UL1 TR000041 pilot project (ELB).

Title: Absence of the serine protease inhibitor neuroserpin alters neurogenesis, neuronal morphology and leads to behavioural abnormalities

Authors: *G. GALLICIOTTI[1], M. NEUMANN[2], R. REUMANN[2], B. SZALAY[2], M. SCHWEIZER[3], F. MORELLINI[3], M. GLATZEL[2];
[1]Univ. Med. Ctr. Hamburg-Eppendorf, [2]Neuropathology, [3]Ctr. for Mol. Neurobio., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Neuroserpin, a functional inhibitor of tissue plasminogen activator, is involved in the pathophysiology of stroke, schizophrenia, depression and fear disorders. Neuroserpin expression is restricted to the central and peripheral nervous system, mainly in hippocampus, amygdala, olfactory bulb and neocortex, and is particularly high at late developmental stages and perinatally. In neurons and neuroendocrine cells neuroserpin is stored in large dense core vesicles from where it is secreted in a regulated manner. Neuroserpin's expression suggests a function in development and maintenance of the nervous system. Indeed, experiments performed with cultured cells demonstrate a role for neuroserpin in neuritogenesis and synaptogenesis. In order to elucidate the function of neuroserpin *in vivo*, we analysed neuroserpin-deficient mice. In particular, we investigated neuroserpin's function in neurogenesis, neuritogenesis and synaptogenesis, and the behaviour of neuroserpin-knock out mice. We found that absence of neuroserpin leads to reduced neuronal precursor cell proliferation and premature neuronal differentiation in the neurogenic subgranular zone of the hippocampus during developmental neurogenesis, resulting in decreased cellularity in the dentate gyrus of adult mice. Golgi impregnation and diolistic labeling of brains from neuroserpin-deficient mice show differences in neuronal morphology in knock out animals. Behavioural testing indicates impairment in social behavior, spatial learning and memory and contextual memory in neuroserpin-deficient mice. In conclusion, we found that absence of neuroserpin impairs developmental neurogenesis and alters neuronal morphology *in vivo*. Neuroserpin's role in neurodevelopment may account for the behavioural changes observed in neuroserpin deficient mice, pointing to a role for neuroserpin in development of neuropsychiatric diseases.

Title: Magnetic nanoparticles for manipulating neuronal growth and differentiation

Authors: *M. MARCUS, K. BARANES, M. KARNI, N. ALON, I. LEVY, S. MARGEL, A. SHARONI, O. SHEFI;
Bar Ilan Univ., Ramat Gan, Israel

Abstract: The ability to manipulate neuronal organization and growth has extensive implications in neuronal regeneration and tissue engineering. It has been shown that physical forces play a key role in shaping neuronal structure and in interactions between neurons and their vicinity. In the present study we use magnetic nanoparticles (maghemite, γ-Fe2O3) as mediators to apply physical forces locally and as carriers of neuronal growth factors. We use these nano-complexes in order to locate cells, promote neuronal growth and affect growth orientation. We designed and generated magnetic fields with controlled magnetic flux densities at multiple scales of size and strength. In addition to strong permanent bar magnets and electromagnets we fabricated a unique device, embedded with micro-patterned pads that can be magnetized selectively. First, we incubated, prior to plating, the treated cells, PC12 cells and primary neurons, in medium enriched with iron oxide nanoparticles conjugated to fluorescent tag. Both types of cells uptake the nanoparticles and turned sensitive to the magnetic stimulation with no cytotoxic effect. We successfully improved the cells motility and attracted the cells to one magnetic pole or the other or towards magnetic 'hot spots'. Plating PC12 cells atop the micro-patterned device has led to an organized network of clusters of cells. After cells adhered to the plate the magnetic field affected the neuronal outgrowth orientation, combining the normal chemical signaling with the applied physical forces. Currently we are mathematically modelling nanoparticles uptake by cells and the organization of magnetized cells in response to various external magnetic fields. In addition, we found that covalent conjugation of the magnetic nanoparticles to Nerve growth factor (β-NGF) which is a critical component in nerve tissue development and repair enhanced the typical effect of NGF. Morphometric and molecular measurements revealed that treatment with the nanoparticle-NGF complex leads to a promoted differentiation progression and to more complex dendritic trees. Even low doses were sufficient to trigger the promoted differentiation process. Moreover, stability and signaling pathway assays suggest conjugation to NPs as a method to extend the half-life of NGF, thereby increasing its availability and efficiency. Our study presents

an emerging magneto-chemical method for the manipulation of neuronal migration and growth opening new directions in non-invasive neuronal repair.

Title: FGF2-mediated signal transduction in human SH-SY5Y neuroblastoma cells involves cross-talk between the ERK1/2 pathway and protein kinase C

Authors: ***L. A. DOKAS**, S. J. WATSON, H. AKIL;
Univ. of Michigan, Ann Arbor, MI

Abstract: The SH-SY5Y human neuroblastoma cell line is an appropriate model system in which to examine FGF2-mediated signal transduction. Coupling of the FGF receptor (FGFR) to the extracellular signal-regulated kinase (ERK1/2) pathway in these cells results in rapid ERK1/2 phosphorylation in response to FGF2 that is blocked by the FGFR inhibitor, PD 173074. SH-SY5Y cells are of the N (neuron)-type and they can be further differentiated to a mature catecholaminergic phenotype by the combination of FGF2 and a phorbol ester that activates protein kinase C (PKC). Cells differentiated in this manner assume a phenotype characterized by increased expression of tyrosine hydroxylase (TH) and of GAP-43, a neuron-specific protein that is a major PKC substrate. Induced morphological changes include elaboration of long processes with varicosities and growth cone-like terminals. Increased GAP-43 expression is primarily caused by activation of PKC while that of TH is more responsive to FGF2. Thus, it is of interest to determine whether and how the ERK1/2 and PKC pathways interact to mediate the cell signaling underlying such effects and to compare these interactions in undifferentiated and differentiated cells. Either FGF2 or the phorbol ester, phorbol 12, 13-dibutyrate (PDB), increases ERK1/2 phosphorylation in SH-SY5Y cells but not in an additive manner. Preincubation of cells with the PKC inhibitor, GF 109203X, not only reduces PDB-stimulated ERK1/2 phosphorylation to basal levels as expected, but also causes a nearly-complete inhibition of ERK1/2 phosphorylation elicited by FGF2. These results suggest a considerable degree of cross-talk

between the ERK1/2 and PKC pathways. Cells differentiated with FGF2 and PDB contain higher levels of phosphorylated ERK1/2 than control cells. However, once differentiated, SH-SY5Y cells lose the ability to activate ERK1/2 phosphorylation upon retesting with FGF2, an alteration that is only seen when cells are differentiated with the combination of PDB and FGF2. The overall conclusion derived from these experiments is that both ERK1/2 and PKC activities are essential components of normal FGF2-mediated signaling in SH-SY5Y neuroblastoma cells and during the differentiation process.

Title: A shared molecular mechanism regulates transcription of tyrosine hydroxylase and glutamate decarboxylase 1 in the olfactory bulb

Authors: ***M. WANG**[1], E. CAI[1], N. FUJIWARA[1], H. BAKER[1,2], J. W. CAVE[1,2];

Abstract: The molecular mechanisms responsible for the preferential co-expression of tyrosine hydroxylase (Th) and glutamate decarboxylase 1 (Gad1) in glomerular layer interneurons of olfactory bulb are not understood. In this study, we show that transcription of Th and Gad1 in the olfactory bulb is regulated, in part, by a shared mechanism mediated by conserved G:C-rich regions within the proximal promoter. These G:C-rich regions form single-stranded DNA secondary structures. In addition, they also recruit heterogeneous nuclear ribonucleoproteins (hnRNP) K and/or LL, which preferentially bind C-rich single stranded DNA and up-regulate promoter activity. Stabilization of DNA secondary structures with small molecules, such as TMPyP4, block hnRNP protein binding and modulate gene promoter activity. These findings suggests that G:C-rich region secondary structures are novel targets for pharmacological modulation of the dopaminergic and GABAergic phenotypes. We also describe studies that test

if either DNA secondary structure formation or recruitment of hnRNP proteins is modulated by synaptic activity, which is known to regulate Th and Gad1 transcription levels in the olfactory bulb. Together, these findings show that conserved G:C-rich regions in Th and Gad1 proximal promoters mediate similar transcription regulatory functions and provide novel insight into the molecular mechanisms underlying the specification and potential modulation of dopaminergic and GABAergic phenotypes.

Title: Cholinergic regulation of the hippocampal output to entorhinal cortex

Authors: ***J. HAAM**, J. L. YAKEL;
NIH/NIEHS, Research Triangle Park, NC

Abstract: The hippocampus is the major brain structure that plays an important role in memory formation; it receives sensory inputs from the cortex during memory encoding while transferring the temporary hippocampal information back to the cortex during memory consolidation. It has been shown that acetylcholine (ACh) stimulates memory encoding while inhibiting the memory consolidation process, but the underlying mechanism is yet unclear. Given that memory encoding and consolidation are mutually exclusive processes, we hypothesized that ACh suppresses the hippocampus to the entorhinal cortex (EC) circuit, which is the gateway to the memory consolidation pathway. The CA1 pyramidal neurons in the hippocampus are the final output of the hippocampus and receive feedback inhibition from the GABAergic interneurons oriens lacunosum-moleculare (OLM) cells which express high levels of ACh receptors (AChRs). Our previous study has shown that cholinergic inputs stimulate OLM interneurons, which increases GABAergic inputs to CA1 pyramidal neurons. To study how ACh regulates the circuits, we used electrophysiological recordings with optogenetics. The blue light-sensitive channelrhodopsin ChR2 was selectively expressed in cholinergic neurons by injecting AAV9-dfloxed hChR2 to cultured slices from the choline acetyltransferase (ChAT)-cre mice.

Photostimulation of cholinergic neurons caused a decrease in depolarizing step-induced firing in CA1 pyramidal neurons. To examine whether the inhibition of CA1 pyramidal neurons modulates the hippocampal output to the EC, we recorded from the layer V EC (ECV) neurons with stimulation of CA1 pyramidal neurons. We used the retrograde monosynaptic tracing method using G-deleted rabies viruses. For this experiment, the red-shifted channelrhodopsin C1V1 was expressed in ChAT neurons to allow the expression of ChR2 specifically in CA1 pyramidal neurons that are presynaptic to ECV neurons. Red light-stimulation of cholinergic neurons caused a decrease in blue-light evoked currents in ECV. The cholinergic suppression of the evoked currents in ECV was blocked by the M1 muscarinic receptor pirenzepine. We also tested whether cholinergic inputs affect hippocampal theta modulation of ECV neurons. Theta burst stimulation in the CA1 pyramidal layer caused an increase in firing activity in ECV neurons. Photostimulation of cholinergic neurons suppressed the theta burst stimulation-induced increase in firing in ECV neurons. Our data demonstrate that ACh may inhibit the memory consolidation process by suppressing the hippocampal output via the OLM-mediated feedback inhibition onto CA1 pyramidal neurons.

Title: Therapeutic hypothermia in neonatal hypoxia-ischemia: neuroprotection through alteration in acetylated metabolites

Authors: T. TAKENOUCHI[1], Y. SUGIURA[1], T. MORIKAWA[1], T. NAKANISHI[2], Y. NAGAHATA[1], T. SUGIOKA[1], K. HONDA[1], *A. KUBO[1], T. HISHIKI[1], T. MATSUURA[1], T. HOSHINO[1], T. TAKAHASHI[1], M. SUEMATSU[1], M. KAJIMURA[1];
[1]Keio Univ., Shinjuku-Ku, Tokyo, Japan; [2]Shimadzu Corp., Kyoto, Japan

Abstract: Mild hypothermia following intrapartum asphyxia has been widely used as a standard therapeutic intervention. However, the exact molecular mechanisms whereby hypothermia improves outcomes remain unclear. To investigate underlying mechanisms responding to the hypothermic intervention, we employed a two-step approach; metabolomics to target metabolic pathways responding to lowering temperature, and quantitative imaging mass spectrometry to reveal spatial alterations in targeted metabolites at specific regions of the brain. Seven-day male

Sprague-Dawley rats underwent surgical ligation of left common carotid artery, followed by systemic hypoxia with 8% oxygen for 2.5 hours. Subsequently, rats were returned to 21% oxygen at either 38°C (normothermia) or 30°C (hypothermia) for 3 hours. Brain metabolic states were rapidly fixed by in-situ freezing. Neurobehavioral outcome was assessed using objective scale of posturing during the reoxygenation period. Non-targeted metabolomics of 107 metabolites showed that hypothermia causes not only decreases but also increases in metabolites. Specifically, hypothermia diminishes the carbon biomass related to acetyl-moieties such as pyruvate and acetyl-CoA. Conversely, it increases deacetylated metabolites such as carnitine and choline. Quantitative imaging mass spectrometry showed that hypothermia decreases acetylcholine contents in hippocampus and amygdala. In the same anatomical regions, there was an inverse increase in carnitine. Collectively, these findings suggests that hypothermia after hypoxia-ischemia exhibits neuroprotection by altering cellular acetylation status with coordinated suppression of acetyl-CoA which resides at metabolic crossroads of glycolysis, amino acid catabolism and ketolysis.

Title: Insulin increases striatal cholinergic interneuron excitability and enhances dopamine release via nAChRs

Authors: *J. C. PATEL[1], C. R. LEE[1], M. A. STOUFFER[1], P. WITKOVSKY[2], R. P. MACHOLD[3], M. E. RICE[1];
[1]Dept. of Neurosurg., [2]Dept. of Ophthalmology, [3]Smilow Neurosci. Program, NYU Sch. of Med., New York, NY

Abstract: Insulin in the brain can act on reward-related circuitry to regulate feeding behavior. Previous studies have focused on insulin actions at the level of mesolimbic dopamine (DA)

neurons via insulin receptors (InsRs) that enhance DA transporter activity and induce long-term depression of excitatory inputs. We reported previously that insulin increases evoked extracellular DA concentration $[DA]_o$ detected by fast-scan cyclic voltammetry in the striatal complex by enhancing DA release (Stouffer et al. SFN, 2011, 732.16). However, whether this is a direct effect on DA axons or indirect via local circuitry is not known. Using immunohistochemistry on rat striatal sections we indeed found striatal InsRs on DA axons. Strikingly, we also found abundant InsR expression on large cell bodies identified as cholinergic interneurons (ChIs) by co-immunostaining for choline acetyltransferase (ChAT), the primary acetylcholine (ACh) synthesizing enzyme. Using whole-cell current-clamp recording in striatal slices we examined the effect of insulin on ChI excitability using a series of 3 s depolarizing current pulses (200, 300 and 400 pA). Each pulse elicited a train of action potentials that exhibited spike frequency adaptation, often with loss of spiking by the end of the current pulse. In the absence of insulin, ChIs showed little change in the number of action potentials evoked by each stimulus over time (n = 12 stimulus pairs, 4 cells; $p > 0.05$). By contrast, insulin (30 nM) attenuated spike frequency adaptation, resulting in an increase in spike number for each current step (from 12.7 ± 3.1 to 19.1 ± 4.6 at 200 pA; 15.6 ± 3.9 to 23.7 ± 5.6 at 300 pA; 18.7 ± 5.2 to 27.3 ± 6.7 at 400 pA; n = 7 stimulus pairs each; $p < 0.05$), with an overall increase in spike number from 15.7 ± 2.3 to 23.4 ± 3.2 (n = 21 stimulus pairs; $p < 0.001$). Importantly, the effect of insulin on spike number was prevented by HNMPA (5 μM), a selective InsR inhibitor, but not by picropodophyllin (1 μM), an inhibitor of IGF-1R (insulin-like growth factor 1 receptor). Given that ChIs potently regulate striatal DA release via nicotinic ACh receptors (nAChRs) on DA axons, we tested their role in the effect of insulin on evoked $[DA]_o$. Indeed, the effect of insulin on elevating evoked $[DA]_o$ in rat striatum was prevented by nAChR antagonists, mecamylamine (5 μM) or DHβE (1 μM). Moreover, insulin failed to enhance evoked $[DA]_o$ in mice with genetic ablation of forebrain ChAT *vs*. controls. Thus, abundant InsR expression on ChIs, enhancement of ChI excitability with acute insulin, and the nAChR-dependence of insulin-enhanced DA release implicate ChIs as novel insulin targets that can enhance striatal DA release, and thereby influence food reward.

Title: Point mutations in the vesicular acetylcholine transporter uncover key roles for central acetylcholine release in organismal survival and behavior

Authors: *S. BOPPANA, A. C. BLAKE, Jr., O. AKINRINSOLA, H. LAWAL;
Biol. Sci., Delaware State Univ., Dover, DE

Abstract: Decline in cholinergic neurotransmission is associated with normal and pathological aging. However, the precise role of changes in acetylcholine (ACh) release in mediating behaviors, such as locomotion, and learning and memory remain poorly understood. The vesicular acetylcholine transporter (VAChT), found in many organisms including worms, flies and humans, is responsible for the packaging and transport of acetylcholine for exocytotic release. A complete loss of VAChT function is lethal, while severe mutations cause decreased locomotor performance in *Drosophila*. To understand the effect of cholinergic release on behavior, we are studying four developmentally lethal point mutation alleles (Vacht1, Vacht2, Vacht4 and Vacht8) of varying severity. Here we report an adult rescue of this developmental lethality through the expression of a <50% expression of wildtype VAChT in each of the mutations analyzed. Analysis of locomotive behavior in the rescued adults shows a differential effect corresponding to the severity of these point mutations. In addition, this genetic rescue analysis reveals a distinction in the level of ACh required for the rescue of lethality and that needed for the restoration of normal locomotion behavior. To further determine the mechanism through which these mutations disrupt the function of the transporter, we generated the point mutant alleles described above *in vitro* and assessed the effects of these mutations on trafficking of VAChT and the transport of ACh by VAChT in the *Drosophila* S2 cell line. Together these studies reveal the importance of central acetylcholine release in regulating survival and synaptic activity and underscore the role of point mutations in dissecting neurotransmitter transporter function.

Title: The distribution within the mouse striatum and specificity of transgenic expression of opsins in cholinergic interneurons

Authors: A.-C. SIENA, N. CHUHMA, *S. RAYPORT, S. MINGOTE;
Psychiatry / Molec Therapeut., Columbia Univ., New York, NY

Abstract: Striatal cholinergic interneurons (ChIs) are involved in motor coordination, cognition, motivated behavior, as well as the pathophysiology of several neuropsychiatric disorders. They make up about 1% of the striatal neuron population, and are the source of all striatal acetylcholine. Despite their integral role in striatal function, a modern stereological analysis of the number and their density has not been performed in the mouse, and there is a lack of knowledge regarding the regional density of ChIs within striatal subdomains. To gain a more comprehensive understanding of neuronal function, researchers are now utilizing optogenetics to selectively drive action potential firing with channelrhodopsin (ChR2) or inhibit action potential firing with halorhodopsin (NpHR). Crucial to optogenetic experiments, we need to know what percent of target cells express the desired opsins and are therefore subject to photostimulation. Here, using unbiased stereological methods, we found that the regional density of ChIs was relatively uniform across striatal subdomains, specifically the nucleus accumbens (NAc), medial dorsal striatum (medial Str), and lateral dorsal striatum (lateral Str). Within NAc subregion, ChI density may be higher in the NAc shell than the NAc core. To address the potential for optogenetic modulation of ChI's, we bred conditional transgenic mice choline acetyl transferase (ChAT) cre driver mice to express ChR2 or NpHR in ChIs (Ai32 mice and Ai39 mcie respectively). We found that transgenic expression of ChR2 or NpHR in ChIs was highly specific and efficient in the NAc, medial Str, and lateral Str. In summary, ChIs are relatively uniformly distributed in the mouse striatum, reliably express ChR2 or NpHR in conditional transgenic mice and should thus be susceptible to reliable optogenetic modulation.

Title: Negative modulation of choline transporter (CHT) function reveals superior cholinergic capacity of CHT-overexpressors

Authors: *P. VALUSKOVA[1,2], A. KOSHY CHERIAN[1], K. PITCHERS[1], Y. KIM[1], C. W. LINDSLEY[3], E. A. ENNIS[3], R. D. BLAKELY[3], M. SARTER[1];
[1]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Inst. of Physiol., First Fac. of Medicine, Charles University, Prague, Prague, Czech Republic; [3]Dept. of Pharmacol., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: The uptake of choline by the hemicholinium-3 (HC-3)-sensitive high affinity choline transporter (CHT) has been described as the rate-limiting step for acetylcholine (ACh) synthesis. We previously demonstrated that the capacity of the CHT to sustain ACh synthesis and release primarily reflects the density of CHTs in synaptosomal plasma membrane. Limitations in the intracellular availability of CHTs for mobilization and surface expression, such as modeled by CHT heterozygosity, diminish the capacity of cholinergic neurons and cause associated impairments in attentional performance. As decline in cholinergic functions greatly contributes to the severity of cognitive impairments we have been exploring the potential usefulness of therapies designed to enhance CHT function. To this end, we demonstrated that cholinergic neurons of mice overexpressing the CHT (CHT-OXP) show a 2 to 3-fold elevation of CHT densities in synaptic plasma membrane and intracellular domains and that CHT-mediated choline uptake is more than 2-fold higher than in wild type (WT) mice (Holmstrand et al., 2013). Here we employed choline-sensitive microelectrodes to measure choline currents in the presence of the CHT blocker HC-3 or the negative modulator ML352 (Ennis et al., 2015). To evoke presynaptic ACh release events ("transients"), we pressure-ejected an α4β2* nAChR agonist into the recording area (see Parikh et al., 2008, 2010). In the absence of a CHT ligands, the amplitudes of evoked transients in CHT-OXP were smaller than in WT mice, reflecting the superior rate of clearance of choline and the underlying, relatively high density of surface CHTs in CHT-OXP. Three pressure ejections of one of the CHT ligands were followed by repeated assessment of evoked currents over the next 40 min. In WT mice, HC-3 and ML352 both reduced the amplitude of evoked transients. This finding is consistent with the pharmacological classification of HC-3 or ML352, indicating that these compounds interfered with choline uptake and thus ACh synthesis and eventually release. In contrast, evoked transient amplitudes in CHT-OXP remained initially unaffected by the CHT ligands but later increased over baseline. These results are consistent with the hypothesis that CHT-OXP models a gain in cholinergic function and suggest that interference with CHT function enhances CHT surface density in over-expressors.

Title: Cholinergic system regulation of behavior in *Drosophila* melanogaster larvae

Authors: *C. ENGLISH, C. MALLOY, R. L. COOPER;
Univ. of Kentucky, Lexington, KY

Abstract: We investigated the role of acetylcholine in the *Drosophila* melanogaster larval CNS to identify how this neuromodulator regulates locomotion and feeding behaviors. We combined pharmacological and genetic approaches in order to deduce acute changes in behaviors upon altering the activity of the cholinergic system. Genomic screens have revealed that there are ten receptors in *Drosophila* that are very similar to the nicotinic acetylcholine receptors (nAchRs) of mammals. In *Drosophila*, acetylcholine is a neurotransmitter within the CNS and is the excitatory neurotransmitter for sensory neurons but not motor neurons, as in mammals. It has been found that this system is important in regulating specific behaviors including medial fiber escape response; however, the integration of cholinergic signaling within the CNS and regulation of motor output in this model organism is not well-known. Thus, we are investigating the role of cholinergic neuronal activity in regulating distinct motor behaviors. In addition, a distinctive advantage of *Drosophila* larvae is the short developmental time (~4 days) in which the development of the CNS can be investigated. Genetic and pharmacological techniques will be employed, including temperature-sensitive silencing and activation of cholinergic neurons in transgenic flies and acute and long-term feeding of cholinergic agonists and antagonists in order to investigate activity based modulation of specific behaviors. Analysis has shown that silencing cholinergic neurons, genetically, decreases body wall contractions significantly, reducing crawling speed. Preliminary pharmacological analysis shows that *Drosophila* larvae fed high concentrations of nicotine for 20 minute displayed a decrease in body wall contractions. Thus, it is evident that this system is integral in regulating two distinct motor behaviors. In addition, the proposed experimental design allows for a multitude of options for future experimentation including investigation of regulation of olfaction and response to light upon altering the cholinergic system. All of these are testable for proof of concept and will provide the degree of

inhibition in sensory-motor responses. This study will help to establish the role of acetylcholine in regulating simple motor behaviors.

Title: Intra-accumbal infusion of endomorphin-1 and endomorphin-2 decreases accumbal acetylcholine efflux via mu2 receptors in the nucleus accumbens of freely moving rats

Authors: *T. SAIGUSA, Y. AONO;
Nihon Univ. Sch. of Dent. at Matsudo, Chiba, Japan

Abstract: Background: Nucleus accumbens (NAc) is a terminal area of mesolimbic dopaminergic neurons that project from the ventral tegmental area. We have shown that local administration of the putative endogenous mu receptor agonists endomorphin (EM)-1 and EM-2 into NAc increased accumbal dopamine (DA) efflux with and without stimulating accumbal mu receptors, respectively (Okutsu et al., 2006). Accumbal cholinergic neurons express mu receptors that are thought to inhibit neural activity. We have shown that intra-accumbal administration of EM-1 and EM-2 reduces accumbal acetylcholine (ACh) efflux. Mu receptors are divided into mu1 and mu2 receptors based on sensitivity to the mu receptor antagonist naloxonazine. In order to study involvement of mu receptor subtypes in regulation of accumbal cholinergic activity, we analysed effects of the mu receptor antagonist CTOP and selective mu1 receptor antagonist naloxonaize on EM-1- and EM-2-induced reduction of accumbal ACh efflux of freely moving rats using *in vivo* microdialysis. We also investigated antagonist effects on EM-1- and EM-2-induced accumbal DA efflux as the perfusate contains a low concentration of physostigmine (50 nM) that may affect EM's effects on accumbal DA efflux. Methods: Male Sprague-Dawley rats were used. ACh and DA levels in accumbal perfusates, taken every 15 and 20 min, were determined by HPLC-ECD, respectively. CTOP, EM-1 and EM-2 were administered

intracerebrally through the dialysis probe. Doses of these compounds indicate total amount (mol) over a 30-min infusion time. CTOP was infused just before and naloxonazine given intraperitoneally 24h before local administration of EM-1 and EM-2, respectively. Results and Discussion: CTOP (3 nmol) inhibited EM-1 (30 nmol)- and EM-2 (30 nmol)-induced reduction of ACh levels. CTOP (3 nmol) also inhibited EM-1 (15 nmol)-induced DA efflux, but failed to alter EM-2 (30 nmol)-induced DA efflux. While naloxonazine (15 mg/kg ip) did not alter EM-1 (30 nmol)- and EM-2 (30 nmol)-induced reduction of ACh levels, it inhibited EM-1 (15 nmol)-induced of DA efflux. The present study shows that locally administered EM-1 and EM-2 into NAc reduce accumbal ACh efflux through mu2 receptor activation. The present results support our reports that EM-1 increases accumbal DA efflux by mu1 receptor stimulation and EM-2 enhances accumbal DA efflux through mechanisms independent from opioid receptor activation (Okutsu et al., 2006). The present study also implies that mu1 receptors play a stimulatory role in regulating accumbal dopaminergic activity and mu2 receptors play an inhibitory role in regulating accumbal cholinergic activity.

Abstract: Introduction: Insomnia is one of the most common sleep disorders in humans. Due to ethical and methodological difficulties involved in human research we use mice models to evaluate what has been called Paradoxical Sleep Deprivation (PSD) which is selective for Rapid eye movement (REM) sleep. By other hand brainstem cholinergic neurotransmission is involved

in the generation and maintenance of rapid eye movement (REM) sleep. There is strong evidence that pontine cholinergic and cholinoceptive neurons, interacting in coordination, trigger and maintain REM sleep. So, for investigate Acetylcholine activity we used Raman spectroscopy which is a technique who involves shining a monochromatic light source on a sample and detecting the scattered light with automated system to manipulate the Raman and locate each sample to bring the same focal length with the intention of bringing the same conditions in each of the samples, this procedure allows to know the active molecules in sleep vs PSD offering the opportunity to know the mechanism of neuronal functioning under these conditions. Thus, Raman spectroscopy provides information about molecular vibrations that can be used for sample identification and quantitation. Objective: Measure the content of acetylcholine and serotonin by Raman spectrophotometry and western blot technique in cerebral cortex. Material and Methods: Adult male Balb-C mice, bred in in the animal house of University Center of Health Sciences of the University of Guadalajara, weighting 23-26g. Mice were housed in groups of 5 and kept in a room with a controlled light-dark cycle (lights on from 8 a.m. to 8 p.m.) and temperature (22 ± 2oC). Groups were 1. Control, 2. PSD. REM sleep deprivation started at 9 a.m. Animals were placed individually in water tanks on a small flower-pot for 96 h. The control mice were kept individually in their home cages at the same room. Results: We found by Raman spectroscopy and western blot technique major content of acetylcholine neurotransmitter in brain cortex of animal exposed to PSD.

Title: Deficits in central acetylcholine release impairs induced locomotion in *Drosophila*

Authors: A. C. BLAKE, Jr[1], M. HEREDIA[1], *H. O. LAWAL[2];
[1]Biol. Sci., [2]Biol., Delaware State Univ., Dover, DE

Abstract: The role of cholinergic dysfunction in the cognitive decline associated with neurological diseases such as Alzheimer's disease is well known. The key elements required for presynaptic acetylcholine (ACh) release and post-synaptic signaling have also been described in detail. However, the precise relationship between alterations in ACh neurotransmission and downstream changes in behavior in the nervous system remain poorly understood. One critical element of cholinergic signaling is the vesicular acetylcholine transporter (VAChT) which is required for the transport of ACh from the cytoplasm into synaptic vesicles for exocytotic release. A complete loss of Vacht is lethal in flies, worms and mammals. Here we hypothesize that subtle changes in Vacht will uncover important roles of ACh release in behavior. Using point mutations to disrupt VAChT function, we report that a series of Vacht mutations impair two locomotion circuits, baseline and touch response locomotion. In particular, Vacht mutants display a deficit in the timing of the response to touch stimulus in a manner corresponding to severity of the mutant alleles studied. We categorized the resulting allelic series as mild, moderate and severe with respect to acetylcholine release. We further report the genetic rescue of Vacht mutant deficits using wildtype VAChT. Interestingly, here too, we find that the expression of the same level of wildtype VAChT in the different mutant backgrounds produces a differential effect on locomotion behavior corresponding to the severity of those mutations. In addition, we conducted a pharmacological rescue study using agonists of the dopaminergic and cholinergic pathways, using dopamine and brucine respectively, and found that both drugs partly rescue the locomotion deficits in the mutants. Together, this report supports a key role for acetylcholine signaling in regulating the timing of the response to a mechanical stimulus and underscores the utility of point mutations that compromise VAChT activity *in vivo* as tools to elucidate the complex relationship between altered ACh release and behavioral deficits.

Title: An essential role of acetylcholine-glutamate synergy at habenular synapses in nicotine dependence

Authors: *A. GORLICH[1], S. FRAHM[2], B. ANTOLIN-FONTES[1], J.-F. ZANDER[2], J. SANTOS-TORRES[3], G. AHNERT-HILGER[2], I. IBAÑEZ-TALLON[1];
[1]Lab. of Mol. Biol., Rockefeller Univ., New York, NY; [2]Charité - Universitätsmedizin Berlin, Berlin, Germany; [3]Max Delbrück Ctr. for Mol. Med., Berlin, Germany

Abstract: Disturbances in transmitter co-release may contribute to a variety of disorders, including drug addiction. Despite the evidence that medial habenula (MHb) neurons regulate nicotine craving and intake, and co-release acetylcholine (ACh) and glutamate, the contribution of ACh to nicotine dependence is not well understood. Here we conditionally deleted the ACh-synthesizing enzyme choline-acetyltransferase (ChAT) in MHb neurons. Postsynaptic recordings revealed that the absence of ACh reduces the glutamate content of synaptic vesicles and eliminates presynaptic facilitation. Electron microscopy and immuno-isolation analyses demonstrated colocalization of ACh and glutamate vesicular transporters. Glutamate reuptake was stimulated in the presence of ACh, indicating vesicular synergy. Mice lacking CHAT in habenular neurons were insensitive to nicotine-conditioned reward and withdrawal. These data demonstrate that ACh controls the quantal size and release frequency of glutamate at habenular synapses, and suggest that the synergistic functions of these neurotransmitters are generally important for modulation of cholinergic circuit function and behavior.

Title: Vagus nerve stimulation drives neural activity in the locus coeruleus and nucleus basalis

Authors: *D. HULSEY, J. RILEY, M. IYENGAR, R. RENNAKER, S. HAYS, M. KILGARD; The Univ. of Texas At Dallas, Richardson, TX

Abstract: Acetylcholine and Norepinephrine modulate neural plasticity. The Locus Coeruleus (LC) and Nucleus Basalis (NB) produce these neuromodulators and their projections supply the cortex. Vagus Nerve Stimulation (VNS) paired with motor training has been shown to drive robust, specific neural plasticity in the motor cortex. Eliminating cholinergic input to the cortex blocks the plasticity-enhancing effects of VNS. VNS may act to enhance cortical plasticity by engaging a neuromodulatory system associated with plasticity. Indirect evidence suggests that VNS acts through noradrenergic and cholinergic function. The plasticity-enhancing effects of VNS have an inverted U function based on stimulation intensity, suggesting that the systems engaged by VNS may display a non-linear response to stimulation. Here we directly measure activity in the LC and NB with simultaneous neurophysiological recordings in response to VNS. In addition we vary the amplitude, duration, frequency, and inter stimulus interval of the stimulations. We find that VNS directly drives neural activity in both the LC and NB. Varying the parameters of stimulation drives differential activity patterns. Understanding the dynamics of neural responses in these brain regions will allow optimizing stimulation parameters for therapeutic purposes.

Title: Analysis of calcium signaling after activation of muscarinic acetylcholine receptors in sympathetic neurons by measurements and mathematical modeling

Authors: *M. KRUSE, O. VIVAS, B. HILLE;
Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: Activation of M_1 muscarinic acetylcholine receptors leads to activation of phospholipase C and hydrolysis of phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$), generating the signaling molecules diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). Binding of IP_3 to IP_3 receptors activates these ion channels and causes release of Ca^{2+} from intracellular stores into the cytoplasm. In many cell types cytoplasmic Ca^{2+} concentrations rise significantly due to this mechanism, however, in superior cervical ganglion (SCG) neurons only small rises in cytoplasmic Ca^{2+} levels have been observed upon muscarinic stimulation. Here, we analyzed the dynamics of $PI(4,5)P_2$ depletion, IP_3 generation and Ca^{2+} release from intracellular stores in SCG neurons by FRET measurements, Ca^{2+} photometry, and mathematical modeling. We found that upon depletion of $PI(4,5)P_2$ by activation of muscarinic receptors, high levels of IP_3 are generated, but again only small increases in cytoplasmic Ca^{2+} levels were observed. Measurements of IP_3 receptor levels by Western blot showed strong expression of the proteins, ruling out low expression levels of the receptors as the reason for the small Ca^{2+} signals. We used the kinetics of IP_3 generation and degradation measured with the FRET probe LIBRAvIII to adapt a kinetic model of phosphoinositide metabolism upon muscarinic stimulation, which we had previously developed for tsA201 cells, to study the diffusion of IP_3 in the soma of SCG neurons. This new three-dimensional spatial model showed rapid diffusion of IP_3 throughout the entire soma, demonstrating the ability of IP_3 to reach IP_3 receptors before its degradation. Our findings led us to postulate a modulation of IP_3 receptor activity by IP_3R-binding proteins like IRBIT (IP_3R binding protein released with inositol 1,4,5-trisphosphate). IRBIT has been shown previously to be expressed in SCG neurons by immunofluorescence analysis, and to modulate IP_3 receptor activity in these cells. We found expression of IRBIT in SCG neurons by Western blot and included modulation of IP_3 receptor availability for IP_3 binding by a protein with IRBIT's properties into our kinetic model. This allowed for successful reproduction of observed kinetics and amplitudes of Ca^{2+} signals in SCG neurons. Our model for phosphoinositide metabolism in SCG neurons indicates that interaction of proteins like IRBIT with IP_3 receptors will restrict release of Ca^{2+} from intracellular stores despite generation of high levels of IP_3. The extended model can be used to analyze the effects of muscarinic stimulation on Ca^{2+} signaling in SCG neurons.

Title: Calcium regulation of sustained cholinergic excitation of prefrontal executive circuitry in the TgCRND8 mouse model of Alzheimer's disease

Authors: *E. PROULX[1], L. KANG[1], P. FRASER[2], J. MCLAURIN[3], E. K. LAMBE[1]; [1]Physiol, Univ. Toronto, Toronto, ON, Canada; [2]Med. Biophysics, [3]Lab. Med. and Pathobiology, Univ. of Toronto, Toronto, ON, Canada

Abstract: The cholinergic modulation of the prefrontal cortex is essential to working memory and attention. In particular, acetylcholine exerts robust excitation of prefrontal layer 6 pyramidal neurons to achieve optimal performance on challenging attention tasks. From an integrated approach of electrophysiology, pharmacology and multi-photon calcium imaging, we demonstrate that nicotinic and muscarinic acetylcholine receptors work together to sculpt the excitation of these prefrontal output neurons in a calcium-dependent manner. We further characterize and pharmacologically reverse a disruption of this signaling in the TgCRND8 mouse model of Alzheimer's Disease. Taken together, our results point to a trade-off between excitation and spiking fidelity in pyramidal cells of the major corticothalamic layer of prefrontal cortex, a compromise that may ultimately have important ramifications for the regulation of excitability of prefrontal executive circuits.

Title: PET imaging with [18F]FEOBV following lesion of cholinergic pedunculopontine tegmental neurons in rat

Authors: *M. CYR[1,2], M. J. PARENT[1,2], N. MECHAWAR[2], P. ROSA-NETO[2,3], J.-P. SOUCY[3], S. CLARK[4], M.-A. BÉDARD[1,2];

Abstract: Background: [18F]fluoroethoxybenzovesamicol ([18F]FEOBV) is a PET radiotracer with high selectivity and specificity to the vesicular acetylcholine transporter (VAChT). It has been shown to be a sensitive *in vivo* measurement of changes of cholinergic innervation densities following lesion of the nucleus basalis of Meynert (NBM) in rat. The current study used [18F]FEOBV with PET imaging to detect the effect of a highly selective lesion of the pedunculopontine (PPTg) nucleus in rats. Methods: Twenty-five male Long-Evans rats (body weight: 250 - 500 g) were used for this study. Eighteen rats underwent stereotaxic surgery to induce either a selective lesion of the PPTg cholinergic neurons (Lesion group; N = 12) or no lesion (Sham group; N = 6). Another group of rats (Control group; N = 7) was used for comparison with the two experimental (Lesion & Sham) groups. After bilateral and selective lesions of the PPTg cholinergic neurons, rats were scanned using [18F]FEOBV, then sacrificed, and their brain tissues collected for immunostaining and quantification of the VAChT. Results: Comparisons with control rats revealed that cholinergic losses can be detected in the brainstem, lateral thalamus, and pallidum by using *in vivo* imaging methods with [18F]FEOBV. Similarily, comparisons with shams revealed that comparable losses can be detected in the same regions using standard *ex vivo* measurements. In the brainstem PPTg area, significant correlations were observed between *in vivo* and *ex vivo* measurements, while this was not the case in the thalamic and pallidal projection sites. Conclusions: These findings support PET imaging with [18F]FEOBV as a reliable *in vivo* method for the detection of neuronal terminal losses resulting from lesion of the PPTg. Moreover, quantification of cholinergic losses using [18F]FEOBV with PET was compared here with ex-vivo immunocytochemistry, allowing to corroborate cholinergic losses in the same brain regions. Useful applications can be found in the study of neurodegenerative diseases in human, such as Parkinson's disease, multiple system atrophy, progressive supranuclear palsy, or dementia with Lewy bodies.

Title: Receptor pharmacology of gamma oscillations induced in the avian hippocampal formation *in vitro*

Authors: ***P. DHEERENDRA**[1], N. M. LYNCH[2], M. O. CUNNINGHAM[1], T. V. SMULDERS[1];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Univ. of Louisville, Louisville, KY

Abstract: Introduction: Gamma rhythms are a physiological feature of the mammalian hippocampus and play an important role in memory processing. However, such oscillations have not been explored in the avian hippocampal formation (HF) whose neuroanatomy is unlike its mammalian counterpart. We therefore investigate how divergent structures perform convergent functions. If similar microcircuitry underlies the avian HF, then we would predict that similar network properties should be detectable. Aims: We investigate the existence of gamma oscillations in avian HF, the underlying mechanisms of rhythmogenesis and the role of different receptors in this activity. Methods: We euthanized newly hatched chicks by cervical dislocation. We employed *in vitro* electrophysiology to record local field potentials in chick brain slices (400 μm). Bath application of various agonists and antagonists allowed us to elucidate the receptor pharmacology of avian hippocampal gamma oscillations *in vitro*. Results: In P0 - P4 chick HF brain slices, persistent gamma frequency oscillations (peak power: 64 ± 24.8 μV2/Hz; peak frequency: 36 ± 1.4 Hz; n = 27 slices) were induced by the bath application of the cholinergic agonist, carbachol (10 μM). However, the bath application of kainate (50 - 800 nM), a glutamate receptor agonist, did not elicit gamma. Similar to other species, carbachol-evoked gamma oscillations were sensitive to GABAA, AMPA/kainate and muscarinic (M1) receptor antagonism. Conclusions: We conclude that in juvenile chick HF, gamma rhythmogenesis is cholinergic in nature. This is unlike in adult mammals where both cholinergic and glutamatergic mechanisms are known to exist. However, similar to mammalian species, muscarinic

acetylcholine receptor (mAChR) activated avian HF gamma oscillations are likely to arise via a pyramidal-interneuron gamma (PING) based mechanism.

Title: A comparative study of the cholinergic innervation of the basal ganglia among human and nonhuman primate species

Authors: *A. STEPHENSON[1], M. K. EDLER[1], L. J. WILSON[1], J. M. ERWIN[2], W. D. HOPKINS[3], B. JACOBS[4], P. R. HOF[5], C. C. SHERWOOD[2], M. A. RAGHANTI[1]; [1]Dept. of Anthrop., Kent State Univ., Kent, OH; [2]Dept. of Anthrop., The George Washington Univ., Washington DC, DC; [3]Emory Univ., Atlanta, GA; [4]Dept. of Psychology, Colorado Col., Colorado Springs, CO; [5]Fishberg Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Cholinergic innervation of the basal ganglia is important in learning and memory, and striatal cholinergic neurons have been implicated in the integration of cognitive and motivational states with behavior. Further, deficits in acetylcholine have been correlated with loss of cognitive function in Alzheimer's disease and schizophrenia. These lines of evidence suggest a potentially important role for this subcortical innervation in the evolution of human cognitive functions. The present study quantified axons and interneurons immunoreactive for choline acetyltransferase (ChAT) in regions of the executive and motor loops of the basal ganglia of humans, great apes

(chimpanzee and gorilla), Old World monkeys (macaque and baboon), and one New World monkey (capuchin). Stereologic methods were used to quantify ChAT-ir axon length density to neuron density (ALv/Nv) and the percentage of cholinergic neurons in striatal regions. The repeated-measures ANOVA for ChAT-ir ALv/Nv revealed significant main effects of species ($F_{5, 23} = 40.26$, $p < 0.05$) and area ($F_{3, 23} = 248.92$, $p < 0.05$), with a significant interaction ($F_{15, 23} = 31.65$, $p > 0.05$). Post hoc tests showed that apes had the highest ALv/Nv in both executive and motor loops. For the percentage of ChAT-ir neurons within the striatum, there was a significant main effect of species ($F_{5, 25} = 35.19$, $p < 0.05$), with gorillas displaying the highest percentage, followed by capuchins. Interestingly, humans did not possess the highest or lowest density of cholinergic innervation, as expressed by axons or neurons. The phylogenetic differences observed were unexpected and indicated that a relative increase in cholinergic innervation was not required to support human cognitive abilities.

Abstract: Making a choice among alternatives requires assigning them a value. This exploitation of known reward sources is under control of dopaminergic (DA) transmission. The firing of DA neurons is tuned by nicotinic acetylcholine receptors (nAChRs), in particular by β2-containing receptors, yet their contribution in value-based decisions remains unclear. Experimental data have implicated VTA β2*nAChRs in slow exploratory locomotion in open-fields without rewards. In the context of decision-making, exploration is opposed to the exploitation of a known reward source. We thus tested whether β2*-nAChRs expressed at the level of the VTA are implicated in the motivation to explore. We developed a mice-adapted multi-armed bandit task,

in which mice had to explore three locations associated with intracranial stimulation (ICSS). We compared the behavior of mice under different settings of the ICSS-bandit task: a certain setting where all locations deliver an ICSS, an uncertain setting where the rewarding locations are associated with different ICSS probabilities, and a dynamic setting where the places delivering ICSS change over time. Two forms of exploration were monitored: exploratory choices, expressed as a proportion of choices between the ICSS-associated locations; and exploratory locomotion, expressed as the time needed to reach the rewarding goals. We used computational models of reinforcement learning and decision-making to assess exploratory strategies in these different settings. We found that both exploratory choices and locomotion were affected by the expected uncertainty of the reward locations. This suggests that mice assigned a positive motivational value to expected uncertainty. Model-based analysis showed that mice lacking the nAChR β2-subunit lacked uncertainty-driven exploration, resulting in lesser adaptive strategies in a dynamic environment. Re-expression of β2*-nAChRs in the ventral tegmental area (VTA) restored uncertainty-driven exploration. Finally, we used electrophysiological recordings to correlate exploratory decisions with DA activity. Overall, our results implicate the nicotinic regulation of the VTA in the translation of expected uncertainty into motivation to explore.

Title: Donepezil-induced c-Fos expression in the rat prefrontal cortex and nucleus accumbens is modulated by acute scopolamine pre-treatment

Authors: *F. WICHERN[1], F. ESCLASSAN[2], G. GILMOUR[2], J. D. MIKKELSEN[1];
[1]Neurobio. Res. Unit, Rigshospitalet, Copenhagen Univ. Hosp., Kobenhavn O, Denmark; [2]Eli Lilly and Co., Lilly Res. Labs., Windlesham, United Kingdom

Abstract: Cholinergic pathways play an important role in cognitive function, and impaired cholinergic neurotransmission is considered to underlie the pathogenesis of schizophrenia and Alzheimer's disease. Lesions of cholinergic neurons in the forebrain or pharmacological

blockade of muscarinic acetylcholine receptors have been shown to impair cognitive function in humans and animals. Administration of donepezil, a reversible acetylcholinesterase inhibitor, increases cholinergic neurotransmission and improves cognitive function and the drug is approved for the symptomatic treatment of mild and moderate cognitive impairments in Alzheimer's disease. In this study, we investigated the impact of acute administration of donepezil on c-Fos expression, a surrogate biomarker for neuronal excitation, in specific forebrain regions known to be involved in cognition. **Furthermore, we investigated to what extent this activation was mediated via muscarinic receptors by pre-administration of muscarinic receptor antagonists**. Adult male Wistar rats were treated with donepezil hydrochloride (5 mg/kg; p.o.) alone or pre-treated with either the non-selective muscarinic antagonist scopolamine hydrobromide (0.1 mg/kg; s.c.), or the scopolamine analogue methylscopolamine (0.1 mg/kg; s.c.). Methylscopolamine is also a non-selective muscarinic receptor antagonist, but is in contrast to scolopamine unable to cross the blood-brain barrier. One hour after donepezil treatment, the animals were perfused and sections of the forebrain were processed for c-Fos-immunohistochemistry. A single dose of donepezil significantly increased the number of c-Fos positive neurons in the medial prefrontal cortex and nucleus accumbens (both shell and core region). While scopolamine pre-treatment prevented the donepezil-stimulated c-Fos induction in the prefrontal cortex and the nucleus accumbens, methylscopolamine pre-treatment blocked donepezil-induced c-Fos expression only in the nucleus accumbens. These studies further support that cholinergic neurotransmission is increased in the prefrontal cortex responsible for improvement of cognitive function. Because scopolamine and methylscopolamine administration differently inhibited donepezil-stimulated c-Fos induction in the brain, this suggests both indirect and direct effects of scopolamine on cholinergic activity in the brain.

Title: Sensitive analysis of acetylcholine in brain microdialysates using the ALEXYS (U)HPLC-ECD system

Authors: *M. EYSBERG, L. M. VAN HEERWAARDEN, H.-J. BROUWER, N. J. REINHOUD;
Antec BV, Zoeterwoude, Netherlands

Abstract: In the central nervous system, acetylcholine levels are associated with attention, learning, memory, consciousness, sleep, and control of voluntary movements. Detection of basal (sub-nanomolar) levels of acetylcholine in brain microdialysate samples, requires an optimized method. The recent release of the new DECADE Elite (electrochemical detector) in combination with the ultra-sensitive SenCell with a platinum working electrode make it possible to quantify basal acetylcholine levels in brain microdialysates. For the measurement of acetylcholine an Immobilized Enzyme Reactor (IMER) was used to convert acetylcholine into hydrogenperoxide, which can be detected either on a glassy carbon electrode coated with Horse Radish Peroxydase (HRP) or directly on a Pt working electrode. The HRP method needs laborious regular preparation of electrodes. The application of a Pt electrode is more user friendly. The robust method is shown to be sensitive and applicable to measure acetylcholine levels in brain microdialysates.

Abstract: The striatum serves as a major relay unit for the basal ganglia, and receives dopaminergic inputs from the substantia nigra pars compacta and glutamatergic inputs from the cerebral cortex and thalamus. The interaction between dopamine (DA) and glutamate (Glu) strongly determines striatal output and regulation of motor function. Reversal of hyperlocomotion induced by the dopaminergic stimulants (i.e. amphetamine), is a widely used animal model of for assessing antipsychotic-like activity of pharmacological agents. D1 receptor (D1R)-mediated activation of the Gαolf/adenylyl cyclase (AC) and protein kinase A (PKA) in striatonigral SPNs (D1-SPNs) is involved in the hyperlocomotor response to psychostimulants, through increase in DARPP-32 phosphorylation and potentiation of NMDA receptor currents (INMDA). The M4 subtype of muscarinic acetylcholine receptor (mAChR), is known to play an important role in the modulation of DA activity in striatum. We have shown that M4 positive allosteric modulators (PAMs) play a pivotal role in the inhibition of *in vivo* responses to amphetamine, suggesting that M4 could represent a novel therapeutic target for the treatment of schizophrenia. However, while these behavioral effects are likely to be partially due to M4-mediated inhibition of DA release, we now show that the novel M4 PAM VU0467154 reverses the increase in locomotor activity induced by the direct-acting D1R agonist SKF82958. This suggests that M4 PAMs could also reduce DA signaling acting downstream from inhibition of DA release. Interestingly, M4 couples to Gαi/o, which inhibits AC and could directly antagonize the effects of D1R activation on the Gαolf/AC/PKA pathway. Consistent with this, mAChR agonists inhibit D1R-mediated activation of striatal AC and phosphorylation of DARPP-32. Furthermore, by monitoring INMDA in SPNs from acute slices we found that M4 activation can prevent the D1-mediated enhancement of INMDA in D1-SPNs. We are also investigating the effects of treatment with VU0456154 on D1R agonist-mediated hyperlocomotion in mice lacking M4 selectively on D1-SPNs. These results demonstrate that M4-mediated antipsychotic effects could also result from direct postsynaptic actions of M4 onto D1- SPNs.

Title: Role of GABAA receptors and mGlu5 signaling in M1-dependent long-term depression in prefrontal cortex

Authors: *A. GHOSHAL, S. P. MORAN, J. M. ROOK, J. W. DICKERSON, Z. XIANG, C. W. LINDSLEY, P. J. CONN;
Pharmacology, Vanderbilt Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Application of carbachol (CCh) can lead to concentration dependent long-term depression (LTD) in the layer 2/3 to layer 5 excitatory synaptic transmission of the mouse prefrontal cortex (PFC). PFC LTD induced by 50μM CCh (mLTD) can be completely blocked by the M1 orthosteric antagonist VU0255035, is absent in M1-KO mice, and can be potentiated by an M1-selective positive allosteric modulator (PAM) when a lower threshold concentration of CCh is used. These data indicate that this mLTD is mediated by the M1 muscarinic subtype. In addition, we demonstrated that mLTD is absent in a mouse model of schizophrenia, achieved by repeated administration of phencyclidine (NMDA receptor antagonist). In the present study we further elucidated the mechanism of mLTD in the mouse PFC. Using slice electrophysiology, we recorded changes of field excitatory post synaptic potentials (fEPSPs) in layer 5 PFC following CCh application under different conditions. When fEPSPs were recorded in presence of GABAA antagonist bicuculline (20μM), 50μM CCh failed to induce any mLTD in the drug-naïve mice, indicating that GABAA receptors play an important role in the induction of mLTD. In contrast, pretreatment with NMDA receptor antagonist AP-V (50μM) failed to block CCh-induced mLTD, suggesting that mLTD is NMDA receptor independent. However, pretreatment with the metabotropic glutamate receptor 5 (mGlu5) negative allosteric modulator, MPEP (30μM) 10 min before and during CCh application completely blocked the induction of mLTD. The involvement of mGlu5 in mLTD was further evident in studies that included the mGlu5 positive allosteric modulator (PAM) VU0409551. 10μM VU0409551 was able to potentiate a threshold form of mLTD (induced by 10μM CCh) into a robust mLTD in the mouse PFC of drug-naïve mice.

Additionally, mGlu5 PAMs were also able to fully rescue mLTD deficits in the PCP-treated mice. Thus, acute pretreatment of 10μM VU0409551 prior to 50μM CCh led to robust LTD in the PCP-treated mice. These studies, taken together, convincingly show that mLTD is NMDA receptor independent but is dependent on inhibitory neurotransmission as well as concurrent activation of mGlu5 receptors. We are currently performing additional whole cell electrophysiology experiments to determine the nature of interactions between muscarinic, metabotropic glutamatergic and GABA receptors in inducing mLTD in the PFC.

Title: M4-muscarinic receptors attenuate striatal dopamine release via production of a local messenger in direct pathway medium spiny neurons

Authors: *D. J. FOSTER[1], J. WILSON[1], T. PANCANI[1], J. WESS[2], C. K. JONES[1], Z. XIANG[1], P. J. CONN[1];

Abstract: Two seminal clinical studies have demonstrated that the M1/M4 preferring agonist xanomeline can provide significant therapeutic efficacy in treating psychosis in patients with Alzheimer's disease or schizophrenia. Unfortunately gastrointestinal side-effects, likely mediated by M2/M3 receptors, have removed xanomeline from consideration for clinical use. However, these studies suggest that compounds that selectively modulate M1 and/or M4 could be therapeutically beneficial in treating psychosis. Recent reports utilizing novel subtype-selective

M4 positive allosteric modulators (PAMs) have demonstrated efficacy in several preclinical models of psychosis. However, the mechanism whereby M4 can mediate these antipsychotic-like effects is not well understood. Here, we utilize a novel M4 PAM (VU0467154) and genetically modified mice to elucidate the role of M4 in regulating striatal dopamine release and dopamine-dependent behaviors. Application of the non-selective muscarinic receptor agonist Oxo-M decreased electrically-evoked striatal dopamine release in a concentration-dependent manner as monitored via fast scan cyclic voltammetry in acute brain slices. The inhibition of dopamine release induced by sub-maximal Oxo-M concentrations was potentiated by inclusion of VU0467154, demonstrating that M4 activation can negatively regulate dopaminergic signaling. In the striatum M4 is found primarily on direct pathway medium spiny neurons but is also expressed on cholinergic interneurons and cortical afferents. Interestingly, VU0467154-mediated reductions in dopamine release were completely absent in conditional knock-out mice in which M4 was selectively deleted from D1-expressing neurons. Additionally, the effects of VU0467154 were blocked by pretreatment with the CB2 antagonist AM630. Collectively, these results suggest that M4 activation attenuates dopamine release via endocannabinoid production in direct pathway medium spiny neurons, a signaling pathway that may be of therapeutic interest to developing novel treatments for schizophrenia.

Title: Functional interaction between histamine H_3 and adenosine A_{2A} receptors in rat striato-pallidal nerve terminals

Authors: *G. E. MORALES FIGUEROA, R. GONZÁLEZ-PANTOJA, J. ESCAMILLA-SÁNCHEZ, J.-A. ARIAS-MONTAÑO;
CINVESTAV, Mexico DF, Mexico

Abstract: In the central nervous system histamine H_3 receptors (H_3Rs) regulate the synthesis and release of histamine, and the release of other neurotransmitters and neuromodulators. The globus pallidus (GP) belongs to the basal ganglia, a rich neural network involved in the control of motor behavior. The high expression of H_3Rs and the very low levels of the corresponding mRNA in GP strongly suggest that H_3Rs are located on the synaptic afferents to the nucleus, mainly on the terminals of striato-pallidal neurons. These neurons also express high levels of adenosine A_{2A} receptors (A_{2A}Rs), coupled to Gs proteins and whose stimulation modulates GABA release from GP synaptosomes and slices. H_3Rs couple to Gαi/o proteins, and in slices from rat striatum and substantia nigra pars reticulata their activation decreases K^+-evoked [^{3}H]-GABA release by opposing the stimulatory action of dopamine D_1 receptors, coupled to Gs proteins. The high expression of the H_3Rs and A_{2A}Rs on GP synaptosomal membranes (1327 and 454 fmol/mg protein, respectively) was confirmed with radioligand binding assays. A_{2A}R activation with the selective agonist CGS-21680 (3 nM) enhanced K^+-evoked [^{3}H]-GABA release from perfused GP synaptosomes (153 ± 20% of controls), and this effect was reduced by the H_3R selective agonist immepip in a concentration-dependent manner (EC_{50} 5.2 nM). In turn, the inhibitory effect of immepip (100 nM) was prevented by the H_3R antagonist/agonist inverse clobenpropit (3 μM). These results indicate that through H_3Rs histamine modulates GABA release from striato-pallidal neurons and that this effect is selectively exerted on the component of release regulated by adenosine A_{2A}Rs. A_{2A}R-mediated facilitation of GABA release depends on the cAMP/PKA pathway, and one plausible explanation for the H_3R selective effect is thus an action on the same signaling pathway. In GP slices A_{2A}R activation increased cAMP accumulation (295% of basal, EC_{50} 3.2 nM) and H_3R activation reduced by 50% this effect in a concentration-dependent manner (IC_{50} 5 nM). Further, direct activation of the cAMP/PKA pathway by forskolin (10 μM) mimicked the effect of A_{2A}R activation on K^+-evoked [^{3}H]-GABA release. An alternative explanation for the H_3R effect is the formation of H_3R-A_{2A}R heteromers, and preliminary experiments with rat GP synaptosomal membranes showed the H_3R agonist immepip to reduce in a modest (2-fold) but significant manner the A_{2A}R affinity for the agonist CGS-21680, whereas CGS-21680 increased the H_3R affinity for immepip, suggesting that H_3R/A_{2A}R dimerization does take place and modulates the affinity of these receptors for their respective agonists.

Title: Adenosine A2A and histamine H3 receptors gather to modulate intra-striatal GABAergic transmission

Authors: *R. MÁRQUEZ GÓMEZ, C. GUTIERREZ-RODELO, J.-A. OLIVARES-REYES, J.-A. ARIAS-MONTAÑO;
Cinvestav, México, D.F., Mexico

Abstract: In the central nervous system histamine modulates the synthesis and the release of several neurotransmitters through the activation of pre-synaptic H3 receptors (H3Rs). These receptors are widely expressed in the striatum, the main input nucleus of the basal ganglia, and in striato-pallidal neurons and cortico-striatal afferents H3Rs are co-expressed with adenosine A2A receptors (A2ARs), which increase glutamatergic cortico-striatal transmission and reduce GABAergic intra-striatal transmission. Although A2ARs and H3Rs canonically activate antagonistic signaling pathways, their modulatory role on assembled striatal synaptic transmission has remained largely unassessed. In this work we set out to determine the effect of A2AR and H3R co-activation on the function of collaterals of GABAergic striato-pallidal neurons. We first studied GABA uptake by striatal isolated nerve terminals (synaptosomes) and found that activation of either A2ARs or H3Rs reduced in a modest but significant manner GABA transport (-8 ± 2% and -12 ± 3%, respectively), and that their co-activation results in additive inhibition (-22 ± 3%). In order to explain these results we have addressed the possibility for these receptors to form a functional heterodimer, and herein we show that H3R activation diminishes A2AR affinity for the selective agonist CGS-21680 (increase in Ki value from 9 to 20 nM) and prevents cAMP accumulation induced by the same agonist. In contrast, A2AR activation had no effect on H3R affinity for the agonist RAMH. Further, co-immunoprecipitation assays suggest that A2AR/H3R interaction may occur on the striatal synapses, presumably on both the collaterals of GABAergic projection neurons and cortico-striatal terminals. A2A and H3 receptors have been proposed as new targets for the treatment of cognitive and motor disorders, and our results suggest an interaction that might bear relevance for the regulation of basal ganglia transmission and therefore for the design of drugs useful for the treatment of some of such disorders.

Title: Differential homologous desensitization of the human histamine H3 receptors of 445 and 365 amino acids

Authors: *A.-M. GARCÍA-GÁLVEZ, C. FLORES-CLEMENTE, R. GONZÁLEZ-PANTOJA, J. ESCAMILLA-SÁNCHEZ, J.-A. ARIAS-MONTAÑO;
Neurosciences, Cinvestav, Mexico City, Mexico

Abstract: Histamine H_3 receptors (H_3R) couple to Gi/o proteins and are primarily found as pre-synaptic receptors in the central nervous system, where they regulate the synthesis and release of histamine and the release of other neurotransmitters. Alternative splicing of the human H_3R (hH_3R) originates 20 isoforms, and in addition to the receptor of 445 amino acids (hH_3R_{445}), an isoform of 365 aa (hH_3R_{365}) is abundantly expressed in several brain regions. Desensitization is a major mechanism to regulate the functional response of G protein-coupled receptors (GPCRs). Homologous desensitization is triggered by the phosphorylation of activated receptors by GPCR kinases (GRKs), and we previously showed that the hH_3R_{445} stably expressed in CHO-K1 cells experiences homologous desensitization. The hH_3R_{365} lacks 80 residues in the third intracellular loop (i3), an important region for GPCR coupling to G proteins, as well as for the phosphorylation by GRKs and the subsequent binding of β-arrestins in the homologous desensitization mechanism. In this work we therefore set to study whether the hH_3R_{365} also experiences homologous desensitization and the possible differences with the hH_3R_{445}. Both hH_3R isoforms were stably expressed in CHO-K1 cells, and receptor levels were determined by [^{3}H]-N-α-methyl-histamine binding assays in membranes and whole cells. Functional desensitization was evaluated in cells pre-incubated with the H_3R agonist R-α-methyl-histamine (RAMH). The lack of 80 aa in the hH_3R_{365} had no effect on the expression by CHO-K1 cells, the affinity for selective ligands or the presence in the cell surface. Pre-incubation for 30 min with *RAMH* (1 μM) reduced by 58 ± 8% hH_3R_{365} signaling through Gi/o proteins and resulted in the loss of receptors from the cellular surface (-64 ± 10%). In contrast to the 445 aa isoform, the hH_3R_{365} affinity for the agonist immepip (pKi 8.65 ± 0.23) was not significantly reduced by RAMH pretreatment (pKi values 8.10 ± 0.15 and 8.20 ± 0.13 for pre-incubation with agonist for 30 and 60 min, respectively). Maximal desensitization differed in both the extent (96 15% and 58 ± 8% for hH_3R_{445} and hH_3R_{365}, respectively) and length of exposure required (60 and 30 min). Further, at 60 and 120 min of RAMH pre-incubation the hH_3R_{365} showed partial re-sensitization, whereas the hH_3R_{445} remained desensitized. These results suggest that the hH_3R_{365} experiences

homologous desensitization, but the process differs from the hH_3R_{445} in time-course, magnitude and re-sensitization.

Title: Functional cross-talk between α1-adrenergic receptors and mGlu7 metabotropic glutamate receptors in heterologous expression systems and brain tissue: possible relevance in stress-relates psychiatric disorders

Authors: L. IACOVELLI[1], L. DI MENNA[2], N. USCHOLD-SCHMIDT[3], D. PETERLIK[3], C. STANGL[3], G. MOLINARO[2], R. ORLANDO[1], P. J. FLOR[3], A. DE BLASI[1], *G. BATTAGLIA[2], V. BRUNO[1,2], F. NICOLETTI[1,2];
[1]Dept. of Physiol. and Pharmacology,, Univ. "Sapienza", Rome, Italy; [2]I.R.C.C.S. Neuromed, Pozzilli, Italy; [3]Fac. of Biol. & Preclinical Med. Lab. of Mol. & Cell. Neurobio., Univ. of Regensburg, Regensburg, Germany

Abstract: Increasing evidence suggests that metabotropic glutamate (mGlu) receptors including mGlu7 receptor are important in the pathophysiology of stress-related psychiatric disorders such as anxiety and major depression. It has also been shown that mice deficient in mGlu7 receptors have an antidepressant-like behaviour and altered stress response. On the other hand, the role of adrenergic signalling in the modulation of mood and depression-related behaviour has also been pointed out both in clinical studies and in animal models. It has been shown that α1A-adrenergic (AR) signalling, but not α1B-AR signalling, produces antidepressant-like behaviour in the mouse and that prolonged stimulation of α1A-AR induces a reduction in anxious and depressive behaviour in animals (Doze et al, Brain Res, 2009, 1285:148-57; Doze et al, Mol Pharmacol, 2011 80:747-58). In the present study, we investigated the cross-talk between α1A-AR and mGlu7 receptors essentially using 3 different approaches. First, we performed experiments in HEK293 cells that were transiently transfected to express α1A-AR and mGlu7. We demonstrated that phenylephrine (PE)-induced polyphosphoinositide (PI)-hydrolysis was significantly reduced by both L-2-amino-4-phosphonobutanoate (L-AP4) and L-serine-O-phosphate (L-SOP), which activate mGlu7 receptors at high concentrations. Co-expression of the 2 receptors with the GRK2

C-terminal tail, completely prevented the mGlu7 effect. This demonstrates that mGlu7 effect on α1A-AR signalling is mediated by Gβγ. Accordingly, we further show that the mechanism of mGlu7 inhibition of α1A-AR-signalling requires MAPK activation because both L-AP4 and L-SOP inhibition of PE-induced PI hydrolysis was reduced in the presence of both UO126 and PD98059. Second, we used brain slices from the mouse cerebral cortex, in which we fully confirmed the ability of high concentrations of L-AP4 and L-SOP to inhibit noradrenaline-stimulated PI hydrolysis. Third, biochemical experiments have been integrated by behavioural and endocrinological experiments. We demonstrated that i.c.v. PE injection induced an anti-depressant behaviour in rats, as measured by the forced swimming test, and this effect was reduced by L-SOP administration. To study the responsiveness of the HPA axis, we collected trunk blood to measure plasma corticosterone levels, 30 min after i.c.v. injection of PE or L-SOP + PE. L-SOP strongly reduced the increase in corticosterone levels induced by PE. Our data demonstrate that mGlu7 receptors negatively modulate α1A-AR signalling and that the interplay between these 2 receptor systems may play a role in the pathophysiology of mood disorders.

Title: Metabotropic glutamate receptor 5 upregulates surface NMDA receptor expression in striatal neurons via CaMKII

Authors: *D. JIN[1], B. XUE[2], L. MAO[2], J. WANG[3];
[1]Basic Med. Sci., Dept. of Anesthesiology, Sch. of Medicine,, Kansas City, MO; [2]Dept. of Basic Med. Science, Sch. of Medicine, Univ. of Missouri-Kansas City, Kansas City, MO; [3]Dept. of Basic Med. Science, Dept. of Anesthesiology, Sch. of Medicine, Univ. of Missouri-Kansas City, Kansas City, MO

Abstract: Metabotropic and ionotropic glutamate receptors are closely clustered in postsynaptic membranes and are believed to interact actively with each other to control excitatory synaptic transmission. Metabotropic glutamate receptor 5 (mGluR5), for example, has been well documented to potentiate ionotropic NMDA receptor activity, although underlying mechanisms

are poorly understood. In this study, we investigated the role of mGluR5 in regulating trafficking and subcellular distribution of NMDA receptors in adult rat striatal neurons. We found that the mGluR1/5 agonist DHPG concentration-dependently increased NMDA receptor GluN1 and GluN2B subunit expression in the surface membrane. Meanwhile, DHPG reduced GluN1 and GluN2B levels in the intracellular compartment. The effect of DHPG was blocked by an mGluR5 selective antagonist MTEP but not by an mGluR1 selective antagonist 3-MATIDA. Pretreatment with an inhibitor or a specific inhibitory peptide for synapse-enriched Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) also blocked the DHPG-stimulated redistribution of GluN1 and GluN2B. In addition, DHPG enhanced CaMKIIα activity and elevated GluN2B phosphorylation at a CaMKII-sensitive site (serine 1303). These results demonstrate that mGluR5 regulates trafficking of NMDA receptors in striatal neurons. Activation of mGluR5 appears to induce rapid trafficking of GluN1 and GluN2B to surface membranes through a signaling pathway involving CaMKII.

Title: Colocalization of mu-opioid receptors and metabotropic glutamate receptors in rat spinal cord and in dorsal root ganglia

Authors: *A. E. KALYUZHNY, M. GRAHEK, A. PTAK, R. ZIMMERMAN, J. HAGEN, J. HOUCHINS, S. STOESZ, K. REAGAN;
R&D Systems, Inc., Minneapolis, MN

Abstract: Glutamate is the major excitatory neurotransmitter in CNS acting via ionotropic (NMDA, Kainate and AMPA) and metabotropic glutamate receptors (mGlu). During neuropathic pain, glutamatergic neurotransmission becomes elevated and impairs the antinociceptive effects of opioid drugs. It has been reported that spinal mGluRs can modulate nociception and mGluR antagonists can potentiate effects of morphine. To analyze the anatomical substrate underlying the interactions between mGluRs and mu-opioid receptors, we have employed multi-color immunofluorescence histochemistry on tissue sections of rat spinal cord and dorsal root ganglia (DRG). Polyclonal and mouse monoclonal antibodies were raised against recombinant mGluR1

(Group I), mGluR2/3 and mGluR2 (Group II), and mGluR8 (Group III) proteins. Rabbit monoclonal antibodies against the rat mu-opioid receptor (OPRM1) were raised against a peptide immunogen from the N-terminal portion of the receptor. There was an overlap in distribution of mGluRs and mu-opioid receptors in spinal cord dorsal horn and we observed co-localization in some punctate profiles. In spinal cord dorsal horn, mGluRs were distributed in lamina I - III with more intense labeling in lamina 2, whereas mu-opioid receptors were mostly in lamina I - II with higher density in lamina I. Labeling for mGluR1, mGluR2, mGluR2/3 and mGluR8 in the DRG was more abundant in medium and large size neurons rather than in small-sized neurons, whereas labeling for mu-opioid receptors was detected predominantly in small-sized neurons. In DRG we observed colocalization of mu-opioid receptors with mGluRs in small-sized neurons but the frequency of colocalization was different depending on the type of mGluR. Our data indicate that there is an anatomical overlap in distribution of mu-opioid receptors and mGluRs in spinal cord. Colocalization of mu-opioid and mGluRs in small-sized DRG neurons suggest direct interactions between mu-opioid and metabotropic glutamate receptors.

Title: Functional cross-talk between group-I and group-II metabotropic glutamate receptors in heterologous expression systems and brain tissue

Authors: L. DI MENNA[1], L. IACOVELLI[2], V. BRUNO[2,1], G. BATTAGLIA[1], *F. NICOLETTI[2,1];
[1]Mol. Pathology, I.R.C.C.S. Neuromed, Pozzilli, Italy; [2]Univ. Sapienza, Rome, Italy

Abstract: One of the dogmas in the field of metabotropic glutamate (mGlu) receptors is that mGlu1 and mGlu5 receptors are coupled to polyphosphoinositide (PI) hydrolysis via a Gq/11 protein, whereas mGlu2 and mGlu3 receptors are negatively coupled to adenylyl cyclase activity via a Gi/o protein. This general belief has conditioned functional studies carried out in cultured neurons and brain tissue. However, an intriguing observation is that the prototypical mGlu1/5 receptor agonist, 3,5-dihydroxyphenylglycine (DHPG), is less efficacious than (1S,3R,4S)-1-aminocyclo-pentane-1,3,4-tricarboxylic acid (1S,3R-ACPD) in stimulating PI hydrolysis in brain

slices. This difference does not reflect a greater intrinsic efficacy of 1S,3R-ACPD at mGlu1 and mGlu5 receptors, but rather the ability of the compound to recruit either mGlu2 or mGlu3receptors. If combined with selective mGlu2/3 receptor agonists, which are inactive on their own, DHPG stimulates PI hydrolysis to the same extent as 1S,3R-ACPD in hippocampal slices (Genazzani et al 1994 Brain Res 659:10-16; Schoepp et al 1996 Neuropharmacology 35:1661-1672). This suggests that a functional cross-talk between group-I and group-II mGlu receptors exists, but the molecular nature of this cross-talk is unknown. In HEK-293 cells co-expressing mGlu1 receptors with either mGlu2 or mGlu3 receptors, DHPG-stimulated PI hydrolysis was amplified by the mGlu2/3 receptor agonist, (-)-2-oxa-4-aminocyclo[3.1.0]hexane-4,6-dicarboxylic acid (LY379268). A similar potentiation was observed when the mGlu5 receptor was co-expressed with either mGlu2 or mGlu3 receptors. In cortical slices prepared from adult mice, LY379268 was able to potentiate DHPG-stimulated PI hydrolysis, as expected. However, potentiation was lost in slices prepared from mGlu3-/- mice and was unaffected in slices prepared from mGlu2-/- mice. This suggested that native mGlu3, but not mGlu2, receptors are functionally linked to mGlu1/5 receptors and play a permissive role on mGlu1/5 receptor-mediated PI hydrolysis. This hypothesis was supported by data obtained in cortical slices prepared from mice at postnatal day 14 (PND14). mGlu5 and mGlu3 receptors are known to be highly expressed in the early postnatal life, and all group-I mGlu receptor agonists are known to cause large stimulations of PI hydrolysis at this age. Interestingly, DHPG-stimulated PI hydrolysis was largely reduced in cortical slices prepared from PND14 mGlu3-/- mice as compared to age-matched wild-type or mGlu2-/- mice. Thus, it appears that endogenous activation of mGlu3 receptors largely contributes to mGlu1/5 receptor-mediated PI hydrolysis during early brain development.

Title: Bidirectional interaction between adenosine A1 receptor and type-1 metabotropic glutamate receptor

Authors: *Y. KAMIKUBO[1], T. TABATA[2], T. SAKURAI[1];
[1]Juntendo Univ., Tokyo, Japan; [2]Grad. Sch. of Sci. and Engin., Univ. of Toyama, Toyama, Japan

Abstract: Adenosine A1 receptor (A1R) is a G protein-coupled receptor (GPCR) for the ubiquitous neuromodulator adenosine and is known to play roles in regulation of neuronal excitability, arousal level, and pain sensitivity. We previously reported a new type of neuronal action of A1R; in cerebellar Purkinje cells, A1R activation leads to the attenuation of neuronal responses involving type-1 metabotropic glutamate receptor (mGluR1), a GPCR for the excitable neurotransmitter. Such a response includes long-term depression of postsynaptic glutamate-responsiveness, a cellular basis for cerebellar motor learning. Here we explore in more detail interaction between A1R and mGluR1 using non-neuronal heterologous expression cells. Our co-immunoprecipitation and FRET analysis revealed that A1R and mGluR1 form complexes even in a non-neuronal cell type. We used cAMP production assay to evaluate the activity of the signaling cascade coupled to A1R and found that mGluR1 activation leads to inhibition of this cascade. These findings demonstrate that the two classes of GPCRs have a cellular environment-independent intrinsic property to form heteromeric complexes and mutually modulate their signaling. This modulation may enable the GPCR complex as a whole to mediate intriguing cellular responses.

Title: Cannabinoid control of GABAergic transmission in the globus pallidus is switched during dopamine D2 receptor (D2Rs) activation

Authors: *R. N. CABALLERO[1], I. CONDE ROJAS[1], R. SÁNCHEZ-ZAVALETA[1], F. PAZ-BERMÚDEZ[1], B. FLORÁN[2], D. ERLIJ[3];

[2]Physiolgy, Biophysics and Neurosciences, [1]CINVESTAV, México D.F., Mexico; [3]Dept. of Physiol. and Pharmacol., State Univ. of New York, Brooklyn, NY

Abstract: Neurochemical evidence shows that activation of CB1 cannabinoid (CB1Rs) with exogenous cannabinoid agonists in the basal ganglia is switched from an inhibitory effect into a stimulatory response by activating D2Rs. This effect has been attributed to restricted Gi/o protein coupling because it is mimicked by pretreatment with pertussis toxin. In the current experiments we use electrophysiological techniques to determine the significance of these effects in the control of pallidal synaptic transmission. Paired pulse technique recorded with whole patch technique in GPe cells showed that the CB1 agonist ACEA depressed GABA release initiated by stimulation of striato-pallidal terminals. The inhibition of release was transformed into stimulation by treatment with either the D2R antagonist quinpirole or pertussis toxin. This stimulation was blocked by treatment with the PKA inhibitor H89. Depolarization of the postsynaptic membrane (DSI) induced a reduction of spontaneous inhibitory currents that was blocked by pretreatment with the cannabinoid antagonist AM 251. Activation of D2R with quinpirole converted the DSI into a stimulatory response. This stimulatory response disappeared when PKA was blocked with H89. These experiments show that cannabinoid effects on GABA transmission in the GPe are modulated by dopamine. The switch in cannabinoid effects appears to be mediated by restricted Gi/o protein coupling because it is mimicked by pertussis toxin treatment. The stimulation of release also appears to be mediated by coupling to Gs protein because it disappears when activation of PKA is blocked with H89. The switch in the effects of depolarization shows that the action of endogenous cannabinoids is controlled by activation of D2Rs.

Title: Group I mGluR-β-arrestin signaling in hippocampal synaptic plasticity

Authors: *A. G. ENG[1,2], D. A. KELVER[1], T. P. HEDRICK[1], G. T. SWANSON[1];
[1]Dept. of Pharmacol., [2]Interdisciplinary Neurosci. Grad. Program, Northwestern Univ., Chicago, IL

Abstract: A novel signaling mode mediated by the β-arrestin (βarr 1 and βarr 2) proteins has been observed in numerous family A and family B seven transmembrane receptors (7TMRs). Far less is known about βarr signaling by family C 7TMRs such as the group I metabotropic glutamate receptors (mGluR1 and mGluR5), which are viewed as promising targets in the treatment of neuropsychiatric disorders including epilepsy, Fragile X syndrome, cocaine addiction, and neuropathic pain. Accordingly, our objectives are to determine whether group I mGluR-βarr signaling underlies synaptic plasticity and to identify downstream effectors of a putative mGluR-βarr signaling pathway. We tested the hypothesis that βarr $1^{-/-}$ or βarr $2^{-/-}$ mice possess selective deficits in mGluR-dependent plasticity by conducting blinded studies comparing hippocampal slice recordings obtained from knockout mice and wildtype littermates. We observed that mGluR1-dependent potentiation of EPSCs induced by low frequency, paired stimulation of hippocampal mossy fiber inputs to CA3 pyramidal neurons was absent in mice lacking βarr 2 (post-train amplitudes were 94 ± 9% of baseline, n=13 for βarr $2^{-/-}$, compared to 131 ± 7%, n=11 for βarr $2^{+/+}$, p=0.004) but intact in mice lacking βarr 1 (137 ± 14% n=14 for βarr $1^{-/-}$, 143 ± 6% n=10 for βarr $1^{+/+}$, p=0.66). In contrast, long-term potentiation of mossy fiber-CA3 synapses induced by high frequency stimulation was unaffected by gene targeting of either βarr isoform (190 ± 23% n=9 for βarr $1^{-/-}$, 163 ± 16% n=7 for βarr $1^{+/+}$, p=0.34; 165 ± 16% n=8 for βarr $2^{-/-}$, 167 ± 14% n=6 for βarr $2^{+/+}$, p=0.94). mGluR-dependent long-term depression of Schaffer collateral-CA1 synapses elicited by low frequency stimulation is also unaffected in βarr $1^{-/-}$ (74 ± 9% n=10 for βarr $1^{-/-}$, 80 ± 8% n=15 for βarr $1^{+/+}$, p=0.6) and βarr $2^{-/-}$ mice (93 ± 11% n=14 for βarr $2^{-/-}$, 72 ± 5% n=18 for βarr $2^{+/+}$, p=0.1). Finally, we tested whether MAPK or Src family tyrosine kinases underlie mGluR1-βarr 2-mediated plasticity of mossy fiber-CA3 synapses. Pharmacological antagonism of MEK1/2 prevented induction (102 ± 7% n=7 for u0126-treated slices, 137 ± 9% n=17 for vehicle slices, p=0.004), as did inhibition of Src family tyrosine kinases (111 ± 8% n=10 for PP2-treated slices, p=0.03 compared to same vehicle group), but inhibition of cRaf-1 kinase had no effect (137 ± 20% n=9 for GW5074-treated slices, p=0.98 compared to vehicle). Together, these data delineate a new role for the βarr 2 isoform in conjunction with mGlu1 receptors, support the involvement of βarrs in learning and memory processes, and suggest that pathway selection could be viable in mGluR-targeted therapeutics.

Title: Group I metabotropic glutamate receptors (mGluRs) regulation in the central nervous system

Authors: *P. K. MAHATO, S. PANDEY, S. BHATTACHARYYA;
Dept. of Biol. Sci., Indian Inst. of Sci. Educ. & Res., Mohali, India

Abstract: Receptor trafficking in a cell is a crucial cellular process which ensures delivery of the receptors to proper destination in the cell membrane either by lateral movement on plasma membrane or direct insertion at the specific site at the neuronal surface. Glutamate is a major excitatory neurotransmitter in the central nervous system and acts through Ionotropic Glutamate Receptors and Metabotropic Glutamate Receptors (mGluRs). Glutamate receptors are localized as clusters at the neuronal membrane through interactions with intracellular scaffolding proteins but are also reported to be found dispersed in other regions of the membrane. There is a dynamic equilibrium between the different pools of receptors and mechanism of the process is poorly understood. Group I mGluRs belong to a family of G-protein coupled receptors (GPCRs) that show widespread distribution in the brain and they primarily localize at the post-synaptic sites. mGluR5, a Group I mGluR family member, is positively coupled to the IP3/DAG pathway. It has been reported that mGluR5 gets desensitized on ligand binding. The objective of our study was to investigate the post-desensitization events of mGluR5. Our finding suggests that the receptor gets internalized on ligand application and subsequent to the internalization mGluR5 enters the recycling compartment followed by the recycling of the receptor to the cell surface. We have also observed that inhibition of specific protein phosphatases either pharmacologically or by endogenous knockdown leads to the blocking of mGluR5 recycling differentially. In addition, we are also exploring the role of Homer proteins in the regulation of Group I mGluRs in the CNS. Homer is a scaffolding protein that has been reported to regulate the surface expression and function of Group I mGluRs. We are addressing these questions using Lentiviral mediated “molecular replacement” approach. This strategy involves knockdown of endogenous Homer protein and simultaneous expression of various forms of Homer for a possible rescue. We are studying the structure-function analysis of Homer in Group I mGluR regulation using this elegant approach.

Title: Regulation of cerebrocortical neuron spontaneous Ca^{2+} oscillations by metabotropic glutamate receptors

Authors: *S. MEHROTRA, T. F. MURRAY;
PHARMACOLOGY, Creighton Univ., Omaha, NE

Abstract: Metabotropic glutamate receptors (mGluRs) are a family of G-protein coupled receptors activated by the neurotransmitter glutamate. These receptors are classified into three groups based on sequence homology, signal transduction mechanism and pharmacological profile. The Group I (mGluR 1 and 5) receptors are mainly postsynaptic, whereas Group II (mGluR 2 and 3) and Group III (mGluR 4, 6, 7 and 8) are primarily presynaptic. Dissociated primary cultures of cerebrocortical cortical neurons exhibit spontaneous Ca^{2+} oscillations in the presence of physiological [Mg^{2+}]; these oscillations are thought to correspond to synchronized bursts of action potentials with attendant release of glutamate. This study was designed to characterize individual contribution of each of the three groups of mGluRs towards spontaneous Ca^{2+} oscillation in murine cerebrocortical neurons. Cerebrocortical primary cultures from Swiss-Webster mice (E17) were used in this study. Cultures maintained for 10 days *in vitro* (DIV) were used. Primary neuronal cultures were loaded with Fluo-3, incubated at 37°C for 1 hour and transferred to a fluorescence plate reader (FLIPR). The emitted fluorescence signals were recorded at 515–575 nm after excitation at 488 nm. We found that the Group I agonist (*RS*)-3,5-dihydroxyphenylglycine, DHPG (EC_{50}= 266 nM, 95% CI=61-1144 nM) produced a concentration-dependent increase in the frequency of spontaneous Ca^{2+} oscillations. In contrast the mixed Group I/II agonist (±)-1-aminocyclopentane-*trans*-1,3-dicarboxylic acid, trans-ACPD suppressed Ca^{2+} oscillations with an IC_{50} of 715 nM (95% CI=410-1,248). This response to trans-ACPD was reversed by the mixed Group I/II antagonist (*RS*)-α-methyl-4-carboxyphenylglycine, (RS)-MCPG. The selective group II agonist (1*R*,4*R*,5*S*,6*R*)-4-amino-2-oxabicyclo[3.1.0]hexane-4,6-dicarboxylic acid, LY379268 (IC_{50}= 3 nM, 95% CI=1.8-4.9 nM) mimicked the response to trans-ACPD in producing a concentration-dependent complete inhibition of Ca^{2+} oscillations. This inhibitory response was reversed by the selective group II mGluR antagonist (2*S*)-2-amino-2-[(1*S*, 2*S*)-2-carboxycycloprop-1-yl]-3-(xanth-9-yl) propanoic

acid, LY341495 (K_B= 0.9 nM). The group III agonist L-(+)-2-amino-4-phosphonobutyric acid, L-AP4 (IC_{50}= 29 nM, 95% CI=29-293 nM) produced a partial inhibition of Ca^{2+} oscillations, which was reversed by the antagonist of group III mGluRs, (*RS*)-α-methylserine-*O*-phosphate, MSOP (EC_{50}= 3.8 μM, 95% CI=0.5-25 μM). These data collectively demonstrate the predominance of inhibitory group II mGluRs in controlling synchronized Ca^{2+} oscillations in murine cerebrocortical neurons.

Title: Cellular and molecular mechanisms of group I mGluR trafficking in the central nervous system

Authors: *S. PANDEY, P. K. MAHATO, S. BHATTACHARYYA;
Dept. of Biol. Sci., Indian Inst. of Sci. Educ. and Res., Mohali, India

Abstract: Central nervous system (CNS) is composed of millions of neurons, which are connected through each other via synapse. Synapse is the junction where preceding neuron transfers its information to later neuron. Proper release of neurotransmitters in the pre-synaptic terminus and trafficking of neurotransmitter receptors in the post-synaptic terminus play crucial role in normal synaptic transmission and any alteration in these regulations could lead to pathological symptoms. mGluR1 is a GPCR that belongs to the group I family of metabotropic glutamate receptors (mGluRs). This receptor is positively coupled to Gαq/11 and activates protein kinase C pathway upon activation. mGluR1 is distributed throughout the CNS and its role has been implicated in various forms of synaptic plasticity including learning and memory along with its role in various neurological disorders like Fragile X syndrome and Autism. In the last few years this receptor has emerged as a potential therapeutic target for various neurological and psychiatric diseases. While studying trafficking of mGluR1, we observed that upon agonist

stimulation mGluR1 gets endocytosed and recycled back to the surface in both non-neuronal and neuronal cells. We also found a crucial role of Protein phosphatase 2A (PP2A) in the recycling of mGluR1. Inhibition of PP2A by various means (pharmacologically, over-expression of dominant negative PP2A and endogenous knockdown of PP2A) resulted in the inhibition of the recycling of mGluR1. Presently we are studying the role of Tamalin/GRASP, a postsynaptic scaffolding protein in the trafficking and signaling of mGluR1. Tamalin has been reported to interact with mGluR1 and regulates its surface stability. We are exploring the role of Tamalin in group I mGluR trafficking using lentiviral mediated "molecular replacement" approach. This approach involves acute knockdown of endogenous protein and simultaneous expression of various forms of that protein for possible rescue. We are currently using this elegant approach to unravel the structure-function analyses of Tamalin in the trafficking of group I mGluRs in the central nervous system.

Title: Regulation of KCC2 expression by group-I metabotropic glutamate receptors in the cerebellum

Authors: *S. NOTARTOMASO[1], G. MASCIO[1], P. SCARSELLI[1], K. MARTINELLO[1], S. FUCILE[1], G. BATTAGLIA[1], F. NICOLETTI[1,2];
[1]I.R.C.C.S. Neuromed, Pozzilli, Italy; [2]Univ. "Sapienza", Rome, Italy

Abstract: The mGlu1 metabotropic glutamate receptor is found in large amounts in cerebellar Purkinje cells, where it is a key player in mechanisms of activity-dependent synaptic plasticity underlying motor learning. The cognate mGlu5 receptor is instead nearly absent in Purkinje cells of adult mice or rats, but is found in Purkinje cells during the first ten days of postnatal life. Interestingly, the mGlu5 receptor is re-expressed in adult Purkinje cells in response to pharmacological blockade of mGlu1 receptors or under pathological conditions, such as type-1 spinocerebellar ataxia or experimental autoimmune encephalomyelitis (Notartomaso et al., Mol. Brain, 2013; Fazio et al., Neuropharmacology, 2012). Here, we examined whether mGlu1 and mGlu5 receptors have any role in regulating the expression of the K+-Cl− co-transporter, KCC2. KCC2 is expressed by mature neurons, where it lowers the Cl- equilibrium potential to more

negative values than the resting potential, thereby allowing the inhibitory action of GABAA receptors. GABAA receptors are instead excitatory in immature neurons, which do not express KCC2. In Purkinje cells, KCC2 is localized at climbing fiber synapses during postnatal development, and at basket cell GABAergic synapses in the adult life (Kawakita et al., Eur. J. Neurosci., 2012). We have found that expression of KCC2 in Purkinje cells is affected by drugs that positively or negatively modulate mGlu1 receptors, and show substantial changes in mice with genetic deletion of mGlu5 receptors. We are currently investigating whether pharmacological modulation of mGlu1 receptors or the lack of mGlu5 receptors cause changes in the Cl- equilibrium potential in Purkinje cells and affect the behavioural response to GABAA receptor activation in mice.

Title: DHPG-stimulated polyphosphoinositide hydrolysis is entirely mediated by mGlu1 receptors in the retina

Authors: M. ROMANO[1], G. MASCIO[1], L. DI MENNA[1], P. SCARSELLI[1], F. BIAGIONI[1], M. MADONNA[1], R. GRADINI[2,1], G. BATTAGLIA[1], *V. BRUNO[2,1], F. NICOLETTI[2,1]; [1]I.R.C.C.S. Neuromed, Pozzilli, Italy; [2]Univ. Sapienza, Rome, Italy

Abstract: Group-I metabotropic glutamate receptors (mGlu1 and mGlu5 subtypes) are coupled to Gq/11 and their activation leads to polyphosphoinositide (PI) hydrolysis with ensuing mobilization of intracellular Ca2+ and activation of protein kinase C. Stimulation of PI hydrolysis by the group-I mGlu receptor agonist, 3,5-dihydroxyphenylglycine (DHPG), is largely mediated by the mGlu5 receptor in most brain regions (e.g., hippocampus, cerebral cortex, and corpus striatum), with the exception of the developing cerebellum in which both receptors equally contribute to the stimulation of PI hydrolysis. Both mGlu1 and mGlu5 receptors are found in the retina, where their precise function is largely unknown. We first measured DHPG-stimulated PI hydrolysis in slices prepared from the bovine retina. We were surprised to find that the PI response to DHPG was abrogated by the mGlu1 receptor negative allosteric modulator (NAM), 3,4-dihydro-2H-pyrano[2,3]b quinolin-7-yl) (cis-4-

methoxycyclohexyl) methanone (JNJ6259685), but was only minimally affected by the mGlu5 receptor NAM, 2-methyl-6-(phenylethynyl)pyridine (MPEP). In contrast, MPEP was more efficient in reducing DHPG-stimulated PI hydrolysis in the bovine hippocampus, as expected. We then measured DHPG-stimulated PI hydrolysis in the mouse retina by incubating one entire retina per single test tube in the PI assay. Individual mouse retinas pre-labeled with [3H]-myo-inositol responded to DHPG with an increased [3H]-inositol phosphate formation. Again, this response was highly sensitive to inhibition by JNJ6259685 but not to MPEP, although both mGlu1 and mGlu5 receptor proteins could be detected in the mouse retina by Western blot analysis and immunohistochemistry. These data show for the first time that excitatory amino acid-stimulated PI hydrolysis in the retina is almost entirely mediated by the mGlu1 receptor. This may facilitate the study of mGlu1 receptor-coupled signal transduction in a native environment, and suggests that the mGlu1 receptor might be a better drug target than the mGlu5 receptor in the experimental treatment of degenerative disorders of the retina.

Title: Regulation of mGluR7 trafficking by SUMOylation in neurons

Authors: ***Y. SUH**[1,2,3], J.-H. CHOI[3], J.-Y. PARK[3], S. PARK[1];
[1]Dept. of Biomed. Sci., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [2]Neurosci. Res. Institute, Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Dept. of Pharmacology, Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Protein SUMOylation is a post-translational modification by which Small Ubiquitin-like MOdifier (SUMO) proteins are covalently linked to the lysine residues of target proteins via an enzymatic cascade. SUMOylation of synaptic proteins plays important regulatory roles in synapse formation, axonal mRNA transport, channel activity, and receptor endocytosis. The metabotropic glutamate receptor type 7 (mGluR7), a presynaptic G protein-coupled receptor

modulates excitatory neurotransmission and synaptic plasticity by inhibiting neurotransmitter release. MGluR7 at Lys889 has been shown to be modified by SUMO proteins *in vitro* assays, and a consensus motif for SUMO conjugation is conserved in the C-terminus of mGluR7. However, recent studies have failed to demonstrate the SUMO conjugation of full-length mGluR7 in mammalian cells and neurons. Here we have explored whether mGluR7 is a target of SUMOylation. Using biochemical approaches coupled with confocal imaging, we find that mGluR7 at Lys889, the sole SUMOylation site on the C-terminus of mGluR7 is a target of SUMO conjugation both by SUMO-1 and SUMO-2/3 in HEK293T cells. The SUMOylation of mGluR7 is prevented by SUMO-specific isopeptidase SENP-1. Although we have failed to detect SUMOylation of mGluR7 in cultured cortical neurons, SUMOylated form of mGluR7 is present in brain lysate. Furthermore, we find that mutation of mGluR7 at Lys889 to Arg markedly increases mGluR7 internalization in hippocampal neurons. Overexpression of SENP-1 leads to increased internalization of mGluR7, whereas SENP-1 Cys603Ser, a catalytic inactive mutant has no effects, suggesting that endocytosis of mGluR7 is enhanced by reduced SUMO conjugation of mGluR7. Taken together, these data support a model in which SUMOylation of mGluR7 at Lys889 is critical for stable surface expression of mGluR7 in neurons.

Title: Group I metabotropic glutamate receptors regulate the excitability of rat retinal ganglion cells

Authors: ***Q. LI**, P. CUI, X.-Y. LI, F. LI, F. GAO, L.-Z. LI, X.-L. YANG, Z. WANG;
Fudan Univ., Shanghai, China

Abstract: Retinal ganglion cells (RGCs), output neurons of the retina, receive inhibitory inputs from amacrine cells and excitatory inputs directly from cone bipolar cells. Changes in RGC excitability may directly influence visual processing in the retina. Group I metabotropic

glutamate receptors (mGluR I) were extensively expressed on retinal neurons. However, the effects of activating mGluR I on excitability of RGCs are largely unknown. Here, we showed that DHPG (10 microM), a mGluR I agonist, significantly increased the firing and caused a depolarization of the membrane potential of the cells, which could be reversed by LY367385 (10 microM), a selective mGluR1 antagonist, but not by MPEP (10 microM), a selective mGluR5 antagonist, suggestive of the involvement of mGluR1 in the DHPG-induced effect. Intracellular dialysis of either U73122 (10 microM), a phosphatidylinositol (PI)-PLC inhibitor or bisindolylmaleimide IV (10 microM), a protein kinase C inhibitor blocked the DHPG effect. Furthermore, intracellular dialysis of BAPTA (10 milliM), a calcium chelator or CaM kinaseIIinhibitor KN-93 (10 microM) showed the similar effects. In the presence of cocktail synaptic blockers (CNQX, D-AP5, bicuculline and strychnine), with spontaneous firing being disappeared, DHPG persisted to depolarize the membrane potential of RGCs and induce the cells to fire action potentials, suggesting that activation of mGluR I directly regulates the excitability of RGCs. The DHPG-induced depolarization of RGCs could not be blocked by TTX, indicating no involvement of Na^+ channels. In contrast, DHPG suppressed hyperpolarization-activated currents. The reverse potential of these currents was approximately -70 mV, very close to potassium equilibrium potential, implying that K^+ channels were mediated the DHPG-induced effects. Further experiments showed that inwardly rectifying potassium (Kir) currents and hyperpolarization-activated cation currents (I_h) could be recorded in RGCs, and extracellular application of DHPG indeed induced suppression on these two channels. Our results suggest that activation of mGluR1 regulates the excitability of rat RGCs by inhibiting Kir and Ih currents, which is mediated by intracellular Ca^{2+}-dependent PLC-PKC and CaMKII signaling pathways.

Title: Intercellular GPCR interaction is involved in the neutrophil-neuron contact and nerve recovery

Authors: Y.-W. LIU, *S.- . DAI, T. YANG, L. ZHAO;
The Third Military Med. Univ., Chongqing, China

Abstract: The brain is generally considered as immune privilege organ since the integrity of blood-brain-barrier(BBB), impeding the influx of immune cells from blood to the brain. However the BBB breaks down under pathological conditions including traumatic brain injury (TBI), stroke and some degenerative diseases, compelling the infiltration of white blood cells (WBCs) and inducing inflammation of central nerves system(CNS). Neutrophil is recognized as the vanguard during acute phase, but its real effects and detailed mechanisms in regulation of neuron function and recovery are still unclear. In our present study, we found that primary isolated neutrophils could “eat or bite” neurons directly in the coculture model, which was accomplished with down-expression of neuron neurotrophic tyrosine kinase type 2 receptor (NTRK2), leading to the atrophy of axons and dendrites and perishment of neuron. This results were confirmed by live cell imaging system *in vitro* and we described this phenomenon as “neutrophils attack and run”. Further investigations showed that the interaction between two G-protein coupling receptors (GPCRs), metabotropic glutamate receptor 5 (mGluR5) and adenosine 2a receptor (A2AR), were involved in the effects of neutrophils on neuron described above. While being different from the classic GPCR interaction mode to form homo or hetero dimers on the same cell membranes, we found that A2AR on neutrophil contact with mGluR5 on neuron between the cell membranes through their extracellular binding sites. This was testified by A2AR/mGluR5 knockout, Co-IP and fluorescence resonance energy transfer (FRET) technologies. These findings that unveil the regulation upon neuron by intruded circulating neutrophils, may not only be brand-new perspectives about connections between central nervous system and peripheral immune system, but also provide novel vision of nerve recovery. Meanwhile this is the first time to confirm GPCRs between different cell membranes, could interact or bind under specific circumstances, which challenges traditional ligand-receptor signal transduction.

Title: Metabotropic glutamate receptor 2 modulates thalamostriatal neurotransmission

Authors: *K. A. JOHNSON, D. M. LOVINGER;
Lab. for Integrative Neurosci., NIAAA/NIH, Rockville, MD

Abstract: The striatum plays important roles in motor control and action learning. The activity of striatal projection neurons is controlled by inputs from several brain regions, and the strength of these inputs can be modulated by presynaptic G protein-coupled receptors (GPCRs). Most previous efforts to evaluate GPCR-mediated modulation of glutamatergic transmission in the striatum have attributed changes in electrically-evoked transmission to modulation of corticostriatal circuits. However, the contributions of excitatory inputs originating in the thalamus, which represent almost half of excitatory inputs to medium spiny neurons (MSNs), are frequently overlooked. Activation of group II metabotropic glutamate receptors (mGlu2 and mGlu3) is known to produce a strong inhibition of electrically-evoked glutamatergic transmission onto striatal medium spiny neurons (MSNs). To evaluate the input specificity of the mGlu2/3-mediated modulation of striatal glutamatergic transmission, we used a viral strategy to express Channelrhodopsin-2 (ChR2) in neurons projecting to the striatum from the intralaminar nuclei of the thalamus of 5-7 week old male C57Bl/6J mice. 3-6 weeks after virus injection, coronal slices containing the striatum were prepared, and optically-evoked thalamostriatal excitatory postsynaptic currents (oEPSCs) were recorded from MSNs in the dorsolateral striatum. Bath application of the group II mGlu receptor agonist LY379268 (100 nM, 5 min) produced a robust reduction of oEPSC amplitude (peak depression 27.4±6.0% of baseline). Inhibition of oEPSCs by LY379268 was long lasting, persisting for at least 45 minutes after the onset of drug application (oEPSC amplitude 44.5±5.0% of baseline 40-45 minutes after LY379268 application). Experiments in which the group II mGlu-preferring antagonist LY341495 (500 nM, 10 min) was bath applied 10 minutes after LY379268 revealed that the long-term depression induced by LY379268 is fully reversible. To identify which receptor subtype(s) contribute to the inhibition of thalamostriatal transmission, we evaluated the effect of the mGlu2 agonist/mGlu3 antagonist LY395756 (10 μM, 5 min). Interestingly, LY395756 produced a strong, reversible inhibition of oEPSC amplitude (peak depression 22.3±2.5% of baseline), suggesting a major role for mGlu2 in the modulation of thalamostriatal transmission. Ongoing studies will evaluate potential contributions of mGlu3 to the inhibition of excitatory transmission at this synapse. These findings add to our limited knowledge of the mechanisms regulating the thalamostriatal system.

Title: Modulatory role of Neuregulin 1 signalling on mGluR1 function in DAergic neurons: effects on neurotransmission and synaptic plasticity

Authors: A. LEDONNE[1], A. NOBILI[1], E. C. LATAGLIATA[1], V. CAVALLUCCI[1], E. GUATTEO[1], S. PUGLISI-ALLEGRA[1,2], M. D'AMELIO[1,3], *N. B. MERCURI[1,4]; [1]IRCCS -SANTA LUCIA FOUNDATION, Roma, Italy; [2]Univ. of Rome "La Sapienza", Rome, Italy; [3]Univ. Campus-Biomedico, Rome, Italy; [4]Univ. of Rome “Tor Vergata”, Rome, Italy

Abstract: Neuregulin 1 (NRG1) is a trophic factor involved in neurodevelopment, neurotransmission and synaptic plasticity. Despite the evidence that NRG1 and its receptors, ErbB tyrosine kinases, are expressed in mesencephalic dopaminergic (DAergic) nuclei, and their functional alterations are reported in schizophrenia and Parkinson’s disease, the functional role of NRG1/ErbB signalling in mesencephalic dopaminergic neurons is still elusive. To this regard, recent evidence from our group (Ledonne et al., Mol Psychiatry, 2014) demonstrate that NRG1 modulates the nigrostriatal DAergic system in rodent brain by selectively regulating the functional expression of metabotropic glutamate receptor 1 (mGluR1) in DAergic neurons. We found that endogenous NRG1/ErbB signalling is essential to preserve mGluR1 function in mesencephalic DAergic neurons, by maintaining its surface membrane expression. Consequently, NRG1 tone regulates striatal mGluR1-induced dopamine outflow in *in vivo* conditions. In consideration of this functional interaction between NRG1/ErbB receptors and mGluR1, we questioned whether NRG1 signalling could participate in modulating mGluR1-dependent forms of synaptic plasticity in DAergic neurons. Therefore, using electrophysiological patch-clamp recordings of DAergic neurons in midbrain rodent slices, we investigated the effects of NRG1/ErbB signalling on the mGluR1-dependent long-term depression (LTD) of glutamatergic synaptic transmission in these neurons. Our data support a regulatory role of NRG1/ErbB signalling in the modulation of glutamatergic synaptic strength in DAergic neurons. In consideration of the genetic association of NRG1/ErbB signalling with schizophrenia, and the likely imbalance of glutamatergic and dopaminergic neurotransmission associated with this disease, the discovery of a functional role of NRG1 in tuning the LTD of glutamatergic synaptic transmission in DAergic neurons might provide a framework to comprehend how the NRG1-dependent pathways contributes to the synaptic dysregulations observed in schizophrenia and other neuropsychiatric disorders.

Title: Glutamatergic inhibition of limbic neural circuits

Authors: *C. C. LEE;
Comparative Biomed. Sci., LSU Sch. of Vet. Med., Baton Rouge, LA

Abstract: The constituent nuclei of the limbic system are integral components for learning, memory and emotive functions in the brain. Among these many nuclei, the mammillary bodies are essential structures for transmitting information to higher forebrain centers via the mammilothalamocortical pathway. As such, understanding the neuronal processing occurring in the mammillary bodies is essential for deciphering its functional roles. Here, the role of group II metabotropic glutamate receptors (mGluRs) in the mammillary bodies was examined using whole-cell patch clamp recordings from *in vitro* slice preparations in the mouse. We measured whole-cell responses in the presence of pharmacological bath application of group II mGluR agonists and antagonists. In addition, we neuroanatomically examined the expression of mGluR2 in the mammillary bodies and other limbic-related structures. Our results demonstrate a direct role of group II mGluRs for inhibiting neural activity in the mammillary bodies and other limbic-related structures. These data suggest possible mechanisms controlling the activity of limbic circuitry and a molecular factor linking disparate elements of these circuits.

Title: Evidence that the $GABA_B$ positive allosteric modulator CGP7930 activates MAPK cascade independently of $GABA_B$ receptor

Authors: *P. ONALI, S. DEDONI, M. C. OLIANAS;
Univ. of Cagliari, Monserrato, Italy

Abstract: The $GABA_B$ positive allosteric modulator (PAM) CGP7930 potentiates $GABA_B$ receptor signaling in transfected cells (Urwyler et al. Mol. Pharmacol. 60, 963-971, 2001) and rat and human brain (Onali et al., Eur. J. Pharmacol. 471, 77-84, 2003; Olianas et al., Neurochem. Int. 46, 149-158, 2005). A number of behavioral studies have also shown that CGP7930 exerts anxiolytic effects and reduces self-administration of drugs of abuse (Adams and Lawrence, CNS Drug Rev. 13, 308-316, 2007). However, little is known on whether this drug can affect neuronal signaling independently of $GABA_B$ receptor activity. In the present study we report that in human SH-SY5Y neuroblastoma cells, CGP7930 (30 μM) induced a rapid increase of dual phosphorylation (activation) of ERK1/2, which reached a maximum at 15 min and lasted for at least 60 min. CGP7930 also triggered CREB phosphorylation at Ser133 with a similar kinetic profile. Under the same experimental conditions, the $GABA_B$ receptor agonist (-)baclofen (100 μM) failed to affect ERK1/2 phosphorylation, and when combined with CGP7930, it did not elicit any further ERK1/2 stimulation. CGP7930-induced ERK1/2 phosphorylation was not prevented by cell pre-treatment with either the $GABA_B$ receptor antagonists CGP55845A and CGP54626, the $G_{i/o}$-receptor uncoupler pertussis toxin, the $G_{q/11}$ antagonist YM254890, or the tyrosine kinase inhibitor genistein. Conversely, it was completely blocked by the MEK inhibitor PD98059 and significantly attenuated by the protein kinase C inhibitors Go 6983 and bisindolylmaleimide I. CGP7930 (30 μM) was also found to stimulate ERK1/2 phosphorylation in CHO-K1 cells, which do not express $GABA_B$ receptors. However, CGP7930 (1-100 μM) had no effect in HEK293 cells, indicating that ERK1/2 activation was not a generalized cellular response to the PAM. These data indicate that CGP7930 can affect ERK1/2 signaling, which is known to be involved in the control of mood and drug addiction, independently of increased $GABA_B$ receptor activity.

Title: mGlu7 is critical for hippocampal plasticity and is a potential therapeutic target for the treatment of Rett Syndrome

Authors: *R. KLAR[1], R. G. GOGLIOTTI[2], A. G. WALKER[2], R. ZAMORANO[2], D. W. ENGERS[2], D. GHOSE[3], B. A. GRUETER[4], C. R. HOPKINS[5], C. W. LINDSLEY[5], Z. XIANG[2], P. J. CONN[2], C. M. NISWENDER[2];

Abstract: Rett Syndrome (RS) is a neurological disorder that is characterized by autism-like symptoms, loss of language skills, seizures, stereotyped behaviors, motor deficits, and cognitive impairments. Most cases of RS result from loss-of-function mutations in the Mecp2 (Methyl CpG Binding Protein 2) gene, which encodes for a protein that binds to methylated CpG islands in DNA and regulates gene transcription. Cell-autonomous knockout (KO) of Mecp2 from neurons recapitulates the cognitive deficits seen in patients with RS and results in impaired synaptic plasticity (induction of long-term potentiation (LTP) and long-term depression (LTD)) at the Schaffer-collateral-CA1 (SC-CA1) synapse in the hippocampus. Metabotropic Glutamate Receptor 7 (mGlu7) is unique from other group III mGlu receptors in that it is located pre-synaptically within the active zones on both glutamatergic and GABAergic terminals, where it

has been shown to regulate neurotransmitter release. Additionally, mGlu7 KO studies have suggested that loss of mGlu7 impairs working memory and fear extinction and results in deficits in short-term plasticity at SC-CA1synapses, similar to synaptic phenotypes seen in Mecp2 KO mice. Our preliminary data show that the GRM7 gene contains an MeCP2 binding site upstream of the transcription start site and that mGlu7 expression is positively regulated by MeCP2. Moreover, loss of Mecp2 in mice results in decreased expression of mGlu7 at the synapse in the hippocampus. Taken together, these data suggest that mGlu7 may be critical for the induction of LTP at SC-CA1 synapses and that potentiation of mGlu7 in Mecp2 KO mice could rescue LTP and improve cognitive impairments. Here we show that mGlu7 is necessary for induction of LTP at SC-CA1 synapses in wild-type mice, and that it facilitates LTP by decreasing GABAergic tone in a frequency-dependent manner. This results in a disinhibition of the synapse and allows for LTP to occur. Additionally, we have shown that application of the group III PAM, VU0422288, is sufficient to restore LTP in Mecp2 KO mice. Furthermore, we have also found that VU0422288 can reverse deficits in the contextual fear conditioning assay. These studies provide evidence for a novel role of mGlu7 in modulating synaptic plasticity in the hippocampus and suggest that activation of mGlu7 is beneficial in improving cognitive deficits in a mouse model of Rett Syndrome.

Title: Role of phospholipase D in mGluR-dependent hippocampal and muscarinic-dependent cortical long-term depression

Authors: *S. P. MORAN, M. ALTMAN, A. GHOSHAL, J. T. MAKSYMETZ, J. I. AGUILAR, C. W. LINDSLEY, P. J. CONN;
Pharmacol. Dept., Vanderbilt Univ., Nashville, TN

Abstract: Activation of metabotropic glutamate receptors (mGluRs) with application of the group I mGluR selective agonist (R,S)-3,5-dihydroxyphenylglycine (DHPG) induces long-term depression (LTD) of excitatory synaptic transmission onto hippocampal CA1 neurons. Previously, we have reported selective activation of mGluRs induces a concentration-dependent increase in phospholipase D (PLD) activity. PLD is a lipid signaling enzyme that catalyzes the hydrolysis of phosphatidylcholine into phosphatidic acid and choline. In mammals, the two isoforms PLD1 and PLD2, sharing ~53% sequence identity, have been implicated in critical cell signaling pathways with roles in cancer and central nervous system (CNS) disorders. Using brain slice electrophysiology, we recorded changes in mouse CA1 field excitatory post synaptic potentials (fEPSPs) following DHPG application in the presence of various PLD inhibitors. We report that 10 minute pretreatment of 2μM ML299 (a dual PLD1/PLD2 inhibitor) reduces subsequent 50 μM DHPG induced acute depression in addition to blocking long term depression. Additionally, we demonstrated that selective inhibition of the PLD1 isoform, by 10 minute pretreatment of 370nM VU0359595, recapitulates the blocking effect of ML299 on DHPG induced LTD. However, selective inhibition of the PLD2 isoform by 2μM VU0364739 failed to inhibit either the acute or long term depression. We also report that, other than its role in hippocampal plasticity, PLD can also modulate plasticity in other synapses. Application of ML299 also blocks 50 μM carbachol induced long term depression in the prefrontal cortex (PFC), a form of LTD that requires co-activation of M1 muscarinic and mGlu5 receptors. These data taken together, implicates that dysregulation of PLD function may play a role in CNS disorders in which synaptic plasticity is altered. We are currently performing additional electrophysiology experiments to demonstrate the role of PLD isoforms in induction and expression of LTD and long-term potentiation in the hippocampus and PFC.

Title: Characterization of a novel mGlu2 radioligand

Authors: *D. E. O'BRIEN[1], A. J. CROSS[2], S. WESOLOWSKI[2], C. S. ELMORE[3], P. J. CONN[1];
[1]Pharmacol., Vanderbilt Univ., Nashville, TN; [2]AstraZeneca Neurosci. Innovative Medicines, Cambridge, MA; [3]AstraZeneca Drug Safety & Metabolism, Molndal, Sweden

Abstract: Positive allosteric modulation of the metabotropic glutamate receptor 2 (mGlu2) offers a promising therapeutic target for schizophrenia, pain, addiction, epilepsy, and anxiety disorders. Medicinal chemistry efforts directed at specifically targeting mGlu2 have successfully developed several chemically distinct mGlu2 PAMs that exhibit therapeutic efficacy in preclinical rodent models. In order to better understand the binding modes of these mGlu2 PAMs, we characterized a novel mGlu2 radioligand *in vitro* using recombinant rat mGlu2. We demonstrated that the mGlu2 radioligand possesses suitable characteristics for binding studies. Moreover, we characterized the binding modes of several chemically distinct mGlu2 PAMs in competition binding assays utilizing the mGlu2 radioligand. Taken together, these studies demonstrate the preclinical utility of this mGlu2 radioligand for studying mGlu2 allosteric modulation.

Title: Stimulus bias by mGlu5 positive allosteric modulators affects long term potentiation in the hippocampus through involvement of endocannabinoids and GABAergic disinhibition

Authors: *J. T. MAKSYMETZ, A. GHOSHAL, X. LV, J. M. ROOK, C. W. LINDSLEY, Z. XIANG, P. J. CONN;
Pharmacology, Vanderbilt Ctr. for Neurosci. Drug Discovery, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Previously, we have demonstrated that unique metabotropic glutamate receptor 5 (mGlu5) positive allosteric modulators (PAMs) differentially potentiate NMDAR currents and long-term potentiation (LTP) at the Schaffer collateral-CA1 synapse in the rat hippocampus. The mGlu5 PAM VU0092273 potentiates both NMDAR currents and theta-burst stimulation-induced LTP (TBS-LTP) while VU0409551 does not affect either. It was previously thought that mGlu5 PAMs potentiate TBS-LTP through enhancement of NMDAR currents. However, we now report that the mGlu5 PAM VU-29 potentiates TBS-LTP but has no effect on NMDAR currents. In contrast, another mGlu5 PAM, 5PAM523, potentiates NMDAR currents but does not potentiate TBS-LTP. Thus, these novel mGlu5 PAMs confer distinct forms of stimulus bias to mGlu5 signaling and allow us to show that potentiation of mGlu5 regulation of NMDAR currents is not responsible for the ability of mGlu5 PAMs to enhance hippocampal LTP. Another possible mechanism by which mGlu5 PAMs could enhance hippocampal LTP is through modulation of GABAergic inhibitory transmission onto CA1 pyramidal cells, which is known to play a role in the regulation of LTP in the hippocampus. Previous studies reveal that activation of mGlu5 on hippocampal pyramidal cells induces endocannabinoid production, which then activates CB1 cannabinoid receptors (CB1Rs) on neighboring interneuron presynaptic terminals and causes a long-term depression of inhibitory postsynaptic currents (IPSCs). Interestingly, we found that the CB1R antagonist AM251 completely blocks the ability of the mGlu5 PAM VU0092273 to potentiate threshold TBS-LTP. Furthermore, preliminary whole-cell patch clamp recordings revealed that that application of 1 μM VU0092273 causes a slight reduction in IPSCs in CA1 pyramidal cells that could represent endocannabinoid-mediated disinhibition by GABAergic interneurons. Together, these experiments suggest that mGlu5 PAM potentiation of TBS-LTP is

not dependent on enhancement of NMDAR currents but may be mediated by release of endocannabinoids and a reduction of inhibitory tone. Additional studies will be performed to determine whether VU0092273 reduces IPSCs by a mechanism that involves endocannabinoid signaling to presynaptic GABAergic interneurons and to determine whether this disinhibition is necessary during TBS for the potentiation of LTP. Furthermore, our series of mGlu5 PAMs that display distinct forms of stimulus bias will allow us to determine whether mGlu5 PAMs that do not potentiate induction of TBS-LTP are also without effects on endocannabinoid-mediated disinhibition.

Title: Co-treatment with anthocyanins and vitamin c ameliorates ethanol-induced neurodegeneration via modulation of gaba b receptor signaling in the adult rat brain

Authors: *H. BADSHAH, T.-H. KIM, H.-Y. LEE, T. ALI, M.-O. KIM;
Div. of Life Sci., Gyeongsang Natl. Univ., Jin-ju, Korea, Republic of

Abstract: Chronic ethanol exposure is known to cause neuronal damage in both humans and experimental animal models. Ethanol induces neurotoxicity via the generation of reactive oxygen species (ROS), while anthocyanins and ascorbic acid (vitamin C) are free radical scavengers that can be used as neuroprotective agents against ROS. In this study the underlying neuroprotective potential of black soybean anthocyanins and vitamin C was determined. For this purpose, adult rats were exposed to 10% (v/v) ethanol for 8 weeks, followed by co-treatment with anthocyanins (24 mg/kg) and vitamin C (100 mg/kg) during the last 4 weeks. Long term ethanol administration increased the expression of γ-aminobutyric acid B1 receptor ($GABA_{B1}R$) and induced neuronal

apoptosis via alterations to the Bax/Bcl-2 ratio, release of cytochrome C and activation of caspase-3 and caspase-9. Anthocyanins alone and supplementation with vitamin C showed an additive effect in reversing the trend of apoptotic signals induced by ethanol in the cortex and hippocampus. Consequently, anthocyanins also decreased the expression of poly (ADP ribose) polymerase-1 (PARP-1) induced by ethanol and prevented DNA damage. Furthermore, anthocyanins and vitamin C reversed the ethanol-induced expression of $GABA_{B1}R$ and its downstream signaling molecule phospho-cAMP response element binding protein (p-CREB). Moreover, histopathology and immunohistochemistry results showed that anthocyanins and vitamin C significantly reduced ethanol-induced neuronal cell death. Our study revealed a neuroprotective role of anthocyanins and vitamin C via modulation of $GABA_{B1}R$ expression in the adult brain. Hence, we suggest that anthocyanins or co-treatment with anthocyanins and vitamin C may be a new and potentially effective neuroprotective agent for alcohol abuse.

Title: CaMKII-dependent K63-linked ubiquitination of GABAB1 drives lysosomal degradation of GABAB receptors

Authors: *K. ZEMOURA[1], C. TRÜMPLER[2], D. BENKE[2];
[1]Inst. of Pharmacol. and Toxicology, Zurich, Switzerland; [2]Inst. of Pharmacol. and Toxicology, Univ. of Zurich, zurich, Switzerland

Abstract: GABAB receptors are heterodimeric G protein-coupled receptors, which control neuronal excitability by mediating slow and prolonged inhibition. The magnitude of GABAB receptor-mediated inhibition essentially depends on the amount of receptors in the plasma membrane. One factor that determines receptor availability is regulated protein degradation. GABAB receptors are constitutively internalized and either recycled to the cell surface or degraded in lysosomes. The signal that sorts GABAB receptors to lysosomes is currently unknown. Here we tested whether ubiquitination is the lysosomal sorting signal for GABAB receptors. We found that inhibition of lysosomal activity in cortical neurons increased total and

cell surface GABAB receptors as well as the level of K63-linked ubiquitinated receptors. Mutational inactivation of four putative ubiquitination sites in the GABAB1 subunit significantly diminished K63-linked ubiquitination of GABAB receptors and prevented their lysosomal degradation. Searching for factors that control lysosomal degradation of GABAB receptors revealed that blocking Ca2+/calmodulin-dependent protein kinase II (CaMKII) decreased K63-linked ubiquitination of GABAB receptors and inhibited lysosomal degradation of GABAB receptors by sorting the receptors to the recycling pathway. Finally, triggering lysosomal degradation of GABAB receptors by sustained activation of glutamate receptors, a condition mimicking in brain ischemia, was accompanied with a massive increase of CaMKII-dependent K63-linked ubiquitination of GABAB receptors. Preventing K63-linked ubiquitination by blocking CaMKII, overexpressing ubiquitin mutants or mutant GABAB receptors deficient in GABAB1 K63-linked ubiquitination prevented down-regulation of the receptors. These findings indicate that CaMKII-dependent K63-linked ubiquitination of GABAB1 at multiple sites controls sorting of GABAB receptors to lysosomes for degradation under physiological and pathological condition.

Title: GABAb-receptor neurotransmission changes in the ventral-pallidum are associated to depressive-like behaviors

Authors: *R. E. CONTRERAS[1,2], M. SKIRZEWSKI[3], S. SALMEN[2], L. BETANCOURT[1], L. HERNÁNDEZ[1], P. RADA[1];
[1]Fisiologia De La Conducta. Univ. De Los Andes, Merida, Venezuela, Bolivarian Republic of; [2]Inst. de Inmunología Clínica, Univ. de Los Andes., Merida, Venezuela, Bolivarian Republic of; [3]NIH, Rockville Pike, MD

Abstract: Depression affects approximately 121 million people worldwide. It causes more than 800,000 completed suicides by year. Major depressive disorder is an idiopathic syndrome characterized by depressed mood, helplessness, anhedonia, disphoria, altered sleep behavior and appetite and loss of concentration. In a published study we found that GABAergic transmission in the ventral pallidum (VP) seems to play a role in depression-like behaviors. We found an

increased basal GABA extracellular concentration in the VP of rats during the forced swimming test (FST) suggesting an enhancement of GABAergic tone upon depression. However, the specific role for GABAB-R in this brain region during depression remains unknown even though we previously described some GABAB receptor contributions in the VP to this behavior while using specific agonist and antagonist molecules. In this work we demonstrated that intra-VP microinjections of saclofen and then baclofen before day-2 FST significantly exacerbated immobility (477.0 ± 8.07; n=10, $F=3.893$; $p<0.05$) compared to the control group with saline solution (348.9± 31.18; n=10). Then we monitored extracellular GABA when intra-VP saclofen pulses were administered and found a significant increase (480.95±178.43; n=4, $F=10.86$, $Df=1$, $p<0.05$) when compared to the saline control group (77.57±78.68; n=4). Finally, we reported GABAB-R protein and GABAB2 mRNA subunit up-regulation in the VP of depressed animals. Thus, we postulate first the synergic effect of GABAB-R antagonist and agonist in the VP upon pre-synaptic and post-synaptic localization respectively. And second, we report a hypersensitive GABAB-R system that is possibly involved in the pathogenesis and perpetuation in depressive-like behaviors and could be considered as plausible therapeutic target.

Title: Aversive experiences depress GABAB signaling in the lateral habenula

Authors: *S. LECCA[1,2,3], R. LUJAN[4,5], M. MAMELI[1,2,3];
[1]Inst. Du Fer A Moulin, Paris, France; [2]INSERM / UMR-S 839, Paris, France; [3]Univ. Pierre et Marie Curie, Paris, France; [4]Inst. de Investigación en Discapacidades Neurológicas, Albacete, Spain; [5]Facultad de Medicina, Univ. Castilla-La Mancha, Almansa, Spain

Abstract: The lateral habenula (LHb), an ephitalamic structure bridging forebrain and midbrain nuclei, encodes aversive stimuli. Work in primates and rodents indicate that aversive stimuli

phasically increase LHb neurons firing rate (Matsumoto and Hikosaka 2007) and optogenetic activation of LHb terminals onto midbrain neurons induces avoidance behavior in mice (Stamatakis and Stuber 2012; Lammel et al, 2012). Furthermore, in rodents previously exposed to aversive stimuli such as foot-shocks, c-fos expression as well as firing activity increase within the LHb (Brown and Shepard 2013; Li et al, 2011). However, the early cellular adaptations eventually occurring in the LHb after an aversive experience remain to be fully elucidated. In order to test the hypothesis that aversive events can trigger cellular modifications in the LHb underlying changes in neuronal excitability, we took advantage of the inescapable footshock paradigm and ex-vivo patch-clamp recordings in acute slices from mice. To obtain information on the spontaneous output firing of neurons we recorded LHb cells in the cell-attached configurations, one hour after the aversive procedure. We found that, in slices obtained from footshock exposed mice (FsE), neurons presented a significantly higher firing frequency than control mice. We then, sought to understand the molecular mechanisms responsible for the increased firing rate. Performing recordings in whole-cell mode, we find that glutamate and GABAA transmission remained unchanged. In contrast, using whole-cell patch clamp recordings we find that the pharmacological activation of GABAB-Rs by baclofen, elicited a GIRK-mediated outward current, which was reduced in FsE. Employing electron microscopy, we show that FsE leads to a significant reduction in membrane expression of both GABAB1 and GIRK2, with a corresponding increase in their intracellular pool. Interestingly, the reduction of GABAB-GIRK signaling occurred after pain-less aversive experience capable to induce aversive behaviors in mice (odor predator and restraint stress). Finally, we find that in FsE mice GABAB-Rs-mediated inhibition of firing resulted strongly weakened. These data indicate that aversive events drive a rapid and persistent functional reduction of the GABAB-GIRK signal along with a loss of inhibitory control on firing activity of LHb neurons, providing a sensitive cellular mechanism underlying LHb neurons hyperexcitability triggered by aversive events.

Title: GABA-B receptor signaling is regulated by assembly of KCTD proteins with matching G-protein subunits

Authors: T. FRITZIUS[1], R. TURECEK[1], V. BESSEYRIAS[1], M. GASSMANN[1], *B. BETTLER[2];
[1]Dept. of Biomedicine, [2]Univ. Basel, Basel, Switzerland

Abstract: GABA-B receptors are the G-protein coupled receptors (GPCRs) for GABA, the main inhibitory neurotransmitter in the central nervous system. Upon agonist stimulation, GABA-B receptors activate K+ channels via release of Gβγ heterodimers from the heterotrimeric G protein. GABA-B receptors comprise principle and auxiliary subunits that regulate receptor properties in distinct ways. The principle subunits GABA-B1a, GABA-B1b, and GABA-B2 form fully functional heteromeric GABA-B(1a,2) and GABA-B(1b,2) receptors, while the auxiliary subunits KCTD8, -12, -12b, and -16 influence the kinetics of the receptor response (Schwenk et al., Nature, 2010). Recently, we showed that all KCTD subunits can interact with the Gβγ subunit of the heterotrimeric G protein. Selectively KCTD12 induces a fast desensitization of receptor-mediated Kir3 channel responses by an activity-dependent uncoupling of the Gβγ subunits from the channel (Turecek et al., Neuron, 2014). We will present an in-depth molecular analysis of the Gβγ/KCTD interaction. Specifically, we determined the regions of Gβγ that bind to the KCTDs in a constitutive and activity-dependent manner. Furthermore, we show that KCTD12-induced desensitization of the GABA-B receptor response is not only governed by the presence or absence of KCTD12, but also by the Gβγ subunits available in the cellular environment.

Title: GABAB receptor-mediated network function is disrupted by loss of KCTD auxiliary subunits

Authors: *M. T. CRAIG[1], X. YUAN[1], G. A. VARGISH[1], M. GASSMANN[2], B. BETTLER[2], C. J. MCBAIN[1];
[1]NIH/NICHD/PDN/SCSP, NIH, Bethesda, MD; [2]Dept. of Biomedicine, Inst. of Physiol., Univ. of Basel, Basel, Switzerland

Abstract: Inhibition from interneurons, acting through ionotropic $GABA_A$ receptors, is well established as being essential for generating and maintaining neuronal network rhythms. It is emerging that metabotropic $GABA_B$ receptors also play an important role in regulating network dynamics. Recently, $GABA_B$ receptors were shown to co-assemble with four auxiliary subunits: KCTD8, KCTD12, KCTD12b and KCT16; expression of KCTD12b is restricted to the habenula, but the remainder are expressed throughout the nervous system, with KCTD12 and KCTD16 being widely abundant in most brain regions. The KCTD auxiliary subunits are cytosolic proteins that influence the agonist sensitivity and G-protein signalling of $GABA_B$ receptors, and KCTD12 polymorphisms are associated with bipolar disorders in humans. $GABA_B$ receptors are heterodimers of $GABA_{B1}$ and $GABA_{B2}$ subunits, and $GABA_{B1}$ subunits exist in two isoforms, $GABA_{B1a}$ and $GABA_{B1b}$. Receptors containing $GABA_{B1a}$ are predominantly found in presynaptic locations while those containing $GABA_{B1b}$ are generally found postsynaptically. Previously, we reported that these isoforms had distinct roles in terminating Up states in an *in vitro* mouse model of slow oscillations in the medial entorhinal cortex (mEC), with $GABA_{B1a}$-containing receptors involved in spontaneous termination of Up states while $GABA_{B1b}$-containing receptors were essential for active termination of Up states via afferent stimulation. Using mice in which either KCTD8, KCTD12 or KCT16 had been genetically ablated, we used the mEC model of slow oscillations to determine whether loss of KCTD auxiliary subunits had any consequences for network function. We found that, in wild type mice or those lacking KCTD8 or KCTD16, electrical stimulation in layer 1 of the mEC could halt an ongoing Up state, but that this effect was abolished in mice lacking KCTD12. This demonstrates a functional loss of post-synaptic $GABA_{B1b}$-containing receptors, implying that KCTD12 is necessary for either their function or trafficking. Examining spontaneous termination of Up states suggested that $GABA_{B1a}$-containing receptor-mediated function was impaired, but not lost, in mice lacking KCTD16. These data show that loss of KCTD auxiliary subunits disrupts normal $GABA_B$ receptor-dependent network function, and work is underway to further study these deficits at the electrophysiological, anatomical, and behavioural levels.

Title: Development of fast and reliable intrinsic excitability in auditory brainstem neurons

Authors: *H. HONG, L. ROLLMAN, J. SANCHEZ;
Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstract: Auditory brainstem neurons can generate extremely fast, reliable and highly synchronized action potentials (APs), a process critical for encoding sound localization and communication cues. This specialization depends on specific potassium and sodium channels found in mature neurons but how these channels shape AP speed and reliability during development are largely unexplored. In this study we characterized the maturation of voltage-gated potassium and sodium channels, and quantified how their currents shape AP properties in the cochlear nucleus magnocellularis (NM) of chickens. Whole-cell patch clamp recordings were obtained from developing chicken embryos before, during, and after hearing onset, corresponding to embryonic (E) days 10-12, E14-16, and E19-21, respectively. Voltage and current steps of varying durations and strengths were injected into the soma of NM neurons. AP properties, along with potassium and sodium currents, were characterized before and during bath application of specific potassium channel blockers. We found that the maturation of both voltage-gated potassium and sodium currents improved AP speed and reliability, in combination with changes in intrinsic membrane properties. With maturation, the time constant of membrane voltage became faster, while input resistance and capacitance decreased. The change in membrane input resistance was due to a significant upregulation in total potassium current. We observed a 2-fold increase in the total amount of potassium current from E10 to E21. Furthermore, we found that high-voltage activated potassium (K^+_{HVA}) channels contribute to the regulation of AP properties during development. When K^+_{HVA} channels were blocked for each age group, APs became significantly slower and less reliable. However, the greatest amount of change in AP properties was most prominent at the youngest ages, suggesting a significant contribution of K^+_{HVA} channels. Indeed, the ratio of K^+_{HVA} current accounted for 86% of the total potassium current for younger neurons; whereas, the ratio dropped to 52% for mature neurons. In addition, sodium currents became larger, faster, and more reliable; there was a 6-fold increase in rise and fall rates with maturation, likely due to changes in the expression of sodium channel subtypes. In conclusion, the refinement of potassium and sodium channels plays an important

role in shaping AP properties in the developing avian NM. Auditory brainstem neuron's ability to fire fast, reliable and synchronized APs is heavily dependent on both potassium and sodium channels and deficits in these channels may underlie aspects of auditory temporal processing disorders.

Title: M-current impact on the *in vitro* neuronal network activity during development

Authors: *F. ROSA[1], H. LÖFFLER[1], S. THEISS[2,3], M. DIHNE[4], H. LERCHE[1], S. MALJEVIC[1];

Abstract: In the last decade, Kv7.2 and Kv7.3 potassium channels underlying the M-current have been linked to epileptic disorders, such as benign neonatal seizures and epileptic encephalopathy. The vast majority of experiments has been performed using single neuron patch clamp recordings or EEG recordings in murine models. Because permanent Kcnq2 knock-out (KO) animals are not viable, little is known about the brain electric activity in the first days after birth in the absence of this subunit. To examine the effect of the M-current on neuronal network activity, we plated E17 hippocampal wildtype (WT), Kcnq2+/- (H) and Kcnq2-/- (KO) cultures on 60-channel microelectrode arrays (MEAs) and recorded the activity on 10, 17 and 24 days *in vitro* (DIV). The network parameters were analyzed before and after application of Kv7.2/7.3 agonist retigabine/ezogabine and the blocker XE991. We assessed standard network activity parameters, including spike and burst frequency, burst duration and number of spikes per burst. The burst parameters refer to the synchronous "population burst" activity observed simultaneously on many electrodes. The characteristic pattern observed at DIV 10 was a regular

firing consisting of short-lasting population bursts, which occurred in all 3 genotypes. However, upon application of 10μM retigabine, mean population burst duration was significantly shorter in WT and H compared to KO networks. Over the following 7 and 14 days, WT and H culture firing patterns massively changed to long-lasting, highly synchronized population bursting, interrupted by long, equally synchronized silent periods. In contrast, KO cultures retained their firing pattern observed on 10 DIV. Application of the XE991 antagonist in a concentration of 20μM altered population burst patterns in WT and H yielding a similar pattern to KO networks. Our results show that the M-current dysfunction in *in vitro* neuronal cultures mostly affects the duration of population bursts. The observed differences between the 3 genotypes and during development corroborate the importance of the M-current for the proper functioning of neuronal networks. Furthermore, this established *in vitro* assay can be used for the substance screening in pharmacological studies targeting the M-channels.

Title: Human gain-of-function Slack (KCNT1) K+ channel mutations increase positive cooperativity between individual Slack channels through C-terminal domain interactions

Authors: *J. KRONENGOLD[1], G. E. KIM[1], V. R. GAZULA[1], B. YANG[1], I. QURAISHI[2], H. C. MARTIN[3], G. BARCIA[4], J. TAYLOR[3], L. R. COLLEAUX[4], R. NABBOUT[4], L. K. KACZMAREK[1];

Abstract: The Na+-activated K+ channel Slack (KCNT1, Slo2.2) is widely expressed in neurons. Slack channels contribute to slow afterhyperpolarizations and regulate firing frequency. We expressed the rat Slack channel in Xenopus oocytes and found two different patterns of channel activity in single channel patch clamp recordings. When few (1-3, low N) channels are

present in the patch, we observe a low channel open probability pattern. In contrast, when 4-5 or more channels are present (high N), a high channel open probability is observed. On-cell recordings of high N patches show coupled gating of the fully open state and all points amplitude histograms show a marked deviation from a binomial distribution expected for independently gating channels. The different patterns of Slack channel activity likely reflect channel-channel interactions that only occur when the channels assemble into clusters, as is the case *in vivo*. Indeed, cortical and hippocampal neurons show Slack channel membrane clusters. Electrophysiological recordings from Slack-expressing auditory brainstem neurons show that the native channels exhibit positive cooperativity. Recent studies have identified KCNT1 point mutations in three early onset epilepsy syndromes; migrating malignant partial seizures in infancy, autosomal dominant nocturnal frontal lobe epilepsy, and Ohtahara syndrome. All three have devastating effects on development and intellectual function. The mutations are found in RCK1 and RCK2 of the large 900aa cytoplasmic C-terminal domain of Slack with one located in the S5 pore forming domain of the channel. Voltage clamp studies of the mutant channels show 3- to 22-fold increases in macroscopic currents with no change in levels of channel protein. Single channel studies show no significant changes in unitary conductance except for the G288S pore mutant which shows a 50% decrease. We found that positive cooperativity is enhanced in all human gain-of-function mutations. Mutations show a significant increase in NPo in multichannel patches relative to the wild type multichannel patches. To explore the allosteric mechanism responsible for channel interactions, we made a C-terminal truncation of Slack to remove RCK2, and found that this eliminated the coupling found in Slack channel clusters. Specifically, there is no difference in open probability in low and high N patches. All points amplitude histograms show that the channel open probability in high N patches follows that predicted from a binomial distribution for independently gating channels. Our findings indicate that cooperative interactions between Slack channels are mediated by the distal cytoplasmic C-terminal domain.

Title: The Slack Na+-activated K+ channel contributes to serotonin-sensitive currents of *Aplysia* sensory neurons

Authors: Y. ZHANG[1], A. B. KOHN[2], L. L. MOROZ[2], *L. K. KACZMAREK[1];
[1]Yale Univ. Sch. Med., New Haven, CT; [2]Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Modulation of ion channels and neurotransmitter release by serotonin in sensory neurons of *Aplysia* has been widely studied as a model for elementary forms of learning and memory. A primary action of serotonin on these neurons is to activate the cyclic AMP-dependent protein kinase (PKA), which reduces potassium current. This reduced potassium current, in turn, causes membrane depolarization, broadening of action potentials and enhanced neurotransmitter release. In mammalian sensory neurons, it has been established that the Slack sodium-activated potassium channel is a major component of potassium current. Activation of PKA in mammalian sensory neurons increases excitability by reducing potassium current through internalization of Slack subunits (Nuwer et al., 2010). To determine if Slack subunits have a similar role in setting the excitability of *Aplysia* sensory neurons, we have isolated several isoforms of *Aplysia* Slack gene from an *Aplysia* sensory neuron library. *In situ* hybridization experiments show that Slack is expressed at very high levels in mechanosensory neurons in all major ganglia including the abdominal, pleural, cerebral and buccal ganglia. In voltage clamp experiments on isolated pleural mechanosensory neurons, potassium current was reduced on removal of sodium from the external medium. In normal media, application of serotonin reduced overall potassium current, and in current clamp experiments caused depolarization of the resting potential and broadening of action potentials. In contrast, if cells were treated with RNAi against Slack to suppress Slack expression, serotonin failed to reduce potassium current. Slack RNAi-treated cells had more positive resting potentials and broader action potentials than those treated with scrambled RNAi, and application of serotonin produced smaller depolarizations with no broadening of action potentials. Our findings suggest that the Slack sodium-activated potassium channel is highly differentially expressed in *Aplysia* mechanosensory neurons, and contributes in a major way to serotonin-induced changes in excitability.

Title: Differential Ca^{2+}-dependent signaling of the neuronal Ca^{2+} sensor proteins, Neurocalcin δ and Hippocalcin, in cultured hippocampal neurons

Authors: N. I. KONONENKO[1], J. VIVIANO[3], A. V. DOVGAN[1], V. P. CHERKAS[1], J. ZHANG[3], V. VENKATARAMAN[3], *P. V. BELAN[2];
[1]Lab. of Mol. Biophysics, [2]Bogomoletz Inst. of Physiol., Kiev, Ukraine; [3]Dept. of Cell Biology, Grad. Sch. of Biomed. Sci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ

Abstract: Hippocalcin (HPCA) and Neurocalcin δ (NCALD) are structurally very similar neuronal Ca^{2+} sensor (NCS) proteins controlling neuronal functions in many types of cells and shown to be crucial in regulating slow afterhyperpolarization (sAHP). It has been demonstrated that a time course of sAHP, which controls patterns of neuronal activity, may depend upon Ca^{2+}-induced NCS protein translocation from the cytosol to the plasma membrane. In spite of minor difference in AA sequence between HPCA and NCALD, a primary structure of the latter promotes its Ca^{2+}-dependent dimerization and results in higher affinity for binding Ca^{2+}. Besides, major distinctions in AA sequence between the proteins are located in their N-terminal region responsible for Ca^{2+}-dependent insertion into the plasma membrane. Altogether these differences in structure and biophysical properties suggest different Ca^{2+}-dependent signaling of these proteins during induction of sAHP. To test this hypothesis we studied Ca^{2+}-dependent translocation of HPCA, NCALD and their chimeras in cultured hippocampal neurons. The neurons were co-transfected with HPCA and NCALD (or chimeras) tagged by different fluorescent proteins and stimulated in a voltage-clamp mode to evoke transient increases of intracellular $[Ca^{2+}]_i$ that may produce sAHP. The same spatio-temporal patterns of $[Ca^{2+}]_i$ changes led to different time courses, amplitudes, and locations of HPCA and NCALD translocation. There was substantial (~1s) latency in NCALD translocation as well as its dramatic (~4 times) prolongation compared to HPCA. Ca^{2+} influx was also spatially differentially decoded by HPCA and NCALD translocation in soma and dendrites of cultured hippocampal neurons. Besides, sensitivity of NCALD to Ca^{2+} at low $[Ca^{2+}]_i$ was 4-fold higher compared to HPCA. Initial experiments with chimeras suggested that differences in kinetics of NCALD signaling compared to HPCA is mainly a result of dimerization that stabilizes Ca^{2+}-bound form and increase NCALD binding to the plasma membrane due to its interaction with 2 myristoyl groups. Thus, minor distinctions in AA sequences of HPCA and NCALD does lead to a substantial difference in their Ca^{2+}-dependent signaling via translocation to the plasma membrane and subsequent activation of sAHP. We conclude that differential expression of HPCA and NCALD in CNS neurons may determine the time course of sAHP in particular neurons, thus far controlling their patterns of activity.

Title: The potassium channel Kv4.2 is regulated by miRNA-induced silencing during seizures

Authors: *C. GROSS[1], X. YAO[2], T. ENGEL[3], L. XING[2], S. W. DANIELSON[2], K. T. THOMAS[2], E. JIMENEZ-MATEOS[3], D. HENSHALL[3], G. BASSELL[2];
[1]Neurol., CCHMC, Cincinnati, OH; [2]Emory Univ., Atlanta, GA; [3]RCSI, Dublin, Ireland

Abstract: Epileptic seizures are bursts of excessive neuronal activity, suggesting that mechanisms controlling brain excitability are compromised. The voltage-gated potassium channel Kv4.2, the predominant mediator of hyperpolarizing A-type currents in the CA1 region of the hippocampus, is a crucial regulator of neuronal excitability. Kv4.2 expression levels are reduced following seizures, but the underlying mechanisms remain unclear. Here, we report that Kv4.2 is translationally repressed by the RNA-induced silencing complex shortly after status epilepticus in mice *in vivo* and after kainic acid treatment of hippocampal neurons *in vitro*. Moreover, we have identified a microRNA that inhibits Kv4.2 protein expression. Antagonizing this microRNA with an antisense oligonucleotide blocks excitotoxicity-induced reduction of Kv4.2 protein in neurons, is neuroprotective, and reduces the severity of kainic acid-evoked status epilepticus in mice. In summary, our results demonstrate that microRNA-mediated

silencing contributes to Kv4.2 suppression during seizures and suggest that Kv4.2-targeting microRNAs might serve as therapeutic targets for epilepsy.

Title: KChIP-like auxiliary subunits of Kv4 channels regulate excitability of muscle cells and control male turning behavior during mating in Caenorhabditis elegans

Authors: *X. CHEN, M.-Y. RUAN, S.-Q. CAI;
Chinese Acad. of Sci., Inst. of Neurosci., Shanghai, China

Abstract: Voltage gated Kv4 channels control the excitability of neurons and cardiac myocytes by conducting rapidly activating-inactivating currents. The function of Kv4 channels is profoundly modulated by K^+ Channel Interacting Proteins (KChIPs) soluble auxiliary subunits. However, the *in vivo* mechanism of the modulation is not fully understood. In this study, we aimed to study the mechanism of KChIPs modulation on Kv4 channels in Caenorhabditis elegans (*C. elegans*). We identified three *C. elegans* KChIP-like (ceKChIP) proteins, NCS-4, NCS-5, and NCS-7. All three ceKChIPs alter electrical characteristics of SHL-1, a *C. elegans* Kv4 channel ortholog, currents by slowing down inactivation kinetics and shifting voltage dependence of activation to more hyperpolarizing potentials. Native SHL-1 current is completely abolished in cultured myocytes of Triple KO worms where all three ceKChIPs genes are deleted. Re-expression of NCS-4 partially restored expression of functional SHL-1 channels, whereas NCS-4(efm), a NCS-4 mutant with impaired Ca^{2+}-binding ability, only enhanced expression of SHL-1 proteins, but failed to transport them from the Golgi apparatus to the cell membrane in body wall muscles of Triple KO worms. Moreover, translational reporter revealed that NCS-4 assembles with SHL-1 K^+ channels in male diagonal muscles. Deletion of either ncs-4 or shl-1

significantly impairs male turning, a behavior controlled by diagonal muscles during mating. The phenotype of ncs-4 null mutant could be rescued by re-expression of NCS-4, but not NCS-4(efm), further emphasizing the importance of Ca^{2+} binding to ceKChIPs in regulating native SHL-1 channel function. Together, these data reveal an evolutionarily conserved mechanism underlying the regulation of Kv4 channels by KChIPs, and unravel critical roles of ceKChIPs in regulating muscle cell excitability and animal behaviors in *C. elegans*.

Title: Intrastriatal administration of retigabine, a pan-Kv7 (KCNQ) channel opener, inhibits post-synaptic neuronal activation

Authors: *H. B. HANSEN[1,3], M. D. MIKKELSEN[3], P. WEIKOP[2], J. D. MIKKELSEN[1,3]; [1]Neurobio. Res. Unit, [2]Neuropsychiatric Lab., Copenhagen Univ. Hosp., Copenhagen, Denmark; [3]NeuroSearch A/S, Ballerup, Denmark

Abstract: Heteromeric Kv7 (KCNQ) channels are voltage-dependent potassium channels composed of four Kv7 subunits being differently expressed in the brain. Striatal neurotransmission is strongly suppressed by systemic administration of various Kv7 channel openers, including the pan-Kv7 channel opener retigabine. This effect presumably involves stimulation of different Kv7 channel isoforms in mesencephalic dopaminergic neurons projecting

to the striatum. However, it remains to be established whether Kv7 channels locally expressed in the striatum may also play an important contributing role in controlling striatal post-synaptic excitability. To further investigate the functional relevance of striatal Kv7 channel expression *in vivo*, we determined the Kv7 subunit mRNA composition in the rat striatum and asked whether retigabine may influence striatal excitability by direct stimulation of striatal Kv7 channel activity. The relative levels of rat striatal Kv7 subunit mRNAs were Kv7.2=Kv7.3=Kv7.5>>Kv7.4. Post-synaptic Kv7 mRNA expression in the rat striatum was suggested by an almost complete ablation of striatal Kv7 mRNA levels following a unilateral intrastriatal application of quinolinic acid. Striatal Kv7 channels were functional, as revealed by a unilateral intrastriatal retigabine application which markedly reduced striatal neuronal c-Fos induction after acute systemic haloperidol administration. Collectively, these data suggests that post-synaptic striatal Kv7 channels play a direct role in modulating striatal excitability.

Title: DPP6 domains responsible for its localization and function

Authors: *L. LIN, L. K. LONG, M. M. HATCH, D. A. HOFFMAN;
NICHD-NIH, Bethesda, MD

Abstract: Dipeptidyl peptidase-like protein 6 (DPP6) is an auxiliary subunit of the Kv4 family of voltage-gated K^+ channels known to enhance channel surface expression and potently accelerate their kinetics. DPP6 is a single transmembrane protein, which is structurally remarkable for its large extracellular domain. Included in this domain is a cysteine-rich motif, the function of which is unknown. Here we show that this cysteine-rich domain of DPP6 is required for its export from the ER and expression on the cell surface. Disulfide bridges formed at C349/C356 and C465/C468 of the cysteine-rich domain are necessary for the enhancement of Kv4.2 channel surface expression but not its interaction with Kv4.2 subunits. The short

intracellular N-terminal and transmembrane domains of DPP6 associates with and accelerates the recovery from inactivation of Kv4.2, but the entire extracellular domain is necessary to enhance Kv4.2 surface expression and stabilization. Our findings show that the cysteine-rich domain of DPP6 plays an important role in protein folding of DPP6 that is required for transport of DPP6/Kv4.2 complexes out of the ER.

Title: Novel KCNJ10 SNPs affect Kir4.1 biophysical properties and their modulation by spermine

Authors: *M. MENDEZ[1], Y. KUCHERYAVYKH[1], A. ZAYAS-SANTIAGO[1], W. VELEZ-CARRASCO[1], L. CUBANO[2], S. SKATCHKOV[3], M. EATON*[1];
[1]Biochem., [2]Anat. and Cell Biol., [3]Physiol., Univ. Central Del Caribe, Bayamon, PR

Abstract: KCNJ10-encoded Kir4.1-containing channels generate the major inward rectifying K+ conductance in astrocytes and are essential for buffering excess extracellular [K+]. Mutations in the KCNJ10 gene are causal in certain forms of epilepsy. This gene contains over 120 coding-region single nucleotide polymorphisms (SNPs) of which their molecular effect remains unknown. Here, we investigate the functional consequences of uncharacterized SNP's reported in publically accessible genome data bases (Q212R, L166Q and G83V) that we hypothesize will alter Kir4.1 channel function. Using whole-cell patch clamp of tSA201 cells expressing wild-type (WT) Kir4.1 or its variants, we evaluated the impact of these SNPs on homomeric Kir4.1

and heteromeric Kir4.1/5.1 channel function. Cells expressing WT Kir4.1, Q212R or L166Q channels displayed a hyperpolarized membrane potential, compared with G83V variant. In response to voltage-steps, macroscopic currents from cells expressing WT and Q212R channels displayed no differences, whereas currents from cells expressing L166Q and G83V were reduced. Surprisingly, the current response was rescued when L166Q was co-expressed with Kir5.1. Kir4.1 channels can be modulated by the polyamine spermine (SPM). Using inside-out excised patches we determined SPM sensitivity of homomeric Kir4.1 and heteromeric Kir4.1/5.1 channels and determined V1/2 and offset values by fitting to the Boltzmann function. Both homomeric Q212R and heteromeric Q212R/5.1 displayed greater V1/2 values indicating reduced block by 1μM SPM. At 100μM SPM, the block of Q212R-containing homomeric channels was the same as WT suggesting that the greater driving force of SPM allowed steady state to be achieved. As homomeric L166Q channels show reduced current, we could only assess the effect of SPM on heteromeric L166Q/Kir5.1. Heteromeric L166Q-Kir5.1 channels achieved a higher block than WT at all SPM concentrations tested and most notably with 100 μM SPM. This could be explained if this residue helps to keep SPM in a stable conformation in the deep pore cavity which is supported by the complete block (i.e., offset of 0) seen in these channels. Overall, our data suggest that SNP's of KCNJ10 may affect channel function via different mechanisms.

Title: The roles of ion channel antibodies on neuron survival

Authors: *N. AYSIT[1], E. TUZUN[2], G. ÖZTÜRK[3];
[1]neuroscience, ISTANBUL Medipol UNIVERSITY -ISTANBUL MEDIPOL UNIV, ISTANBUL, Turkey; [2]Saglik Bilimleri Enstitusu, Istanbul Universitesi, Istanbul, Turkey; [3]Physiol., Istanbul Medipol Univ., Istanbul, Turkey

Abstract: Neuronal excitability is finely controlled by various membranous channels and associated proteins. In the central nervous system (CNS), the rapidly inactivating voltage-gated potassium channels (VGKC) are the major determinants of dendritic excitability. VGKCs play a critical role in regulating neuronal excitability and synaptic plasticity in the hippocampus.

NMDA receptors and VGKCs are critical for the development of the CNS, generation of rhythms for breathing and locomotion, and the processes underlying learning, memory, and neuroplasticity. Consequently, abnormal expression levels and altered NMDAR function have been implicated in numerous neurological disorders and pathological conditions. NMDAR hypofunction can result in cognitive defects, whereas overstimulation causes excitotoxicity and subsequent neurodegeneration. Subconductance levels have been observed in virtually every type of ion channel, although the number of levels, stability, and abundance vary widely. Sublevels have been well-characterized in potassium channels, which are evolutionarily related to NMDARs. The aim of the study is the contribution of VGKC-complex protein leucine rich glioma inactivated 1 (LGI1) and NMDAR of neuronal survival/death in hippocampal cells. Primary hippocampal cultures were prepared from the brains of newborn Balb-c mice approximately 4 days old. The hippocampus was isolated from the brain of each mice and treated at 4 °C. The cells were suspended in neurobasal medium and were plated at several densities 200 -1600 cells per mm2. IgG was isolated from healthy participants and limbic patients who were NMDAR or LGI1 antibody positive. Different concentrations of isolated IgG were added to the preperation at days 1, 3 and 7 *in vitro*. Imaging was performed on same days by confacal microscobe and dead cells were determined using propidium iodide. In this study t-test was used for analysis and showed that high concentrations of anti-NMDAR and LGI1 IgG cause neuronal and astrocytic death. These result showed that ion channel antibodies do not only cause neuronal dysfunction but also dysregulate neuronal-astrocytic survival.

Title: TWIK-1 /TASK-3 heterodimer contributes to the intrinsic excitability of dentate granule cells in mouse hippocampus

Authors: J. CHOI[1], O. YARISHIKIN[2], E. KIM[3], J.-Y. PARK[3], *E. HWANG[1];
[1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]The university of Utah, Salt lake city, UT; [3]Korea university, Seoul, Korea, Republic of

Abstract: Two-pore domain K^+ (K2P) channels control resting membrane potential and cellular excitability in neuronalcells. Among the K2P channels, TWIK1 is the first identified member of

K2P channel and highly expressed in brain, but its neuronal role is almost unknown.We recently reported that TWIK-1 contributes to the intrinsic excitability of dentate gyrus granule cells (DGGCs) in mouse hippocampus. However, homodimer function of TWIK-1 is still controversial. Recently, we and Goldstein suggest that TWIK-1 can make heterodimer with TREK-1 in astrocyte and TASK-3 in cerebellum granule cells and act as a functional channel. Talley and his colleagues were already shown that TASK-3 mRNAs were intensively detected in DGGCs as well as cerebellum granule cells, but its protein expression level was not reported.Therefore, we determined TASK-3 expression and the subcellular localization and tested its real- heterodimerization with TWIK-1 using PLA assay in DGGCs. As a result, TASK-3 is highly expressed in DGGCs and can make real-hetrodimers with TWIK-1. In order to verify TWIK-1/TASK-3 heterodimer function in DGGCs, we used TWIK-1 KO mice and TASK-3 specific shRNA containing viral vector. Expectedly, both TWIK-1 KO mice and TASK-3-shRNA infected mice exhibit significantly reduced outwardly rectifying potassium currents and enhanced intrinsic excitability in DGGCs. Interestingly,TASK-3 shRNA infected TWIK-1 KO mice have no additional effect when comparing each condition. Taken together, we suggest that TWIK-1 and TASK-3 mostly make heterodimers in DGGCs and contribute to the intrinsic excitability

Title: Ca^{2+}-dependent modulation of Kv4.2-mediated currents

Authors: *J. J. GUTZMANN, A. M. CHAREST, D. A. HOFFMAN;
NICHD, NIH, Bethesda, MD

Abstract: The sub-threshold activating, A-type potassium current (IA) has long been recognized as a critical component for regulating dendritic excitability and shaping back propagating action potentials. In CA1 pyramidal cells of the hippocampus IA is carried predominantly by Kv4.2 potassium channels, which are associated with a variety of accessory proteins that modulate their trafficking and kinetics. Among these interacting proteins are K-channel interacting proteins

(KChIPs), small cytoplasmic proteins with four calcium binding EF-Hand motifs. IA shows a distinct functional gradient along the apical dendrites of CA1 pyramidal neurons. Synaptic localization and activity dependent trafficking of Kv4.2 indicates an additional, and possibly distinct, role of Kv4.2 in synaptic physiology. The strong and reciprocal relationship between Kv4.2 and the GluN2B subunit of the Calcium conducting N-methyl-D-aspartate (NMDA) receptor opens up the possibility of calcium dependent effects on Kv4.2 function in the synapse. Using a mutated KChIP construct that is unable to bind calcium but still interacts with Kv4.2, we show that changes in intracellular and extracellular calcium concentrations alter Kv4.2 mediated currents in the presence of KChIPs in a heterologous expression system, as well as CA1 pyramidal neurons in acute slices. Specifically, current densities and current decay constants, as well as voltage dependent activation and inactivation states of Kv4.2 depend not only on the presence or absence of KChIPs, but also on the availability of calcium. Since intracellular calcium concentrations are tightly regulated *in vivo*, especially in dendritic spines, and Kv4.2 has a demonstrated intimate relationship with calcium conducting channels as well as calcium binding proteins, understanding the effect of calcium on Kv4.2 mediated currents will be of great value for the understanding of the role that IA plays in shaping postsynaptic currents and dendritic integration in the hippocampus.

Title: Ketogenic diet promotes the upregulation of K_{ATP} channels expression by mediating ketone activity

Authors: H. OH, T. J. METTLER, *D. KIM;
Barrow Neurolog. Institute, St. Joseph's Hosp. & Med. Ctr., Phoenix, AZ

Abstract: Metabolic alteration is being considered as a potential intervention for various neurological disorders, based in part on the functional protection of the high-fat, low-

carbohydrate ketogenic diet (KD) and its metabolic substrates, ketone bodies [KBs; β - hydroxybutyrate (BHB) and acetoacetate (ACA)]. The KD and KBs are involved in producing anticonvulsant properties as well as in broad disease-modifying effects, but the mechanisms underlying their actions have yet to be fully elucidated. Our recent findings have demonstrated that KBs can protect synaptic plasticity against oxidative insults by modulating ATP-sensitive potassium (K_{ATP}) channels (PMID; 25848768). To expand this observation, we asked whether expression profiling of mRNAs and proteins of K_{ATP} channels augments following the administration of the KD or KBs, and if pharmacological blockade and genetic ablation of K_{ATP} channels counteract the neuronal protective effects afforded by KBs. C3HeB/FeJ mice were fed either the KD or a standard diet (SD) from weaning until postnatal day 35 and 60. Hippocampal lysates collected from the KD-fed mice showed a significant increase in the inwardly rectifying K^+ channel subunit Kir6.2 and SUR1, critical components of K_{ATP} channels, as compared to mice fed SD. Consistent with incidence of mild ketosis in KD-fed mice, murine hippocampal HT22 cells exposed to a cocktail of KBs (BHB and ACA, 1 mM each) underwent a higher expression of mRNAs and proteins of Kir6.1, Kir6.2, and SUR1, accompanied with elevation of cell viability against 500 μM H_2O_2 - evoked oxidative insult. The neuroprotective effect was reversed when pharmacological blockers, such as glibenclamide and 5-hydroxydecanoate, or shRNA of K_{ATP} channels were applied with KBs. Further, under lipopolysaccharide (LPS)-induced microglial cell activation, KBs-treated microglial cells (BV2) had a reduction in the release of pro-inflammatory mediators induced by LPS and its effect was linearly correlated with the upregulation of expression profiling of K_{ATP} channels. Kir6.2 immunoreactivity was significantly increased in both HT22 cells and BV2 cells exposed to KBs for 6 hrs. Taken together, our findings suggest that metabolic change by the KD may provide the upregulation of K_{ATP} channels expression through ketone activity to help contribute to its diverse protective actions.

Title: The regulation of Slack K(Na) channel trafficking by p38 MAP Kinase

Authors: S. GURURAJ[1], *A. BHATTACHARJEE[2];
[1]Pharmacol. & Toxicology, SUNY at Buffalo, Buffalo, NY; [2]SUNY, Buffalo, Buffalo, NY

Abstract: Nociceptive sensitization is a central component of neuropathic pain, involving an alteration in the membrane properties of the sensory neurons of the Dorsal Root Ganglion (DRG) such that they have a lowered threshold for activation and hence, increased spontaneous activity. This DRG hyperexcitability manifests as the painful physiological symptoms of hyperalgesia and allodynia in patients of neuropathic pain, in whom there is as yet a large unmet need for medical treatment due to a lack of proper understanding of the precise molecular mechanisms involved. The key role of sodium activated potassium (K_{Na}) channels in the maintenance of firing accommodation in DRG neurons makes them important targets to study in the context of DRG excitability, which then deems mechanisms of K_{Na} channel regulation as potential ways to regulate DRG hyperexcitability. In this context, we examined the K_{Na} channel Slack's extensive intracellular C-terminus for possible sites of regulatory protein interactions and found that it contains two putative p38 MAPK phosphorylation sites that are highly conserved across species. While there is no direct link between p38 MAPK and K_{Na} channels, there is evidence for p38 MAPK's role in facilitating neuronal regeneration after nerve crush of the sciatic nerve, indicating that the kinase could be an important player in neuropathy and potentially, in nociceptive sensitization. To answer the question of whether p38 MAPK regulates Slack channels via phophorylation of the C-terminus, we have performed electrophysiology experiments to demonstrate that Slack current is subject to modulation by p38 MAPK, and biochemical experiments to show that Slack is basally phosphorylated by p38 MAPK. Site-directed mutagenesis of the p38 MAPK phosphorylation sites indicates that modulation occurs via phosphorylation at both the sites. Finally, biotinylation assays suggest that the mechanism of modulation of Slack current by p38 MAPK is likely at the membrane via a trafficking mechanism. Together, these results are the first direct demonstration of Slack as a p38 MAPK substrate, and provide evidence for p38 phosphorylation playing a role in Slack channel trafficking and hence, DRG membrane excitability.

Title: An ALS-associated mutant SOD1 alters sodium-activated potassium currents and neuronal excitability in *Aplysia* neurons

Authors: *Y. ZHANG, W. NI, A. HORWICH, L. L. KACZMAREK;
Yale Univ. Sch. Med., New Haven, CT

Abstract: Mutant human Cu/Zn superoxide dismutase 1 (SOD1) is associated with motor neuron toxicity and death in an inherited form of amyotrophic lateral sclerosis (ALS).The ALS-linked mutations have been associated with a toxic gain-of-function, including the formation of cytotoxic oligomers and aggregates of misfolded SOD1 subunit. The precise forms of the mutant SOD1 that are toxic and the mechanisms by which they produce toxicity and alter neuronal excitability are, however, not clear. To address these questions, we recorded from bag cell neurons of *Aplysia*, a model system to study neuronal excitability. We found that injection of fluorescently-tagged wild-type SOD1YFP or monomeric mutant G85R SOD1YFP had no effect on net ionic currents measured under voltage clamp. In contrast, outward potassium currents were significantly reduced by microinjection of fluorescently-tagged cross-linked dimers of mutant G85R SOD1YFP or by mutant SOD1YFP that was preincubated at 37 degrees. Reduction of potassium current was also seen with G85R SOD1YFP that had been cross-linked to multimeric species of ~300 KDa or to > 300 KDa. In current clamp recordings, microinjection of 300KDa cross- linked G85R SOD1YFP increased excitability by causing depolarization of the resting membrane potential, and decreasing the latency of action potentials triggered by depolarization. The effect of cross-linked 300KDa G85R SOD1YFP on potassium current was reduced by removing sodium from the bath solution, or by knocking-down levels of the Slack sodium-activated potassium channel using RNAi. It was also prevented by pharmacological inhibition of ASK1 (apoptosis signal-regulating kinase 1) or of JNK (c-Jun N-terminal kinase), but not by an inhibitor of P38 mitogen-activated protein kinases. These results suggest that mutant SOD1 aggregates trigger a kinase pathway that regulates levels of sodium-activated potassium current in neurons.

Title: Phosphatidylinositol 4,5-bisphosphate (PIP2) differentially modulates afterhyperpolarizations in oxytocin and vasopressin magnocellular supraoptic neurons

Authors: *M. KIRCHNER, R. FOEHRING, W. E. ARMSTRONG;
Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Oxytocin- (OT) and vasopressin- (VP) secreting neurohormonal cells play a crucial role in many physiological functions including lactation, parturition (OT) and cardiovascular regulation (VP). The release of both hormones is optimized by a burst-firing pattern of action potentials. Afterhyperpolarizations (AHPs) play a crucial role in shaping bursts and thus are critical for robust hormone release. Three components of the AHP have been described: fast (fAHP), medium (mAHP), and slow (sAHP). Because previous work demonstrated that the lipid phosphatidylinositol 4,5-bisphosphate (PIP_2) enabled the sAHP current in cortical neurons (Villalobos et al., 2011: J Neurosci 31: 18303), we investigated whether PIP_2 served a similar function for OT and VP neurons of the supraoptic nucleus (SON). Using whole cell recording in coronal hypothalamic slices from adult female rats, we demonstrated that wortmannin, which inhibits the rate limiting enzyme of PIP_2 production, PI4Ka, robustly reduced both the sAHP and mAHP of OT neurons with high affinity (EC_{50} = 64 nM). In contrast, VP neurons typically showed no inhibition to wortmannin, even at high concentrations. In VP and OT neurons, the PIP_3 kinase inhibitor LY294,002 (100nM) failed to affect AHPs, suggesting the wortmannin effects were specific to PIP_2 synthesis. We further tested this by introducing a PIP_2 analog (diC_8-PIP_2) into neurons through the patch pipette, which slowed rundown of mAHP and sAHPs over 30+ minutes of recording in both cell types and even enhanced the mAHP and sAHP in VP neurons. Finally, wortmannin failed to inhibit AHPs in the presence of diC_8-PIP_2 in both OT and VP neurons. The results indicate that PIP_2 is necessary for the normal expression of mAHPs and sAHPs in OT neurons, but may nevertheless contribute to the enhancement of AHPs in VP neurons when made available in large quantity.

Title: The relative contribution of Kir4.1, two-pore domain K+ channels and KCNN2 to the passive conductance of mature hippocampal astrocytes

Authors: *C. M. KIYOSHI, Y. DU, Q. WANG, C. C. ALFORD, B. MA, S. ZHONG, M. ZHOU;
Dept. of Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Mature hippocampal astrocytes display a characteristic linear current - voltage (I-V) membrane conductance, or passive conductance. While the K^+ channels are known as the molecular identities underlying the passive conductance, a complete list of these channels remains to be fully identified. The inwardly rectifying Kir4.1 is one of the identified channels, however we have shown that Kir4.1 contributes to less than 50% of the total membrane conductance, leaving the remaining channels to be further uncovered. In an effort to identify these channels, we have previously focused on the two-pore domain K^+ channels, TWIK-1 and TREK-1. However, the functional study from either single-knockouts or double-knockout of these genes resulted in an insignificant alternation in both passive conductances and membrane potentials. We extended the search to genes in other K^+ channel subfamilies that could be responsible for the passive conductance by examining their mRNA expression levels in freshly dissociated hippocampal astrocytes, which includes $K_{ir}5.1$, KCNG4, KCNK10, and KCNN2. We found that the potassium intermediate/small conductance calcium-activated channel, KCNN2, shows the highest mRNA expression among other candidate genes. In addition, KCNN2 shows comparable expression levels to the highest expressing potassium channel, TWIK-1. Interestingly, KCNN2 is a voltage-independent leak K^+ channel that can be dynamically regulated by intracellular Ca^{2+} concentration. Thus KCNN2 is likely a channel contributing significantly to the passive conductance, as well as being able to coordinate intracellular Ca^{2+} signaling with membrane K^+ conductance.

Title: Kv3 channel subunit localisation and co-expression with phenotypic markers in the murine spinal cord

Authors: *P. MULLEN[1], C. LARGE[2], J. DEUCHARS[1], S. DEUCHARS[1];
[1]Fac. of Biol. Sci., Univ. of Leeds, Leeds, United Kingdom; [2]Autifony Therapeut. Ltd., London, United Kingdom

Abstract: Kv3 voltage-gated potassium ion channels form tetrameric assemblies comprised of alpha subunits Kv3.1-Kv3.4 and are expressed in interneurons throughout the spinal cord (Deuchars et al. 2001). Kv3 subunits decrease with age in the auditory brainstem, a loss thought to underlie age-related hearing deficits (Zettel et al. 2007). We postulate a similar age-related decline in the spinal cord and present here an initial characterisation of the expression of Kv3 subunits in the adult murine spinal cord. 3 wild-type (WT) C57Bl/6 and 3 transgenic GAD67-GFP C57Bl/6 mice (4-6 weeks) were anaesthetised by intraperitoneal injection of sodium pentobarbitone (60mg/kg), perfused with 4% paraformaldehyde (PFA) and dissected to isolate spinal cords and post-fixate in 4% PFA. Spinal cords were sectioned at 40 μm using a vibrating microtome. WT tissue was processed for double labelling immunohistochemistry (IHC) of Kv3 α-subunits and various protein cell markers; parvalbumin and calretinin are calcium binding proteins found in certain interneurons; ChAT (choline acetyl transferase) is expressed in motoneurons and sympathetic preganglionic neurons; and finally vGluT1, vGluT2 and GlyT2 are synaptic transporters for glutamate and glycine, respectively. Transgenic GAD67-GFP tissue was processed for double labelling of Kv3 α-subunits with glutamic acid decarboxylase 67(GAD67). Kv3.1, Kv3.3 and Kv3.4 but not Kv3.2-positive neurons were situated around autonomic and motor regions within the adult murine spinal cord. These neurons were not GABAergic (not containing GAD67) but mostly glycinergic (GlyT2) and/or glutamatergic (vGlut2 but not vGluT1). Kv3.1 and Kv3.4 subunits were expressed in the membranes of ventral horn CHAT-positive putative motoneuron cell bodies. Kv3 subunits were also observed on the membranes of parvalbumin and calretinin positive cell bodies; Kv3.1 with parvalbumin around the intermediolateral horn (IML) and in the ventral horn and both Kv3.3 and Kv3.4 co-expressed with parvalbumin on the membranes of cell bodies in the ventral horn. Kv3.1 was extensively co-expressed with calretinin in cell bodies around the central canal, IML, dorsal horn and ventral horn, the latter thought to represent Renshaw cells. A similar pattern of co-expression was also observed for Kv3.3. We hypothesise that the expression of these ion channels in the murine spinal cord may change through age at a level paralleled by changes in both autonomic and motor outputs. This initial characterisation of Kv3 expression in adult mice will be compared to

that of aged and young mice to elucidate any age-related changes in expression and the functional consequences of these changes.

Title: Novel physiological modulators of Kv3 channels regulate firing rate and temporal accuracy of auditory brainstem neurons in a mouse model of Fragile X syndrome

Authors: *L. EL-HASSAR[1], M. R. BROWN[1], L. SONG[2], C. H. LARGE[3], G. ALVARO[3], L. K. KACZMAREK[1];

Abstract: Fragile X syndrome (FXS) is the most common form of inherited intellectual disability. In common with autism, FXS is characterized by hypersensitivity to many types of sensory stimuli, including environmental sounds. Our previous work has shown that mice lacking FMRP (Fragile Mental Retardation Protein), which are a mouse model for Fragile X syndrome, have abnormally elevated levels of Kv3.1-like "high-threshold" potassium currents and significantly decreased levels of Slack Na+-activated K+ currents. Both of these are predicted to increase the firing rate of the postsynaptic neurons and to substantially degrade the accuracy of timing of action potentials in auditory brainstem neurons of the medial nucleus of the trapezoid body (MNTB). Consistent with this, we have found that the firing pattern of MNTB neurons in response to repeated stimulation is severely abnormal in Fragile X mice. We have also found that waves IV of the Auditory Brainstem Response (ABR) recorded *in vivo* are significantly enhanced in Fragile X mice, suggesting that loss of FMRP alters central processing

of auditory signals. Based on these results we are now testing, in Fragile X mice, the physiological effects of two potential therapeutic compounds, AUT1 and AUT2, which modulate the activity of Kv3 family channels in cell lines. To our surprise, we found that the effects of AUT1 on MNTB firing in Fragile X mice are completely opposite to their effects on neurons from wild-type animals. More specifically, while AUT1 decreased firing in MNTB neurons from wild-type animal, it enhanced firing in Fragile X mice. In contrast to AUT1, AUT2 decreased firing in Fragile X mice. Because AUT1 and AUT2 both shift the voltage-dependence of Kv3.1 activation to more negative potentials, but AUT2 is more potent that AUT1, one potential explanation for this difference is that while both compounds increase Kv3.1-like "high-threshold" potassium currents in the Fragile X mice, the greater shift produced by AUT2 increases currents close to the resting potential, raising the threshold for action potential generation. Consistent with this, our preliminary voltage-clamp experiments on MNTB neurons indicate that AUT2 increases K+ current at negative potentials. Ongoing experiments are characterizing the full difference in K+ current responses of wild type and Fragile X mice.

Title: Differential expression of voltage-gated potassium conductances in genetically-defined layer 5 neocortical pyramidal neurons

Authors: *D. GUAN[1], R. C. FOEHRING[2];
[2]Anat. & Neurobio., [1]Univ. Tennessee, Memphis, TN

Abstract: We studied neurons from two BAC transgenic mouse lines that uniquely express EGFP in different subpopulations of layer 5 pyramidal neurons (*etv1* and *glt*) with distinct firing patterns. Our previous study revealed major differences in spike frequency adaptation and firing gain between *etv1* and *glt* cells that were primarily due to differential expression of Ca^{2+}-dependent K^+ conductances (sK and sAHP channels). Here we tested for differential expression of voltage-gated K^+ channels in etv1 and glt neurons. We obtained somatic whole cell recordings

from EGFP-positive neurons in acute brain slices from 2-4 week old mice and then withdrew the pipette to obtain macroscopic outside-out patches whose capacitances were 2 - 4 pf (to overcome space-clamp limitations of the highly dendritic pyramidal cells). Membrane patches were held at -70 mV and 33^{o}C. Outward current was elicited by a 500 ms voltage step to +10 mV. Na^{+} and Ca^{2+} currents were blocked by applying 0.5 μM TTX and 0.2 mM $CdCl_2$ to the external solution. We observed outward currents with both transient and persistent components. Transient components were isolated biophysically and showed slower inactivation in glt patches than in etv1 patches. Persistent currents were measured at 200 ms from the onset of the voltage step. We first recorded current in the control external solution, and then switched to external solution with specific Kv channel blockers to test for the expression of specific Kv channels. Kv1 current was defined by sensitivity to 100 nM Dendrotoxin plus 20 nM Margatoxin. Kv1-mediated current was larger in etv1 patches (18.8% of the current, n = 21) than in glt patches (13.3%, n = 8). Kv2 current was defined by 100 nM Guangxitoxin sensitivity and was significantly larger in glt patches (58.8%, n = 9) than in etv1 patches (30.7%, n = 25). Kv7 current was defined by 2 μM XE991 sensitivity and comprised 7.9% of current in etv1 patches (n = 11) vs. 1.8% in glt patches (n = 6). In additional experiments we perfused the internal solution with Kv2.1 or Kv2.2 antibodies to selectively block Kv2.1 or Kv2.2 channels. Internal perfusion with Kv2.1 antibodies reduced a larger portion of the persistent current in glt patches (55.8%, n = 14) than in etv1 patches (35.5%, n = 11). Internal perfusion with Kv2.2 antibodies inhibited 44.7% of the persistent current in etv1 patches (n = 17) but had no effect in glt patches (n = 7). The greater expression of Kv2.1 conductance in glt cells may facilitate their higher gain and firing rate. Kv2.2 expression in etv1 cells may contribute to lower firing rates and gain. Additional experiments elucidated the biophysical properties and biological roles of these Kv channels in both etv1 and glt cells.

Title: Expression and function of ATP-sensitive potassium channels in the stellate neurons of the mouse ventral cochlear nucleus

Authors: *A. HIM[1], R. BAL[2], G. OZTURK[3], E. ONALAN ETEM[4], N. CENGIZ[5], T. KULOGLU[4], M. TUZCU[4];
[1]Ondokuz Mayis Univ., Samsun, Turkey; [2]Gaziantep Univ., Gaziantep, Turkey; [3]Istanbul Medipol Univ., Istanbul, Turkey; [4]Firat Univ., Elazig, Turkey; [5]Sakarya Univ., Sakarya, Turkey

Abstract: ATP-sensitive potassium (KATP) channels play important roles in many cellular functions by coupling metabolic and electrical activity of the cells and expressed in many types of cells including neurons. Although major voltage-activated ionic channels of stellate cells in the ventral cochlear nucleus are largely characterized previously, the presence of KATP channels in these cells is not known. We aimed to investigate presence, subunit composition and functional role of KATP channels in stellate cells using whole-cell patch clamp and immunohistochemical techniques. Immunohistochemical analyses showed that stellate cell somata were strongly labelled with antibodies against SUR1 and Kir6.2 subunits and moderately labelled with SUR2 antibodies, whereas labelling signals for Kir6.1 subunit were very week. Kir6.2 subunit was strongly co-localized with SUR1 and SUR2 subunits. Whole-cell patch clamp recordings from stellate cells in ventral cochlear nucleus slices revealed that KATP agonists including cromacalim, diazoxide, 3-amino-1,2,4-triazole, NNC 55-0414, NNC 55-0118 and 5-nitro pyridine, and hydrogen peroxide induced membrane hyperpolarization which was accompanied by a decrease in spontaneous firing rate. The hyperpolarizing effects of KATP agonists and hydrogen peroxide were blocked by KATP channel antagonists. Extracellular application of catalase and KATP channel blockers glybenclamid, tolbutamide and 5-hydroxydeconoic acid depolarized stellate cells and increased spontaneous action potential firing rate, suggesting that the channels actively contribute to determine the level of resting membrane potential. We showed that stellate cells of the ventral cochlear nucleus express KATP channels, which are dominantly composed of Kir6.2, SUR1 and SUR2 subunits. Since KATP channels are active at rest and respond oxidative stress they are involved in regulation of the excitability and firing properties of stellate cells, which may be important in processing voice signals in the cochlear nucleus.

Title: Roles of Kv potassium channels in action potential repolarization in neocortical pyramidal neurons from mouse somatosensory cortex

Authors: D. PATHAK, *R. C. FOEHRING;
Anat. & Neurobio., Univ. Tennessee Hlth. Sci., Memphis, TN

Abstract: In neocortical pyramidal cells (PCs), synaptic inputs are transduced into trains of action potentials (APs). Our understanding of this basic integrative property of PCs is incomplete. Further, the electrical properties of PCs vary between cortical layers and between subtypes of PCs in layer 5. To test for roles of specific Kv channels in AP repolarization, we performed whole cell current-clamp recordings from PCs in layer 2/3 as well as two genetically defined subtypes of layer 5 PCs (etv1 and glt). Previously, we showed that glt cells have narrower APs than either etv1 or layer 2/3 cells and that Ca-dependent K^+ channels did not contribute to AP repolarization in neocortical PCs (Guan et al. 2015. *J Neurophysiol* 113: 2014). APs were elicited with a single 5 ms suprathreshold current injection. We used pharmacological blockers of Kv1 (100 nM α-dendrotoxin: DTX), Kv2 (100 nM guangxitoxin: GTX) or Kv4 (4 mM 4-AP, 150 μM $BaCl_2$, or 200 nM AmmTX3) channels to determine the roles of these voltage gated K^+- channel subtypes in the repolarization phase of the AP. All recordings were obtained in the presence of the synaptic blockers APV (50 μM), DNQX (20 μM) and picrotoxin (100 μM). We concentrate here on AP width (at half amplitude) and rate of repolarization (dV/dt for AP downstroke). Our main findings were (1) DTX significantly broadened the AP and slowed the rate of AP repolarization in layer 2/3 and etv1 PCs but not glt cells, suggesting that Kv1 channels contribute to AP repolarization in layer 2/3 and etv1 cells but not glt cells. (2) GTX had no effects on AP width or repolarization in PCs from layer 2/3, etv1 or glt, indicating no contribution of Kv2 channels to AP repolarization. (3) 150 μM $BaCl_2$ has been reported to block Kv4 channels in dendrites. We found that $BaCl_2$ significantly broadened the AP and slowed repolarization in layer 2/3, etv1 and glt cells. The magnitude of the effects was largest in glt cells. (4) 4 mM 4-AP is frequently used to block Kv4 (A-type) channels. In the presence of 4-AP, APs were broader and repolarization slower in layer 2/3, etv1 and glt cells. Results (3) and (4) are consistent with a major role for Kv4 channels in AP repolarization but both of these agents are relatively unselective. (5) We also tested the peptide blocker AmmTx3, which selectively blocks Kv4 channels associated with DPP10 or DPP6 (Maffie et al. (2013. *J Physiol* 591: 2419). AmmTx3 broadened APs and slowed repolarization in PCs from layer 2/3 as well as etv1 and glt cells. We conclude that AP repolarization mechanisms vary between PC subtypes: Kv4 channels regulate repolarization in glt cells, while the combination of Kv1 channels and Kv4 channels underlie AP repolarization in etv1 and layer 2/3 PCs.

Title: Assembly and regulation of functional domains in myelinated axons

Authors: *C. GU;
Biol. Chem. and Pharmacol., Ohio State Univ., Columbus, OH

Abstract: Action potentials propagating along axons play a central role in cell-to-cell communication in the nervous system. Proper action potential firing relies on sequential activation and precise targeting of voltage-gated Na+ (Nav) and K+ (Kv) channels. Nav channels are clustered at the axon initial segment and nodes of Ranvier via ankyrin-G in myelinated axons to support action potential initiation and saltatory conduction, whereas Kv1 channels are clustered in juxtaparanodal domains to prevent repetitive firing. Together with other membrane proteins clustered in nodal or juxtaparanodal domains, they define the function of these key domains in myelinated axons. However, little is known about the mechanisms governing precise delivery of these proteins over long distances and the regulation by myelination and neuronal activity. Here we report that kinesin superfamily 5B (KIF5B) directly binds to ankyrin-G to transport Nav channels into axons, whereas KIF3A transports Kv1.2 channels. Deleting ankyrin-G or interrupting ankyrin-G-KIF5B binding specifically disrupts nodal Nav but not juxtaparanodal Kv1.2 targeting. These results indicate ankyrin-G functions as an adaptor to link Nav channels to KIF5 during axonal transport, before anchoring them to the axon initial segment and nodes of Ranvier. On the other hand, deleting juxtaparanodal proteins only disrupts Kv1 channel targeting, suggesting different assembly mechanisms underlying the axonal domains. Our studies provide new mechanistic insights into the assembly of key functional domains in myelinated axons and elucidate how this process is regulated at the level of axonal transport. These results may in turn contribute to the development of new strategies for treating brain disorders involving disrupted axonal transport and function.

Title: Cell depolarization induced by low pHo causes a switch from tonic to burst firing supported by a marked inhibition of BK channels in mouse chromaffin cells

Authors: L. GUARINA[1], D. H. F. VANDAEL[1], *E. CARBONE[2];
[1]Dept. of Drug Sci., [2]Univ. of Turin, Turin, Italy

Abstract: Cell depolarization leads to major changes in spontaneous firing patterns and catecholamine secretion in chromaffin cells. We recently showed that reduced availability of Nav1.3 and Nav1.7 channels induced by steady depolarizations boosts a change from tonic to bursts firing in spontaneously active mouse chromaffin cells (MCCs) (*Vandael et al, J Physiol, 2015*) . As burst firing induces a plateau depolarization that increases ~20-fold the Ca^{2+} flux through Cav1.3 channels, the switch from "tonic" to "bursts" firing appears as a novel command to enhance catecholamine release in a non-neurogenic manner. In the view of identifying the physiological conditions in which chromaffin cell depolarization could induce burst firing, we analyzed the effect of lowering external pH (pHo),which is reported to induce membrane depolarization and catecholamine release by blocking TASK1 channels (*Inoue et al, J Neurochem, 2008*). The mechanism is at the basis of the feedback loop in which adrenaline released from the adrenal medulla triggers the body response to acidosis (*Clausen et al, J Physiol, 1993*). In current-clamp experiments on spontaneously firing MCCs, we first confirmed that lowering pHo from 7.4 to 6.8 the cell depolarized by about 8 mV from their resting potential (V_{rest}). The depolarization was sufficient to cause a net switch from tonic to burst firing of spontaneously active MCCs that was preserved for long periods at a frequency of 1 to 2.5 Hz. Burst firing occurred in most of the cells tested and was characterized by slow plateau depolarizations lasting 100-200 ms on which 3 to 5 action potentials of progressively decreasing amplitude were riding on top. Concerning the firing switch induced by low pHo, we specifically checked whether mild pHo changes from 7.4 to 6.8 besides blocking TASK1 channels affect also Nav, Cav and BK channels that contribute to burst firing generation. We found that Cav channels activation was shifted by about 4 mV toward more positive potentials with little effects on channel conductance, while none of both changes was observed in Nav1.3 and Nav1.7 channels. Regarding the BK channel we found a marked depression of BK currents when activated by either constant or variable pre-conditioning Ca^{2+} loading. The effects were associated to a nearly 60% inhibition of BK channel conductance. In conclusion, the switch from tonic to burst firing in MCCs appears to be induced not only from the expected lowered availability of Nav1.3/Nav1.7 channels that enter a closed-state inactivation during prolonged depolarizations (*Vandael et al, J Physiol, 2015*) but also by a reduced BK channel conductance (*Martinez-Espinosa et al, J Gen Physiol, 2014*).

Title: Expression and contributions of the Kir2.1 inward-rectifier K+ channel to proliferation, migration and chemotaxis of microglia in unstimulated and anti-inflammatory states

Authors: ***D. LAM**, L. C. SCHLICHTER;
Genet. and Develop., Krembil Discovery Tower/ Toronto Western Hosp., Toronto, ON, Canada

Abstract: When microglia respond to CNS damage, they can range from pro-inflammatory (classical, M1) to anti-inflammatory, alternative (M2) and acquired deactivation states. It is important to determine how microglial functions are affected by these activation states, and to identify molecules that regulate their behavior. Microglial proliferation and migration are crucial during development and following damage in the adult, and both functions are Ca2+-dependent. In many cell types, the membrane potential and driving force for Ca2+ influx are regulated by inward rectifier K+ channels, including Kir2.1, which is prevalent in microglia. However, it is not known whether Kir2.1 expression and contributions are altered in anti-inflammatory states. We tested the hypothesis that Kir2.1 contributes to Ca2+ entry, proliferation and migration of rat microglia. Kir2.1 (KCNJ2) transcript expression, current amplitude, and proliferation were comparable in unstimulated microglia and following alternative activation (IL-4 stimulated) and acquired deactivation (IL-10 stimulated). To examine functional roles of Kir2.1 in microglia, we first determined that ML133 was more effective than the commonly used blocker, Ba2+; i.e., ML133 was potent (IC50=3.5 μM) and voltage independent. Both blockers slightly increased proliferation in unstimulated or IL-4 (but not IL-10)-stimulated microglia. Stimulation with IL-4 or IL-10 increased migration and ATP-induced chemotaxis, and blocking Kir2.1 greatly reduced both but ML133 was more effective. In all three activation states, blocking Kir2.1 with ML133 dramatically reduced Ca2+ influx through Ca2+-release-activated Ca2+ (CRAC) channels. Thus, Kir2.1 channel activity is necessary for microglial Ca2+ signaling and migration under resting and anti-inflammatory states but the channel weakly inhibits proliferation.

Title: NMDAR-induced plasticity of A-type Kv4 current contributes to long-term potentiation of mossy fiber input in granule cells of posterior cerebellum

Authors: *A. RIZWAN, G. W. ZAMPONI, R. W. TURNER;
Dept. of Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: The mossy fiber (MF) afferents to cerebellum carry information at ultrafast frequencies (~ 1000 Hz) and contact granule cells, a major synaptic relay in cerebellum. In other regions of the brain such high input frequencies can induce long term potentiation (LTP) of synaptic efficacy through a combination of pre- and postsynaptic mechanisms that shape the response to subsequent inputs. We have shown that Kv4 ion channels form a nanodomain complex with Cav3 channels in lobule 9 granule cells, where Cav3 channel-mediated calcium influx selectively promotes a rightward shift in the voltage for inactivation of A-type (IA) current. As a result, the availability of IA is increased in lobule 9 cells, reducing excitability and promoting the tonic rate of firing necessary to respond to vestibular-like sensory stimuli. LTP of synaptic input in hippocampus has been shown to induce a leftward shift in Kv4 voltage for inactivation not unlike that found upon block of the Cav3-Kv4 complex. The current study used *in vitro* slices of rat cerebellum to test the hypothesis that LTP of MF EPSCs modifies the properties of IA in lobule 9 granule cells. We found that LTP of MF input induced by pairing theta burst stimulation with postsynaptic depolarization to -40 mV invoked a select leftward shift of IA voltage for inactivation. Moreover, a late long-lasting slow EPSC (sEPSC) of up to ~ 1 sec was unmasked following LTP of MF input. The LTP-induced shift in IA voltage for inactivation was dependent on calcium influx through NMDA receptors, providing evidence for a novel interaction between NMDAR-mediated calcium influx and Kv4 channels. In contrast, the sEPSC was NMDAR-independent and instead mediated by mGLUR1,5 receptors. Infusion of an antibody against the calcium sensor of the Cav3-Kv4 complex was also sufficient to unmask the sEPSC, indicating a Kv4-mediated baseline suppression of the sEPSC in lobule 9 granule cells. Moreover, the effects of LTP on IA and the sEPSC were observed with or without block of GABAergic inhibition, highlighting the physiological relevance of the results. These data

indicate that there is a novel NMDAR-Kv4 interplay in cerebellar granule cells that functions to regulate postsynaptic excitability and synaptic responses to MF input.

Title: Modulation of Kir4.1 protein and mRNA by activation of mGluR I in rat retinal Müller cells

Authors: ***F. GAO**[1,2], F. LI[2], Y. MIAO[2], L.-D. DONG[2], S.-H. ZHANG[1,2], J. WU[1,2], X.-H. SUN[1,2], Z. WANG[1,2];
[1]Dept. of Ophthalmology at Eye &ENT Hosp., Shanghai, China; [2]Inst. of Brain Sci., Shanghai, China

Abstract: K^+ channels, especially Kir channels, are essential for retinal Müller cells to maintain homeostasis of $[K^+]_o$. Downregulation of Kir currents, which disturbs the characteristic hyperpolarized resting potential of the cells, has been found to contribute to Müller cell gliosis. In the present work, whether and how activation of group I metabotropic glutamate receptor (mGluR I) modulate membrane Kir4.1 protein internalization and Kir4.1 mRNA expression were investigated in purified cultured rat retinal Müller cells by using immunocytochemistry, Western blot and real-time PCR techniques. Our results showed that more than 95% of the cells were Müller cells under our cultured condition. DHPG (10 μM, a selective mGluR I agonist) treatment for different times (0.5 h to 24 h) induced Müller cell gliosis, as evidenced by progressively enhanced glial fibrillary acidic protein (GFAP) expression with a peak at 9 h. Although total Kir4.1 proteins extracted from the DHPG-treated cells kept unchanged, Kir4.1 proteins in the cell membrane compartment were significantly decreased from 0.5 h after DHPG treatment, with a peak at 3 h, which was prior to the change of GFAP in time course. In addition, DHPG (10 and 100 μM) treatment induced a transient decrease in Kir4.1 mRNA expression in the cells. These results suggest that activation of mGluR I may decrease the number of functional Kir4.1

channels in cultured rat retinal Müller cells through modulating Kir4.1 protein and mRNA, thus contributing to Müller cell gliosis.

Title: Structural basis for the positive modulation of SK2 channel by Riluzole

Authors: T. N. ALEXANDER, S. A. ALI, S. C. CHIANG, *M. ZHANG;
Dept. of Biomed. and Pharmaceut. Sci., Chapman Univ. Sch. of Pharm., Irvine, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating movement disorder resulting from neurodegeneration of motor neurons in the motor cortex and the brainstem/spinal cord. Evidence indicates that the excitability of ALS patient motor neurons is abnormally elevated. Positive modulation of potassium ion channels has been suggested as a potential therapeutic strategy to reduce the toxic hyperexcitability of ALS motor neurons. Small conductance Ca2+-activated potassium (SK) channels play important roles in regulation of membrane excitability in motor neurons. Riluzole, which positively modulates SK channels, is the only FDA approved drug for ALS, although its therapeutic effects are only modest. One reason that limits the therapeutic effects of riluzole might be its low potency on SK channels. Here we elucidate the binding pocket of riluzole in SK2 channels with crystallography. Site directed mutations in the binding pocket effectively change the potency of riluzole to potentiate SK2 channel. These data suggest that the binding pocket identified by crystallography is indeed the functional binding pocket through which riluzole exerts the positive modulation of channel activity. These studies lay the foundation for structure based drug discovery research with the goal of developing more effective therapeutics for ALS treatment.

Title: Conserved role of the atypical MAP kinase SWIP-13/ERK8 in the regulation of presynaptic dopamine transporters

Authors: *D. BERMINGHAM, J. A. HARDAWAY, S. L. SNIDER, S. M. WHITAKER, R. D. BLAKELY;
Vanderbilt Univ., Nashville, TN

Abstract: The neurotransmitter dopamine (DA) is used across phylogeny, including in the soil-dwelling nematode, *C. elegans*, to modulate a wide range of complex behaviors. The capacity for DA signaling is tightly regulated by the presynaptic DA transporter (DAT/DAT-1), which limits DA availability in space and time. In nematodes, loss of *dat-1* results in a paralysis phenotype that is observed when worms are placed in water, a behavior we have termed Swimming-Induced Paralysis, or Swip. Swip can be reversed by genetic ablation of the TH ortholog *cat-2*, as well as the D2-like receptor *dop-3*, demonstrating a dependence on DA signaling. We identified the mutation vt32 in a forward genetic screen of worms that exhibit DA-dependent Swip, and mapped the molecular lesion to an uncharacterized gene C05D10.2, henceforth called *swip-13*. The *swip-13* gene encodes an ERK-family MAP kinase, orthologous to the mammalian atypical MAP kinase ERK7/8. Functional, GFP-tagged SWIP-13 protein localizes to DA terminals, consistent with a presynaptic contribution to DA signaling. Consistent with these studies, pharmacological and genetic studies of *swip-13* mutants demonstrate the DA-dependence of Swip in these animals and that loss of *swip-13* expression in DA neurons studies accounts for Swip behavior. Using a fluorescence recovery after photobleaching (FRAP) approach to monitor DA neuron synaptic vesicle fusion rates, we found that *swip-13* animals display normal basal

vesicle fusion. However, loss of *swip-13* results in reduced sensitivity to the DAT-1-dependent neurotoxin 6-OHDA, suggesting that a loss of DAT-1 activity may drive Swip. In support of this hypothesis, Swip experiments with *swip-13* and *dat-1* double mutants indicate a lack of additivity, consistent with contributions to swimming behavior in the same pathway. Together, these results are consistent with *swip-13* as a positive regulator of *dat-1*. Excitingly, studies with human ERK8 and human DAT in the human neuroblastoma cell line SH-SY5Y demonstrates a positive functional interaction between these two proteins, with overexpression of ERK8 increasing the uptake capacity of co-transfected DAT. This increase in DA uptake is paralleled by an increase in total and surface DAT protein levels, effects that are lost when DAT is co-transfected with a "kinase-dead" ERK8 mutation. Ongoing studies seek to elucidate the mechanism by which SWIP-13/ERK8 regulates nematode and mammalian DAT expression and function with an eye to whether kinase function can be manipulated for potential therapeutic benefit in disorders linked to perturbed DA signaling.

Title: The sigma-1 receptor modulates methamphetamine regulation of dopamine transporter activity

Authors: *D. O. SAMBO[1], M. LIN[2], H. KHOSHBOUEI[2];
[1]Dept. of Neurosci., [2]Univ. of Florida, Gainesville, FL

Abstract: The dopamine transporter (DAT) is a presynaptic membrane protein implicated in multiple physiological and pathological conditions, including movement, reward, neurodegeneration, and drug addiction. DAT functions to translocate dopamine across the plasma membrane and to modulate the excitability of dopaminergic neurons, making it a crucial

regulator of dopamine homeostasis. DAT is also the primary target for methamphetamine (METH), a highly addictive psychostimulant. What is not often recognized, however, is that METH is both a substrate for DAT as well as a ligand for the sigma-1 receptor (σ1R), an intracellular chaperone protein. We have previously shown that the σ1R is a novel protein partner with DAT at the plasma membrane and that both METH and the selective σ1R agonist PRE-084 treatment increases the association of σ1R with DAT. Importantly, we found that σ1R overexpression or σ1R agonist treatment prevented METH-induced, DAT-mediated increases in firing activity in dopaminergic neurons and σ1R agonist also decreased METH-mediated DA efflux, without affecting dopamine uptake or DAT trafficking. Expanding upon these preliminary findings, our current work investigates the potential intracellular mechanisms of σ1R modulation of METH-mediated DAT activity, with a focus on the role of σ1R on METH-mediated, DAT-dependent changes in intracellular calcium homeostasis as well as METH-mediated changes in membrane microdomain distribution of DAT. These findings are important in determining the molecular mechanisms of σ1R modulation of METH-mediated responses and will further examine the potential therapeutic role of σ1R for the treatment of METH addiction.

Title: Impact of S2 disruption on dopamine transporter function

Authors: *J. ZHEN, M. E. REITH;
Dept Psychiatry, New York Univ. Lagone Med. Ctr., New York, NY

Abstract: The structures of the leucine transporter (LeuT) and *drosophila* dopamine transporter (dDAT) show a secondary binding site (designated S_2) for drugs and substrate in the extracellular vestibule towards the membrane exterior in relation to the primary substrate recognition site (S_1). It still is a matter of debate whether the S_2 site plays a role in substrate translocation in human DAT (hDAT) as proposed for LeuT, in which binding of a second substrate molecule to S_2 triggers the release of substrate bound to S_1. The present experiments are aimed at disrupting S_2 by (i) mutating Asp476 to Ala (with D476 in S_2 interacting with DA in the modeling studies of

the Weinstein group and in our own studies), and (ii) mutating Ile159 to Ala (with I159 in S_2 interacting with DA in same models and corresponding to I111 in LeuT mutation of which is known to disrupt S2). D476A hDAT expressed in LLC-pK1 cells displayed a 90% decrease in uptake of 10 nM [^{3}H]DA compared with wild type (WT): the uptake K_m was increased 4-fold, whereas the V_{max} was reduced by an order of magnitude. With the study of binding of [^{3}H]CFT- the cocaine analog- to intact cells, compared with WT, no change was found in the K_d of [^{3}H]CFT and 2-fold reduction was found in the maximal binding sites in D476A. Accordingly, surface expression of D476A DAT, as measured by biotinylation and western blot, was approximately half of that of WT. In turn, D476A hDAT turnover rate was significantly reduced by 7-fold than WT. In LLC-PK_1 I159A-hDAT, [^{3}H]DA uptake was not detectable. Experiments are in progress to enhance expression of I159A hDAT in order to better measure its properties. The results taken together indicate that disruption of S_2 has a more severe impact on transport function of DAT than on cocaine analog binding. These data suggested that S_2 plays a crucial role in DA transport, perhaps by an allosteric interaction between S_2 and S_1. In consonance, the affinity of DA (likely for S_1) as measured by [^{3}H]CFT binding to S_2-disrupted D476A was reduced compared to WT with S_2 intact.

Title: Vesicular monoamine transporter-2: Interaction with parkin and mechanism of degradation

Authors: *E. K. STACHOWSKI, T. B. BAUST, G. E. TORRES;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The vesicular monoamine transporter-2 (VMAT2) is essential for monoaminergic homeostasis, as it packages monoamines into synaptic vesicles, readying neurotransmitters for synaptic release. VMAT2 also has a neuroprotective role, given that free monoamines in the cytosol have the potential to auto-oxidize and form dangerous free radicals that can ultimately contribute to oxidative stress and neuronal vulnerability. Despite the importance of VMAT2,

little is known about mechanisms involving VMAT2 degradation. The balance of protein synthesis and degradation is vital in maintaining normal cellular function and deregulation of degradation systems can be detrimental to neurons, as evidenced in disorders such as Parkinson's disease. There are two primary organelles responsible for degradation in mammalian cells: the lysosome and the 26S proteasome. Although synaptic vesicle proteins are thought to be degraded by the lysosome via the endo-lysosomal pathway, little direct evidence exists for this. Furthermore, it remains unclear if these proteins can be differentially regulated or degraded at the vesicle. Utilizing an *in vitro* cellular model we demonstrate here that VMAT2 is degraded primarily through the UPS (ubiquitin-proteasome system), and not by the lysosome. Our data suggests UPS-related degradation of mature VMAT2 is a process independent of endoplasmic-reticulum-associated degradation (ERAD). Specificity for the UPS is primarily determined by E3 ligases, enzymes that tag a specific protein with ubiquitin, destined for the proteasome. We provide evidence that an E3 ligase, parkin, physically and functionally interacts with VMAT2. Since parkin mutations have been associated with autosomal recessive juvenile-onset Parkinsonism, our results suggest that VMAT2 deregulation may be implicated in the pathology of Parkinson's disease.

Title: Locating the binding site of the benztropine photoaffinity ligand,[125I]GA II 34, on the dopamine transporter

Authors: *M. J. TOMLINSON[1], D. KROUT[1], A.-B. PRAMOD[1], J. R. LEVER[2,3], A. H. NEWMAN[4], L. K. HENRY[1], R. A. VAUGHAN[1];

Abstract: The dopamine transporter (DAT) is an integral membrane protein responsible for reuptake of dopamine from the synapse. Psychostimulant drugs target the DAT and block reuptake of dopamine thereby affecting dopamine homeostasis. Benztropine, a dopamine reuptake inhibitor, contains a tropane pharmacophore homologous to cocaine, yet has distinct behavioral effects, which has been hypothesized to result from a different mode of interaction with the DAT. Incorporating a photoreactive arylazido group into DAT inhibitors has allowed for covalent attachment of these photoaffinity ligands to the transporter and analysis of inhibitor binding. Our lab has extensively studied the cocaine photoaffinity analogs [^{125}I]MFZ 2-24 and [^{125}I]RTI 82 to characterize their interactions with the DAT. Determining the adduction sites of both [^{125}I]MFZ 2-24 and [^{125}I]RTI 82 and computational ligand docking models identified cocaine coordinates with specific amino acid residues of the DAT. To characterize the binding of benztropine with DAT we labelled the transporter with the irreversible benztropine photoaffinity analog, [^{125}I]*N*-[*n*-butyl-4-(4’’’-azido-3’’’-iodophenyl)]-4’,4’’-difluoro-3α-(diphenylmethoxy)tropane ([^{125}I]GA II 34) and performed trypsin and cyanogen bromide-based peptide mapping. The results narrowed adduction of [^{125}I]GA II 34 to the amino acids Asp-79 and/or Leu-80 in the unwound region of TM1, placing the ligand in close proximity to residues essential for dopamine binding. Computational ligand docking studies, supported by peptide mapping, position [^{125}I]GA II 34 in the high affinity substrate binding site(S1) in a pose similar to MFZ 2-24. To verify this conclusion, the substituted-cysteine accessibility method will be used to determine residues protected by GA II 34 from methanethiosulfonate reagent attack. If the distinct behavioral effects of cocaine and benztropine are due to differential transporter binding properties, our results indicate that these differences are likely to be subtle.

Title: Palmitoylation of the Dopamine Transporter on Cysteine 6

Authors: *D. J. STANISLOWSKI, R. VAUGHAN, J. FOSTER;
Basic Sci., Univ. of North Dakota Sch. of Med. and, Grand Forks, ND

Abstract: The dopamine transporter (DAT) controls synaptic dopamine (DA) levels by reuptake after presynaptic neuronal vesicular release. Several neurological disorders including Parkinson disease, addiction, and ADHD are associated with abnormal DA homeostasis, and DAT dysregulation is hypothesized to contribute to these disorders. DAT function is regulated through posttranslational modifications including S-palmitoylation, the reversible, catalytic addition of palmitate to cysteine via a thioester linkage. S-palmitoylation of DAT opposes PKC-mediated down-regulation and increases DA transport Vmax without altering DAT surface expression. In previous studies we mutated the intracellular Cys residues to alanine, and determined that Cys580 was a major but not sole site of [3H]palmitic acid metabolic labeling. To identify the other site we used the more sensitive acyl-biotinyl exchange (ABE) method to analyze these mutants. The results confirmed the modification of Cys580, but did not detect reduced palmitoylation for other mutated sites (Cys6, Cys135, Cys342, Cys522), suggesting the presence of compensatory modification in response to mutagenesis. We then mutated all but one of the intracellular cysteines to alanine, leaving a single site available for palmitoylation. ABE analysis of these mutants showed significantly elevated palmitoylation of DATs containing Cys6 or Cys580 relative to those containing only Cys135, Cys341, or Cys522, suggesting that Cys6 is the second palmitoylation site. To determine if endogenous palmitoylation is occurring on Cys6, we performed peptide mapping of rat striatal DAT using endoproteinase Asp-N digestion and ABE analysis of N-terminal fragments. Asp-N cleavage of DAT occurs at Asp174, producing a 19 kDa peptide fragment containing Cys6 and Cys135 that can be detected by immunoblotting. ABE analysis of this fragment demonstrated the presence of palmitoylation, indicating that one or both of these residues is palmitoylated. In conjunction with the mutagenesis findings these results strongly support the palmitoylation of DAT at Cys6, suggesting the potential for tethering of the N-terminus to the plasma membrane. The N-terminus of DAT mediates many regulatory functions and is the site for ubiquitylation and phosphorylation. Palmitoylation of Cys6 thus has major implications for transporter structural and functional properties.

Title: Regulation of the Dopamine Transporter by heterotrimeric G-proteins depends on N-terminal phosphorylation

Authors: J. A. BORIS[1], *J. GARCIA-OLIVARES[2], S. G. AMARA[1];
[1]Lab. of Cell. and Mol. Neurobio., Natl. Inst. of Mental Health/NIH, Bethesda, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Dopaminergic neurotransmission has an important role in many complex psychiatric conditions including depression, attention-deficit hyperactivity disorder and drug addiction. Many current therapeutic approaches used in the treatment of these conditions target the dopamine transporter (DAT). A member of the SLC6A family, the DAT clears extracellular dopamine through a sodium-coupled transport mechanism. DAT function is regulated by intracellular mechanisms such as phosphorylation, ubiquitination, and a variety of interactions with other proteins. We recently reported a novel mechanism of regulation of the DAT by heterotrimeric G-proteins. We found that Gβγ subunits bind directly to the C-terminus of the DAT and upon G-protein activation, the release of Gβγ results in a decrease in dopamine (DA) accumulation. In recent studies, we found that the decrease in DA accumulation does not involve a change in uptake, but is instead the result of an increase in DA efflux. Efflux is a complex mechanism that depends on calcium, sodium, and membrane potential and has been linked to the actions of DA-releasing properties of amphetamine. Efflux also involves phosphorylation of residues at the N-terminus, as well as interactions of the C-terminus with Serine/Threonine kinases such as protein kinase C and calmodulin kinase II. To explore whether the DA efflux promoted by the activation of Gβγ subunits also requires phosphorylation of the N-terminus, we used two DAT mutants, hDAT-S/A and hDAT-S/D. These mutants have five N-terminal serines (S2, S4, S7, S12, S13) substituted with alanine (S/A) to eliminate putative phosphorylation sites, or aspartate (S/D), where the negatively charged side chains simulate phosphorylation. We also used pharmacological tools to inhibit kinases and phosphatases in order to explore how the general phosphorylation state of DAT contributes to the regulation of DAT by Gβγ subunits. Our data suggest that the effect on efflux mediated by Gβγ activation depends on the presence of N-terminal serine residues implying that N-terminal phosphorylation is required. Moreover, changes in the global phosphorylation state also modify DAT function. Phosphatase inhibition decreases cytosolic DA, whereas inhibition of Serine/Threonine kinases increases cytosolic DA. Interestingly, the enhanced efflux induced by Gβγ activation is not affected by these manipulations. These results provide a basis for further studies to establish whether substitutions at the N-terminal phosphorylation sites modify the binding of Gβγ to the C-terminus or whether phosphorylation of these residues facilitates a shift in transporter conformation towards an efflux mode

Abstract: 4-methyl-N-metylchathinone (mephedrone, MEPH) is a popular psychostimulant and one of the major representatives of former legal highs, commonly referred to as “bath salt” or “plant food”. MEPH impinges on monoaminergic signaling in the brain in an amphetamine-like fashion and most closely resembles 3,4-methylenedioxymethamphetamine (MDMA, “ecstasy”). Thus, MEPH acts at the high-affinity transporters for dopamine (DAT), serotonin (SERT) and norepinephrine (NET) and induces efflux via their cognate transporters. However, the exact interaction of MEPH with monoamine transporters still remains enigmatic and the discrepancy between the long duration of the MEPH induced high and its plasma-half life is unresolved. We sought to investigate the molecular mechanism of action of MEPH and to test its metabolites for psychoactive properties. We investigated the impact of MEPH and its metabolites on DAT, NET and SERT in radiotracer flux experiments using heterologous expression systems as well as rat brain synaptosomes. In addition, we examined the interaction of MEPH with monoamine transporters by use of Foerster resonance energy transfer (FRET) microscopy and electrophysiology. Moreover, we characterized each substance in an *in vivo* approach for their stimulant profiles and generated in silico models of the fit in the binding pockets of DAT, NET and SERT. MEPH was found to increase the proportion of transporters in the inward-facing

conformation and to elicit a depolarizing current. The MEPH-derived metabolites were found to competitively inhibit uptake of radiolabeled substrates via DAT, NET and SERT. Efflux-studies revealed that the examined MEPH metabolites are capable of inducing efflux of preloaded substrates via DAT, NET and SERT. Consistent with *in vitro* findings, the metabolites mimicked the actions of the parent compound *in vivo*. The fact that MEPH is subject to a fast metabolic turnover, yet induces a long lasting high appeared to be inconsistent. Our data unravel the mode of action of MEPH on a molecular level and indicate that the presence of MEPH per se is not the only parameter determining the stimulating effect of this drug.

Title: Interplay between the serotonin transporter (SERT) and $5HT_{1A}$ receptors to modulate quantal catecholamine release events in adrenal chromaffin cells

Authors: *R. L. BRINDLEY[1], M. B. BAUER[1], R. D. BLAKELY[2], K. P. M. CURRIE[3]; [1]Dept. of Anesthesiol., [2]Departments of Pharmacol. and Psychiatry, Silvio O. Conte Ctr. for Neurosci. Res., [3]Departments of Anesthesiol. and Pharmacol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: The serotonin transporter (SERT) mediates the reuptake of 5HT at CNS synapses and is a clinically relevant target for some anti-depressants, including the selective serotonin reuptake inhibitors (SSRIs). SERT is also prominently expressed in adrenal chromaffin cells, the neuroendocrine arm of the sympathetic nervous system. In response to stressors, chromaffin cells release catecholamines and neuropeptides that in turn regulate the cardiovascular, endocrine, immune, and nervous systems. However, the effects of 5HT / SERT on chromaffin cell function remain unclear. We show that intracellular 5HT content is >1000 fold lower than the

catecholamines (epinephrine and norepinephrine). One role of SERT is to mediate uptake of this 5HT into chromaffin cells as demonstrated by the ~80% reduction of 5HT in adrenal glands isolated from SERT knockout mice compared to wild-type littermates. The catecholamine content of the same glands was unaltered. To investigate regulation of stimulus-secretion coupling by 5HT / SERT, we used carbon fiber amperometry. Secretion was evoked in chromaffin cells isolated from wild-type or SERT knockout mice by bath perfusion with 30mM KCl for 60s. In control conditions (no extracellular 5HT) there was a significant reduction (~ 35%) in the overall amount of secretion in SERT knockout cells compared to wild-type cells. The number of amperometric spikes (vesicular release events) was not different, but the duration and the charge (i.e. the amount of oxidizable transmitter released) of individual spikes were significantly reduced in SERT knockouts. In SERT knockout cells, acute application of extracellular 5HT (1μM) had an additional effect, significantly inhibiting the number of amperometric spikes. This was prevented by pretreating cells with pertussis toxin (300ng/ml). In wild-type cells, the $5HT_{1A}$ receptor agonist (R)-(+)-8-OH-DPAT (300nM) mimicked the inhibition of number of spikes but 5HT did not unless SERT activity was blocked by acute application of escitalopram (1μM). Under these conditions, 5HT reduced the number of amperometric spikes and this was abolished by the $5HT_{1A}$ receptor antagonist WAY100635 (25nM). Using patch-clamp electrophysiology and fluorescent Ca^{2+} imaging experiments we found no effect of 5HT or escitalopram on baseline intracellular [Ca^{2+}], or Ca^{2+} entry through voltage-gated Ca^{2+} channels. Overall our data identify a complex interaction between SERT and $5HT_{1A}$ receptors to control stimulus-secretion coupling in chromaffin cells. Ongoing work will dissect the underlying mechanisms, and the contribution of adrenal gland 5HT/ SERT to the (patho)physiology of stress and stress-related disorders.

Title: Interaction of neurokinin signaling and catecholamine transport in amphetamine behavior

Authors: *P. MANNANGATTI, S. RAMAMOORTHY, M. S. BOWERS, L. D. JAYANTHI; Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: The psychostimulants cocaine and amphetamine (AMPH) target all three monoamine transporters with AMPH having nearly equal affinity for the catecholamine transporters, the norepinephrine and dopamine transporters (NET & DAT). It is known that both AMPH and activation of the neurokinin-1 receptor (NK1R) can downregulate NET as well as DAT. Interestingly, Substance P, the endogenous NK1R agonist is released in the rat ventral striatum following AMPH, and while Substance P is known to enhance acute stimulatory effects of AMPH, NK1R antagonists decrease psychostimulant locomotor activation. Our previous work demonstrated that Substance P and AMPH mediated NET downregulation is dependent on the transporter T258/S259 trafficking motif (PMC2939970; PMID: 16740633). In addition, NET regulation by NK1R is facilitated by protein-protein interactions that occur in membrane rafts (PMC3789959). These observations indicate that NK1R can modulate the impact of AMPH on catecholamine transporter function. Interestingly, studies examining the behavior of monoamine transporter knockout mice in response to psychostimulants indicate that each amine transporter plays distinct roles in mediating the reinforcing effects of psychostimulants. Here, we extend our studies to in-vivo manipulation of catecholamine transport regulation to test the hypothesis that NK1R-mediated T258/S259-specific downregulation of NET and/or DAT independently or coordinately contributes to AMPH-evoked behaviors. We demonstrate that AMPH administration down-regulated NET in the rat ventral striatum and that the NK1R antagonist aprepitant (emend) prevented these AMPH-mediated effects. Importantly, ventral striatal microinjections of a TAT-peptide targting the T258/S259 motif attenuated AMPH-induced locomotor activation. Our data suggest that catecholamine transport is coupled to NK1R signaling mechanisms and interrupting T258/S259-specific NK1R-mediated NE transport regulation affects AMPH-elicited behavior. The NK1R-mediated T258/S259-dependent catecholamine transport regulation represents a novel molecular mechanism not previously recognized as a potential target of AMPH, and our ongoing studies seek to explore the significance of this molecular mechanism in the rewarding effects of AMPH.

Title: Tyrosine 470 and 88 of human dopamine transporter are critical for Tat-mediated allosteric modulation on human dopamine transporter

Authors: *W.-L. SUN[1], A. SUBRAMANIAM[2], P. M. QUIZON[1], C.-G. ZHAN[3], J. ZHU[1]; [1]Dept. of Drug Discovery and Biomed. Sci., Univ. of South Carolina, Columbia, SC; [2]Dept. of Organic Chem., Southern Res. Inst., Birmingham, AL; [3]Mol. Modeling and Biopharmaceutical Ctr. and Dept. of Pharmaceut. Sci., Univ. of Kentucky, Lexington, KY

Abstract: HIV-1 Tat protein and cocaine synergistically disrupt dopamine (DA) transmission by inhibiting human dopamine transporter (hDAT), which exacerbates the progression of HIV-1-associated neurocognitive impairment. Our previous study demonstrated that compared to cocaine alone, Tat slowed cocaine-induced dissociation rate of [^{3}H]WIN35,428 binding and increased IC_{50} value of cocaine inhibiting [^{3}H]DA uptake in wild type (WT) hDAT, indicating that Tat allosterically modulates hDAT. Through the integrated computational modeling and experimental studies, we have identified that mutations of tyrosine470 (Y470H) and tyrosine88 (Y88F) of hDAT, via changing transporter conformational transitions, attenuate Tat-induced inhibition of DAT. Therefore, the present study evaluated the role of Y470H and Y88F in Tat-mediated allosteric modulation of hDAT. SoRI-20041, a novel allosteric modulator of the DAT, significantly increased IC_{50} value for cocaine inhibiting DA uptake by 34% (IC_{50} in nM: cocaine, 323 ± 19; cocaine + SoRI-20041, 443 ± 31) in WT hDAT but did not alter IC_{50} value for cocaine in Y470H (IC_{50} in nM: cocaine, 195 ± 23; cocaine + SoRI-20041, 208 ± 28). Compared to cocaine alone, SoRI-20041 following the addition of cocaine significantly decreased the dissociation rate of [^{3}H]WIN35,428 by 79% (K_{-1}: cocaine, 0.161 ± 0.029; cocaine + SoRI-20041, 0.033 ± 0.008) in WT hDAT, by 42% (K_{-1}: cocaine, 0.169 ± 0.041; cocaine + SoRI-20041, 0.097 ± 0.044) in Y88F and by 18% (K_{-1}: cocaine, 0.076 ± 0.006; cocaine + SoRI-20041, 0.062 ± 0.019) in Y470H, respectively. Collectively, these results demonstrate that tyrosine470 and tyrosine88 are functional recognition residues in hDAT for Tat-induced inhibition of DA uptake and play different roles in Tat-mediated allosteric modulation of DAT. Through known allosteric modulators of DAT, identifying other potential allosteric binding sites in hDAT for Tat is our important ongoing study.

Title: Membrane properties of attention-deficit hyperactivity disorder associated dopamine transporter coding variant (A559V) linked with altered palmitoylation and phosphorylation

Authors: *M. J. SHETTY, J. MORRELL, M. HOVLAND, B. GROVE, R. A. VAUGHAN, J. D. FOSTER;
Dept. of Basic Sci., Univ. of North Dakota Sch. of Med. & He, Grand Forks, ND

Abstract: The dopamine transporter (DAT) plays a vital role in maintaining synaptic dopamine (DA) homeostasis in the central nervous system. Many neurological disorders including Parkinson disease, addiction, and attention-deficit hyperactivity disorder (ADHD) are associated with abnormal DA homeostasis, and DAT dysregulation is hypothesized to contribute to these disorders. Recently a DAT coding variant (A559V) has been associated with ADHD that displays anomalous DA efflux and increased distal N-terminal phosphorylation independent of amphetamine (AMPH) stimulation, suggesting alterations in regulatory properties. In previous studies, our laboratory has characterized effects of signaling pathways and abused drugs on DAT palmitoylation, membrane raft localization and site-specific phosphorylation. Here we analyzed the effect of this mutation on these properties using the hDAT A559V form and/or the rat homolog (A558V rDAT), finding multiple alterations in post-translational modifications and regulatory properties. Using a phospho-specific antibody we examined phosphorylation of Thr53, a proline-directed site in the membrane proximal region of the N-terminus that has been linked to altered uptake and efflux kinetics. Our findings show a striking increase in phosphorylation that is equivalent to that induced by AMPH, suggesting a possible mechanistic connection to transmitter efflux. We also found that these mutants induced significant decreases in palmitoylation, the reversible addition of palmitate to a cysteine via a thioester linkage. Palmitoylation is known to influence protein membrane properties including lateral mobility and microdomain targeting. Using fluorescence recovery after photobleaching we found that both A559V hDAT and A558V rDAT showed increased lateral membrane mobility, and using density gradient centrifugation we found that both mutant forms were enriched in membrane rafts compared to the WT proteins, suggesting these properties may contribute to the altered functionality. Ala558/559 is found at the extracellular side of TM12, and DAT is palmitoylated at Cys580/581 at the intracellular side of TM12. The alteration in the palmitoylation properties by this mutation thus suggests the propagation of a structural alteration in the TM12 helix that results in suppression of this modification. We have previously demonstrated the presence of a

reciprocal relationship between DAT palmitoylation and N-terminal phosphorylation, which may be related to the enrichment of the ADHD variants in membrane raft microdomains that may serve as platforms for DAT-mediated DA efflux.

Title: Effects of diet and insulin on DAT activity and expression in rat CPu, NAc and midbrain

Authors: ***K. T. JONES**[1], C. WOODS[2], T. ANTONIO[1], J. ZHEN[1], K. D. CARR[1,3], M. E. A. REITH[1,3];
[1]NYU Dept. of Psychiatry, [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Dept. of Biochem. and Mol. Pharmacol., NYU, New York, NY

Abstract: Given that the dopamine transporter (DAT) is regulated by insulin, we wanted to investigate the effects of diet and insulin on DAT expression and function in brain regions important for reward, in particular, the nucleus accumbens (NAc), caudate/putamen (CPu) and midbrain. Freshly processed tissue was studied for dopamine (DA) uptake *in vitro* with rotating disk electrode voltammetry (RDEV), and for binding of the phenyltropane cocaine analog [^{3}H]CFT. We found that the influence of diet differs between NAc, CPu and midbrain. In synaptosomes from NAc, we found no difference in V_{max} and K_m for DA uptake in food restricted (FR) rats compared to *ad libitum* (AL) fed rats but a reduction in V_{max} in obesogenic (OB) rats, in agreement with other reports. [^{3}H]CFT binding to DAT, a reflection of surface DAT, in synaptosomes from NAc showed a reduction in B_{max} with no change in K_d in OB rats while AL and FR rats showed similar values. In contrast, synaptosomes from CPu showed a trend towards a reduction in V_{max}, without a change in K_m, for FR and OB (~30%) animals. The V_{max} effect is likely a result of a decreased surface DAT as indicated by reduced B_{max} of [^{3}H]CFT binding in FR (~24%) and OB (~37%) animals. Direct assessment of surface DAT is

underway in biotinylation studies. Preliminary data collected on somatodendritic DAT in midbrain suggest that diet affects DAT levels as assessed by [^{3}H]CFT binding without changing total DAT protein in synaptoneurosomes. To examine insulin's effect on striatal DAT activity, we monitored DA uptake using classical [^{3}H]DA uptake studies and RDEV. Preliminary voltammetry studies reveal that exogenous addition of insulin (30 nM) enhanced V_{max} in CPu synaptosomes from FR (~70%) rats compared to AL (~50%) fed rats but had less of an effect in synaptosomes from OB rats (~35%). This phenomenon was observed in the NAc to a lesser degree. Additionally, classical [^{3}H]DA uptake studies from AL rats confirmed the voltammetry data and indicated that insulin's effect on V_{max} in both NAc and CPu (~30%) was blocked by an insulin antibody (InsAb), whereas InsAb alone or IgG was without effect. This data along with the existing literature supports a role for diet in affecting DAT in CPu, NAc and midbrain while insulin can increase DAT-mediated DA uptake in both CPu and NAc.

Title: Enhanced vesicular monoamine transporter level modifies synaptic L-DOPA-derived dopamine handling

Authors: *K. M. LOHR, G. W. MILLER;
Envrn. Hlth., Emory Univ., Atlanta, GA

Abstract: The vesicular monoamine transporter 2 (VMAT2) is responsible for the packaging of monoamine neurotransmitters into vesicles for their subsequent release following an action potential. We have previously shown that elevated VMAT2 levels in mice (VMAT2-HI mice) increases vesicular storage capacity for dopamine, vesicle size, and stimulated dopamine release, suggesting that vesicular transporter expression is able to dictate dopaminergic output. Since VMAT2 overexpression augments dopamine handling in this way, we wanted to examine the

effects of a flooded dopamine system. To address this question, we applied L-DOPA to a striatal slice and, following a wash, recorded the stimulated dopamine release in the presence of exogenously stored dopamine using fast-scan cyclic voltammetry. We find that both wildtype and VMAT2-HI mice have significantly increased peak dopamine release following L-DOPA administration, with VMAT2-HI mice still showing an enhancement in dopamine release in the presence of drug. However, when L-DOPA is applied, the plasma membrane dopamine transporter (DAT)-mediated uptake of extracellular dopamine is significantly faster in the VMAT2-HI mice as measured by the rate constant tau ($p<0.05$). The level of the DAT is unchanged between the genotypes, suggesting a change in the function of the DAT. Taken together, these results suggest that vesicular filling is capable of modifying synaptic handling of exogenous dopamine.

Title: Amphetamine increases NMDA-GluN2B synaptic currents in substantia nigra dopamine neurons

Authors: *S. L. INGRAM[1], M.-H. LI[1], T. J. PHILLIPS[2], S. G. AMARA[3], S. M. UNDERHILL[3];

Abstract: The psychostimulant amphetamine and it's derivatives have significant abuse potential, but the cellular mechanisms underlying amphetamine addiction are not understood.

Here we show that amphetamine increases evoked NMDA-mediated synaptic currents (EPSCs) at -70 mV in 0 Mg2+ extracellular solution by 35% (control: -134 ± 20 pA, amphetamine: -202 ± 36 pA; paired t-test, $t(5) = 3.456$, $p < 0.05$). AMPA/NMDA ratios measured at +40 mV in normal extracellular solution were decreased by approximately 30% (control: 2.6 ± 0.24; amphetamine: 1.9 ± 0.12; paired t-test, $t(6) = 3.872$, $p < 0.01$). The potentiation of NMDA EPSCs is dependent on the dopamine transporter (DAT) but not on activation of dopamine receptors. The DAT inhibitor GBR12909 (1 μM) was superfused prior to amphetamine and completely blocked potentiation of NMDA EPSCs by amphetamine (GBR12909: -184 ± 18 pA compared to -200 ± 20 pA in GBR12909 + amphetamine). NMDA-GluN2B subunit inhibitors, ifenprodil (1 - 10 μM) and Ro 25-6981 (1 μM), inhibited the effects of amphetamine without affecting basal evoked NMDA currents indicating that different NMDA receptors are activated in the presence of amphetamine. A selective peptide inhibitor of amphetamine-dependent trafficking of the neuronal excitatory amino acid transporter (EAAT3 blocked the ability of amphetamine to potentiate NMDA EPSCs (scrambled peptide: 58 ± 19 % increase compared to EAAT3 peptide: -19 ± 8%, $t(9) = 4.437$, $p < 0.05$). In addition, the amphetamine-mediated potentiation was absent in mice lacking EAAT3. These data provide evidence that EAAT3 internalization increases extracellular glutamate concentrations and activates GluN2B-containing NMDA receptors. Experiments with the use-dependent NMDA blocker, MK-801, indicate that potentiated NMDA receptors are localized to the plasma membrane and are not inserted de novo. Finally, inhibition of NMDA-GluN2B receptors with Ro 04-5595 blocked methamphetamine (2 mg/kg, IP)-induced locomotor stimulation in a dose-dependent manner indicating that these receptors are important in the behavioral effects of amphetamines. These results reveal an important interaction between dopamine and glutamatergic signaling in midbrain dopamine neurons that is dependent on amphetamine modulation of neurotransmitter transporters.

Title: Prolonged METH exposure suppresses BK channel activity in the dopamine neurons

Authors: M. LIN[1], D. SAMBO[1], *H. KHOSHBOUEI[2];
[2]Box 100244, [1]Univ. of Florida, Gainesville, FL

Abstract: Previous studies have shown acute methamphetamine (METH) rapidly increases the excitability of dopamine neurons. However, the effect of longer METH exposure on the intrinsic firing activity of dopamine neurons is unknown. In cultured midbrain dopamine neurons, we found METH initially (1-2 min, 10 microM) increases the rate of spontaneous spike activity of dopamine neurons followed by a progressive reduction of the spontaneous spike activity (10-15 min, 10 microM). Longer METH exposure slows action potential repolarization and decreases the amplitude of afterhyperpolarization (AHP). These results suggest methamphetamine potentially affects the activity of large-conductance Ca2+-activated K+ (BK) channels in these neurons. We found both METH and blockade of BK channels increase the spike half-width and decrease the amplitude of afterhyperpolarization (AHP). Therefore, we tested the hypothesis that prolonged METH exposure inhibits the activity of BK channels to modulate the excitability of dopamine neurons. Using excised patch single-channel recordings, we identified the BK channels by their voltage-dependence and responsiveness to pharmacological manipulations such as using a specific channel blocker paxilline (10 microM) or channel opener NS1619 (10 microM). While METH exposure suppressed the amplitude of BK channel-mediated unitary currents, the BK channel opener, NS1619, attenuated the effects of METH on the AP half-width, AHP and the rate of spontaneous spike activity. Western blot and immunostaining analysis revealed the α1 / β4 subunits of BK channel are expressed in the midbrain dopamine neurons. The literature suggests the α1 subunit of BK channel increases the activity of the channel, whereas the β4 subunit suppresses the activity. While METH exposure decreased α1 subunit level, it enhanced β4 subunits level at the plasma membrane of these neurons. Taken together, our results support a fundamental role for BK channels' fine-tuning of the intrinsic firing activity of dopamine neurons and METH regulation of neuronal activity. Our ongoing experiments examine the mechanism of METH regulation of α1 / β4 subunits of BK channel in the dopamine neurons.

Title: Dopamine transporter expression, transport capacity, and membrane lateral mobility is regulated by palmitoylation

Authors: *D. E. RASTEDT, J. D. FOSTER, R. A. VAUGHAN;
Basic Sci., Univ. of North Dakota, Sch. of Med. and Hlth. Sci., Grand Forks, ND

Abstract: The dopamine transporter (DAT) mediates the reuptake of synaptic dopamine and thus regulates the spatio-temporal dynamics of dopaminergic neurotransmission. Complex control of DAT is exerted by various regulatory processes including posttranslational modifications. We previously found that DAT is palmitoylated, via the addition of a 16-carbon palmitic acid moiety to Cys 580, and that depalmitoylation led to reductions in Vmax and transporter levels. Palmitoylation is a reversible process catalyzed by palmitoyl acyltransferases (PATs) (also called DHHC enzymes based on the conserved active site sequence Asp-His-His-Cys), and palmitoyl-protein thioesterases (PPTs). Recent studies identified a family of 23 PAT enzymes in the human genome with distinct tissue distributions (e.g. neuronal vs non-neuronal), and with some associated with DA diseases such as schizophrenia. To identify PATs that can catalyze DAT palmitoylation and alter function, we co-expressed a specific subset of DHHC enzymes individually with DAT and assessed DAT palmitoylation, expression, surface levels, DA transport capacity, and lateral mobility. Palmitoylation assessed by acyl-biotin exchange revealed that the neuronal PATs, DHHC2, DHHC3, DHHC8, DHHC15, and DHHC17 increased DAT palmitoylation, while several others had no effect. We observed a correlation between increased DAT palmitoylation and increased total DAT levels, consistent with a role for palmitoylation in opposing DAT degradation. Increased DAT palmitoylation also led to enhanced DA uptake with no effect on surface levels, suggesting palmitoylation increases transport capacity via an alteration of DAT transport kinetics. Finally, increased DAT palmitoylation increased the time for recovery after photobleaching, suggesting that increased palmitoylation decreases the membrane lateral mobility of the transporter. Palmitoylation of DAT thus plays a role in both short- and long-term regulation of DAT, and may represent a point of DA reuptake dysregulation in dopaminergic disorders.

Abstract: Syntaxin 1 (STX1) is a presynaptic plasma membrane protein that coordinates synaptic vesicle fusion. STX1 also regulates the function of neurotransmitter transporters, including the dopamine (DA) transporter (DAT). The DAT is a membrane protein that controls DA homeostasis through the high-affinity re-uptake of synaptically released DA. We adopt newly developed animal models and state-of-the-art biophysical techniques to determine the contribution of the identified gene variants to impairments in DA neurotransmission observed in autism spectrum disorder (ASD). Here, we characterize two independent autism-associated variants in the genes that encode STX1 and the DAT. We demonstrate that each variant dramatically alters DAT function. We identify molecular mechanisms that converge to inhibit reverse transport of DA and DA-associated behaviors. These mechanisms involve decreased phosphorylation of STX1 at Ser14 mediated by casein kinase 2 as well as a reduction in STX1/DAT interaction. These findings point to STX1/DAT interactions and STX1 phosphorylation as key regulators of DA homeostasis. We determine the molecular identity and the impact of these variants with the intent of defining DA dysfunction and associated behaviors as possible complications of ASD.

[5]Pharmacol. and Therapeutics, Col. of Med., Univ. of Florida, Gainesville, FL

Abstract: The dopamine transporter (DAT) regulates extracellular dopamine (DA) levels and signaling via uptake and efflux. Addictive psychostimulants such as amphetamine increase extracellular DA levels in motivational and reward brain areas by targeting DAT. Examining the basic mechanism(s) that affect DAT efflux is critical for understanding both fundamental aspects of DA regulation and for clinical intervention in DA-related brain disorders associated with the therapeutic use and abuse of psychostimulants. Several studies have revealed a plethora of protein-protein interactions influencing DAT distribution and activity; suggesting that the fine-tuning of dopamine homeostasis occurs via an elaborate interplay of multiple mechanisms. We recently reported that beta-gamma (βγ) subunits of G proteins bind directly to the C-terminus (residues 582-620) of DAT to down-regulate uptake activity. Here, we report that the novel DAT/ Gβγ interaction also promotes DA efflux through DAT. Specifically, activation of Gβγ subunits using mSIRK increased DA efflux through DAT using both heterologous cells and primary neurons in culture. This effect was blocked in the presence of gallein, a Gβγ inhibitor. Likewise, a TAT-peptide containing the Gβγ interacting domain of DAT blocked the ability of mSIRK to induce DA efflux, suggesting the effect of Gβγ on efflux is a result of a direct interaction with the transporter. Based on these data, we hypothesized that Gβγ may also be

involved in the actions of amphetamine. In similar efflux experiments, amphetamine induced a dose-dependent increase in DA efflux in both heterologous cells and primary neurons in culture. More importantly, amphetamine-induced efflux was blunted in the presence of either gallein or the TAT-peptide containing the DAT interacting domain. Collectively, our data suggest that the direct interaction of Gβγ subunits with DAT has an important role in both physiological and amphetamine-induce DA efflux. Additional studies are examining the role of the DAT/ Gβγ interaction on amphetamine-evoked behaviors *in vivo*.

Title: Brain region-specific trafficking of the dopamine transporter

Authors: ***A. SORKIN**[1], E. BLOCK[1], J. J. BALCITA-PEDICINO[2], J. NUTTLE[2], S. SESACK[2]; [1]Cell Biol., [2]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The dopamine (DA) transporter (DAT) controls dopaminergic neurotrasmission by removing extracellular DA. While DAT activity is proposed to be regulated by its traffic to and from the cell surface, the membrane trafficking system involved in the endocytic cycling of DAT in the intact mammalian brain has not been characterized. Hence, we performed immunostaining and quantitative analysis of the subcellular and regional distribution of DAT using the transgenic knock-in mouse expressing hemagglutinin (HA) epitope tagged DAT (HA-DAT), and by employing a combination of electron microscopy and a novel method for immunofluorescence labeling of HA-DAT in acute sagittal brain slices. Both approaches demonstrated that in midbrain somatodendritic regions, HA-DAT was present in the plasma membrane, endoplasmic reticulum, and Golgi complex, with a small fraction in early and recycling endosomes, but not in late endosomes and lysosomes. In the striatum, as well as in axonal tracts between the midbrain and striatum, HA-DAT was detected predominantly in the plasma membrane, and quantitative

analysis revealed increased DAT density in striatal compared to midbrain plasma membranes. Endosomes were strikingly rare and lysosomes were absent in striatal axons, where there was little intracellular HA-DAT. Acute administration of amphetamine *in vivo* or to slices *ex vivo* did not result in detectable changes in the patterns of DAT distribution. Altogether, these data provide evidence for regional differences in DAT plasma membrane targeting and retention, and suggest a surprisingly low level of endocytic trafficking of DAT in the striatum along with limited DAT endocytic activity in somatodendritic areas.

Title: HIV-1 Tat protein augments methamphetamine-induced impairment of dopamine transporter activity

Authors: ***R. STEGER**[1], K. SAHA[1], D. SAMBO[1], T. ALONGE[1], B. BUTLER[1], C. APPADOO[1], J. GOODWIN[2], S. BUCH[3], H. KHOSHBOUEI[1];
[1]Neurosci., Univ. of Florida, Gainesville, FL; [2]Univ. of Texas Med. Br., Galveston, TX; [3]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: HIV-1 contributes to cognitive and behavioral decline in infected individuals, in part, through the production of HIV-1 transactivator of transcription (Tat) protein. While antiretroviral agents reduce viral load, they do not eliminate the production of Tat and thus are ineffective against neuropathologies caused by HIV-1. Specifically, the Tat protein has been shown to play a critical role in perturbations of the dopamine neurotransmission in the brain. In addition, there also exists a high comorbidity between HIV-1 infection and methamphetamine (METH) abuse. Both the Tat protein and METH exert their effects through the dopamine transporter (DAT). DAT is a major regulator of extracellular dopamine and thus dopamine neurotransmission in the

brain and it is implicated in neurological and neuropsychiatric disorders such as Parkinson's disease and drug addiction. Recent reports suggest the Tat protein enhances METH-induced impairment of dopamine transmission, albeit with a less understood mechanism. Under control conditions, METH increases the DAT-mediated inward current, increases the spontaneous firing activity of dopaminergic neurons and increases DAT-mediated DA efflux. However, we found that intracellular Tat-101(200ng/ml) protein attenuated basal and METH (10μM) induced DAT-dependent DA efflux, in both bath solution or delivered directly into the dopamine neurons via the patch electrode. Furthermore, we found intercellular Tat-101 significantly decreases METH-induced inward current, supporting the hypothesis that Tat-101 might affect ionic permeability of DAT regulating dopamine neurotransmission. Consistent with previous reports we found methamphetamine or Tat-101 alone decreases dopamine uptake, while pretreatment of DAT cells with 100 nM Tat for 15 minutes synergistically decreases dopamine uptake. Previously we have shown DA efflux via DAT is regulated by intracellular calcium and its associated kinases including Calcium calmodulin-dependent protein kinase II (CaMKII) and Protein Kinase C (PKC). Currently we are examining the hypothesis that Tat-101 regulates DAT activity by regulating intracellular calcium homeostasis and signaling molecules such as PKC and CaMKII. These preliminary findings provide mechanistic insight involved in the combined deleterious effects of HIV-1 Tat and methamphetamine in the brain with the ultimate goal of testing novel therapeutics.

Title: Role of interaction between the Dopamine Transporter and G protein βγ subunits in amphetamine-induced hyperlocomotion

Authors: ***J. C. MAUNA**[1], M. R. MARKS[1], N. ARIAS[1], T. B. BAUST[1], S. HARRIS[1], G. E. TORRES[1,2], E. THIELS[1,3,4];

Abstract: Dopamine (DA) plays a crucial role in several brain functions, including locomotion and motivated behavior. Consequently, DA deregulation contributes to the development of a number of brain disorders such as ADHD, Parkinson's disease, and drug addiction. The primary mechanism used by neurons to maintain extracellular levels of DA is reuptake of the transmitter through the Dopamine Transporter (DAT). DAT is a symporter protein that uses the sodium gradient to pump DA back into the presynaptic terminal. It was shown that amphetamine reverses DAT directionality, causing a massive efflux of DA into the extracellular space. The molecular mechanism by which DAT works in reverse is poorly understood. Recently, our laboratory identified a novel interaction between the intracellular carboxy terminal region of DAT and G protein βγ subunits. Experiments in cells in culture demonstrate that activation of Gβγ subunits induces DA efflux similar to that observed with amphetamine. Here, we examined the effect of pharmacological manipulation of Gβγ subunits on amphetamine-induced locomotor activity and on DAT/Gβγ interaction *in vivo*. Adult rats received bilateral infusions into the nucleus accumbens (NAc) of either the Gβγ activator mSIRK, scrambled mSIRK peptide (control), the Gβγ inhibitor gallein, or vehicle solution (control) before being injected i.p. with either amphetamine (3mg/kg), cocaine (20 mg/kg), or physiological saline (control). Activity in an open-field chamber was monitored before and after drug treatment. We found that neither the Gβγ activator nor the Gβγ inhibitor alone (saline-injected controls) had an effect on locomotor activity compared to the respective control groups. In sharp contrast, the Gβγ activator markedly enhanced amphetamine-induced hyperlocomotion, whereas the Gβγ inhibitor significantly attenuated it. Different from the Gβγ activator's effect on amphetamine-induced hyperlocomotion, the activator had no effect on cocaine-induced hyperlocomotion. Because cocaine blocks DAT whereas amphetamine reverses DAT directionality, these data suggest that amphetamine's actions on DAT are mediated through Gβγ interaction with DAT. To test this idea directly, we treated rats as described above and harvested striatal tissue for co-immunoprecipitation of DAT and Gβγ subunits. We found that amphetamine increases the interaction between DAT and Gβγ and that prior intra-NAc infusion of the Gβγ inhibitor attenuates this effect. Taken together, our results identify Gβγ subunits as a novel mechanism in the regulation of amphetamine actions *in vivo*.

Title: State-dependent protein interactions with the presynaptic serotonin transporter

Authors: *M. A. QUINLAN[1], R. YE[1,2], Q. HAN[1], S. RAMAMOORTHY[4], R. D. BLAKELY[1,2,3];
[1]Pharmacol., [2]Silvio O. Conte Ctr. for Neurosci. Res., [3]Psychiatry, Vanderbilt, Nashville, TN; [4]Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Disruptions in serotonin (5-hydroxytryptamine, 5-HT) signaling have been implicated in multiple neurological disorders, including depression, autism and schizophrenia. The antidepressant-sensitive 5-HT transporter (SERT, SLC6A4) affords powerful control over 5-HT signaling via rapid clearance of 5-HT from the extracellular space. Evidence suggests that SERT responds to intrinsic and extrinsic factors to modulate 5-HT uptake activity, regulating 5-HT availability. For example, systemic administration of lipopolysaccharide (LPS) in rodents shifts the transporter to a high-affinity state (SERT*), in a p38 MAPK dependent manner, promoting efficient clearance at low 5-HT concentrations. Recently, our lab identified a gain-of-function, autism-associate coding variant, SERT Ala56, and provided evidence that its conformations and insensitivity to PKG/p38 MAPK signaling are such as to suggest constitutive occupancy of the SERT* state. Interestingly, stimulation of kinase-linked pathways that alter SERT activity appears to also modulate SERT interacting proteins (SIPs). We hypothesize that SERT exists in multiple activity states, defined and mediated by distinct SIP complexes. Clearly defining the protein complexes of the different SERT conformational states will be useful in identifying possible drug targets to modulate SERT activity. However, identifying these macromolecular complexes is technically challenging as biochemical preparations of native SERT likely feature multiple such complexes that are difficult to follow independently. We developed a SERT Ala56 knock-in mouse model, providing access to an enriched pool of SERT* and a platform for the identification of proteins that differentially interact with the SERT* state *in vivo*. Using candidate and proteomic-based approaches, we are assessing differences between WT and SERT Ala56 SIPs, as well as whether these changes identified are paralleled by SIP changes obtained when comparing saline vs. LPS injected animals. Co-immunoprecipitation analysis reveals that previously reported SIPs, such as protein phosphatase 2A and syntaxin 1A, differentially associate with SERT Ala56 compared to wild-type SERT (WT). Ongoing studies seek to validate and characterize novel SIP interactions with the SERT* state and to relate these interactions to SERT trafficking/activation mechanisms *in vivo*.

Title: The betaine-GABA transporter (BGT1; slc6a12) may play its main roles in the liver rather than in the brain by help preserving choline levels in hepatocytes

Authors: *Y. ZHOU[1], K. CORBIN[2], Y. XIANG[3], W. ESKILD[3], S. ZEISEL[2], N. DANBOLT[1]; [1]Inst. of Basic Med. Science, Univ. of Oslo, Oslo, Norway; [2]Dept. of Nutr., UNC Nutr. Res. Inst., Kannapolis, NC; [3]Dept. of Biosci., Inst. of Mol. Biosci., Oslo, Norway

Abstract: The betaine/GABA transporter (BGT1; slc6a12) has received attention both as an osmolyte transporter in the kidney and as a potential controller of transmitter GABA in the brain. The expression of BGT1 in the brain, however, is low and is mostly limited to the leptomeninges suggesting a minor role in inactivation of GABA (Epilepsy Res 95:70-81). Most of the BGT1 protein turns out to be in the liver (Am J Physiol Renal Physiol 302:F316-28). Hepatocytes contain large amounts of betaine as well as betaine homocysteine S-methyltransferase (BHMT). This enzyme allows betaine to be used as a methyl donor. Hepatocytes can acquire betaine either by oxidizing choline to betaine, or by absorbing betaine (by means of transporters) from the portal blood. These observations make it important to determine (a) the precise localizations of BGT1 in the liver, (b) the contribution of BGT1 to the total betaine uptake, and (c) the importance of betaine uptake for hepatocyte betaine content and health. Here we have isolated cells from mouse liver (from both wildtype mice and BGT1-deficient mice). The cells were examined for BGT1 content (Western blots and immunocytochemistry) and for betaine uptake activity. BGT1 was detected only in hepatocytes and not in the other cell types found in the liver (Kuppfer cells, stellate cells and endothelial cells). The betaine uptake activity was significantly impaired in BGT1-deficient hepatocytes while GABA and choline uptake activities were unaffected in agreement with the notion that these compounds are primarily transported by other mechanisms. Further choline metabolites analysis showed that the livers from mice lacking

BGT1 had reduced concentrations of choline (78 ± 2 %; $p < 0.03$). **Conclusions**: BGT1 expression is limited to hepatocytes under normal physiological conditions. Deletion of BGT1 reduces the capacity of betaine transport by hepatocytes and affects the liver choline content possibly by increasing choline consumption.

Title: Differential effects of maternal and fetal genetic disruption of the serotonin transporter on placental and fetal brain biogenic amine function and thalamocortical axon pathway formation

Authors: *J. C. VELASQUEZ[1], E. HUGHES[2], K. FISH[2], E. EMERY[2], A. BONNIN[1], S. HEROD[2];
[1]Zilkha Neurogenetic Inst., Keck Sch. of Med. of USC, Los Angeles, CA; [2]Dept. of Biol. and Chem., Azusa Pacific Univ., Azusa, CA

Abstract: Serotonin (5-HT) is a monoamine neurotransmitter that is fundamental to brain development, and low circulating levels of 5-HT are associated with clinical psychopathologies including anxiety and depression. Interestingly, the placenta is a significant source of 5-HT to the fetus early in fetal development. It remains unclear whether hyposerotonemia in mothers with such pathologies might affect fetal brain development, either directly or through alteration of placental function. B6.129(Cg)-*Slc6a4*^{tm1Kpl}*/J* serotonin transporter knockout (SERT-KO) mice were used as a model of genetically-induced hyposerotonemia. Mice were bred heterozygous (HET) by HET to generate wildtype (WT), HET, and knockout (KO) experimental genotypes. Females of each genotype were bred with HET males, and fetal and placental tissue was harvested at four different timepoints during embryonic development (E12.5, E14.5, E16.5, E18.5). High performance liquid chromatography (HPLC) was used to measure concentrations of 5-HT and 5-HIAA, the main metabolite of 5-HT, present in fetal forebrains, hindbrains, and placentas across all maternal and fetal genotypic combinations. Results reveal an age-dependent influence of maternal and fetal genotypes on these parameters. At E14.5, a significant decrease of 5-HT concentration was observed in the KO placenta; a change driven by the maternal

genotype, independent of fetal genotype. The impact on fetal brain 5-HT was minimal, consistent with a placental (fetal origin) source of 5-HT to the fetus. In contrast, at E18.5 fetal brain 5-HT levels appeared to be driven by the genotype of the fetus, and not the mother, reflecting an impact of SERT function on the endogenous (fetal dorsal raphe) source of 5-HT. At both ages, absence of SERT function in either the mother or the fetus led to a decrease in 5-HIAA in the fetal brain, suggesting that 1) maternal blood 5-HT drives fetal brain levels of 5-HIAA, and 2) absence of SERT in the fetus affects fetal 5-HT metabolism. In addition, immunohistochemical analyses of fetal brains were performed by co-staining for 5-HT and Netrin-G1a (NetG1), a marker of developing thalamocortical axons (TCAs). Initial analyses of fluorescent imaging of WT and KO fetal brains at E14.5 from the same HET mother showed no differences in the 5-HT neuronal localization. However, NetG1 staining in the KO revealed decreased fasciculation of TCAs in the midbrain region as compared to WT. These results suggest that even small alterations of 5-HT metabolism in the forebrain can alter the early phase of TCAs pathfinding and/or TCAs expression of NetG1.

Title: Organic cation transporter 3 (OCT3) and plasma membrane monoamine transporter (PMAT) are increased in parietal cortex following chronic administration of citalopram

Authors: *J. C. MOLINARO[1], J. S. TALBOOM[1,2,3], M. ORCHINIK[1];
[1]Arizona State Univ., Tempe, AZ; [2]Banner Sun Hlth. Res. Inst., Sun City, AZ; [3]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: The activity of extracellular monoamine neurotransmitters in the brain can be regulated not only by the uptake of presynaptic transporters that have high affinity for a single neurotransmitter, but also by lower affinity “polyspecific” transporters which can take up several different neurotransmitters. Among these polyspecific neurotransmitters are the organic cation transporter 3 (OCT3) and the plasma membrane monoamine transporter (PMAT), both of which

appear to be widespread in the human and rodent brain. OCT3 and PMAT are each capable of transporting serotonin, and OCT3 has been reported to be increased in the brains of mice lacking the serotonin transporter. We hypothesized that these transporters might compensate for increased serotonin levels produced by selective serotonin reuptake inhibitor (SSRI) antidepressant drugs and might thereby mitigate the efficacy of SSRIs. To test this hypothesis, we investigated if chronic SSRI administration causes changes in OCT3 and PMAT protein levels in the hippocampus and parietal cortex as these brain regions have been implicated in the behavioral changes induced by SSRI drugs. Young adult male Sprague-Dawley® rats were administered either the SSRI citalopram, or vehicle, for 28 days via subcutaneous Alzet® mini-osmotic pumps at a dosage of 10/mg/kg/day. This dose has been shown to result in plasma serum levels of citalopram comparable to that of human serum levels during citalopram pharmacotherapy and corresponds to the typical length of pharmacotherapy required for the development of therapeutic effects. Western blots showed that OCT3 and PMAT protein levels were both significantly increased in the parietal cortex of rats given citalopram compared to controls, although OCT3 and PMAT levels were unchanged in the hippocampus. Increases in these transporters could attenuate the behavioral effects of SSRIs. On the other hand, since OCT3 is inhibited by physiological levels of corticosteroids (CORT), this might represent a mechanism through which SSRIs alter neuronal-sensitivity to CORT or affect the stress response. Future investigations will test if there is an interaction between SSRIs, polyspecific transporters in the cortex, and behavior.

Title: Transgenic mouse model to selectively identify alpha$_3$ Na,K-ATPase expressing cells in the nervous system

Authors: ***M. DOBRETSOV**[1], D. D. PIERCE[2], K. E. LIGHT[3], N. T. KOCKARA[4], M. KOZHEMYAKIN[5], P. A. WIGHT[4];

[1]Anesthesiol., [2]Pharmaceut. Sci., [3]Pharnaceutical Sci., [4]Physiol. and Biophysics, [5]Neurol., Univ. Arkansas Med. Sci., Little Rock, AR

Abstract: The α_3 Na^+,K^+-ATPase (α_3 NKA) is one of four known α isoforms of the mammalian transporter. A deficiency in the α_3 NKA associates with severe impairment of movement control, and in some cases, seizure disorder. Understanding the pathogenesis of these disorders is limited by incomplete knowledge of the expression of the various isoforms in brain tissue, as well as the challenges in exploring the functional alterations of these isoforms in electrophysiological studies. To address this problem, a 1,758-bp fragment of the mouse α_3 subunit gene (*Atp1a3*) for Na^+,K^+-ATPase, which encompasses the promoter and 5′-untranslated region, was fused to a promoterless ZsGreen1 reporter gene, and α_3 NKA-ZsGreen1 transgenic mice were generated in the C57BL/6 genetic background. Founder mice were bred to C57BL/6 wild-type (WT) mice, and three transgenic lines were established. Expression of ZsGreen1 does not interfere with expression of the endogenous α_3 subunit of NKA as evidenced by normal growth, phenotype and breeding capacity of α_3 NKA-ZsGreen1 mice in our colonies. Transverse and sagittal sections of whole brain from five adult transgenic mice were analyzed. Consistent with published results on α_3 NKA distribution, the display of ZsGreen1-labeled neurons varied considerably (non-uniform), with highest density observed in hypothalamic, midbrain, pontine, brain stem, deep cerebellar and select thalamic nuclei. Intensively labeled neurons were also present in the cerebellar cortex, neocortex, and hippocampus. ZsGreen1-labeling was not observed in glial cells or white matter-enriched brain regions. In electrophysiological experiments, discharges of ZsGreen1-labeled hippocampal interneurons were sensitive to 1 μM ouabain (a concentration too small to inhibit rodent α_1 NKA), while non-fluorescent interneurons did not show this sensitivity. Thus, the α_3 NKA-ZsGreen1 transgenic mice model constitutes a novel and versatile tool to elucidate the properties, regulation, and functional significance of α_3 NKA in its native environment. Identification of functional α_3 NKA-expressing neurons *in situ* simplifies electrophysiological and biophysical studies addressing the discharge properties of these neurons, as well as provides a means to study the biophysical properties of the transporter and understand its spatiotemporal regulation under normal and pathological conditions. Title: Generation and characterization of BAC transgenic GABA transporter 2 (GAT2; slc6a13) tdTomato reporter mice

Authors: *N. C. DANBOLT[1], Y. ZHOU[1], J. XU[2], B. S. KHAKH[2];
[1]Univ. of Oslo, Oslo, Norway; [2]Physiology, David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: Background: GABA transporters 1 and 3 (GAT1 and GAT 3) are known for their functions in uptake of the neurotransmitter GABA in the central nervous system, but less is known about the function of GAT2. We have recently reported that GAT2 acts as a taurine transporter in both peripheral organs and in the brain (Journal of Biological Chemistry 287, 35733-46). We reasoned that generation of GAT2 reporter mice would advance the study of GAT2 expression and distribution as well as permit detailed study of the cells where it is expressed. GAT2-tdTomato reporter mice were generated by bacterial artificial chromosome (BAC) mediated transgenesis. Since BACs are about 200 kb, they should retain the transcriptional regulatory elements that regulate GAT2 expression and thus GAT2-tdTomato reporter mice should faithfully report GAT2 endogenous expression by virtue of the orange/red fluorescence of tdTomato. Here, we test this by comparing the distribution of tdTomato in GAT2-tdTomato reporter mice with the distribution of GAT2 immunoreactivity (using GAT2 knockout mice as negative controls). The GAT2-tdTomato transgenic mice were viable and fertile. Neither abnormal behavior nor abnormal brain amino acid composition was observed. In adult mice, we found tdTomato expression in hepatocytes and proximal tubules as well as in the leptomeninges and some cerebral blood vessels. **Conclusions**: The GAT2-tdTomato mice faithfully report the expression patterns of GAT2. These mice will be useful in studies of GAT2 in liver, kidney and leptomeninges.

Title: GABAA receptor activation in newborn male rats modifies the developmental profile of NKCC1, KCC2 and alpha1 and gamma2 GABAA receptor subunits in entorhinal cortex

Authors: *J. MURGUIA CASTILLO[1], M. E. UREÑA-GUERRERO[1], S. A. OROZCO-SUAREZ[2], C. BEAS-ZÁRATE[1], A. I. FERIA-VELASCO[1];
[1]Univ. De Guadalajara (CUCBA), Zapopan, Jalisco, Mexico; [2]Unidad de Investigación Médica en Enfermedades Neurológicas, Hosp. de Especialidades, CMN Siglo XXI, IMSS, Mexico, Mexico

Abstract: GABA is considered as the main inhibitory neurotransmitter in adulthood, but it can induce neuronal depolarization and excitation during early development of the brain. Both, GABA-mediated inhibition and excitation depend on the GABAA receptor (GABAA-R) activation, which mainly promotes facilitated diffusion of chloride (Cl-). NKCC1 acts as Cl- importer and is highly expressed when GABA induces neuronal depolarization, whereas KCC2 operates as Cl- exporter and it is expressed in neurons to reach the establishment of the GABA-mediated inhibition. *In vitro* studies have been suggested that in early developmental stages, the GABA-mediated neuronal excitation increases the KCC2 expression and improves the neuronal inhibitory response to the GABA application. In this work, an *in vivo* GABAA-R activation was induced in newborn male Wistar rats through the subcutaneous (s.c.) administration of muscimol (1 mg/kg of body weight) at postnatal day (PD) 0. After the treatment, the expression levels of NKCC1, KCC2, and alpha1 and gamma2 GABAA-R subunits were estimated in entorhinal cortex at PD1,3,5,7,9,11,13,15,21,30,60, 90 and 120 using western-blotting assays. The muscimol treatment modified the developmental profile of all proteins studied. Briefly, the expression peak of NKCC1 protein observed at PD11 in the control group was not observed after muscimol treatment. However, after the treatment, the expression of NKCC1 increased gradually to reach lightly higher levels than control group from PD30 to PD120. In respect to KCC2 protein, muscimol treatment increased significantly its expression at PD9-120, reaching its maximal level at PD15 in four fold higher respect to control group and before the expression peak observed at PD30 in control group. Similarly, the expression peak for alpha1 GABAA-R subunit and the maximal expression level for gamma2 GABAA-R subunit, both observed at PD21 in the control group, were observed before in the muscimol treated group at PD13. Results suggest that the early activation of GABAA-R with muscimol modifies the developmental profile expression of NKCC1, KCC2 and alpha1 and gamma2 GABAA-R subunits in male entorhinal cortex, in a way where GABA-mediated inhibitory signaling could be improved in magnitude and in its time for establishment, which should be better characterized.

Title: An allosteric mechanism for lipid inhibition of glycine transporter 2

Authors: ***R. J. VANDENBERG**[1], S. MOSTYN[2], J. E. CARLAND[2], R. M. RYAN[2];
[2]Pharmacol., [1]Univ. Sydney, Sydney, Australia

Abstract: The glycine transporter, GlyT2, is the target for a number of drugs that can alleviate neuropathic and inflammatory pain. We have identified a series of lipids that inhibit GlyT2 and also show promise as leads for the development of a novel class of analgesics. The three lipids that show highest affinity and efficacy are N-Arachidonyl-Glycine (NAGly), N-Oleoyl-Glycine (NOGly) and Oleoyl-L-Carnitine (OLCarn). All three lipids are non-competitive inhibitors and are unlikely to bind at the substrate binding site. We have investigated the mechanism of inhibition by first constructing a homology model of GlyT2 based on the crystal structures of the related bacterial amino acid transporter, LeuT, and the *drosophila* melanogaster dopamine transporter, dDAT. We then used site-directed mutagenesis to selectively disrupt the inhibitory actions of the lipids, whilst retaining glycine transport function. Mutations in four distinct regions of the protein influence lipid potency and efficacy, extracellular loop 4 (EL4), transmembrane domain 7 (TM7), TM8 and the substrate binding site . EL4 undergoes considerable conformational changes during the transport cycle, and the I545L mutation at the apex of this loop disrupts inhibition by all three lipids. This site is unlikely to form a lipid binding site, but it may influence the conformational changes of the protein. We reasoned that the transmembrane domains flanking EL4, TM7 and TM8, may also influence the conformational changes required for lipid inhibition. The L569F mutation on the membrane-exposed surface of TM8 reduced the potency of OLCarn and NOGly, but had no effect on NAGly. This suggests that TM8 may influence lipid tail interactions. The F515Y mutation in TM7 caused an increase in both potency and efficacy of all three lipids. Finally, we investigated

how disruptions in the substrate binding site may alter lipid activity. The S479G mutation relaxes the substrate selectivity to also allow sarcosine to be transported, and also reduces the potency of all three lipids. No other mutations in the substrate binding sitealtered lipid inhibition. We propose a model where the lipids bind to the external membrane-exposed surface of the transporter, which then alters the conformational changes in EL4 and disrupts substrate interactions, causing a reduced rate of transport.

Title: Regulation of cation-chloride cotransporters by N-methyl-D-aspartate receptors

Authors: *J. CHEVRIER, V. MAHADEVAN, M. WOODIN;
Cell & Systems Biol., Univ. of Toronto, Toronto, ON, Canada

Abstract: The strength of gamma-aminobutyric acid (GABA)-mediated inhibitory synaptic transmission is determined by the electrochemical gradient of chloride across the plasma membrane. Within the electroneutral family of transmembrane cation-chloride cotransporters (CCCs), NKCC1 and KCC2 are the primary transporters responsible for regulating chloride transport in the central nervous system. In immature neurons, NKCC1 expression predominates and mediates chloride influx, resulting in high intracellular chloride ([Cl-]i) and depolarizing GABA potentials. In mature neurons, the chloride-extruding transporter KCC2 is upregulated and maintains low [Cl-]i, which is required for hyperpolarizing GABAergic inhibition. Recently, excitatory kainate-type glutamate receptors (KARs) were observed to post-translationally regulate KCC2 expression and function by physical interaction. In the present study, we used biochemical techniques to investigate the regulation of KCC2 and NKCC1 by another class of glutamate receptors: N-methyl-D-aspartate receptors (NMDARs). Previously, the Ca2+-dependent protease calpain was found to cleave KCC2 and attenuate its function upon pathophysiological NMDAR activation. *In vivo* and in heterologous expression systems, our immunoprecipitation assays revealed that NMDAR subunits interact with KCC2 and NKCC1 in a developmentally-dependent manner. These interactions between excitatory ionotropic glutamate receptors and inhibitory cation-chloride cotransporters suggest the existence of a

functional glutamate-dependent complex capable of regulating local neuronal chloride homeostasis.

Abstract: Seizures caused by hyper-excitable neurons can be alleviated by enhanced inhibitory neurotransmission via GABAergic signalling. The inhibitor N-[4,4-bis(3-methyl-2-thienyl)-3-butenyl]-3-hydroxy-4-(methylamino)-4,5,6,7-tetrahydrobenzo[d]isoxazol-3-ol (EF1502) targeting GAT1 and BGT1, exerts a synergistic anticonvulsant effect in several mouse seizure models when tested in combination with GAT1-selective compounds. BGT1-selective compounds that can enter the brain are limited, however, a newly developed compound in our laboratories, (1*R*,2*S*)-2-((4,4-bis(3-Methylthiophen-2-yl)but-3-en-1-yl)(methyl)amino)cyclohexanecarboxylic acid (SBV-114), seems to fulfil these criteria. A pharmacological characterization of SBV-114 was performed using the [^{3}H]GABA uptake assay in recombinant HEK293 cells stably expressing mouse GABA transporters (GAT1-3 or BGT1), tsA cells transiently expressing human BGT1 and MDCK cells endogenously expressing BGT1. The anticonvulsant activity and motor impairment of SBV-114 were examined using the audiogenic seizure-susceptible Frings mouse, and the scPTZ-induced seizure threshold test, maximal electroshock seizure (MES) test and Rotarod test in the CF-1 mouse. SBV-114 inhibited mouse BGT1 with a biphasic inhibition profile (27% and 60% uptake-inhibition at the low (4.0μM) and high (411.3μM) IC_{50}, respectively). SBV-114 displayed negligible inhibitory activity at GAT1-3 (IC_{50}>1,000μM). The biphasic inhibition profile was also observed at the

human BGT1 and in MDCK cells. The profile was neither due to kinetic differences between SBV-114 and GABA (no profile change after 10 minute pre-incubation) nor to differences in expression levels of BGT1 across cell types. Interestingly, the calcium chelator BAPTA-AM converted the biphasic profile into a monophasic inhibition profile, indicating that the biphasic behaviour of SBV-114 is Ca^{2+}-dependent. When administered systemically, SBV-114 displayed anticonvulsive effects in the audiogenic seizure (50 and 120mg/kg) and MES test (ED_{50}=139mg/kg), but was unable to block seizures induced by scPTZ(150mg/kg). SBV-114 (150mg/kg) did not cause any motor impairment at doses tested. We report that SBV-114, a novel GABA-analogue, is a BGT1-selective compound with a unique biphasic inhibition profile at recombinant transporters and anticonvulsant properties in mouse seizure models.

Title: Suprachiasmatic nucleus chloride cotransporter (nkcc1) regulation of behavioral circadian rhythms

Authors: *J. K. MCNEILL, IV[1], J. C. WALTON[2], H. E. ALBERS[2];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: γ-aminobutyric acid (GABA) and ionotropic GABAA receptors are expressed throughout the suprachiasmatic nucleus (SCN); the location of the master circadian pacemaker. Evidence from our lab shows that acute activation of GABAA receptors (GABAARs) inhibits the phase shifting effects of photic cues and promotes the phase shifting effects of non-photic cues. More recently, we have shown that the sustained activation of GABAARs can mimic the phase delaying effects of light and that the sustained inhibition of GABAARs can inhibit the phase delaying effects of light. Although GABA is most commonly described as the primary

inhibitory neurotransmitter in the CNS, *in vitro* studies suggest the presence of excitatory GABAA responses in the adult SCN. The ratio of inhibitory to excitatory responses to GABAAR binding depends on chloride ion gradients as maintained by chloride co-transporters. Importantly, excitatory GABA responses in the adult SCN disappear upon inhibition of the inward chloride co-transporter, Na+/K+/Cl- co-transporter 1 (NKCC1). We have previously shown that the sustained inhibition of NKCC1 enhances phase delays to light. The following experiments aimed to further characterize the role of chloride co-transporter activity in behavioral entrainment. Adult male Syrian hamsters were housed in constant dark conditions until the formation of stable free-running activity rhythms. Hamsters received injections of bumetanide (a NKCC1 inhibitor) or vehicle into the SCN region followed by phase delaying (CT 13.5) or advancing (CT 19) light pulses. Phase shifts were calculated using regression lines fitted to activity onsets before and after test days. Acute NKCC1 inhibition did not alter the magnitude of light-signaled phase delays. However, NKCC1 inhibition in the late subjective night decreased the magnitude of photic phase advances and when injected alone led to substantial phase delays. These data suggest that endogenous excitatory SCN responses to GABA in the late subjective night may advance the behavioral rhythm.

Title: Functional consequences of a loss-of-function mutation in the SLC39A8 (ZIP8) gene in NMDA receptor signaling

Authors: ***M. L. WEBER**[1,2], P. O'DONNELL[1,2], T. A. LANZ[1,2], V. REINHART[1,2], D. L. BUHL[1,2], D. BERTRAND[4], C. R. SCHUBERT[1,3];
[1]Pfizer Worldwide Res. & Dev, Cambridge, MA; [2]Neurosci. & Pain Res. Unit, [3]Pharmatherapeutics Clin. Res., Pfizer, Cambridge, MA; [4]HiQscreen, Geneva, Switzerland

Abstract: The trace element zinc (Zn2+) is found in most all tissues throughout the body, including the CNS, and is known to modulate a variety of ligand- and voltage-gated ion channels such as NMDA, GABAA, calcium, and potassium channels. In the CNS, Zn2+ concentration is highly regulated in cells and at the synapse by a number of transporters including ZnT and ZIP transporters. Zn2+ may be best known for its potent (low nM) inhibition of NMDA receptors,

specifically allosteric modulation of GluN2A subunit-containing receptors. Genome wide association studies on schizophrenia patients have recently implicated a mutation (A391T) in the SLC39A8 gene, which encodes the ZIP8 Zn2+ transporter. Our data show that this mutation, which resides in a coding region, results in a partial loss-of-function in the Zn2+ transport (or see SFN poster - Schubert & Bertrand). To elucidate the role of ZIP8 in NMDA-mediate currents at the synapse, we created SLC39A8 shRNA to selectively knock down ZIP8-mediated Zn2+ transport in primary rat cortical co-cultures and measured NMDA-mediated current density in pyramidal neurons using whole-cell patch clamp. Following ~75% ZIP8 mRNA knockdown measured by RT-PCR, we observed an apparent paradoxical increase in NMDA current density. In another set of studies measuring spontaneous synaptic activity (sEPSCs) in rat cortical neurons, we observed a decrease in NMDAR-mediated sEPSC amplitude after ZIP8 shRNA knockdown, indicating that loss of the ZIP8 transporter at cortical synapses has a negative effect on glutamatergic signaling. We hypothesize that this mutation is a loss-of-function in ZIP8-mediated transport, impairing Zn2+ uptake and contributing to NMDA receptor hypofunction observed in schizophrenia.

Title: Developmental expression patterns of KCC2 and functionally-associated molecules in the human brain

Authors: M. PUSKARJOV[1], G. SEDMAK[2], N. JOVANOV-MILOŠEVIC[2], M. ULAMEC[3], B. KRUŠLIN[3], *K. KAILA[1], M. JUDAŠ[2];

Abstract: Work on rodents has shown that steep up-regulation of KCC2, a neuron-specific Cl-extruder of the SLC12 cation-chloride cotransporter (CCC) family, commences in supraspinal structures at around birth, leading to the establishment of hyperpolarizing GABAergic responses. KCC2 is also a structural protein necessary for spinogenesis in cortical principal cells. Here, we describe the spatiotemporal expression profiles of the entire SLC12 gene family, using microarrays, in the human cerebrum, thalamus and cerebellum. Translation of KCC2 was validated by immunohistochemistry. KCC2 mRNA was observed already at the 10th postconceptional week (PCW) in the amygdala, cerebellum and thalamus. KCC2-immunoreactive neurons were abundant in the neocortical subplate at 18 PCW. Commencing at 19-24 PCW, most subplate and cortical plate neurons became KCC2-positive by 25 PCW. The mRNA expression profiles of Na-K ATPase α and β isoforms as well as TrkB were consistent with what is known from studies on rodents about their interactions with KCC2. Thus, in the human brain, expression of KCC2 and its functionally-associated proteins begins in the early fetal period. Our work facilitates translation of results on CCC functions from animal studies to the human and, more specifically, refutes the view that the poor efficacy of anticonvulsants in the term human neonate is attributable to a lack of KCC2.

Title: Deciphering ZIP8 activity using an electrophysiology reporter assay

Authors: *C. R. SCHUBERT[1], T. D. HELTON[3], J. A. ALLEN[2], J. R. WENDLAND[2], P. O'DONNELL[2], D. BERTRAND[4];

Abstract: Zinc (Zn^{2+}) is the second most important metal ion in the body, and its tight regulation is a key element in the functioning of the central nervous system. Best known for its intracellular

modulation of many biochemical events, including the regulation of transcription or modulation of enzymes, Zn^{2+} also plays an important role in the modulation of ion channels such as N-methyl-D-aspartic acid receptors (NMDA), gamma-aminobutyric ($GABA_A$) ligand-gated receptors, or voltage-gated calcium channels (VGCC). To date, Zn^{2+} activity has been monitored mainly using radioactive or fluorescent measurements, both methods with intrinsic limitations. The observation that activity of the voltage-gated calcium channel $Ca_v1.2$ is exquisitely modulated by intracellular Zn^{2+}, however, offers novel possibilities to investigate Zn^{2+} activity using an electrophysiological reporter assay. Here, we investigate at the single cell level properties of the zinc transporter *SLC39A8* (ZIP8) and its naturally occurring mutant A391T that was found to be associated with schizophrenia (Schizophrenia Working Group of the Psychiatric Genomics Consortium, 2014). Monitoring ZIP8 activity using $Ca_v1.2$ as a reporter assay revealed that increase in the submicromolar range of Zn^{2+} in the extracellular fluid is sufficient to trigger a rapid inhibition of calcium channel activity. These findings indicate that augmentation of the intracellular Zn^{2+} occurs with a time constant in the seconds range and reveals both the efficiency of ZIP8 activity and its sensitivity to Zn^{2+}. In addition, these data also demonstrate the functional relevance of intracellular free Zn^{2+} on ion channel activity. Measurements conducted at the naturally occurring ZIP8 mutant A391T confirmed that this mutation alters Zn^{2+} transport that could, at least in part, be contributing to the origin of neuropsychiatric disorders. Offering several advantages, the use of a voltage-gated ion channel as reporter assay for the intracellular Zn^{2+} concentration allows for the first time to investigate the role of this divalent cation in the vicinity of the plasma membrane. Placed in perspective of intracellular recordings conducted *in vitro* and *in vivo*, this work illustrates the determinant role of this often neglected metal ion and its possible contribution in the manifestation of neuropsychiatric and neurological diseases.

Title: SorLA trafficking in physiological barriers

Authors: ***M. S. NIELSEN**[1], S. C. KLINGER[1], A. HØJLAND[1], P. MADSEN[1], J. BONIFACINO[2];
[1]Univ. of AARHUS, Aarhus, Denmark; [2]NIH, Washington, DC

Abstract: Cells throughout the body are polarized in order to achieve and support the specialized functions of the organs. Epithelial and endothelial cells are essential in maintaining the barriers separating different parts of the body, like the brain endothelial cells in the blood-brain barrier, epithelial cells in plexus choroideus and epithelial cells in the intestine. Cells like astrocytes and neurons are polarized having end-feet, axons and dendrites. To generate and maintain polarized structures, cells express a subset of specialized cytosolic adaptor proteins that facilitates asymmetric trafficking of receptors and their cargo. The adaptor proteins bind to motifs in the cytosolic domain of the receptors, thereby guiding them to their appropriate polarized cellular destination The Vps10p domain receptor SorLA, is a type I sorting receptor that harbors several functional adaptor binding motifs in its short cytosolic domain. Using MDCK cells as an epithelial model and primary hippocampal neurons, we have demonstrated that SorLA displays a polarized localization in these cell types. In a tight epithelial MDCK cell barrier, SorLA is localized on the basolateral membrane from where it is sorted to apically-localized endosomes. Using antibodies, we have furthermore demonstrated that SorLA mediates transcytosis across the MDCK barrier. In neurons, SorLA is localized throughout the dendrites but not found the axons. Using yeast 2-hybrid screens and expression of cytosolic mutated SorLA constructs, we are now mapping the sites and some of the adaptor proteins involved in polarized localization and sorting. Although there are some redundancies in the signals, preliminary results points to an extended acidic cluster in SorLA as the main actor in the observed polarized sorting. In addition, we find that the adaptor complex AP-1 is involved in the asymmetric sorting. Although there is evidence that epithelial and endothelial cells as well as neurons use a similar cytosolic sorting machinery to orchestrate polarized organizations, there are also some differences. We have recently found that SorLA is expressed in primary brain endothelial cells and we are currently investigating whether SorLA shows a similar polarized trafficking in these cells.

Title: Calcium dynamics in boutons of layer V pyramidal neurons in the rat somatosensory cortex

Authors: *L. TRAN[1], C. STRICKER[1,2];
[1]Eccles Inst. of Neurosci., The Australian Natl. Univ., Canberra, Australia; [2]ANU Med. Sch., Canberra, Australia

Abstract: In response to stimulation, a transient rise in intracellular [Ca^{2+}] causes transmitter release from presynaptic terminals. As presynaptic Ca^{2+} dynamics can affect the efficacy, reliability, and plasticity of synaptic connections, it is essential to understand Ca^{2+} homeostasis in nerve terminals. **Objective:** Ca^{2+} dynamics associated with action potentials (APs) was investigated in boutons of layer V pyramidal neurons in the rat somatosensory cortex. **Methods:** Brain slices were obtained from male Wistar rats (P15-20). Layer V pyramidal cells were filled through the patch pipette with Alexa Fluor 568 (50 μM) and various concentrations of Oregon Green 488 BAPTA-1 (OGB-1, K_D = 205 nM; 40, 80, 120, 240 μM) or OGB-6F (K_D = 3 μM; 50, 100, 200 μM). Imaging was done at 35 ± 1 °C, using a laser-scanning confocal microscope equipped with a 40x 1.0 NA objective. For each bouton, three increases in [Ca^{2+}] were measured: one evoked by an AP and two by AP trains of different frequencies (OGB-1: 10-40 APs at 10-40 Hz, OGB-6F: 60-80 APs at 80-100 Hz). APs were evoked with 2 ms somatic current injections. [Ca^{2+}] increases caused by AP trains were used to determine the maximal fluorescence at saturating [Ca^{2+}]. All calculations of [Ca^{2+}] from fluorescence intensity were done according to a published method (1). **Results:** Analysis of Ca^{2+} transients measured from fluorescence of OGB-1 and OGB-6F under steady-state conditions (> 90 min after break-in) shows similar results (p = 0.1-1.0); thus, data with these two dyes are pooled (94 boutons, 34 cells). The free volume-averaged [Ca^{2+}] is 43 ± 7 nM at rest and rises by 820 ± 320 nM immediately after an AP. The ratio of endogenous buffer-bound Ca^{2+} to free Ca^{2+} measured under steady-state conditions is 66 ± 27, similar to that measured during OGB-1 loading (< 60 min after break-in; 73 ± 19, 9 boutons, 9 cells). This suggests that the majority of endogenous buffers in these boutons are fixed, while mobile buffers contribute minimally. In addition, the total [Ca^{2+}] increase immediately after an AP is calculated to be 55 ± 31 μM, corresponding to influx through 20 ± 10 voltage-gated Ca^{2+} channels. The decay time constant of Ca^{2+} transients evoked by an AP is 37 ± 15 ms, indicating an extrusion rate of 1800 ± 1000 s^{-1}. These values for Ca^{2+} increases, endogenous Ca^{2+} binding ratio, and clearance kinetics are similar to those in boutons of layer II/III pyramidal neurons (2). **Conclusion:** There exists a large variation in presynaptic Ca^{2+} dynamics. This may reflect target cell-specific differences in transmitter release properties. 1. M. Maravall, Z.F. Mainen, B.L. Sabatini, K. Svoboda, *Biophys. J.* **78**, 2655 (2000). 2. H.J. Koester and B. Title: Acute inhibition of the ubiquitin signaling system induces changes in the synaptic ubiquitome and alters synaptic transmission in mammalian neurons

Authors: *A. CAPUTO[1], K. M. MYERS[1], A. A. VASHISHT[2], Y. WU[3], J. WOHLSCHLEGEL[2], F. E. SCHWEIZER[1];
[1]Neurobio., [2]Biol. Chem., [3]Dept. of Anesthesiol., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: The ubiquitin signaling system (USS) regulates several cellular processes including synaptic development and physiology. Available data indicate that proteasomal degradation of synaptic proteins can profoundly impact synaptic function. Much less is known about the non-degradative roles of protein ubiquitination at the synapse. Here we show that in rat primary cortical neurons inhibition of *de novo* ubiquitination or inhibition of deubiquitination acutely and rapidly affect synaptic activity. In particular, we found that both inhibitions strongly augment the frequency of minis and drastically diminish the amplitude of evoked responses. To identify the molecular mechanisms involved, we used a quantitative proteomic approach in synaptoneurosomes derived from primary neurons. We thus defined a set of synaptic proteins that change their ubiquitination levels following acute USS inhibition. In addition, we validated some of the hits of our proteomic analysis and provide evidence that ubiquitination modulates synaptic transmission by affecting the levels of SNARE complexes, the microtubule cytoskeleton and the activity of CaMKII. Our results highlight new functions of protein ubiquitination at synapses and pave the way for a better understanding of the complex role of this post-translational modification in governing neuronal health and disease.

Title: G-protein beta-gamma subunits regulate synaptic vesicle exocytosis by cone photoreceptors

Authors: *M. VAN HOOK[1], Z. ZURAWSKI[2], H. E. HAMM[2], W. B. THORESON[1]; [1]Ophthalmology & Visual Sci., Univ. of Nebraska Med. Ctr., Omaha, NE; [2]Dept. of Pharmacol., Vanderbilt Univ. Med. Sch., Nashville, TN

Abstract: The earliest stages of visual processing in the vertebrate retina are under dynamic control by a variety of G-protein coupled receptors (GPCRs) that regulate gap junctional coupling, voltage-dependent currents, and synaptic transmission. As at other synapses, G-protein α subunit (Gα)-dependent signaling pathways act on voltage-gated Ca2+ currents (ICa) to regulate neurotransmitter release by rod and cone photoreceptors. Synaptic output can also be influenced by the G-protein βγ complex (Gβγ), which modulates ICa and K+ currents and can directly interact with the vesicle fusion machinery (SNARE complex). Because it is unknown whether or how Gβγ influences photoreceptor exocytosis, we tested for direct effects of Gβγ on synaptic transmission by cone photoreceptors in the vertebrate retina. Experiments were performed using whole-cell voltage-clamp recordings in vertical slices of retinas from tiger salamanders (Ambystoma tigrinum). We measured synaptic transmission using paired recordings of cones and post-synaptic horizontal cells and capacitance measurements from cones. Gβ1γ1 subunits (100 nM - 2 μM) were introduced directly into the cone via the whole-cell patch pipette. For control recordings, we boiled the Gβ1γ1 stock solution for >20 minutes before diluting to the working concentration. ICa was recorded with a P/8 leak subtraction protocol. Spontaneous glutamate transporter current amplitude and kinetics were measured to test for effects of Gβ1γ1 on quantal content and vesicle fusion mode. In paired whole-cell recordings, dialyzing cones with Gβ1γ1 caused a gradual, dose-dependent reduction (IC50 = 80 nM) in the cone-driven

responses recorded from post-synaptic horizontal cells. Consistent with an inhibition of vesicle fusion rather than vesicle glutamate content or a switch in fusion mode, Gβ1γ1 also caused a reduction in exocytosis measured with whole-cell capacitance recordings. Gβ1γ1 had no effect on quantal glutamate transporter current amplitude or kinetics, but did cause a slight reduction in spontaneous event frequency. The reduction in exocytosis was not the result of changed ICa properties, as Gβ1γ1 altered neither the amplitude nor voltage-dependence of cone ICa. The use of voltage-clamp recordings precluded potential effects of Gβγ on K+ currents from altering the presynaptic voltage-response. Thus, Gβγ subunits appear to inhibit exocytosis by cone photoreceptors by a mechanism downstream of ICa. This suggests that Gβγ subunits in photoreceptors can directly inhibit synaptic transmission by acting on the vesicle fusion machinery.

Title: Modulation of synaptic transmission by Gbetagamma: specificity of Gbeta and Ggamma to inhibitory adrenergic A2a receptor and SNARE

Authors: ***Y. YIM**[1], K. BETKE[1], H. MCDONALD[2], R. GILSBACH[3], Y. CHEN[4], K. HYDE[1], Q. WANG[4], L. HEIN[3], K. SCHEY[2], H. HAMM[1];
[1]Pharmacol., [2]Biochem., Vanderbilt Univ., Nashville, TN; [3]Univ. of Freiburg, Freiburg, Germany; [4]Univ. of Alabama at Birmingham Sch. of Med., Birmingham, AL

Abstract: The modulation of neurotransmitter exocytosis by activated Gi/o-type G-protein coupled receptors (GPCRs), such as the α_{2a} adrenergic receptor (α_{2a}-ARs), is a universal regulatory mechanism used both to avoid overstimulation and to influence circuitry. Upon the activation of α_{2a}-ARs, Gβγ are released to directly interact with soluble N-ethylmaleimide-

sensitive factor attachment protein receptor (SNARE) to inhibit neurotransmitter release. There are 5 Gβs and 12 Gγs, and it is not known whether specific Gβγs are activated by a given GPCR. Presynaptic α_{2a}-ARs in both adrenergic (auto α_{2a}-ARs) and non-adrenergic neurons (hetero α_{2a}-ARs) work in a similar manner to inhibit neurotransmitter release and have various physiological functions such as anesthetic sparing and working memory enhancement. It has been shown that synaptic regulatory mechanisms can go awry in various neurological disorders such as anxiety and working memory deficits. In this project, we are investigating whether autoreceptors in sympathetic neurons use the same Gβγ subunits as heteroreceptors in other neuronal types. We use several mice models including transgenic Flag-α_{2a}-ARs, knock-in HA-α_{2a}-ARs, and wild-type mice. The Gβγ specificity is determined by co-immunoprecipitating Gβγ with α_{2a}-ARs and SNARE from synaptosomes, followed by mass spectrometry analysis. We hypothesize that specific Gβγ subunits interact with activated auto- and hetero α_{2a}-ARs and inhibit exocytosis by interacting with SNARE. We have identified Gβ1, Gβ2, Gβ4, Gβ5, Gγ2, Gγ3, Gγ4, Gγ7, Gγ12, and Gγ13 which interact with α_{2a}-ARs and SNARE. Out of these G protein, Gβ2, Gγ4, and Gγ13 preferentially interact with activated auto α_{2a}-ARs. We found no difference in Gβγ specificity to SNARE following α_{2a}-ARs activation. Further understanding Gβγ specificity may offer new insights into the normal functioning of the brain, as well as better understanding of disease progression. The Gβγ-SNARE interaction may be a new therapeutic target to modulate exocytosis in neural disorders in combination with drugs targeted to Gi/o-type GPCRs.

Abstract: Old organelles can become a hazard for cellular function, due to the accumulation of damaged molecules. Mechanisms that measure organelle age, and prevent old organelles from participating in cellular reactions, are therefore necessary. The prevaling assumption is that organelles are funtionally employed in cells until degradation via damage response mechanisms. We have identified an additional mechanism, which measures the usage of synaptic vesicles and functionally inactivates them long before degradation. Using cultured hippocampal neurons, we found that newly synthesized vesicles are preferentially employed in neurotransmitter release. They recycle only ~270 times, over ~24 hours. During recycling they become contaminated with a molecule from the plasma membrane, which interferes with a vital component of the synaptic vesicle release machinery. This process renders the old vesicles less competent to release than their newly synthesised counterparts. The inactivation can be accelerated by increasing the activity of neurons, suggesting that the cell uses this mechanism to directly measure the number of times a vesicle has been used, rather than its age. The old vesicles are eventually targeted for degradation, but their functional inactivation precedes degradation by several days. We conclude that the contamination is a timing mechanism needed to ensure that old vesicles are not used in neurotransmitter release. Synaptic transmission is presumably too sensitive to tolerate accumulation of damage on synaptic vesicles until they can be recognised by classical damage response mechanisms, necessitating this additional functional inactivation.

Title: Intersectin1 is required for developmental enhancement of Ca^{2+}-dependent replenishment of the readily-releasable synaptic vesicles

Authors: *Y. YANG, A. SENGAR, J. AITOUBAH, S. EGAN, M. SALTER, L.-Y. WANG; The Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Intersectin1 (Itsn1) is an evolutionally conserved scaffold protein engaged in recruiting dynamin and other accessory proteins for clathrin-mediated endocytosis, and hence a key molecular substrate for the coupling between exocytosis and endocytosis. However, it remains unknown if Itsn1 is required for development of synaptic functions in mammalian central synapses. To address this issue, we examined synaptic properties of the developing calyx of Held synapse in the auditory brainstem from wild-type (WT) and Itsn1 knockout (KO) mice at different postnatal (P) stages (immature P8-10 vs mature P16-20). Immunohistochemical analyses showed that Itsn1 proteins co-localized with a presynaptic marker vGlut1 in WT synapses for both age groups but completely absent in Itsn1 KO synapses. By stimulating presynaptic axons, we found that deletion of Itsn1 had little effect on basal excitatory synaptic transmission or short-term depression (STD) as a result of depletion of synaptic vesicles (SVs) from the readily-releasable pool (RRP) in immature and mature synapses. In contrast, the fast Ca2+-dependent component of recovery from STD was selectively attenuated in mature Itsn1 KO synapses but remained unaltered in immature Itsn1 KO synapses. Surprisingly, blockade of the interactive partner of Itsn1, dynamin, with specific inhibitors did not slow down the recovery time course at the mature WT synapses. These results indicate that the fast Ca2+-dependent replenishment of SVs in the RRP to the depleted sites is mediated by distinct mechanisms at different developmental stages, being strongly enhanced by Itsn1-dependent and dynamin-independent signaling during synapse maturation.

Title: The role of synaptotagmin-1 C2B domain in synaptic vesicle docking in hippocampal neuron

Authors: *S. CHANG, T. TRIMBUCH, C. ROSENMUND;
Neurocure, Charité - Universitätsmedizin Berlin, Berlin, Germany

Abstract: Synaptotagmin-1 (Syt-1) is a Ca2+ sensor for neurotransmitter release. Whether it plays a role in vesicle docking remains unclear. While studies examining the ultrastructure of presynaptic terminal in Syt-1 knock-out (KO) mice using conventional chemical fixation show unaltered docked vesicle number (Geppert et al, 1999), those using the high-pressure freezing (HPF) for fixation show a 39%-50% reduction in docked vesicle number (Liu et al, 2009; Imig et al 2014). Using HPF technique, we indeed found that the docked vesicle number was reduced by 53% in Syt-1 knockout mass culture neurons, while the total number of vesicles within 100 nm of the active zone was not significantly altered. Furthermore, we utilized mutations in three regions of the C2B domain of Syt-1 that severely impair vesicle exocytosis by 70%-95% (Li et al 2006; Xue et al 2008; Nishiki et al, 2004) to investigate whether there is a link between exocytosis and vesicle docking. We expressed the mutant proteins in autapic/mass cultured Syt-1 KO hippocampal neuron, and surprisingly found that mutating either the residues at polybasic stretch (K325, K327) or at the bottom of the C2B domain (R398, R399) led to a reduction of docked vesicle by 49% to 63% compared to wild-type synapses. In contrast, while mutating residues for Ca2+ binding in the top loop (D309, D363, D365) did not affect vesicle docking. However, none of the mutants displayed a difference in the primed vesicle number as assayed by sucrose-mediated response in autapic culture. This argues against the notion that functional priming of vesicles from the electrophysiology results is the same process as morphology docking in the EM images. Subsequently, we investigated whether Ca2+ entry influences vesicle docking by using flash and freeze technique to resolve changes in vesicle-plasma membrane distance upon action potential triggering. Surprisingly, we found an increased number of vesicles in the proximity of active zone after Ca2+ influx on the timescale of milliseconds, suggesting that the Ca2+ induced phospholipid binding of C2B may be capable of compensating for the loss of membrane tethering before Ca2+ influx. These results indicate 1) Syt-1 regulates synaptic docking via its side and bottom loops of C2B domain, 2) vesicle priming and docking are not necessary linked and 3) Ca2+ triggering may induce vesicle docking via its Ca2+ dependent phospholipid binding ability of top loop of C2B domain.

Title: The role of SNAP-25 in presynaptic mechanisms of long-term plasticity of vesicular release at glutamatergic synapses in the hippocampus

Authors: *K. R. GOPAUL[1], M. IRFAN[1,2], X.-L. ZHANG[1], C. BARK[2], P. K. STANTON[1]; [1]Cell Biol. and Anat., New York Med. Col., Valhalla, NY; [2]Dept. of Mol. Med. and Surgery, Rolf Luft Ctr. for Diabetes Res. & Endocrinol., Karolinska Inst., Stockholm, Sweden

Abstract: Two glutamate receptors, N-methyl-D-aspartate receptors (NMDAR) and group II metabotropic glutamate receptors (mGluRII), can independently induce long-term depression (LTD) of presynaptic transmitter release at hippocampal synapses. Recent work from our laboratory indicates that presynaptic LTD involves the interaction of a G protein with one of the SNARE proteins, synaptosomal-associated protein 25 (SNAP-25). LTD, but not long-term potentiation (LTP), is significantly impaired when the 9 amino acid c-terminal region of SNAP-25 is cleaved, suggesting that a differential interaction with SNAP-25 is required for the coordination of these distinct forms of long-term, activity-dependent presynaptic plasticity. Elevation of cyclic guanosine monophosphate (cGMP) by NMDAR-mediated generation of the intercellular messenger nitric oxide, when paired with Gα liberated by activation of G protein-coupled receptors such as mGluRIIs, is sufficient to induce LTD. Given that Gα and Gβγ are co-released by activation of G protein-coupled receptors, we hypothesized that elevated [cGMP], inhibition of PKA by Gαi, and binding of Gβγ to the C-terminus of SNAP-25, are all in a common final pathway of NMDAR and mGluRII induction of presynaptic LTD of vesicular glutamate release. We tested this hypothesis by monitoring changes in vesicular release from rodent hippocampal Schaffer collateral synapses with the fluorescent membrane dye, FM1-43, using two-photon laser scanning microscopy. In SNAP-25 transgenic mice that express only an immature form of SNAP-25 (SNAP-25a) and not the mature form (SNAP-25b), we found that paired-pulse facilitation and presynaptic transmitter release from the sucrose-loaded readily-releasable vesicle pool were reduced compared to wildtype littermate control mice. SNAP-25b deficient mice also showed impairments in both LTD and LTP of synaptic strength. We are examining the relative expression of NMDAR and mGluRII-dependent forms of LTD in these mice, and how blocking components of each pathway alters the expression of LTD of vesicular

release. Our findings suggest that synaptic plasticity that plays an important part in learning and memory is functionally modulated by isoforms of the SNARE protein SNAP-25, and that both LTP and LTD can be influenced by this protein.

Abstract: The somata of primary sensory neurons, including dorsal root ganglion (DRG) neurons, release neurotransmitters and neuropeptides. Following physiological action potentials, in addition to Ca^{2+}-dependent secretion, we have discovered and studied Ca^{2+}-independent but voltage-dependent secretion (CiVDS) in somata of freshly isolated DRG neurons (Zhang et al, 2002, 2004; Zheng et al, 2009, Liu et al, 2011). Major open question of CiVDS is molecular mechanism, including 3 components: fusion pore machinery (FP), voltage sensor (VS) and the FP-VS linker (LK). Here we report, by using exocytosis assays of patch-clamp recording of membrane capacitance, and single vesicle imaging (EM and TIRF), (1) FP is jointly contributed by 2 components of FP-complex SNARE, SNAP25 and syntaxin; (2) VS is jointly contributed by 2 voltage-gated Ca channels (VGCCs), Cav2.2 (N-type VGCC) and Cav1.3 (L-type VGCC); (3) LK is the “synprint”, Cav-S2-S3 intracellular loop718-963aa (Catterall, 1999); (4) following

automatic knockdown of CiVDS by 3d-culture of DRG neurons, CiVDS is rescued by overexpressing any component of FP (SNAPE25or syntaxin) or VS (Cav2.2 or Cav1.3); (5) CiVDS is inhibited by blockers against FP (SNAP25 or sytaxin), Cav(2.2 or 1.3) and FL (synprint-truncated); (6) finally, CiVDS is blocked by Cav2.2-RNAi-KD in DRG pre-transfected *in vivo*. *Supported by grants from NSFC, MOST and DOE 2011-program*

Title: Facilitation of vesicle endocytosis by rho kinase at immature calyx of held synapses

Authors: H. YUE, L. LI, A. SATHYAMURTHY, L. MEI, *J. XU;
Dept. of Neurosci. and Regenerative Med., Georgia Regents Univ., Augusta, GA

Abstract: A kinase closely related to cellular cytoskeleton, Rho kinase (ROCK) affects synapse development and neuronal functions. In the calyx of Held synapses after maturation, vesicle endocytosis can be accelerated by retrograde activation of ROCK by nitric oxide released from postsynaptic cells, which involves presynaptic cyclic GMP-dependent protein kinase (PKG) and phosphatidylinositol-4,5-bisphophate (PIP2). Because this pathway of retrograde activation is suggested to function only in mature calyces, a role of ROCK in endocytosis at immature synapses remains to be determined. This possible regulation of synaptic endocytosis was now explored at the calyces from postnatal 7-11 days old rat pups by performing the whole-cell membrane capacitance measurement to monitor endocytosis. In our tests, pharmacological inhibition of ROCK activity led to slower endocytosis. Elevation of intracellular PIP2 or block of NMDA receptor did not influence effects of ROCK inhibition, excluding the involvement of PKG and PIP2. In addition, the slow calcium chelator, EGTA, did not generate synergistic effect when combined with ROCK inhibitors. These observations suggest that ROCK can regulate endocytosis in immature synapses by a potentially calcium-dependent and PKG-independent

pathway. It is possible that ROCK participates in regulation of endocytosis in both immature and mature synapses, but using different molecular mechanisms for its activation.

Title: Unique role of complexin in shaping the biphasic response at a mammalian ribbon synapses in the rod pathway

Authors: ***L. S. MORTENSEN**[1], J. KE[2], K. REIM[1], C. IMIG[1], B. H. COOPER[1], E. KALOGERAKI[3], S. LÖWEL[3], N. BROSE[1], J. H. SINGER[2], J. RHEE[1];

Abstract: At the rod bipolar cell (RBP) to amacrine AII cell ribbon synapse in the inner retina, contrast and luminance is encoded in the transient and sustained components of the response to sustained input. While it is well described that the partial depletion of the readily releasable pool (RRP) underlies this biphasic response, the molecular players involved in regulating vesicle release in RBP to AII synapses have not been investigated in depth. Complexins (Cplx) are synaptic proteins that exist in four isoforms in mammals. All isoforms bind to and stabilize SNARE complexes, and their deletion leads to disturbances in vesicle release. Cplx-3 is the only isoform found at RBP to AII cell ribbon synapses. We performed paired recordings from synaptically coupled RBP and AII cells in acute retinal slices from Cplx-3 genetic deletion mutants and wild type controls. While synchronous release was strongly reduced in Cplx-3 deletion mutants, we found that asynchronous, sustained and delayed release was unaltered. Studies regarding the clamping function of Cplx-1/2 in conventional synapses have caused some controversy, however, we do not report any sort of clamping function upon loss of Cplx-3.

Although the readily releasable pool (RRP) was significantly reduced, we still observed coordinated multivesicular release, which was not depressed by partial depletion of the RRP. This finding is in contrast to previous studies linking multivesicular release to a high initial release probability. Electron tomographic analysis suggests that Cplx-3 is not involved in tethering/docking of vesicles at the presynaptic active zone. By simulating physiological stimuli electrophysiologically and by behavioural analysis we show the importance of Cplx-3 in generating the biphasic response needed to faithfully encode contrast in the inner retina. Our data indicate that the release machinery driving synchronized and sustained/delayed release rely of different components, with complexin being significant only for the transient phase of release, and that the molecular configuration of the release machinery is crucial for signal processing in the retina.

Title: Complexin increases the coupling of presynaptic calcium influx and quantal release

Authors: E. A. QUIROZ[1], *R. A. JORQUERA[1,2];
[1]Neurosci., Univ. Central Del Caribe, Sch. of Med., Bayamon, PR; [2]Physiol. and Biophysic Program, Univ. de Chile, Sch. of Medicine, Inst. of Biomed. Sci., Santiago, Chile

Abstract: At nerve terminals, the coupling between the Ca^{2+} influx and the quanta ready for release is critical for synaptic communication. However, the molecular mechanism by which the coupling occurs remains under investigation. Complexin binds the SNARE complex necessary for vesicle docking and fusion, preventing the spontaneous vesicle fusion and increasing a pool of quanta ready for release. In addition, Complexin speeds the timing for quantal release and may affect coupling. Nevertheless, Complexin function is still under debate. Here, using the *Drosophila* NMJ we investigate the role of Complexin coupling the Ca^{2+} influx and quantal release at complexin null ($cpx^{-/-}$). Kinetic analysis of glutamatergic EPSCs in the presence of

Cd^{2+}, Ca^{2+} channel inhibitor PLTXIIa, Sr^{2+} or intracellular Ca^{2+} buffers EGTA and BAPTA were explored at different frequency of nerve stimulation. Cd^{2+} and PLTXIIa display different effects in control and *cpx*$^{-/-}$ at the EC50 and EC75 values indicating a role of complexin in the sensitivity of Ca^{2+} influx in the release process. Sr^{2+} promotes asynchronous release in a higher extent in *cpx*$^{-/-}$ vs control, suggesting an increased pool or sensitivity of asynchronous quanta. Intracellular Ca^{2+} buffering with EGTA has a minor effect in control but suppresses the asynchronous release in *cpx*$^{-/-}$ without affecting the spontaneous release, confirming the role of complexin in coupling. As is expected, in null and control animals, BAPTA slows the EPSCs kinetics and decreases the spontaneous release in *cpx*$^{-/-}$. Our data is consistent with a modulatory role of complexin in the Ca^{2+} sensitivity of the release machinery. In addition, complexin increases coupling, probably by clamping the SNARE complex at the release site.

Title: Local nanometer organization and the function of PI(4,5)P2 during vesicle exocytosis

Authors: *C. JI[1], Y. ZHANG[2], T. XU[2], X. LOU[1];
[1]Univ. of Wisconsin-Madison, Madison, WI; [2]Natl. Lab. of Biomacromolecules, Inst. of Biophysics, Chinese Acad. of Sci., Beijing, China

Abstract: PI(4,5)P2 has been identified as an independent plasma membrane determinant inositol lipid that is essential for multiple cellular functions. However, their nanometer scale organization in native cell plasma membrane (PM) remains controversial and the exact function of PI(4,5)P2 in differential dynamic stages of exocytosis remains elusive. Using single-molecular super resolution imaging, photo-activatable PH-domain probes, and optogenetic tools, we

explored the structure and function of PI(4,5)P2 in different molecular interactions during vesicle trafficking. We examined different imaging approaches and variable conditions for PI(4,5)P2 nanoscale distribution, and we found relatively homogeneous distribution of PI(4,5)P2 in the large areas of PM. Moreover, using optogenetic tools, we successfully manipulated PI(4,5)P2 levels in live cells, we are aiming to dissect its interactions with different effectors proteins in exocytosis. Our preliminary data suggest PI(4,5)P2 regulated exocytosis at multiple steps, including docking, priming, and final membrane fusion via different mechanisms.

Title: Spontaneous and evoked recycling pools of synaptic vesicles in cultured striatal neurons of a DYT1 dystonia mouse model

Authors: *N. C. HARATA, S. IWABUCHI;
Dept Mol Physiol & Biophys, Univ. Iowa Col. Med., Iowa City, IA

Abstract: Body movement is severely affected in the brain disorder dystonia. Hallmarks of this disease are involuntary skeletal muscle contractions and abnormal postures. In spite of the fact that dystonia is the third most common movement disorder in humans, treatment options remain limited. In part this is because the mechanisms whereby dystonia affects brain functions remain unclear. One of the pathophysiological features of this disease is thought to be abnormal synaptic transmission, e.g. in the striatum, a brain region that plays an important role in motor control. We

previously reported that in DYT1 dystonia - the most common form of inherited dystonia - synaptic vesicle recycling is affected in the nerve terminals of cultured mouse striatal neurons. Using live-cell imaging of the vesicle-recycling indicator FM1-43 dye, we had demonstrated the presence of two vesicle pools, which were mobilized during spontaneous or evoked synaptic activities (spontaneous and evoked recycling pools, respectively). We further found that the size of spontaneous recycling pool was increased in mutant neurons that bear a TOR1A mutation that is present in human patients (i.e. in a heterozygous ΔE-torsinA knock-in mouse). We have extended the previous study, evaluating the changes in the evoked recycling pool and also the transfer of vesicles between the two pools. We found that in the mutant neurons, the size of the evoked recycling pool is slightly reduced relative to that in wild-type counterparts. Moreover, vesicles that were loaded with FM dye during a synaptic activity of one type later unloaded the dye during an activity of the other type, indicating that vesicles can be transferred from one pool to another. The amount of this transfer from the evoked to the spontaneous pools was higher than in wild-type neurons, and was lower in the opposite direction. These results suggest that the mutant neurons tended to rely more on the spontaneous than the evoked recycling pools. Overall, our findings demonstrate a high level of complexity in the influence of the dystonia-associated mutation on the presynaptic factors.

Title: Measuring glutamate transients in the cleft of individual Schaffer collateral synapses

Authors: ***C. D. DÜRST**, J. S. WIEGERT, C. SCHULZE, T. G. OERTNER;
Ctr. For Mol. Neurobio. Hamburg (ZMNH),, Hamburg, Germany

Abstract: Whether central synapses can release only a single vesicle, or multiple vesicles per action potential, or even sub-quantal amounts of glutamate, is still a matter of debate. It is possible to detect glutamate release indirectly by electrophysiological recordings of postsynaptic AMPA receptor mediated currents (EPSCs). It is not straightforward, however, to distinguish between multisynaptic connections and multivesicular release from a single synaptic site. In addition, due to cooperative glutamate binding, saturation, and desensitization of AMPA receptors, EPSC amplitudes are not linearly related to cleft glutamate concentrations. The

complex nature of postsynaptic responses makes it difficult to investigate the mode of transmitter release at central synapses. To directly monitor cleft glutamate during synaptic transmission, we took advantage of the genetically encoded membrane-bound glutamate sensor iGluSnFR that we expressed in CA3 pyramidal neurons through single cell electroporation. Fast two-photon imaging of single boutons in CA1 during propagation of single action potentials allowed us to optically measure glutamate release from individual release sites with high spatial and temporal precision. We show that our method is sensitive enough to detect the release of individual transmitter vesicles at a single presynaptic terminal. Release events could be mapped to an area smaller than the resolution limit of the microscope. By altering external calcium concentrations, we found that increased release probability was accompanied by increased glutamate concentrations in the synaptic cleft. This increase in glutamate concentration followed binomial statistics and most likely arose from the simultaneous release of several vesicles at a single release site. Multivesicular release was also observed at near-physiological calcium concentrations, suggesting that synaptic transmission at Schaffer collateral synapses is not limited to a single quantum per action potential and release site.

Title: Synaptotagmin-1 and synaptotagmin-7 differ in their stimulus and Ca^{2+}-dependence of activation

Authors: ***T. RAO**[1], A. R. PELEMAN[1], D. R. GIOVANNUCCI[2], A. ANANTHARAM[1]; [1]Biol. Sci., Wayne State Univ., Detroit, MI; [2]Raymond & Beverly Sackler Lab. for Neuroendocrine Tumor Res., The Univ. of Toledo, Toledo, OH

Abstract: The secretory response of adrenal chromaffin cells varies in accordance with the stimulus applied. Mild stimulation favors limited release of granule cargo through a narrow fusion pore while strong stimulation leads to greater release through wide pore expansion. The trigger for release in these cells is a rise in intracellular Ca2+ through voltage-gated channels. The level of intracellular Ca2+ accumulation varies directly with the strength of depolarization. Ca2+ triggered exocytosis in chromaffin cells also requires the protein synaptotagmin (Syt) as a sensor. The two isoforms expressed in these cells - synaptotagmin-1 (Syt-1) and synaptotagmin-

7 (Syt-7) - have distinct Ca2+ affinities, are usually sorted to separate granules, and favor fundamentally different modes of exocytosis. Therefore, we wanted to determine whether changes in stimulation intensity drive release by selectively, or differentially, activating granules with Syt-1 or Syt-7. To address this question, we depolarized cells with varying levels of extracellular KCl. We found that while 56 mM KCl equally drove fusion of Syt-1 and Syt-7 granules, 10 and 25 mM KCl were far more effective at driving fusion of Syt-7 granules. To directly investigate Ca2+-dependence of Syt isoform fusion, we perfused permeabilized cells with Ca2+ buffered to different concentrations with EGTA. Both Syt granule populations fused effectively at highest concentrations of Ca2+ (30 μM and 100 μM), although there were small differences in their overall rate constants for activation. A greater fraction of docked Syt-7 granules fuse with significantly faster kinetics at a lower Ca2+ concentration (10 μM). Our results demonstrate chromaffin cells exploit Syt isoform diversity to modulate the secretory response. A significant consequence of synaptotagmin isoform segregation is that individual granules are endowed with unique Ca2+-sensitivities, allowing rapid and local control of the fusion mode based on local Ca2+ levels.

Title: A chimeric approach to studying the Syntaxin Habc domain uncovers roles in exocytosis and Syntaxin trafficking

Authors: *L. A. PARRA, M. PALFREYMAN, E. JORGENSEN;
Univ. of Utah, Salt Lake City, UT

Abstract: Synaptic vesicle fusion is mediated by the concerted action of Munc18 and SNARE proteins. Munc18 has multiple binding modes with syntaxin. Key to understanding this interaction is the highly conserved three-helix bundle (known as the Habc domain) that is present on the SNARE protein syntaxin. This domain is the major interaction interface between Munc18 and the SNARE proteins. To test the role of the Habc domain and Munc18 proteins *in vivo*, we are analyzing different Habc domain variants using the nematode *C. elegans*. Specifically, we are exchanging the Habc domain of the worm with the respective Habc domains of other species.

Using this chimeric approach we hope to identify key components that will help to mechanistically characterize the interaction between the SNAREs and the Munc18 proteins. Previous evidence suggests the interaction of Munc18 and the SNAREs serves a role in trafficking and in exocytosis. Our evidence shows that replacing the worm Habc with the choanoflagellate Monosiga brevicollis (MoBr) Habc does not disrupt trafficking whereas the yeast Saccharomyces cerevisiae (SaCe) Habc domain does result in partial trafficking defects. Despite the correct localization, the choanoflagellate Habc chimera animals are still uncoordinated and have dramatic decrease in synaptic vesicle fusion -thus, demonstrating the important role for the Habc domain downstream of trafficking. Interestingly, the roles downstream of trafficking might result from specific interactions between the Habc domain and Munc18. Specifically, the inviability of yeast Habc chimeras can be rescued by expression of Sec1p, the yeast homolog of Munc18. In this combination the viability is restored independent of an observable restoration of wild-type syntaxin localization. I am currently performing further chimeric analyses to understand the physiological implication of syntaxin Habc domain interaction with Munc18. These experiments will parse the roles of Munc18 in the trafficking of syntaxin and the exocytosis of synaptic vesicles.

Title: Quantitation and simulation of presynaptic evoked calcium signals

Authors: *E. Y. HAMID[1], E. CHURCH[2], S. ALFORD[2];
[1]NIH, Bethesda, MD; [2]Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Presynaptic Ca^{2+} entry evokes neurotransmitter release, compensatory endocytosis, and short-term plasticity. The true spatiotemporal profile of Ca^{2+} entry and diffusion at synaptic molecular targets is difficult to determine, because imaging has limited resolution. To overcome these limitations, we used Ca^{2+} dyes as buffers to compute presynaptic Ca^{2+} signals and constructed models of diffusion and Ca^{2+} binding. Action potential-evoked Ca^{2+} responses in CA1 pyramidal cell varicosities were quantified using Ca^{2+} dyes as buffers. Peak transient

amplitudes (789 ± 39 nM) and decay times (119 ± 10ms), which showed little variation when measured with low affinity Fluo-5F, occurred within 2 ms of stimulation. A higher affinity Ca^{2+} dye (Fluo-4) was used to buffer Ca^{2+} transients. We determined endogenous Ca^{2+} buffering capacities, single action potential evoked free [Ca^{2+}] and total molar Ca^{2+} entering terminals. These results provided the basis of a Monte Carlo (MCell) simulation of Ca^{2+} entry, buffering and dispersal. Data were well fit using a model of Calbindin with two high and two moderate-rate binding sites (40 μM Calbindin). The model, while reproducing experimentally obtained data, demonstrates that Ca^{2+} enters varicosities with non-uniform distribution and diffused to fill the structure within 8 ms. During stimulus trains, free Ca^{2+} throughout the terminal showed super-linear summation from one period of entry to the next. At nm domains around primed vesicles Ca^{2+} peaks remained constant with repetitive stimulation as diffusion dominated. A kinetic model of synaptotagmin Ca^{2+} binding indicates that even with high (10 μM) total varicosity Ca^{2+} concentrations, synaptogmin must be with tens of nm of a channel but can be activated at greater distances with repetitive stimulation.

Title: Calcium-dependent activator protein for secretion function in murine dorsal root ganglion neurons

Authors: ***A. H. SHAIB**[1], M. KLOSE[2], R. MOHRMANN[2], J. RETTIG[2], U. BECHERER[2]; [1]Universty of Saarland, Physiol. Inst., Homburg, Germany; [2]Univ. of Saarland, Homburg, Germany

Abstract: Dorsal root ganglion (DRG) neurons transmit sensory information to the central nervous system through glutamatergic synaptic transmission that can be modulated by neuropeptides. They are contained in large dense core vesicles (LDCVs) and can be as diverse as calcitonin gene-related peptide (CGRP), neuropeptide Y (NPY), substance P, etc. LDCVs are exocytosed in response to specific stimulus at the cell somata and in afferent terminals along with synaptic vesicles (SVs). The release machinery of these LDCVs is poorly understood. Thus, we investigate the role of both isoforms of the priming the factor Calcium-dependent Activator Protein for Secretion (CAPS1 and CAPS2). Using PCR and immunocytochemistry, we verified

that both CAPS isoforms are expressed. With total internal fluorescence reflection microscopy, we visualize in real time the release of LDCVs that are labeled through Lenti virus driven expression of NPY-Venus. We found that the amount of secreting neurons was raised by 20% upon CAPS 1 or CAPS 2b overexpression and that the number of secreted LDCV per responding neuron was more than twice as high in comparison to WT control. CAPS1 and 2 double Knockout showed significant reduction in the number of secreted vesicles and 20% decrease in the amount of secreting cells was observed. Since the density of LDCVs at the plasma membrane was not affected by CAPS expression level, our result suggest that CAPS can be a priming factor for LDCVs in DRG-neurons. We also examine the role of CAPS in SV priming. For this we have established a DRG-dorsal horn neurons co-culture to allow synapse formation. Additionally, we designed a Lenti virus encoding for vGlut tagged to the pH sensitive fluorescent protein mNectarine to specifically label SVs and visualize their exocytosis. With these tools we are investigating whether CAPS plays a differential role in priming of LDCV vs. SV.

Title: The role of vti1a- and VAMP7-driven spontaneous vesicle fusion in synaptic plasticity

Authors: *D. C. CRAWFORD, D. M. O. RAMIREZ, B. TRAUTERMAN, L. M. MONTEGGIA, E. T. KAVALALI;
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Spontaneous neurotransmission is a ubiquitous feature of neuronal synapses and occurs when synaptic vesicles fuse with the plasma membrane irrespective of the presence of action potentials. It is becoming increasingly apparent that this form of neurotransmission plays important roles in synaptic development and plasticity, for example in synaptic homeostasis. Prior studies probing the physiological functions of spontaneous neurotransmission, however, have been hampered by an inability to selectively manipulate vesicles destined for spontaneous fusion. Recently two vesicular soluble NSF attachment protein receptors (v-SNAREs), vps10p tail interactor 1a (vti1a) and vesicle-associated membrane protein 7 (VAMP7/TI-VAMP), were identified as specific facilitators of spontaneous vesicle fusion. To determine how spontaneous neurotransmission modulates synaptic function *in vitro* and *in vivo*, we used lentiviral and AAV vectors to deliver shRNAs against both of these proteins to rodent hippocampal neurons (hereafter referred to as double knockdown, or DKD). DKD in cultured rat hippocampal neurons significantly reduced the frequency of miniature AMPA receptor-mediated excitatory postsynaptic currents but increased their amplitudes, and these effects were rescued by co-expression of shRNA-resistant vti1a. Additionally presynaptic terminals from DKD cultures that were treated with tetrodotoxin took up significantly less antibody against the luminal domain of synaptotagmin 1. Spontaneous network activity, which requires action potential propagation in neurons, and inhibitory miniature postsynaptic current amplitudes were, however, unchanged after DKD. These results suggest that excitatory spontaneous neurotransmission specifically driven by these v-SNAREs is important for synaptic homeostasis but does not grossly alter action potential-driven activity. In brain slices from mice stereotaxically injected with an AAV driving DKD, axons from infected neurons exhibited reduced spontaneous uptake of antibody against the luminal domain of synaptotagmin 1 in a manner similar to DKD in cultured neurons. Using field potential recordings of Schaffer collateral synapses after CA3-specific injections of the DKD AAV, we observed that paired-pulse ratios and long-term potentiation were unaltered by DKD, suggesting that at least some short-term and long-term forms of synaptic plasticity were intact. Together our data suggest that vti1a and VAMP7 specifically modulate spontaneous vesicle fusion events *in vitro* and *in vivo*, and we are currently investigating how these proteins alter synaptic plasticity and animal behavior.

Title: Quantitative analysis of vesicle recycling at the calyx of Held synapse

Authors: Q. ZHU, *X. QIU, J. SUN;
Inst. of Biophysics, Chinese Acad. of Sci., Beijing, China

Abstract: Vesicle recycling is pivotal for maintaining reliable synaptic signaling, but its basic properties remain poorly understood. Here, we developed an approach to quantitatively analyze the kinetics of vesicle recycling with exquisite signal and temporal resolution at the calyx of Held synapse. The combination of this novel electrophysiological approach with electron microscopy revealed that ~80% of vesicles (~270,000 out of ~330,000) in the nerve terminal are involved in recycling. Under sustained stimulation, recycled vesicles start to be reused in tens of seconds when ~47% of the preserved vesicles in the recycling pool (RP) are depleted. The heterogeneity of vesicle recycling as well as two kinetic components of RP depletion revealed the existence of a replenishable pool of vesicles prior to the priming stage and led to a realistic kinetic model that assesses the size of the sub-pools of the RP. Thus, our study quantified the kinetics of vesicle recycling and kinetically dissected the whole vesicle pool in the calyceal terminal into the readily-releasable pool (~0.6%), the readily-priming pool (~46%), the pre-mature pool (~33%) and the resting pool (~20%).

Title: Synapse-specific determinants of single-vesicle recycling kinetics in central presynaptic terminals

Authors: *M. WAGNER, K. STARAS;
Life Sci., Univ. of Sussex, Falmer Brighton, United Kingdom

Abstract: In small central synaptic terminals efficient stimulus-driven fusion and recycling of neurotransmitter-filled synaptic vesicles is critical for the maintenance of synaptic performance. In recent years considerable effort has been invested in understanding these processes, facilitated by advances in imaging techniques and development of improved fluorescent reporters of synaptic function. It is widely accepted that synapses exhibit striking heterogeneous activity across populations but the factors that underlie this variability are poorly understood. Here we exploited high-sensitivity imaging approaches to examine whether expression of synaptic profiles was predictable at the level of individual release events and the rules that underlie this. Specifically, we imaged synaptophysin-2x-pHluorin (sypHy2x)-expressing synapses in dissociated rat hippocampal neurons. Using minimal stimulation protocols, we collected response profiles and generated frequency distribution plots. These were highly quantized, allowing us to sub-divide profiles into quantal and multi-quantal events using simple custom-written algorithms. Regarding the timecourse of endocytosis, we found that individual traces were highly variable across the whole population of synapses. Nonetheless, the expression of different profiles was not random but instead determined by factors related to the identity of individual terminals. This relationship was true for single vesicle retrievals but became less robust in the case of multiple fusion events. By inducing a form of homeostatic plasticity we were able to manipulate these parameters and change vesicle kinetics in predictable ways, suggesting that they are highly linked. Our findings offer new insights into the rules that determine single vesicle retrieval events in individual synapses.

Abstract: Calcium-dependent activator protein for secretion 1 (CAPS1) is a cytosolic protein, which associates with dense-core vesicle secretion in endocrine cells, however, their neuronal function is still largely unknown because of Caps1 knock-out (KO) results in prenatal death. Here we show that CAPS1 stabilizes the docking state of synaptic vesicle (SV) to presynaptic active zone using forebrain specific Caps1 conditional KO (cKO) mice. The synaptic transmission is strongly reduced and paired-pulse facilitation shows significant alteration in Caps1 cKO. Morphological analysis shows accumulation of SVs in presynapse without any other morphological changing. Interestingly, even though SV accumulation is occurred, the percentage of presynaptic button contained docked vesicle is markedly reduced in Caps1 cKO. These data suggest that CAPS1 stabilizes SV docking state to enhance SV release.

Title: Dynamin-1 is required for short-term synaptic plasticity and transmission fidelity independent of vesicle re-availability at a mature central synapse

Authors: *S. MAHAPATRA, F. FAN, X. LOU;
Dept of Neurosci., Univ. of Wisconsin, Madison, Madison, WI

Abstract: Endocytosis is critical to generate new synaptic vesicles (SVs) during sustained synaptic transmission and to promote efficient clearance of vesicle components from release sites (1). The latter may become a rate-limiting step in response to high frequency action potential (AP) firing (2), when vesicle fusion demand at the active zone is strongly enhanced. Dynamin is

a large GTPase that plays a key role in membrane fission by pinching off the SVs from plasma membrane (3, 4). Perturbation of dynamin function, which delays the reformation of new SVs, may hinder the release site clearance and rapidly affect transmission in a much fast time scale. However, still after more than two decades of work on dynamin, such role of dynamin remains elusive. Calyx of Held is a fast relay synapse in the auditory brainstem that fires very high frequency APs with high fidelity. Using patch-clamp recording from mature Calyx of Held synapses (P16-20) from the tissue-specific dynamin-1 knockout (Dyn-1f/f Krox20Cre+ or KO) and their littermate controls (Dyn-1f/f), we examined *in vivo* function of dynamin 1 in short-term synaptic plasticity. We found that the basal transmission in KO mice was largely intact. However, strikingly, KO synapses exhibited a significant reduction of short-term synaptic depression (STD) and loss of transmission fidelity during high frequency stimulations. The STD reduction did not depend on the commonly known mechanisms for STD at central synapses, such as postsynaptic receptor desensitization/saturation, presynaptic calcium channel modulation, or vesicle recovery from depletion. But disruption of actin polymerization by Latrunculin B blocked such effect and brought the STD in KO synapses to the same levels as control. This data suggest actin plays a critical role at downstream of vesicle fusion, such as enhanced site clearance presumably through the up-regulated bulk endocytosis as demonstrated by EM tomography in dynamin-1 KO synapses (5, 6). Moreover, transmission failure in KO was not due to vesicle depletion but a presynaptic AP failure. These data demonstrated that dynamin is required to preserve the normal synaptic plasticity and transmission fidelity in a native circuit. This study uncovers a distinct role of dynamin-1 to regulate neurotransmission through an ultrafast feedback directly from endocytosis, in addition to its classical function in membrane fission. Title: The role of synaptotagmin 1 in single synaptic vesicle endocytosis

Authors: *Y. LI, B. TRAUTERMAN, E. T. KAVALALI;
Neurosci., UT Southwestern, Dallas, TX

Abstract: Synaptic vesicle recycling is essential for maintaining normal synaptic function. The coupling of exo- and endocytosis allows for continued rapid synaptic transmission; however, the molecular mechanisms of this process are not well understood. A key candidate for the regulation of vesicle trafficking is synaptotagmin 1 (syt1) which has been established as the calcium sensor for fast synchronous neurotransmitter release. Biochemical experiments show that syt1 interacts with a variety of endocytosis associated proteins including clathrin adaptor protein 2 (AP-2). Live fluorescence imaging experiments show slowed endocytosis after strong stimulations in syt1 knockout neurons. However, the impaired exocytosis in these models is a major confounding variable. To uncover the specific role of syt1 in endocytosis, I am using single-vesicle imaging to isolate unitary exo- and endocytosis events and analyzing the properties of activity-driven synaptic vesicle trafficking. By knocking down syt1 and expressing a pHluorin-tagged vesicular probe I am able to examine the role of syt1 in single vesicle endocytosis. These experiments demonstrate minimal regulation of single vesicle endocytosis after syt1 knockdown, although there is still slowed endocytosis after larger stimulations as previously observed. Earlier studies from our lab have shown a slowing of single-vesicle endocytosis with increasing calcium however this effect is greatly diminished in the syt1 knockdown (KD) background, suggesting syt1 may function as a calcium sensor for single-vesicle endocytosis.

Title: Evidence for PKA dependent regulation of tomosyn

Authors: *S. J. ZINN[1], D. FEATHERSTONE[2], J. RICHMOND[2];
[2]Biol. Sci., [1]Univ. of Illinois, Chicago, Chicago, IL

Abstract: Tomosyn, a syntaxin binding protein, has been postulated to negatively regulate synaptic vesicle fusion by forming nonfusogenic complexes with the plasma membrane SNAREs, syntaxin and SNAP-25, thereby inhibiting SNARE complex assembly. Using RNAi

knockdown we recently demonstrated that *Drosophila* tomosyn not only inhibits synaptic transmission but also disrupts PKA-dependent aversive olfactory learning in flies1. Biochemical evidence indicates that vertebrate tomosyn is a direct PKA-target. Phosphorylation reduces the ability of tomosyn to inhibit fusogenic SNARE complex assembly by lowering its syntaxin binding affinity2. The possibility that tomosyn is a potentially important PKA-target *in vivo* is supported by the following observations: 1) Acute activation of cAMP phenocopies the tomosyn loss-of-function mutant and manifests as increased synaptic vesicle docking and enhanced release. 2) cAMP activation results in the translocation of tomosyn away from the plasma membrane and 3) cAMP activation combined with tomosyn RNAi shows no additivity, suggesting they act in the same pathway. To definitively establish that the phosphorylation of tomosyn accounts for these cAMP synaptic effects we are generating a tagged tomosyn construct using CRISPR/Cas9 for pull down and subsequent kinase activity assays to determine the most probable PKA binding site. Based on both bioinformatics and molecular evidence potential phosphomimetic and non-phosphorylatable tomosyn fly strains will be generated using CRISPR/Cas9 and will be the subject of electrophysiological and immunohistochemical analyses. 1 Chen, Richlitzki, Featherstone, Schwärzel and Richmond (2011). Title: Quantification *in vivo* of protein SV2A in hippocampus of rats with temporal lobe epilepsy

Authors: *L. PICHARDO-MACIAS[1,2], V. U. DÍAZ[2], G. GÓMEZ LIRA[3], I. J. CONTRERAS[2], S. R. ZAMUDIO HERNÁNDEZ[1], S. GUZMÁN[1], S. M. NAVARRETE[2], J. G. MENDOZA[2];

Abstract: In recent years, there has been considerable interest in determining the function of the synaptic vesicle protein 2A (SV2A) and its role as target for epileptic drugs. It is know that the SV2A is involved in normal synaptic vesicle function, albeit its participation in synaptic vesicle cycling and neurotransmitter release in normal and pathological conditions is unclear. In some

animal models of epilepsy, SV2A expression decrease in similar way as in the tissue from patients with intractable epilepsy. This implies that the decreased expression of the SV2A is a consequence of seizure activity and could contribute to the progression of epilepsy. However, unfortunately to date, it has not made a detailed quantitative study about SV2A expression in different regions of the hippocampus (epileptogenic region). Thus the aim of this study was to determine the expression of SV2A in animal model of temporal lobe epilepsy (TLE). Male adult Wistar rats were administrated with lithium and pilocarpine to induce status epilepticus (SE). The rats were sacrificed in different periods of the pathology (SE, epileptogenesis and chronic epilepsy) by overdose of sodium pentobarbital and perfused intracardially with 0.9 % saline solution, the brains were removed and process by immunohistochemestry. Randomized SV2A staining was quantified by optical density (OD) using NIH ImageJ software, it was also obtained the volume estimation using Cavalieri's test from twelve different regions of the hippocampus. The result show that the volume of hippocampus was decreased in rats with chronic epilepsy especially in internal molecular layer, CA3 and CA1 Ammon horn, with respect to the OD we observed that during SE, SV2A staining increase in all the regions sampled, while in epileptogenesis, OD increase in external molecular layer but decreased in internal molecular layer without changes in the other regions. Finally in chronic epilepsy there were no significant changes in OD in any region. The preliminary results suggest that a major structural change appears during epileptogenesis and this change was restored in chronic epilepsy whereby SV2A expression could be a possible damage neuronal biomarker.

Title: Localization of Ca^{2+}-channels and their connections to specific 'Active Zone Material' macromolecules at frog neuromuscular junctions

Authors: *J. SZULE, J. JUNG, U. MCMAHAN;
Biol., Texas A&M Univ., College Station, TX

Abstract: A subset of synaptic vesicles docked on the presynaptic membrane at the active zone is triggered by the influx of Ca^{2+} through voltage-gated channels to secrete their neurotransmitter into the synaptic cleft when an electrical impulse arrives at an axon terminal. The cytosolic Ca^{2+} interacts with the vesicle-associated protein synaptotagmin to trigger fusion of the docked vesicle's membrane and presynaptic membrane to form a pore, through which the neurotransmitter is secreted. Ca^{2+}-channels must be located nearby the docked vesicles to provide synaptotagmin with sufficient concentrations of Ca^{2+} to trigger membrane fusion. At frog neuromuscular junctions, a highly ordered network of macromolecules called 'active zone material' is connected to both the docked vesicles and the presynaptic membrane. Transmembrane macromolecules in the presynaptic membrane at the active zone, thought to include Ca^{2+}-channels, are connected to specific macromolecules of the active zone material, called 'pegs'. Each docked vesicle is linked to 4 pairs of pegs; one member of each pair is proximal to the docked vesicle, the other distal to it. In a recent study (see abstract: Jung, Szule and McMahan), we proposed that certain macromolecules of the active zone material regulates the probability of membrane fusion in part by moving the proximal pegs and their associated presynaptic membrane macromolecules toward the docked vesicle, increasing the amount of Ca^{2+} that reaches synaptotagmin when an electrical impulse arrives. Here, we labeled voltage-gated Ca^{2+}-channels at frog neuromuscular junctions with gold colloid (5 nm in diameter) indirectly linked to omega-conotoxin GVIA and, by imaging with electron tomography, tested the hypothesis that pegs proximal to the docked vesicle are connected to voltage-gated Ca^{2+}-channels. We found that although the gold colloid was off-set from the extracellular surface of the presynaptic membrane by its linkers to the Ca^{2+}-channels, it was highly enriched immediately adjacent the region of the presynaptic membrane occupied by the pegs, which would be expected if pegs are connected to the transmembrane macromolecules that contain the voltage-gated Ca^{2+}-channels. Moreover, we found that the distributions of the measurements between the gold colloid to each class of pegs closely matched simulated distributions that assumed the voltage-gated Ca^{2+}-channels were associated with the proximal pegs. From these results, we concluded that the voltage-gated Ca^{2+}-channels are not uniformly associated with all pegs, but rather, most, if not all, are associated with the pegs that are proximal to the docked vesicles.

Title: Multiple functions of PKG at the *Drosophila* larval neuromuscular junction

Authors: *J. S. DASON, A. M. ALLEN, M. B. SOKOLOWSKI;
Univ. of Toronto, Toronto, ON, Canada

Abstract: The foraging gene in *Drosophila* encodes a cGMP-dependent protein kinase (PKG). PKG is thought to regulate several aspects of synaptic function, including synaptic plasticity, synaptic vesicle exocytosis and endocytosis, and neurite outgrowth. However, the mechanisms by which PKG regulates these processes are not fully understood. In addition, much of the evidence for its putative role in these processes is based on the use of pharmacological inhibitors. Pharmacological approaches can be limiting because of their non-specific effects and the inability to distinguish between presynaptic, postsynaptic and glial effects. To overcome these limitations, we used a genetic approach to understand the role of PKG. Here, we used a newly created foraging null mutant to characterize the synaptic effects of PKG at the *Drosophila* larval neuromuscular junction. In addition, we used RNAi to selectively knockdown PKG in neurons, glia or muscles to determine where PKG was required for these synaptic effects. Overall, we found that PKG negatively regulates synaptic transmission and nerve terminal growth.

Abstract: Neuropeptide Y (NPY) is an endogenous neuropeptide found abundantly in the nervous system. NPY has been implicated in a variety of processes, including epilepsy and feeding behavior. It has also been shown to exhibit robust anxiolytic properties. Anxiety disorders are considered a maladaptive form of learning, and the hippocampus has been implicated in a variety of anxiety disorders, including Posttraumatic Stress Disorder (PTSD). NPY in hippocampus is important for regulating anxiety; hippocampal NPY is reduced in a rodent model of PTSD, and injection of NPY into CA1 has been shown to reduce the anxiety symptoms. However, the effects of NPY on hippocampal synaptic and circuit function are only partially understood. CA1 pyramidal cells receive two major excitatory inputs, the Schaffer collateral (SC) pathway that projects from the CA3 region of hippocampus onto the proximal dendrites of CA1 pyramidal cells in s. radiatum, and the temporoammonic (TA) pathway that projects from entorhinal cortex onto the distal dendrites of pyramidal cells in s. lacunosum-moleculare. While the SC pathway is important for spatial learning, the TA pathway has been shown to be important for memory consolidation and fear learning. NPY is expressed in a subset of GABAergic interneurons in CA1, including Ivy cells that have axons in s. radiatum, and neurogliaform cells that have axons targeting s. lacunosum-moleculare. Previous studies have shown that application of exogenous NPY to acute hippocampal slices decreases excitatory synaptic responses from SC excitatory synapses onto proximal dendrites of CA1 pyramidal cells. However, it had not been shown whether NPY also affects excitatory TA synapses onto the distal dendrites of CA1 pyramidal cells. Here we show that that exogenous NPY application also causes a reduction in synaptic responses at the TA-CA1 synapses. The dose-response curve is different between these two pathways, indicating potential differences in the subtype of NPY receptors. NPY functions as the ligand for a family of G-protein coupled receptors, of which Y1, Y2, and Y5 receptors are found in the central nervous system. Previous studies have shown that NPY reduces synaptic transmission at SC synapses through activation of presynaptic Y2 receptors that inhibit voltage-dependent calcium channels. In contrast, our preliminary results suggest that NPY inhibits TA synapses through activation of Y1 receptors. Investigating the effects of NPY on TA synapses and determining the receptor subtypes involved will be important for advancing our understanding of how endogenously released NPY modulates hippocampal circuit function and behavior.

Title: Rapid dynamic changes of dendritic inhibition in the dentate gyrus by presynaptic activity patterns

Authors: *Y.-C. LIU, C.-C. LIEN;
Inst. of Neurosci. & Brain Res. Ctr., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The dentate gyrus (DG) serves as a primary gate to control information transfer from the cortex to the hippocampus. Activation of incoming cortical inputs results in rapid synaptic excitation followed by slow GABA-mediated (GABAergic) synaptic inhibition onto DG granule cells (GCs). GABAergic inhibitory interneurons (INs) in the DG comprise fast-spiking (FS) and non-fast-spiking (non-FS) cells. Anatomical analyses of DG INs reveal that FS cells are soma-targeting INs, whereas non-FS cells are dendrite-targeting INs. These two IN classes are differentially recruited by excitatory inputs and in turn provide exquisite spatiotemporal control over GC activity. Yet, little is known how FS and non-FS cells transform their presynaptic dynamics into varying postsynaptic response amplitudes. Using paired recordings in rat hippocampal slices, we show that inhibition in the DG is dominated by somatic GABAergic inputs during periods of sparse presynaptic activity, whereas dendritic GABAergic inputs are rapidly shifted to powerful and sustained inhibition during periods of intense presynaptic activity. The variant dynamics of dendritic inhibition is dependent on presynaptic IN subtypes and their activity patterns and is attributed to Ca2+-dependent increases in the probability of release and the size of the readily releasable pool. Furthermore, the degree of dynamic GABA release can be reduced by blocking voltage-gated K+ channels, which increases the efficacy of dendrite-targeting IN output synapses during sparse firing. Such rapid dynamic modulation of dendritic inhibition may act as a frequency-dependent filter to prevent overexcitation of GC dendrites and thus set the excitatory-inhibitory synaptic balance in the DG circuits.

Title: Specific types of interneurons regulate input pattern-dependent recruitment of dentate granule cells

Authors: *C.-T. LEE, M.-H. KAO, C.-C. LIEN;
Inst. of Neuroscience, Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The dentate gyrus (DG) serves as a gateway to the hippocampus, filtering and processing incoming afferent information from the cortex and passing output to other hippocampal areas. The DG comprises a heterogeneous population of granule cells (GCs). Among them, mature GCs, the largest neuronal population of the DG, are under tight inhibitory control by various GABAergic interneuron (IN) types. However, the causal link between identified GABAergic INs and mature GC activation in response to afferent activity from entorhinal inputs remains unknown. Here we show that pharmacological GABAA receptor blockade not only greatly enhances the sensitivity of mature GCs to afferent inputs, but also recruits a subset of non-spiking mature GCs. Using cell type-specific optogenetic silencing, we found that parvalbumin-expressing (PV+) INs, but not somatostatin-expressing (SST+) INs, primarily suppress mature GC responses to single-shock stimulation of cortical input. By contrast, PV+ INs and SST+ INs differentially regulate mature GC dynamics in response to θ and γ frequency inputs. Notably, PV+ INs control the onset of the spike series, whereas SST+ INs regulate the late spikes in the series. Together, these results demonstrate that GABAergic IN types differentially regulate mature GC input transformations in response to different cortical input patterns.

Title: Mapping serotonin modulation of excitatory and inhibitory synapses in the limbic mouse brain

Authors: *A. BELMER, O. PATKAR, S. E. BARTLETT;
QUT-IHBI-TRI, Woolloongabba, Australia

Abstract: Serotonin (5-Hydroxytryptamine, 5-HT) is complex neuromodulator acting both at excitatory (glutamate) and inhibitory (GABA) synapses to regulate complex behavioural functions such as mood, appetite, reward and learning. Dysregulations of the 5-HT system have been extensively involved in anxiety, stress, depression, impulsivity and addiction. Serotonin neurons originating from the brainstem Raphe nuclei send broad and diffuse projections all over the brain. However, the exact nature of synapses (excitatory or inhibitory) modulated by serotonin transmission throughout the brain is still unclear. Thus, we have developed a method combining immunohistochemistry, confocal imaging and 3D processing to quantify the density of 5-HT synaptic boutons on excitatory and inhibitory synapses in the limbic system of the mouse brain. Presynaptic boutons within serotonin axons were colocalized with excitatory and inhibitory postsynaptic markers to compare the density of 5-HT appositions on glutamate and GABA synapses throughout several regions of the limbic mouse brain (prefrontal cortex, nucleus accumbens core and shell, bed nucleus of the stria terminalis, basolateral amygdala, hippocampus, ventral tegmental area). This technique will further allow for mapping the changes in 5-HTergic neuroplasticity associated with various psychopathologies (generalized anxiety disorders, acute and post-traumatic stress disorders, major depressive disorders, impulse control disorders and addictive disorders).

Title: How activation of 5-HT2 receptors increases spontaneous but depresses evoked transmitter release in layer 2/3 pyramidal cells of rat somatosensory cortex

Authors: *F. AGAHARI[1], C. STRICKER[1,2];
[1]The John Curtin Sch. of Med. Res., The Australian Natl. Univ., Canberra, Australia; [2]ANU Med. School, The Australian Natl. Univ., Canberra, Australia

Abstract: Serotonergic modulation of glutamate release in neocortex plays important physiological role in depression. However, the mechanism(s) of action is still not understood. **Objective:** To investigate how serotonin (5-HT) modulates glutamate release in barrel cortex, focusing on signalling downstream of 5-HT G-protein-coupled receptor (GPCR) activation. **Methods:** Recordings were performed in 300 μm thick parasagittal slices of P15-19 male Wistar rats. Miniature excitatory postsynaptic currents (mEPSCs) were recorded from layer 2/3 pyramidal cells in barrel cortex at 36 ± 1°C in the presence of 1 μM tetrodotoxin and 3 μM gabazine. For paired recordings, the pre- and postsynaptic pyramidal cells were current- and voltage-clamped, respectively. Presynaptic action potentials were evoked at 0.2 Hz using short current pulses of ~1.8 nA @ 5 ms. Short-term depression (STD) was induced by 20 or 40 action potentials (APs) at a rate of 50 Hz. Recovery was measured 500 ms after the last AP in STD. **Results:** In 5/12 cells, 10 μM 5-HT increased mEPSC frequency transiently but significantly by 35 ± 3% from 51 ± 4 to 69 ± 5 Hz, without changing its amplitude. 20 μM α-methyl-5-HT (5-mHT, pan-5-HT_2 agonist), but not 1 μM DOB (5-HT_{2C} K_i = 69 nM), produced the same increase (n = 2/9). After application of PKC inhibitor Gö 6983 (100 nM), 5-HT caused a maintained increase in mEPSC frequency by 27 ± 2% from 60 ± 5 to 75 ± 6 Hz (n = 3/7). 5-HT failed to cause any significant change with the PLC inhibitor edelfosine (30 μM; n = 5) or the IP_3 receptor antagonist 2-APB (16 μM; n = 7). In paired recordings, 5-HT depressed EPSC amplitude by 54 ± 3% from -7.4 ±1.3 to -3.4 ± 0.5 pA (p = 0.003; n = 6) independent of $GABA_A$ inhibition. 5-mHT produced the same decrease of 57 ± 4% from -12.1 ± 4.8 to -5.5 ± 2.6 pA (p < 0.05; n = 3). This depression was completely blocked when the Gβγ binding peptide mSIRK (100 μM) was included in the presynaptic patch solute (n = 5). mSIRK also blocked noradrenaline (α_1 adrenergic receptor)-induced EPSC depression (n = 7), suggesting a similar mechanism. 5-HT increased recovery from STD, as the ratio of recovery *vs*. 1st EPSC amplitude increased significantly (n = 8). Quantal analysis for this depression showed that monoamine application presynaptically decreased both quantal content and size by 60 ± 10 and 27 ± 3%, respectively. **Conclusion:** 5-HT activates 5-HT_{2A} G_qPCR to increase mEPSC frequency via signaling downstream of PLC, but concurrently decreases EPSC amplitude (likely) via Gβγ binding to SNAP-25 that results in fusion pore limitation. Our findings establish this mechanism as G_q-mediated pathway, and suggest a common mechanism for monoamine modulation.

Title: Spontaneous somatostatin cell activity and the regulation of disynaptic, Martinotti inhibition in neocortical networks

Authors: *J. URBAN CIECKO, A. P. GOSWAMI, J. PILLI, A. L. BARTH;
Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: High basal firing of low-threshold-spiking, somatostatin (Sst+)-expressing inhibitory neurons suppresses excitatory transmission between pyramidal cells via tonic activation of presynaptic GABAb receptors. Here we investigate how the spontaneous activity of Sst+ interneurons influences synapses in a ubiquitous cortical module of inhibition, the pyramidal-Martinotti disynaptic loop. Because Martinotti cells themselves are Sst+, we hypothesized that they might suppress their own activity and GABA release via GABAb activation. First, we examined whether disynaptic inhibition might be suppressed when spontaneous Sst+ activity was high. This was not the case. Furthermore, electrophysiological recordings from pairs of synaptically connected pyramidal and Sst+ neurons in layer 2 of primary somatosensory cortex in mice indicate that Sst+ neurons do not show tonic pre- or postsynaptic GABAb receptor activity. Although presynaptic GABAb receptors could be pharmacologically detected at pyramidal to Sst+ cell synapses, spontaneous activity of Sst+ cells was not associated with tonic activation of these GABAb receptors. Optogenetic Sst+-silencing did not significantly change the efficacy of excitatory, pyramidal inputs onto Sst+ cell synapses. Thus, we conclude that disynaptic inhibition through Sst+ Martinotti cells is not regulated by tonic GABAb activity. We propose that the spatial location of Sst+-mediated GABA release is not permissive for the tonic activation of presynaptic GABAb receptors at pyramidal to Sst+ cell connections.

Title: GABA-B receptor regulation of extracellular glutamate in the prefrontal cortex of adolescent and adult C57Bl/6J mice

Authors: *R. I. MELENDEZ, R. A. J. BROOKS, L. M. MELECIO;
Dept. Anat. and Neurobio. A-543, Univ. Puerto Rico, San Juan, PR

Abstract: The prefrontal cortex (PFC) underlies executive cognitive functions that require elevated capacity for synaptic plasticity, which is mediated by glutamate. However, the *in vivo* processes contributing to extracellular glutamate in the PFC are not well understood. Microdialysis was used to determine the synaptic and/or glial sources contributing to extracellular glutamate release in the PFC of adolescent and adult C57BL/6J (B6) mice (n=4-8/age/drug). A microdialysis probe (1 mm membrane) was inserted into the medial PFC and aCSF was perfused through the probe at 1 μl/min. Following the collection of baseline samples, reverse microdialysis (i.e., local drug infusion) began by replacing the aCSF perfusate with one the following compounds: (a) the GABAB agonist, baclofen (1mM), (b) the AMPA/kainate antagonist, DNQX (100 μM), or (c) system xc- (i.e., glial glutamate) antagonist, carboxyphynylglycine (CPG; 100 μM). Concentrations of glutamate were determined by HPLC analysis. The mean (SEM) basal extracellular glutamate levels in adolescent and adult mice were (in μM) 4.4 + 1.5 and 3.8 + 0.4, respectively. Infusion of baclofen led to a rapid and robust decrease in extracellular glutamate levels in both age groups. Mean (SEM) inhibition of baseline (in percentage) following intra-PFC baclofen was 84.2 ± 1.8 in adolescent and 79.2% ± 3.2 in adult mice, suggesting that GABAB receptor activation is sufficient to regulate nearly 80% of total glutamate release in the PFC. Infusion of DNQX also resulted in a significant reduction in extracellular glutamate levels, and to a greater extent in adolescent (56.6% ± 9.9) compared to adult (38.7% ± 9.7) mice, suggesting greater AMPA and/or kainate receptor glutamate release during adolescence. Interestingly, infusion of CPG resulted in a significant decrease in extracellular glutamate levels in adult mice (23.5 ± 8.0 inhibition), whereas no significant effects were shown in adolescent mice (17.1 ± 3.4 % inhibition), suggesting greater glial-mediated glutamate release during adulthood. In separate mice, we determined the effect of intra-PFC baclofen (1 mM) infusions on the acquisition of spatial learning using a water maze task, and demonstrated a nearly 50% reduction in spatial learning following baclofen relative to aCSF-controls. Together, these findings suggest that the majority of extracellular glutamate levels in the PFC derive from synaptic origins, especially during adolescence. It also appears that GABAB receptors are sufficient for modulating presynaptic glutamate release in PFC, which appears to be necessary for learning and synaptic plasticity.

Title: Analgesic synergy between alpha2A-adrenergic and delta-opioid receptors occurs presynaptically on nociceptive afferent terminals in spinal cord

Authors: D. J. BRUCE[1], J. J. WAATAJA[2], C. A. FAIRBANKS[3], *G. L. WILCOX[4];
[1]Dept Pharmacol., [2]Dept Neurosci., [3]Dept Neurosci, Pharmacol, Pharmaceutics, [4]Dept Neurosci, Pharmacol, Dermatol, Univ. Minnesota Med. Sch., Minneapolis, MN

Abstract: Delta-opioid receptor (DOR) and α2A-adrenergic receptor (α_{2A}AR) agonists produce synergistic antinociception spinally. We have previously shown that i) α_{2A}ARs co-localize with DORs on peptidergic primary afferent terminals in superficial dorsal horn, ii) clonidine (α_{2A}AR-selective agonist) or deltorphin II (DOR-selective agonist) inhibit CGRP release from spinal cord slices stimulated by K^+, and iii) intrathecal co-administration of clonidine and deltorphin II produces PKC-epsilon-dependent analgesic synergy. The literature documents that either DOR or α_{2A}AR agonists reduce evoked excitatory postsynaptic current (eEPSC) size and miniature EPSC (mEPSC) frequency, indicating that they act presynaptically to inhibit glutamate release from primary afferent terminals; however, no study has tested for synergy using these measures. To test this hypothesis, we recorded from rat and mouse substantia gelatinosa neurons in spinal cord slices. In rat spinal cord slices, nociceptive afferent terminals expressing TRPV1 receptors were tonically driven by continuous superfusion with 300 nM capsaicin (in the presence of 1 μM tetrodotoxin (TTX), 100 μM picrotoxin, 100 μM AP5 and 5 μM strychnine); capsaicin treatment increased mEPSC frequency over baseline 2-10-fold, documenting increased vesicular glutamate release from nociceptive afferent terminals. Superfusion with brimonidine (UK-14,304) or deltorphin II decreased capsaicin-driven mEPSC frequency 10-75% in a concentration-dependent manner (range 1-10 nM). Co-administered brimonidine and deltorphin II decreased mEPSC frequency at 100-fold lower concentrations (0.01-0.1 nM), and isobolographic analysis confirmed that this interaction was synergistic. A similar increase in potency to inhibit electrically evoked C-fiber-mediated EPSCs was evident with co-application in mouse spinal cord slices. These data strongly support the hypothesis that DOR- α_{2A}AR synergy takes place presynaptically on nociceptive afferent terminals.

Title: Effect of CB1 receptor antagonist on habituation and prepulse inhibition of the acoustic startle response

Authors: *A. G. LOUTTIT, C. DE OLIVEIRA, S. SCHMID;
Anat. and Cell Biol., Univ. of Western Ontario, London, ON, Canada

Abstract: The acoustic startle response (ASR) is a rodent model system used to measure sensory filtering. It consists of a short primary startle pathway modulated by short-term habituation and prepulse inhibition (PPI). The cellular mechanisms underlying short-term habituation and PPI are not fully understood, but a potential role for the cannabinoid type 1 (CB1) receptor exists through inhibition of neurotransmitter release. We hypothesized that CB1 receptors in the caudal pontine reticular nucleus (PnC), the sensorimotor interface of the ASR, are involved in short-term habituation and PPI of the ASR. We investigated the role of CB1 receptors with systemic and intracranial administration of the CB1 receptor antagonist N-(Piperidin-1-yl)-5-(4-iodophenyl)-1-(2,4-dichlorophenyl)-4-methyl-1H-pyrazole-3-carboxamide (AM251) to male Long Evans rats. Bilateral intracranial injections were made into the PnC through chronically implanted cannulae. Following injections, short-term habituation and PPI were monitored using Med Associates startle boxes. Systemic administration of AM251 at the dose of 1 mg/kg had no effect on short-term habituation; however, both the 3 mg/kg and 5 mg/kg dose improved short-term habituation. Local microinfusions of AM251 (0.5 µL per side) had no effect on short-term habituation at both the doses of 10 µM and 1 mM. Both systemic and intracranial injections had no effect on PPI. These findings suggest CB1 receptors modulate either short-term habituation or sensitization through actions outside the PnC and that they are not involved in PPI or PPI modulation.

Title: Medial pre-frontal cortex CB1 receptors modulate the conditioned emotional response: involvement of the glutamatergic and nitrergic neurotransmissions

Authors: *D. L. ULIANA[1], L. S. ANTERO[2], S. F. LISBOA[2], L. B. M. RESSTEL[2];
[1]Pharmacol. Departament, [2]Pharmachology Departament, Univ. of São Paulo, Ribeirao Preto, Brazil

Abstract: Cannabinoid receptor type 1 (CB1) present in the ventral portion of medial pre-frontal cortex (vMPFC) modulates the conditioned emotional response (CER), in contextual fear conditioning (CFC). CB1 receptor activation has been related with decrease behavior and cardiovascular response during contextual re-exposure. Furthermore, the vMPFC NMDA glutamate receptor and neuronal nitric oxide synthase (nNOS) are involved with CER modulation. Possibly, the response induced by CB1 involves modulation of glutamate release and NO production. Therefore, this study tests the hypothesis that CB1 receptor modulates CER through NMDA activation and NO pathway. Male Wistar rats (250-270g) with bilateral guide cannula targeted to the vMPFC were first exposed to a chamber during 10 min (habituation). In a second exposure to the same chamber, they received 3 electrical footshocks (0.85 mA, 2 s). 24h later, a polyethylene catheter was implanted in the femoral artery for cardiovascular recordings. After additional 24h, the behavioral and autonomic responses (mean arterial pressure - MAP, heart rate - HR and cutaneous temperature - CT) were continuously assessed during the 10 minutes of the re-exposition to the same chamber with no footshocks (test session). Vehicle (Saline or DMSO10%) or/and the CB1 antagonist (NIDA; 25, 55, 100pmol); NMDA antagonist (LY 2 nmol); nNOS inhibitor (NPLA; 0.04 nmol); NO scavenger (c-PTIO; 1nmol) or cCG inhibitor (ODQ; 1 nmol) were administered in the vMPFC 10 min before the test session. The Institution's Animal Ethics Committee approved housing conditions and experimental procedures (process number: 157/2013). CB1 antagonism receptor in the dose of 55 and 100 pmol increased the time spent in freezing behavior ($F_{3,22}=11,14$; $p<0.05$, ANOVA, Tukey pos-hoc), and also induced an enhancement of the rise in MAP ($F_{3,22}=10,23$, $p<0.05$, ANOVA,

Tukey pos-hoc), HR ($F_{3,22}=8,259$, $p<0.05$, ANOVA, Tukey pos-hoc) and the CT decrease ($F_{3,22}=3,276$, $p<0.05$, ANOVA, Tukey pos-hoc) during the re-exposure. LY, NPLA, c-PTIO, ODQ were not able to change either freezing behavior ($p>0.05$) or autonomic response (MAP, $p>0.05$; HR, $p>0.05$; CT, $p>0.05$). However, when administrated previously to the CB1 antagonist, NIDA 55 pmol, prevented the CER enhancement. The present data demonstrate that the CB1 antagonist, NIDA, changed freezing behavior and autonomic response in the re-exposure session, suggesting that CB1 receptor in vMPFC modulate CER, in CFC model. And also, this response seems to be dependent NMDA activation and NO pathway.

Title: Neuromodulatory control of intercalated cell-associated synapses within the amygdala: implications for anxiety disorders

Authors: *B. L. WINTERS, E. E. BAGLEY;
Sch. of Med. Sciences/Discipline of Pharmacol., Univ. of Sydney, Sydney, Australia

Abstract: The intercalated cells (ITC) of the amygdala are small, densely populated GABAergic interneurons that form a large nucleus surrounding the basolateral amygdala (BLA) and provide a significant inhibitory interface between the BLA and central amygdala (CEA). ITCs have been found to play an important role in fear memory and the modulation of ITC activity is thought to affect amygdala output and formation of anxiety-related behaviour. In particular, ablation of ITC control has been shown to impede fear extinction, a memory process that is thought to be impaired in anxiety disorders such as post-traumatic stress disorder. These cells can be identified by their high expression of both enkephalin and the mu-opioid receptor. Similarly, ITCs highly express the dopamine D1 receptor, which has been shown to hyperpolarise ITCs through the activity of G-protein inwardly rectifying potassium channels (GIRK). ITCs receive multiple inputs including: glutamate afferents from the BLA and medial prefrontal cortex, dopamine afferents from the ventral tegmental area and local GABAergic inputs within the ITC nucleus.

Convergence of these synaptic inputs and intrinsic opioid signalling likely plays an important role in gating ITC activity. Indeed, both dopamine and opioid-dependent signalling has been implicated in the acquisition and extinction of fear memory. However, the effects of these neuromodulators on ITC-associated synaptic activity are unknown. Using whole-cell, voltage-clamp electrophysiology we recorded electrically evoked synaptic currents from ITCs in coronal slices of the amygdala, isolated from male Sprague-Dawley rats (3-5 weeks). We show that exogenous application of met-enkephalin (ME) reduces the amplitude of excitatory postsynaptic currents (EPSC) at both BLA- and cortical-ITC synapses by decreasing presynaptic glutamate release. Similarly, ME reduced inhibitory postsynaptic currents (IPSC) at local ITC-ITC synapses. Further, following modest field stimulation and inhibition of enkephalin-related peptidases, we show the opioid antagonist naloxone increases EPSCs at BLA-ITC associated synapses indicating endogenous opioids are present and acting to reduce glutamate release. Similarly we find dopamine decreases BLA-ITC synaptic activity via D2 receptor-mediated inhibition of glutamate release. Together, these data indicate endogenous opioids and dopamine have the capacity to be significant modulators of ITC function and may participate in regulating key circuitry underlying fear memory.

Title: Acid Sensing Ion Channels can follow high frequency 'synaptic' stimuli

Authors: *D. M. MACLEAN, V. JAYARAMAN;
Biochem., UT- Houston, Houston, TX

Abstract: Acid sensing ion channels (ASICs) are trimeric cation-selective ion channels activated by protons in the physiological range. Recently, synapses have been identified which activate ASICs using the protons stored in synaptic vesicles as neurotransmitters. Like virtually all neurotransmitter-gated ion channels, ASICs activate very rapidly and in the continual presence

of agonist they show fast and near complete desensitization with a time constant of approximately 1 second. However during physiological synaptic transmission the acidification of the synaptic cleft does not last for 1 second. Rather, the cleft experiences very transient pH dips of approximately 1 milisecond in duration. Here we examined the responses of ASICs to such physiologically relevant 1 milisecond 'synaptic' acidifications as either single events or as trains of events to mimic high volume synaptic transmission. Whereas virtually every other neurotransmitter receptor desensitizes during such high frequency (50 Hz) trains, we find that ASICs are able to follow these trains with high fidelity and no desensitization. Thus, during the high volume synaptic activity which drives memory formation and synaptic plasticity, when all other neurotransmitter receptors experience desensitization neuronal ASICs may function unimpeded. This unique capacity might underlie ASICs roles in learning, fear memory and drug addiction.

Title: The role of kainate receptors in modulating hilar network excitability

Authors: *T. HEDRICK[1], W. P. NOBIS[2], G. T. SWANSON[2];
[1]Pharmacol., Northwestern University, Feinberg Sch. of Medici, Chicago, IL; [2]Northwestern University, Feinberg Sch. of Med., Chicago, IL

Abstract: Many models of temporal lobe epilepsy are typified by hippocampal hyperexcitability that arises from altered activity and connectivity of hilar neurons, which induces aberrant excitation/inhibition balance and perpetuates seizures. Kainate receptors (KARs) modulate the excitation/inhibition balance elsewhere in hippocampus through actions on synaptic and intrinsic excitability, and recent evidence suggests that enhanced KAR function in the dentate gyrus in part drives hyperexcitability in temporal lobe epilepsy. However, the role of KARs in the healthy hilus is unknown. In this project, we test the hypothesis that KARs modulate synaptic and

intrinsic excitability at defined synapses and in subpopulations of hilar neurons. To address this hypothesis, we are making whole-cell patch clamp recordings of hilar mossy cells (HMC), granule cells (GC), and populations of hilar interneurons (HI) in acute slices from adult mice. We will determine: 1) if KARs are present at various hilar synapses and what subunits and accessory proteins they are composed of, and 2) how KARs impact synaptic or intrinsic excitability. These results will provide a framework for future studies which examine how KAR function is altered in hilar pathology. Our initial results demonstrate that KARs modulate synaptic and intrinsic excitability in the hilus, and that the role of hilar KARs is synapse-specific. At GC-HMC synapses, KARs mediate postsynaptic currents that are impacted by association with neuropillin and tolloid-like (Neto)1 and Neto2 auxiliary proteins (decay kinetics for WT: 45.5 ± 4.4, Neto1 knockout: 21.8 ± 1.9, and Neto2 knockout: 64.8 ± 8.9 ms). Future studies will examine the subunit composition of these KARs and their role in synaptic plasticity. In contrast, at HMC-GC synapses, presynaptic KARs modulate glutamate release (AMPA-mediated current amplitude is decreased to 66.0 ± 5.7% of its original amplitude after kainate application) thus mediating short-term synaptic plasticity. In addition to synaptic effects, KAR activation modulates intrinsic excitability in HMCs by decreasing the Ih current (sag ratio is decreased 4.0 ± 1.2% after kainate application). Thus KARs modulate both synaptic and intrinsic excitability at specific locations within the hilar circuit. Our results show that KARs can help set hilar network excitability at various stages in the hilar circuit via modulation of synaptic and intrinsic excitability. These data shed light on the role of KARs in the healthy hilar circuit, as well as provide a jumping off point for future research which examines alterations in KAR function in hilar pathology.

Title: Propofol facilitates pyramidal cells firing synchrony in rat cerebral cortex

Authors: *Y. KOYANAGI[1], Y. OI[1], N. KOSHIKAWA[2], M. KOBAYASHI[2];
[1]Dept. Anesthesiol., [2]Dept. Pharmacol., Nihon Univ. Sch. Dent., Tokyo, Japan

Abstract: The general anesthetic propofol rises frontal alpha rhythm at the dose that is sufficient to induce loss of consciousness (Purdon at al., 2013; Ching et al., 2010; Feshchenko at al., 2004). However, the neural mechanisms of propofol-induced alpha rhythm in the cerebral cortex remain unknown. We previously demonstrated that inhibitory fast-spiking cells (FS) to excitatory pyramidal cells (Pyr) connections are the most sensitive to propofol-induced facilitation of unitary inhibitory postsynaptic currents (uIPSCs; Koyanagi et al., 2014). Taken together with the finding that inhibitory postsynaptic potentials (IPSPs) promote a high degree of synchrony (Hu et al., 2011), it is reasonable to propose the hypothesis that propofol-induced facilitation of uIPSPs results in firing synchrony among postsynaptic Pyr that receive inhibition from the same presynaptic FS. Triple or quadruple whole-cell patch-clamp recordings were performed from one FS and two or three Pyr in rat insulocortical slices. We recorded the uIPSCs, and the synchronicity was evaluated in the pairs with ≥ one connection of FS◊Pyr. After checking the connections, Pyr were depolarized to generate repetitive spike firing, and we examined how presynaptic FS action potentials modulate the timing of spike firing among Pyr. In control, inhibitory inputs from FS had little effect on spike timing synchrony among Pyr. Bath application of 10 μM propofol significantly potentiated uIPSPs, and reduced the coefficient of variation of spike timing among Pyr during FS activation. Propofol had little effect on spontaneous firing synchronicity. These results suggest that propofol facilitates Pyr firing synchrony by enhancing inhibitory inputs from FS. This synchrony of Pyr may induce the frontal alpha rhythm that associates with propofol-induced loss of consciousness.

Title: Cyclic-AMP transients in CA1 neurons are greatest in intermediate and distal dendrites during β-adrenergic receptor activation

Authors: *V. LUCZAK[1], T. ABEL[1], J.-A. GIRAULT[2,3], N. GERVASI[2,3];
[1]Biol., Univ. of Pennsylvania, Philadelphia, PA; [2]Inst. Du Fer À Moulin INSERM U839, Paris, France; [3]INSERM UMRs 839, Paris, France

Abstract: In the hippocampus, cyclic-adenosine monophosphate (cAMP) is a critical second messenger required for long-lasting forms of synaptic plasticity, learning and memory. Cyclic-AMP is a direct substrate of protein kinase-A (PKA), exchange protein activated by cAMP (EPAC), and hyperpolarization-activated/cyclic-nucleotide gated channels (HCN channels), and therefore regulates multiple aspects of neurophysiology that include kinase activity, transcription, translation and excitability. To better understand how cAMP operates within the structural complexity of neurons to contribute to synaptic plasticity and memory, we used live two-photon microscopy and a genetically-encoded cAMP FRET sensor to monitor cAMP in live hippocampal slices. Bath application of isoproterenol, a β-adrenergic receptor agonist, produces local cAMP transients with greater amplitude and rate in intermediate and distal dendrites compared to somatic compartments and this effect is most dramatic with 100 nM isoproterenol. Furthermore, NMDA application alone slightly reduced cAMP levels and coapplication of NMDA and 1 μM isoproterenol attenuated cAMP production. Taken together, localized cAMP transients in CA1 neurons suggest that dendritic segments coordinate cAMP signaling and may differentially influence downstream effectors like PKA in specific dendritic compartments.

Title: Investigation of hippocampal pathways in a mouse model of lead exposure relevant to the El Paso region

Authors: A. TENA, E. PERU, *L. E. MARTINETTI, K. FENELON;
Dept. of Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: Lead (Pb) is a ubiquitous environmental heavy metal that can cause behavioral and cognitive deficits. Even Low-level Pb induces learning and memory impairments in children from low income neighborhoods found across the United States, including the El Paso-Ciudad Juarez border region. Numerous studies reported that high-levels Pb exposure alters the function of the hippocampus. However, the mechanisms by which lowest-level Pb affects neuronal function are still ill defined, due to the lack of animal models of low Pb exposure. In this study, we compared adult mice that were not exposed to Pb (control) to adult mice exposed from birth to post-natal day 28 to either high Pb levels (330 ppm) or low Pb levels (30 ppm). The 30 ppm exposure was specifically used because it was shown to yield blood Pb levels matching those observed in children of the El Paso region (Sobin et al., 2009 and 2011). Mice exposed to such low-level Pb showed poorer exploratory ambulation (Flores-Montoya and Sobin, 2014) and poorer novel odor discrimination (Flores-Montoya et al, in review), behaviors which are hippocampus-dependent. Using both high and low Pb exposed mice, extracellular field electrophysiological recordings were performed in the CA1 region of acute hippocampal slices. Our results revealed synaptic transmission and short-term synaptic depression abnormalities in both low (N = 9) and high (N = 9) Pb levels exposed mice compared to control mice (N = 17). In addition, previous work in children had shown that low-level Pb exposure is associated with deficits in working memory (Sobin et al, unpublished data), which depends on the functional integrity between the hippocampus and the prefrontal cortex (PFC). Therefore, we performed Optogenetics experiments in acute slices using these Pb exposed mice to determine if the hippocampus-PFC synapses were altered. Our preliminary results suggest that the synaptic strength and short-term synaptic depression are also altered by both high (N = 3) and low Pb (N = 2) levels at hippocampus-PFC synapses. Overall, these results will contribute to better understand the long-term effects of low-level Pb exposure on learning and memory in children living in low-level environmental Pb conditions.

Title: Selective cholinergic modulation of layer 5 projection neurons in the mouse prefrontal cortex

Authors: *A. L. BAKER[1], R. J. O'TOOLE[3], A. T. GULLEDGE[2];
[2]Physiol. & Neurobio., [1]Geisel Sch. of Med. at Dartmouth, Lebanon, NH; [3]Biol. Sci., Dartmouth Col., Hanover, NH

Abstract: Pyramidal neurons in layer 5 of the mouse prefrontal cortex comprise two broad classes of projection neurons: commissural/callosal (COM) neurons, and corticopontine (CPn) neurons. These two neuron subtypes have distinct morphological and physiological characteristics, including divergent responses to neuromodulators such as serotonin, acetylcholine (ACh), and norepinephrine. To further characterize the role of ACh in regulating cortical circuits, we compared phasic responses to exogenous and endogenous ACh in labeled COM and CPn neurons in the medial prefrontal cortex (mPFC) of wild-type mice and mice expressing channelrhodopsin-2 in cholinergic neurons (ChAT-ChR2 mice; Jackson Labs). When paired with suprathreshold depolarization, exogenous ACh (100 μM for 100 ms) generated a brief inhibitory response followed by an excitatory response in COM and CPn neurons (data pooled from wild-type and ChAT-ChR2 mice). Apamin-sensitive inhibitory responses were qualitatively similar in COM (n= 22) and CPn (n = 16) neurons, but were of substantially longer duration in COM neurons (1.773 ± 0.176 s vs. 0.807 ± 0.119 s in COM and CPn neurons, respectively; $p < 0.05$). Excitatory responses to exogenous ACh, quantified as the peak increase in firing rate (% over baseline) following ACh application, were preferentially enhanced in CPn neurons. ACh increased firing rates by 191 ± 31% in CPn neurons, and 88 ± 13% in COM neurons ($p < 0.05$, when comparing CPn to COM neurons). Endogenous ACh release triggered by flashes of blue light (100 pulses, 5 ms each, at 59 Hz) had no effect in COM (n = 3) or CPn (n = 5) neurons from wild-type animals, and did not induce inhibitory responses in neurons from ChAT-ChR2 mice, but increased firing rates (by 27 ± 8% and 38 ± 10%, respectively) in both COM (n = 10) and CPn (n = 9) neurons ($p = 0.39$) from ChAT-ChR2 mice. Remarkably, single flashes of light (5 ms duration) enhanced action potential generation selectively in CPn neurons. In baseline conditions, periodic current steps (1.5 s duration) generated 9.2 ± 0.6 and 8.5 ± 0.4 action potentials in CPn neurons and COM neurons, respectively. Single flashes of blue light increased the number of action potentials in CPn neurons by 33 ± 5% (n = 9; $p < 0.05$), but had negligible impact (6 ± 6%; $p = 0.14$) on action potential generation in COM neurons (n = 13). Together, our results demonstrate cell-type selectivity in phasic cholinergic signaling in projection neurons in the mPFC, with ACh preferentially promoting excitation in CPn neurons.

Title: The role of acetylcholine in neural circuit modulation, behavior and development in *Drosophila* melanogaster

Authors: *C. MALLOY, C. ENGLISH, R. L. COOPER;
Biol., Univ. of Kentucky, Lexington, KY

Abstract: Acetylcholine (Ach) is the major excitatory neurotransmitter within the CNS of many insects, including the model organism, *Drosophila* melanogaster. The cholinergic system is integral in regulating specific behaviors in this animal, including the medial fiber escape response, in stimulating grooming and jumping, and in hyperactive geotaxis ability. This suggests that this system is important in mediating distinct sensory-CNS-motor circuits; however, the specific cholinergic receptor subtypes that are involved in regulation of these circuits is currently not well-defined. The larval CNS is readily accessible for direct recordings of identifiable sensory and motor neurons associated with the locomotive behaviors. In addition, sensory-CNS-motor circuits are able to be driven for pharmacological studies associated with acetylcholine receptors (AChRs) and genetic manipulation of cholinergic receptors is highly amenable. Thus, a combined genetic and pharmacological approach can be taken in order to examine the functional role of specific cholinergic receptor subtypes in modulating a defined sensory-CNS-motor circuit. In this study, we use electrophysiological and behavioral analyses to study neural circuit modulation in the presence of classic AChR agonists and antagonists. In addition, genetic knockdown of individual receptor subunits are used in order to identify specific receptor subunits that are integral in mediating these behaviors. Analysis has shown that AChR agonists, nicotine and muscarine, enhance motor activity when exposed directly to a larval CNS, while the classic muscarinic acetylcholine receptor (mAChR), scopolamine decreases motor activity. In addition, exposure to Ach and nicotine enhance larval locomotion after long-term exposure but decrease mouth hook movements providing evidence that these agonists have varying modulatory effects on two distinct circuits. We are now using these techniques in order to advance our knowledge regarding the role of this system in various developmental processes. Developmental assays can be performed in order to deduce the role of specific receptor subtypes in regulating nervous system development. Loss of specific AChR receptor subunits may prove detrimental in neural circuit formation and associated behaviors; however, compensatory mechanisms may act to override the loss of function of individual subunits. Thus, investigation into neuronal plasticity can be used in this model, and this analysis can act as a building block for these future studies.

Title: Removal of D2 receptors on striatal cholinergic interneurons impairs sequence learning

Authors: *J. H. CHANCEY[1], D. M. LOVINGER[2];
[1]LIN, [2]Lab. for Integrative Neurosci., NIH-NIAAA, Rockville, MD

Abstract: The dorsal striatum (dStr) plays a critical role in encoding action initiation and action sequences. Projection neurons from dStr, medium spiny neurons (MSNs), encode the start and stop of learned action sequences and are able to encode entire action sequences as a single event through sustained changes in firing throughout the sequence. Acetylcholine (ACh) plays an important role in striatal function by regulating MSN excitability, presynaptic glutamate release, GABAergic interneuron excitability, and plasticity. ACh can also drive the release of dopamine and possible co-neurotransmitters through nicotinic receptors on presynaptic terminals. Cholinergic interneurons (CINs) are the main source of ACh in the striatum and are tonically active, thereby establishing a cholinergic tone. Previous studies show that CINs in the dStr pause their firing during action sequences, but the significance of this physiology for behavioral performance has not been explored. We hypothesize that the pausing behavior of CINs is critical for mediating learning by regulating dopamine and glutamate release, and MSN excitability, allowing for the plasticity necessary for learning. Activation of D2 receptors (D2Rs) on CINs drives pauses in firing. Here we test how removing D2Rs from CINs affects learning a sequence of actions to obtain a sucrose reinforcer. We selectively eliminated D2Rs from CINs by crossing $D2^{flox/flox}$ with ChatCre mice (D2F-ChatCre) and tested sequence learning using an adapted fixed-ratio lever-pressing task that produces reliable action sequences in mice. Mice lacking D2Rs in CINs were able to learn the sequence task, but at a slower rate than $D2^{flox/flox}$ littermates. Trained D2F-ChatCre mice also demonstrated fewer lever presses and received fewer reinforcers per session than controls. The behavioral deficits were not due to overall deficits in motor skill learning or general motivation, because D2F-ChatCre mice perform similarly to controls in accelerated rotarod and progressive ratio breakpoint tasks and showed similar levels of homecage sucrose intake. Thus, the deficits we see in sequence learning may be specific to

action initiation, action chunking or behavioral flexibility required for the sequence task. We are currently performing, *in vivo* recordings of unit activity in dStr throughout acquisition of the sequence to determine if D2F-ChatCre mice have deficits in sequence encoding.

Title: The role of the cholinergic midbrain in sensory filtering and sensorimotor gating

Authors: *E. C. AZZOPARDI[1], S. SCHMID[2];
[2]Anat. and Cell Biol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Acetylcholine (ACh) is an important neurotransmitter that is involved in many aspects of cognition, but perhaps most notably in attention. Here, we aim to investigate the role of ACh in the pre-attentive processes of sensory filtering and sensorimotor gating. Sensory filtering is the removal of unnecessary sensory information from our conscious perception, freeing cognitive resources for more important information, whereas sensorimotor gating suppresses sensory evoked motor responses in favor of an orienting response towards a sensory stimulus. We study this using habituation and prepulse inhibition (PPI) of the acoustic startle response, respectively. Habituation is the exponential decrease in startle magnitude after repeated presentation of the startling stimulus. PPI occurs when the presentation of a prepulse inhibits the processing of the startling stimulus, resulting in a reduced startle magnitude. Traditionally, it has been assumed that cholinergic projections from the pedunculopontine tegmental nucleus (PPT) mediate PPI. To test this, we bilaterally injected 8 transgenic rats (Chat-Cre) with the DREADD vector rAAV8-hSyn-DIO-hM4Di-mcherry (or control) in the PPT. After 21 days of recovery, rats received an IP injection of CNO (3 or 10 mg/kg in 7% DMSO) or vehicle prior to sensory filtering testing. This specifically silenced cholinergic neurons of the PPT. Preliminary data shows that our highest dose of CNO did not disrupt short-term habituation or PPI at both prepulse levels (75 or 85 dB SPL) or across all interstimulus intervals tested (15, 30 or 100 ms). We did see a trend toward reduced baseline startle with CNO administration compared to vehicle. Preliminary immunohistochemistry showed good expression of the viral tag, mCherry, in the PPT and LTD.

Moreover, there was a very high overlap between mCherry and the cholinergic marker, Choline Transporter (ChT). Our ongoing experiments are investigating cholinergic PPT stimulation during sensory filtering tasks through optogenetics to continue to address this question. Additionally, we are using chemogenetic cholinergic PPT silencing in to investigate the role of this structure in orienting responses and attention.

Title: Optogenetic activation of medial septum cholinergic neurons improves contextual fear learning and alters choline levels in hippocampus

Authors: *S. J. HERSMAN, J. CUSHMAN, K. WASSUM, M. S. FANSELOW, S. LOTFIPOUR;
UCLA, Los Angeles, CA

Abstract: Cholinergic inputs to hippocampus, primarily from medial septum through the fimbria fornix, have long been thought to play an important role in contextual learning. Hippocampal blockade of muscarinic receptors using scopolamine prevents contextual learning, and inhibition of cholinesterase can lead to memory improvements in a variety of tasks. However, the effects of selective depolarization of cholinergic medial septal neurons on acetylcholine release in hippocampus and hippocampal-dependent learning and memory is not well understood. Using newly developed choline biosensors, we activated channel rhodopsin in medial septum cholinergic neurons (ChAT-Cre rats and mice) and measured light-evoked choline release in hippocampus. Choline release was timed to laser onset and offset and scaled with pulse width and laser power. Furthermore, pulse trains at moderate power levels led to sustained increases in choline throughout the duration of the pulse train stimulation. In order to test the selective effect of these pulse trains on contextual learning, we separated the contextual learning epoch from the

fear conditioning epoch using the context pre-exposure facilitation paradigm. ChAT-ChR2 mice and littermate controls were surgically implanted with fiberoptic ferrules targeting medial septum, and allowed to explore a novel environment while receiving concurrent blue light stimulation. The following day, mice were returned to the same environment and given a mild foot shock after 10 seconds in the environment. During a test of fear the following day, mice that received ChR2 stimulation during training demonstrated significant enhancements in freezing. These findings demonstrate the correspondence between choline increases detectable by the choline biosensor and changes to behavior, and suggest that increased acetylcholine in hippocampus during training facilitates contextual processing.

Title: Cholinergic modulation of the gain of hippocampal CA1 pyramidal neuron is synaptic input layer-dependent

Authors: *K. PARK, J. KWAG;
Dept. of Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of

Abstract: The spike outputs of hippocampal CA1 pyramidal cell (PC) contain neural information important for memory and spatial information processing. Thus, understanding how CA1 PC transforms its synaptic input into spike output and how neuromodulators change the sensitivity of the CA1 PC to its input could help us elucidate the principles underlying hippocampal neural computation. Among many different neuromodulators, acetylcholine (ACh) is known to play critical roles in hippocampal function, but its role in modulating CA1 PC's input-output transformation and its gain is not well understood. Therefore, we characterized the gain of CA1 PC in response to CA3-stimulated excitatory inputs via two synaptic layers, stratum oriens (SO) and stratum radiatum (SR), and investigated how the gain of CA1 PC is cholinergically modulated in the hippocampal circuit using whole-cell patch-clamp recording *in vitro*. Either SO or SR in the CA1 area were electrically stimulated at 1, 3, 5, 10, 20 and 30 Hz

and the corresponding spike outputs were analyzed to quantify the input-output (IO) curve and its gain. All experiments were conducted in the presence of D-AP5 (50 μM) to block the NMDA receptor-mediated plasticity. Cholinergic modulation of gain was investigated by applying ACh antagonist, atropine (10 μM) and agonist, carbachol (5 μM). When the stimulation frequency of SO was increased, the firing rate of CA1 PC increased sub-linearly, while the same stimulation protocol in the SR resulted in the spike output frequency of CA1 PC being buffered at 6 Hz. The gain of CA1 PC by SO stimulation was significantly higher than that by SR stimulation (gain: SO = 0.55 ± 0.07, SR = 0.14 ± 0.05, n = 8, $p < 0.001$), suggesting that CA1 PC gain is modulated in a synaptic layer-dependent way. Next, to investigate the effect of ACh on such synaptic input layer-dependence of gain modulation, we applied atropine. Atropine abolished the difference in gain (gain: SO = 0.27 ± 0.06, SR = 0.16 ± 0.02, n = 4, $p > 0.05$). Interestingly, atropine significantly decreased the gain of CA1 PC with inputs from SO only. When we applied carbachol, it increased the gain of CA1 PC with inputs from the SO but had little effect on the gain with inputs from the SR (gain: SO = 0.67 ± 0.10, SR = 0.23 ± 0.06, n = 4, $p < 0.01$). These results demonstrate that cholinergic modulation of CA1 PC's gain is synaptic layer-dependent and specific to input from SO. Such hippocampal circuit and neuromodulatory control of CA1 PC's gain may contribute to dynamically modulate the computational modes of CA1 PC to efficiently process the spatio-temporally dynamic inputs.

Title: Dissecting the roles of M1 and M4 receptors in CA1 excitatory transmission

Authors: ***C. A. THORN**, J. EDGERTON;
Pfizer Inc., Cambridge, MA

Abstract: Xanomeline, a muscarinic M1/M4 preferring agonist, has been shown to exhibit pro-cognitive and antipsychotic effects in patients with Alzheimer's Disease (Bodick et al., 1997) and schizophrenia (Shekhar et al., 2008); however, the mechanisms by which it exhibits these effects remain unknown. While the etiologies of Alzheimer's Disease and schizophrenia differ dramatically, both diseases are associated with severe dysregulation of hippocampal circuitry, which is thought to underlie psychotic symptoms and deficits in cognitive function. The CA1

region of the hippocampus integrates information from two excitatory pathways - the temporoammonic (TA) pathway from entorhinal cortex and the Schaffer collaterals (SC) from CA3. In the CA1 area, increased levels of acetylcholine are thought to bias transmission toward the more direct sensory input from entorhinal cortex over the more processed input from CA3 by acting at both muscarinic and nicotinic receptors in these two pathways (Hasselmo et al., 1996). In Alzheimer's Disease, reduced cholinergic tone in CA1 is thus thought to bias transmission toward SC inputs over the TA. Hyperdopaminergic function, seen in schizophrenia, has likewise been shown to produce selective inhibition of TA input with sparing of SC transmission (Otmakhova & Lisman, 1999). Within CA1, M1 receptors are expressed post-synaptically on pyramidal cells and interneurons, whereas M4 receptors are expressed pre-synaptically on SC terminals. Co-activation of these two receptor subtypes with compounds such as xanomeline could therefore normalize excitatory transmission within CA1 by selectively inhibiting SC pathway signaling while simultaneously enhancing TA signaling. Muscarinic acetylcholine receptors have been shown to modulate synaptic transmission in CA1, but determining the role of specific receptor subtypes has been historically difficult due to a lack of specificity of available agonists and antagonists. Recently, however, highly selective M1 and M4 agonists and positive allosteric modulators have become available to address this question. Using novel selective compounds, we have begun testing the effects of M1 or M4 activation in CA1 using whole cell *ex vivo* recordings from adult rat hippocampal slices. Here, we present preliminary results suggesting that M4 activation selectively reduces SC transmission in CA1 while sparing TA transmission.

Title: Effects of M1 and M4 muscarinic receptor activators on rat hippocampal neuron activity

Authors: E. UYKAL[1], S. J. NEAL[2], S. GRIMWOOD[1], *J. R. EDGERTON[1];
[1]Neurosci. & Pain Res. Unit, Pfizer, Inc, Cambridge, MA; [2]Novartis, Inc, Cambridge, MA

Abstract: Hippocampal dysfunction is implicated in many neurological and neuropsychiatric disorders. Both hyperexcitability and hypoactivity of hippocampal neurons have been associated with learning and memory deficits. Acetylcholine (ACh) is a key modulator of neural excitability and synaptic transmission in the hippocampus, and loss of cholinergic innervation has also been implicated in episodic memory deficits associated with ageing and disease. Muscarinic receptors (mAChRs) of subtypes M1, M2, M3 and M4 are expressed in the hippocampus, and non-selective mAChR antagonists induce severe learning and memory deficits in both humans and animals. The respective functional roles of the mAChR subtypes have been partially addressed using knockout mice and relatively non-selective modulatory compounds, but the development of highly selective agonists and positive allosteric modulators (PAMs) for M1 and M4 in recent years is enabling more precise dissection of individual mAChR contributions. To gain a better understanding of M1 and M4 regulation of hippocampal circuitry, we have used multi-electrode arrays to record synaptic field potentials and neuronal action potentials from acute hippocampal slices prepared from 7 to 10 week-old rats. Field potential responses were recorded in CA1 stratum radiatum during Schaffer collateral stimulation, and in CA3 stratum radiatum during stimulation of the longitudinal association fibers. Extracellular spike rates were measured in CA1 and CA3. Activation of M1 receptors with the allosteric agonist GSK1034702 increased CA1 neuron firing by a factor of 32 ± 8 fold over baseline, with an EC_{50} of 443 ± 89 nM (n=9). M1 PAMs were active at significantly lower concentrations when applied in the presence of a low dose of an orthosteric agonist, compared to when applied alone, correlating with the results of cell-based assays. Activation of M4 receptors with the M4 PAM VU-0152100 potently inhibited glutamatergic transmission from CA3 to CA1 (EC_{50} = 77 nM $\pm$ 15.3 (n=3); max = 55%). Another M4 PAM, PT-1148, also inhibited the CA3 auto-associative network. These results suggest that M1 activators will increase hippocampal pyramidal neuron excitability and potentially benefit disorders of hippocampal hypofunction, while M4 activators will dampen the CA3 auto-associative network and reduce CA3-to-CA1 transmission, making them attractive therapeutics for disorders of hippocampal hyperexcitability.

Title: Characterization of a novel M1 mAChR positive allosteric modulator radioligand, [^{3}H]PF-1284

Authors: *D. L. SMITH[1], J. E. DAVOREN[2], J. T. LAZZARO[3], L. ZHANG[2], S. GRIMWOOD[1];

Abstract: The orthosteric muscarinic acetylcholine receptor (mAChR) agonist xanomeline achieved a proof of concept in human clinical trials for schizophrenia and Alzheimer's disease. Although reportedly selective for mAChR M1 and M4-subtypes, xanomeline caused adverse effects presumed to be mediated through mAChR M2 and M3 subtypes, which led to a high drop-out rate in these clinical trials. In 2009 the highly M1-selective positive allosteric modulator (PAM) BQCA was disclosed. Based on distribution studies, activation of M1 subtypes should bestow a pro-cognitive effect. The development of an M1 PAM radioligand will be a useful tool in characterizing the allosteric binding site as well as a probe to explore effects of M1 PAMs. PF-1284 is a novel M1 mAChR PAM shown to have an EC_{50} of 21.5 ± 4.37 nM (mean ± SEM; n=6) for stably expressing human M1 CHO cells (hM1), measured using a Ca^{2+} mobilization assay (FLIPR), in the presence of an EC_{20} concentration of ACh. PF-1284 also reduced the affinity of ACh required to inhibit [^{3}H]NMS binding to hM1, left-shifting the ACh EC_{50} by approximately 12-fold at 10 μM. The affinity and binding capacity of [^{3}H]PF-1284 were found to increase in the presence of increasing concentrations of ACh. In the presence of 1 mM ACh (EC_{max}), [^{3}H]PF-1284 was demonstrated to have saturable binding to hM1 with K_d = 6.18 ± 0.097 nM (n=3) and a maximal binding capacity of 6583 ± 373 fmol/mg protein (n=3). The M1 selective PAMs PF-8862 and PT-8345 were shown to inhibit [^{3}H]PF-1284 binding to hM1 with Ki values of 23 ± 3.31 and 68 ± 17 nM, respectively (mean ± SEM; n=3). Conversely, the M1 mAChR allosteric agonist, GSK1034702, showed weak affinity (>30 μM) in the [^{3}H]PF-1284 binding assay. M1 FLIPR EC_{50} values for a cohort of >20 compounds correlated well (r=0.8) with K_i values generated using the [^{3}H]PF-1284 binding assay in the presence of EC_{max} ACh. The [^{3}H]PF-1284 binding assay has been shown to be a useful tool for the investigation of M1 PAMs.

Title: Interplay between cholinergic and galaninergic modulation of GABA release in the basal forebrain

Authors: *J. C. DAMBORSKY, J. L. YAKEL;
Neurobio., NIEHS, Research Triangle Park, NC

Abstract: The basal forebrain (BF) is an important regulator of hippocampal and cortical activity. In Alzheimer's disease, there is significant dysfunction of cholinergic neurons within the BF, along with a hypertrophy of fibers containing the neuropeptide galanin. Despite its potential impact on BF function in Alzheimer's disease, little is known about the role that galanin plays in regulating BF activity under normal or pathological states. To examine the role of galanin in modulating synaptic transmission in the basal forebrain, we performed whole-cell patch clamp recordings from medial septum/diagonal band of broca (MS/DBB) neurons in acute brain slices from 6-10 week old C57/Bl6 mice. Galanin (500 nM) significantly decreased the frequency of spontaneous inhibitory postsynaptic currents (sIPSCs) with no effect on spontaneous excitatory postsynaptic currents (sEPSCs). Miniature (m)IPSCs were not significantly altered by galanin, indicating that galanin is working through an action potential-dependent mechanism. In addition to decreasing baseline inhibition within the MS/DBB, galanin also attenuated the increase in sIPSC frequency induced by the nonspecific cholinergic agonist carbachol (50 μM). These results suggest that galanin decreases GABA release in the MS/DBB, and may also interfere with the function of cholinergic receptors on GABAergic neurons. In order to selectively record from and stimulate cholinergic cells within the BF we injected AAV9-dfloxed hChR2(H134R)mCherry into the MS/DBB of 5-7 week old ChAT-cre mice. Whole-cell recordings were performed in acute slices 2-3 weeks following virus injection. Similar to what was seen in WT mice, we found that galanin significantly decreased sIPSC frequency onto identified cholinergic neurons in injected ChAT-cre mice. Activation of cholinergic neurons in the MS/DBB using 470 nm light to stimulate ChR2 increased sIPSC frequency in a subset of cholinergic neurons, an effect that was reduced by galanin. Together, our data point to an intricate relationship between galaninergic and cholinergic signaling in the MS/DBB, whereby galanin decreases inhibitory input onto cholinergic neurons and also attenuates cholinergic-mediated increases in GABA release. This balance between cholinergic and galaninergic modulation of GABA release is likely to be altered in patients with Alzheimer's disease, who have increased galanin expression and diminished cholinergic function in the BF.

Title: Firing statistics of parvalbumin neurons are selectively altered under isoflurane anesthesia

Authors: *A. E. HUDSON[1], J. T. TRACHTENBERG[2];
[1]Anesthesiol., [2]Neurobio., David Geffen Sch. of Medicine, UCLA, Los Angeles, CA

Abstract: General anesthetics suppress neuronal firing rates *in vivo*, yet unconsciousness is produced long before electrical quiescence. As volatile anesthetic concentration increases, population electrical activity becomes dominated by large amplitude, low-frequency oscillations. Using the genetically-encoded calcium indicator GCAMP-6 in mouse prefrontal cortex, we show that firing rates of parvalbumin-expressing inhibitory cells are less suppressed than pyramidal cells in layer 2/3 for isoflurane concentrations greater than 1.25%. Moreover, correlations between parvalbumin cells are higher than between pyramidal cells. This effect persists whether the continuous fluorescence signal or quantal fluorescent events corresponding to calcium fluxes are considered. This suggests that individual members of the cortical microcircuit are differentially affected by isoflurane and that the synchronization observed in population electrical activity may be, at least in part, mediated by increased correlation of firing in parvalbumin expressing inhibitory interneurons.

Title: Coordinated activation of neuronal patterns in synchrony of dissociated cortical neurons

Authors: *Y. YADA[1,2,3], R. KANZAKI[1,2], H. TAKAHASHI[1,2];
[1]Res. Ctr. for Advanced Sci. and Technol., [2]Mechano-Informatics, The Univ. of Tokyo, Tokyo, Japan; [3]JSPS Res. Fellow, Tokyo, Japan

Abstract: Coordinated neuronal activity in spontaneous synchrony has been observed in various types of neuronal networks. Even population bursting of dissociated cortical neurons has stable activity patterns, and it has been reported that some neurons act like “leaders” of bursting. Cortical neurons derived from rat embryos were cultured on CMOS-based microelectrode arrays. Spontaneous activity was recorded, and reproducible spatial patterns and their activity were extracted with non-negative matrix factorization. Then, activity of a specific spatial pattern always appeared before occurrence of burst; the pattern was defined as a leader pattern. We expressed the activity propagation from spatial patterns to spatial patterns with the state-space representation, where the activity of leader patterns acts as input to the model and the others as internal state variables. With only the activity of a leader pattern, spatiotemporal activity in population bursts was reconstructed from the model. The results suggested that activation patterns through neuronal synchrony are highly stable and leader neurons play important roles in generation of spontaneous synchrony.

Title: The dependence of the structural and functional changes of inhibitory neurons and glial cells of the human neocortex during chronic ischemia

Authors: *V. AKULININ[1], S. S. STEPANOV[2], A. SERGEEV[2], A. MYTSIK[2];
[1]Omsk State Med. Acad., Omsk, Russian Federation; [2]Omsk State Med. Univ., Omsk, Russian Federation

Abstract: The study of brake interneurons and glial cells of different lobes of the human neocortex during chronic ischemia. The actual data obtained on the intraoperative material (removal of tumors, n=19). For immunofluorescence studies of brake interneurons used primary rabbit polyclonal antibodies to calbindin D28k and neuropeptide Y (NPY), for glial cells to glial fibrillary acidic protein (GFAP). Visualization of the immune reaction was performed using goat polyclonal secondary antibody to rabbit immunoglobulin, Goat polyclonal Secondary Antibody to Rabbit IgG - H&L (TR) No. ab6719; Abcam, Cambridge, England), diluted 1:200. Antibodies associated with the fluorescent dye Texas Red® Sulfonyl Chloride (molecular weight 625 daltons). On the microscope, Axioskop 40, Karl Zeiss, equipped with a mercury lamp HBO 100, camera on the CCD sensor - Axio CamMRc and lens EC Plan-Neofluar x40, aperture of 0.9, was done digital micrograph image size x pixels, the actual size h μm (38280 μm2). Morphometric image analysis was performed using the ImageJ 1.46. We determined the overall numerical density (per 1 mm2) and total area (μm2) of the fluorescent marker pellets NPY and GFAP in the field of view of the drug. The statistical hypotheses were carried out using the software StatSoft Statistica 8.0. Used the nonparametric Mann-Whitney test and Spearman correlation analysis. The results are presented as median (lower, upper quartiles). The null hypothesis was rejected at $p < 0.05$. It is established that chronic ischemia in all fractions of neocortex in the brake interneurons activated synthesis calbindin and NPY, and in glial cells GFAP. The relative size of the labels NPY in the frontal cortex, in comparison with the control, increased from 2.20 (1.87; 2.50) to 4.28 (3.80; with 4.86) %. parietal - 2.13 (1.66; 2.76) to 3.93 (3.07; 4.61) %. temporal - 1.80 (1.50; 2.34) to of 3.91 (3.47; 4.67) %. occipital - 1.91 (1.71; 2.41) to 4.11 (3.30; 4.24) %. The area of GFAP on average increased in to 1.93 times - from 5.9 (4.0-8.3) % to 11.4 (8.7-14.5) % field of view. Revealed a strong positive stochastic relationship ($r = 0.82$; $p = 0.002$) between the relative area of the field of view of the brake interneurons and astrocytes. High level of expression of a specific protein in inhibitory interneurons was accompanied by high levels of expression of GFAP in glial cells. Probably, in the aggregate, it provides the regulation of distribution etc. excitatory impulses and the removal of excess glutamate from the extracellular space.

Title: A long-range disinhibitory circuit between the hippocampal area CA1 and the subiculum

Authors: R. FRANCAVILLA[1], E. P. MUNOZ[1], S. CHAMBERLAND[1], X. LUO[1], O. CAMIRE[1], K. WAGNER[2], P. SOMOGYI[2], *L. TOPOLNIK[1];

Abstract: Hippocampal long-range GABAergic projection (LRP) neurons comprise a diverse population of cells projecting to the medial septum, the subiculum, the medial entorhinal cortex, the retrosplenial cortex, the contralateral hippocampus as well as to the indusium griseum. Despite their potentially important role in coordinating rhythmic activity among functionally relevant brain areas, very little is currently known about their physiological parameters and cellular synaptic targets. Using a combination of retrograde labeling, dual patch-clamp recordings, anatomical analysis and optogenetics, we identified a subtype of vasoactive intestinal polypeptide (VIP)/muscarinic acetylcholine receptor type 2 (soma and dendrites) coexpressing interneuron with somata and dendrites located within stratum oriens and alveus of the hippocampal CA1 region, and an axon making local collaterals within CA1 as well as projecting to the subiculum (VIP-LRPs). Locally, VIP-LRPs could establish type 2 synapses with perikarya and dendrites of CA1 nonpyramidal neurons. In particular, VIP-LRPs innervated oriens-lacunosum moleculare interneurons via dendritically located synapses with a high probability and large unitary conductance. Furthermore, VIP-LRPs were coupled through GABAergic synapses and gap junctions. Interestingly, the electrotonic delay changed little with coupling ratio, pointing to phase compensation between electrically coupled neurons depending on dendritic gap junction location. In summary, the molecular profile and local targets of VIP-LRPs distinguish them from other hippocampo-subicular projecting nonpyramidal cells. The functional significance of this synaptically and electrically coupled disinhibitory circuit is currently under investigation.

Title: Investigation of theta-gamma coupled cortical traveling waves based on electrocorticography

Authors: Y. PARK[1], T. KIM[1], J. KIM[1], J. PARK[1], J. KANG[2], I. KIM[1], *D. JANG[1];

Abstract: In recent studies, coupled oscillations between the theta- and gamma-frequency bands have been investigated by electrocorticography (ECoG) signals in humans. Cortical propagation of low-frequency activity has also been shown in several studies. In this study, we observed the cortical traveling theta waves coupled with gamma power and showed regions that gamma activities coordinated by traveling theta waves. ECoG data were used that were acquired from grid electrodes covered frontal, temporal and parietal regions. To remove line noise, a 60Hz notch filter was used. Independent component analysis and common average reference were also applied to noise rejection. In order to verify the center frequencies of coupled low-frequency phase and high-frequency power, we obtained the phase-amplitude coupling (PAC) index that is calculated by entropy difference between the power distribution for each phase and the uniform distribution. Low- and high-frequency of maximum PAC index were selected as coupled frequencies. To observe traveling theta waves, we used concepts of reference location and motifs (Bahramisharif et al., 2013). Motifs consisted of four or more consecutive electrodes that have a linear increasing (or decreasing) pattern of phase respect to a reference location. In addition, only electrodes with a phase-locking value (PLV) over 0.1 with respect to the reference location. The band-pass filtered data with theta center frequency were used to calculate PLV and count motifs. To estimate PLV, the averaged phase difference between different electrodes over time was calculated and the angle of averaged phase difference was applied to confirm motifs respect to reference locations. We counted the number of motifs with respect to all reference locations and higher counted motifs were considered as main motifs of traveling theta waves. Furthermore, in order to identify which motifs coordinate some gamma activities, we also considered PAC index of motif electrodes with theta and gamma center frequency, As results of this study, we observed two streams of traveling theta waves coupled with gamma power activities. First coupled traveling waves propagated from anterior to posterior middle temporal lobe. The other traveling waves propagated from dorsal to ventral posterior parietal lobe.

Title: Abnormal cell-intrinsic excitability and cortical network activity in serotonin-deficient mice

Authors: *R. FERNANDEZ GALAN[1], P. A. PUZEREY[2], N. X. KODAMA[2];
[1]Dept Neurosci, [2]Case Western Reserve Univ., Cleveland, OH

Abstract: Neurons originating from the raphe nuclei of the brainstem are the exclusive source of serotonin (5-HT) to the cortex. Their serotonergic phenotype is specified by the transcriptional regulator *Pet-1*, which is also necessary for maintaining their neurotransmitter identity across development. Transgenic mice in which the *Pet-1* gene is genetically knocked out (KO), show a dramatic reduction (ca. 80%) in forebrain 5-HT levels, yet no investigations have been carried out to assess the impact of such severe 5-HT depletion on the function of target cortical circuits. Using whole-cell patch clamp techniques, 2-D electrode arrays, morphological reconstructions of cortical neurons, and animal behavior, we investigated the impact of 5-HT depletion on cortical cell-intrinsic and network excitability. We found significant changes in several parameters of cell-intrinsic excitability in cortical pyramidal cells, as well as an increase in spontaneous synaptic excitation through 5-HT3 receptors. These changes are associated with increased cortical network excitability and oscillatory activity in a 5-HT2 receptor-dependent manner, consistent with previously reported hypersensitivity of cortical 5-HT2 receptors in mutant mice. In contrast, recordings of network activity with 2-D arrays (120 electrodes; 100 um pitch) revealed that neuronal activity propagates less and more slowly in the neocortex of *Pet-1* KO mice than in wild-type controls. A possible, mechanistic explanation for these results is provided by the analysis of pyramidal cell morphology, which reveals a significant reduction in the complexity of their dendritic arbors. This likely leads to reduced network connectivity, acting as a compensatory mechanism for increased excitability at the single-cell level. Consistent with this interpretation, when we carried out experiments with convulsant-induced seizures to asses cortical excitability *in vivo*, we observed no significant differences in seizure parameters between wild-type and *Pet-1* KO mice. Our findings provide the first evidence for functional changes in neuronal and network excitability in target structures of serotonergic neurons in mice lacking the *Pet-1* gene.

Title: Imaging neuronal network activity with 2D electrode arrays

Authors: ***N. KODAMA**[1], P. PUZEREY[3], R. FERNANDEZ GALAN[2];
[1]Dept. of Neurosciences, [2]Case Western Reserve Univ., Cleveland, OH; [3]Cornell Univ., Ithaca, NY

Abstract: Current approaches to visualizing and analyzing neuronal activity at the circuit and microcircuit levels are mostly based on optical imaging techniques, using calcium and voltage-sensitive dyes. The former offers good spatial resolution to identify cell clusters and microcircuits but relatively poor temporal resolution, which is limited by the dissociation time constant of the dyes. In contrast, voltage-sensitive dyes offer high temporal resolution, comparable to that of electrophysiological recordings, but poor visualization of neuronal circuits, since the dyes mostly localize in dendritic arbors. For both techniques, the multiplexing of data acquisition hardware also imposes a trade-off between spatial and temporal resolutions. We present an alternative approach to imaging neuronal activity, not with optical signals but electric ones, which has both high temporal and spatial resolutions. To this end we use high-density, two-dimensional electrode arrays (120 electrodes; 1.2 sq. mm). Simultaneous recordings from all the electrodes over a patch of brain tissue are plotted as dynamic maps of the electric potential across neuronal networks, from which we can quantify the emergence, propagation speed and direction of neuronal activity, either evoked or spontaneous. Also, a current source density analysis allows us to track over time the current sources and sinks in the network, and determine their co-localization with different cell groups and types. We demonstrate how this approach to investigating neuronal network activity allows us for the first time to detect abnormalities of cortical circuits in animal models of disease in an accurate and highly efficient manner.

Title: Disinhibitory control of CA1 signal propagation through 5HT3a+ interneurons

Authors: *B. SUUTARI, R. W. TSIEN;
NYU Neurosci. Inst., New York, NY

Abstract: Signal transduction and information flow through the hippocampus is dependent on the strength and timing of excitatory and inhibitory transmission. Inhibitory neurons (INs) regulate the synaptic integration window and spike threshold of pyramidal (pyr) neurons. Given the variety of IN types in the hippocampus, the interplay between excitation and inhibition is dynamic and complex. One recently described aspect of the hippocampal excitatory-inhibitory circuit is disinhibition, or the inhibition of INs by other INs. Some CA1 INs that express the 5HT3a receptor (5HT3aR) inhibit parvalbumin (PV+), 5HT3a- INs. PV+ INs exert the greatest influence on feed-forward, perisomatic inhibition, which is responsible for regulating the ability of CA1 pyr cells to spike in response to excitatory synaptic input. Thus, 5HT3aR+ interneurons could in principle affect the entire CA1 microcircuit through disinhibition. Indeed we found that application of the 5HT3aR specific agonist 1-(m-chlorophenyl)-biguanide (mCPBG) caused a significant increase in the responsiveness of pyr neurons to Schaffer collateral (SC) inputs, consistent with the disinhibitory hypothesis. To dissect the mechanism of this improvement in spike throughput, we analyzed the interactions between 5HT3aR+ INs, PV+ INs and CA1 pyr neurons, specifically focusing at first on possible disinhibitory effects. To isolate the effect of the 5HT3aR+ IN→PV+ IN→Pyr neuron pathway, we held pyr neurons at 0 mV to trigger endocannabinoid (EC) release and thus depress the 5HT3aR+ IN→ Pyr synapse. Under these conditions, we observed a significant decrease in IPSC frequency in Pyr cells. Direct recordings from PV+ INs demonstrated a corresponding increase in the frequency but not the amplitude of sIPSCs. The situation was more complex when the 5HT3aR+ IN→ Pyr connections were also allowed to participate, either by holding pyr neurons at their resting potential or by blocking CB1Rs with the antagonist AM251 while holding at 0 mV. In either case, mCPBG caused a slight, transient increase in sIPSC frequency, suggesting that 5HT3aR+ INs directly inhibit pyr

cells. The direct influence on pyr neurons may provide a useful inhibitory tone to suppress spontaneous pyr activity, even as the disinhibitory influence of 5HT3aR+ INs on PV+ neurons is dominant in enhancing spike throughput. In future experiments, we plan to use optogenetic stimulation in transgenic mouse lines with labeled 5HT3aR INs to clarify the role of 5HT3aR+ synapses on the CA1 microcircuit in both disinhibition and direct inhibition. These studies will provide insight on microscopic and mesoscopic aspects of CA1 information processing.

Title: Neuronal avalanches during motor and cognitive tasks in macaque monkeys

Authors: ***S. YU**[1,3], T. LINS RIBEIRO[1], S. CHOU[1], A. MITZ[2], R. SAUNDERS[2], D. PLENZ[1]; [1]Section on Critical Brain Dynamics, [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Brainnetome Ctr., Inst. of Automation, Beijing, China

Abstract: Ongoing neuronal dynamics has been shown to be maintained at a phase transition between an inactive (subcritical) and a self-sustained state (supercritical), through a precise balance of excitation/inhibition. At this critical point, spatiotemporal clusters of synchronized firing (as measured through large negative deflections of local-field potentials, or nLFPs) emerge as a scale-free activity, called neuronal avalanches, and characterized by power-law size distributions. Those were studied in many different experimental setups, but mostly restricted to ongoing dynamics (avalanches in freely-behaving animals were studied in the context of spiking activity). Here we analyze neuronal avalanches using chronically implanted 10x10 microelectrode arrays in monkeys (adult Macaca mulatta) subjected to either 1) self-initiated touching of a sensor pad for rewards (premotor cortex) or 2) a visual-motor mapping task in which food rewards were retrieved from dispensers according to a visual cue (dorsal-lateral prefrontal cortex): they had to reach for the feeder either at the left or at the right side, depending on which cue was presented. We found that there was a modulation of the rate of nLFPs before the touching (task 1) and during the cue presentation (task 2), but only for trials in which the correct feeder was the left one (we call these left trials). Together with that increase in the

activity rate, we observed a decrease in the Fano factor, a measure of the variance in the signal over different trials, in agreement with what is found in the literature. This period with increased activity rate also lead to larger avalanches which was reflected in the corresponding size distributions, suggesting the conclusion that the system transiotions to the supercritical state during processing of information. However, when a normalization of the temporal binning employed in the avalanche analysis was performed the size distributions recovered their power-law nature, indicating that the critical state is maintained even though there is an evoked response.

Title: Dynamic activation of feedforward and feedback inhibition enables reliable propagation of sparse *in vivo* spike patterns in feedforward network

Authors: *H. JANG, J. KWAG;
Dept. of Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of

Abstract: Spike patterns *in vivo* are sparsely-activated in subsets of neurons and are temporally complex, containing precisely timed spikes with instantaneously varying spike rate. Understanding how these neural code-containing *in vivo* spike patterns propagate in neural network is critical for elucidating the principles for neural information processing. Feedforward network (FFN) consisting of sequentially connected layers of neural network has been used as a general framework in investigating the network conditions for neural code propagation. While most studies focused on FFNs composed of only excitatory (EX) neurons, the function of inhibition in neural code propagation has never been investigated. By including two distinct inhibitory networks, feedforward (FF) or feedback (FB) inhibitory circuit, to FFN, we investigated the network requirements for the reliable propagation of sparse *in vivo* spike patterns. Six-layer EX FFN was constructed with 200 single compartment Hodgkin-Huxley EX neurons per layer. Three different types of FFNs were built with 50 inhibitory neurons per layer:

EX FFN with intra-layer FB (EX-FB), with inter-layer FF (EX-FF) and with both FB and FF (EX-FB-FF) inhibition. To make the *in vivo* input sparse, the *in vivo*-recorded spike train from thalamus was simulated to 20% of layer 1 EX neurons while the remaining 80% EX neurons were made to fire asynchronously. Similarity ratio (*SR*) between *in vivo* spike train and the output-layer spike train was used to quantify the reliability of propagation. Instantaneous firing rate (IFR) was used to measure rate code propagation. The sparse *in vivo* spike train could not reliably propagate to the final layer of the EX FFN model (*SR* = 0.43). In contrast, EX-FB and EX-FF FFNs could reliably propagate the *in vivo* spike train (EX-FB: *SR* = 0.56; EX-FF: 0.63), suggesting that inclusion of inhibitory network enhances spike pattern propagation. Analysis of the relationship between IFR of *in vivo* pattern and *SR* revealed that spikes with high IFR (α and β band) reliably propagated in EX-FB FFN (α: *SR* = 0.78; β: 0.64), while spikes with low IFR (δ and θ band) reliably propagated in EX-FF FFN (δ: *SR* = 0.79; θ: 0.81). Due to the complementary frequency-selective band-pass filtering feature of FB and FF, the sparse *in vivo* spike pattern could be reliably propagated in EX-FB-FF FFN (*SR* = 0.86), especially with FF:FB ratio of 0.66:0.34. Our results demonstrate for the first time that critical balance between FB and FF inhibition is essential for reliable propagation of sparse *in vivo* spike patterns containing neural codes and the dynamic recruitment of FB and FF inhibition might serve as a key gating mechanism for neural code propagation *in vivo*.

Title: Exactly solved models of neuronal spike statistics with absolute refractory period

Authors: ***S. CHANDRA**, B. RICHMOND;
NIMH, Lab. of Neuropsychology, NIH, Bethesda, MD

Abstract: An accurate description of the statistics of spike trains in the human brain is essential to understand how the information in the brain is coded and processed. As a first approximation the spike trains in the cortical neurons have a statistics resembling a Poisson process. An obvious reason for deviations from Poisson statistics is the refractory period of a neuron which prevents

two consecutive spikes from occurring very close to each other. Here we present several simple exactly solvable models of neuronal spike dynamics. We start with dynamical rules for spike dynamics without any refractory period that gives a Poisson spike train as the output when a Poisson spike train is given to it as an input. This model is exactly equivalent to an analytically solvable queueing model called M/M/1 queue. We then present three more models of neuronal spike dynamics which take into account the absolute refractory period of a neuron. Due to finite decay time of conductances, an EPSP during the absolute refractory period may cause a spike after the absolute refractory period is over. Alternately, an EPSP during the absolute refractory period may simply be lost. Our models for the absolute refractory period have dynamical rules that take in account these various possibilities. We solve them exactly using Markov chains and equivalence to queueing models to obtain simple analytic expressions for the quantities of interest.

Title: A novel Carbon Nanofibers-based 3D nanoscaffold to promote regrowth and bridging between cultured spinal explants

Authors: *S. USMANI[1], E. AURAND[1,3], D. SCAINI[3], S. BOSI[3], M. MEDELIN[3], M. PRATO[3], L. BALLERINI[2];
[1]Neurobio., [2]SISSA, Trieste, Italy; [3]Univ. of Trieste, Trieste, Italy

Abstract: Functional rehabilitation of injury in the Central Nervous System (CNS) is a major challenge in the field of neuroscience. Carbon-based materials made up of multi walled carbon nanotubes (MWCNTs) interfaced to neural networks have previously been shown to impact synapse formation and neuronal growth [1,2,3,4,5,6]. In this work, we demonstrate an innovative, implantable scaffold, which could effectively reconstruct neural growth *in vitro*.

However, issues such as biocompatibility, structural framework, and functional effectiveness of the material pose serious questions as to their practical uses [7]. We tested a carbon-based freestanding self-assembly of nanotubes [8] in the form of three-dimensional carbon nano-fibers scaffold (3DCNF) to mimic the native CNS tissue topography. We obtained embryonic organotypic spinal slices, which were then cultured on 3DCNF in pairs at a distance known to cause impaired functional re-connection in basal conditions [9]. Electrophysiological recordings of the local field potential were performed on 10-17 days *in vitro* cultures. Simultaneous assessment of rhythmic activity triggered by Strychnine and Bicuculline application [10,11] revealed a higher cross correlations between each pair of slices on 3DCNF samples compared to controls (88% in 3DCNF vs 27% in Control). Moreover, 77% of stimulated 3DCNF samples were cross entrained by dorsal horn stimulation of one of the two slices, while this effect was seen in only 29% of stimulated Control samples. Immunohistochemistry demonstrated rewiring of neurites in a complex mesh of neuronal network outgrowth throughout the scaffold, including into the third dimension. Furthermore, 3DCNF scaffolds were implanted into adult rat brain and showed a lack of significant glial scar response, assessed by GFAP immunostaining, demonstrating good *in vivo* biocompatibility. Moreover, the presence of β-tubulin III-positive neurons within the scaffold suggests that neurons were able to migrate into the 3DCNF implant. Our results show that these 3DCNF materials provide an innovative scaffold for increased neuronal reconnection and a promising tool for future interfaces developments. Abstract: We have shown an important role of the medial septal nucleus and the diagonal band of Broca (MSDB) in the control of locomotion and theta oscillations. Three major cell types have been described in the MSDB: Excitatory glutamatergic VGluT2 neurons, inhibitory PV interneurons and cholinergic ChAT neurons. To better understand the role of each of these neuron types during locomotor behavior, we first attempted to characterize their properties and their synaptic connectivity within the medial septal network. Using VGluT2-cre, PV-cre and ChAT-cre mouse lines and a medial septal injection of pAAV2.1-EF1a-double floxed ChR2-EYFP-WPR (H134R) we could identify the respective cell types in acute brain slices via eYFP expression. In whole-cell patch-clamp recordings of eYFP labeled neurons we could clearly separate the three neuron types according to their electrophysiological parameters. Thus, a discriminant analysis allowed the discrimination of non-labeled neurons. Using light activation of ChR2 expressing neurons, we could assess the connection probabilities. We found a strong non-selective connectivity of VGluT2 neurons onto all three cell types. Following VGluT2 stimulation 87 % neurons received monosynaptic EPSPs with an average latency of 3.9±0.17 ms (n=100). PV stimulation led to monosynaptic IPSPs in 54 % of all neurons (n=62). In ChAT-cre mice single light stimulation (15 ms) or 2 s train stimulation at 10 Hz did not evoke synaptic responses in standard experimental conditions (n=29). With increasing the stimulation duration to 6 s a slow depolarization was observed in 7 neurons, consistent with volume transmission. We concluded that VGluT2 neurons represent a main source of excitation within the MSDB, whereas PV interneurons suppress network activity via recurrent inhibition. To understand the role of recurrent PV mediated inhibition during locomotor behavior, we then blocked the glutamatergic excitation of recurrent PV interneurons using intraseptally applied NBQX/D-AP5 in head-fixed mice performing o a linear treadmill. We hypothesized that this manipulation would lead to higher activity of VGluT2 neurons due to the loss of inhibitory control during VGluT2 stimulation. Higher activity of VGluT2 neurons then should in turn result in increased locomotor activation. Indeed, with reduced recurrent inhibition VGluT2-stimulation-induced locomotion was performed at higher speed and initiated more promptly. Strikingly, in the presence of NBQX/D-AP5 locomotion of the mice persisted even after the cessation of stimulation confirming an important role of recurrent MSDB PV interneurons in the control of locomotor activity.

Title: Emergent frequency components by non-linear dynamics of pyramidal cells in visual cortex

Authors: *N. KOGO;
Lab. of Exptl. Psychology, Univ. of Leuven, Leuven, Belgium

Abstract: Frequency tagging technique is a powerful tool applied in the “steady state visual evoked potential” (SSVEP, Regan, 1966, Electroen Clin Neuro 20, 238-248) in EEG recording. It allows detecting specific neural responses to specific (tagged) input components from entangled populations of neural activities. Furthermore, non-linear frequency components (intermodulation components, IMs) can be detected which indicate the neural interaction between the signals carrying separate frequencies. Recent advance has shown that IM can be used as “neural signature” of interactions that are linked to perceptual organization such as figure-ground organization, multi-stable perception, illusory surface perception and face perception (Aissani et al., 2011, Brain Res 1408, 27-40; Appelbaum et al., 2006, J Vision 8(9), 1-19; Boremans et al., 2013, J Vision 13(11), 1-18; Gundlach et al., 2013, Biol Psychol 94(1), 55-60; Sutoyo et al., 2009, Brain Res, 1251, 245-255). As this approach to investigate the neural activities underlying visual perception advances, it is quite important to investigate the non-linear neural dynamics that give rise to IMs. Magnai et al. (2011, J Comput Neurosci, 31(3), 595-607; 2014, Frontiers Cellular Neurosci, 8(239)) showed non-linear neural responses to multi-frequency current injection to stellate cells in rat entorhinal cortex. To further investigate the phenomenon, I recorded the frequency responses of pyramidal cells in layer 2/3 of mice primary visual cortex to a combined frequency inputs. Patch (or double patch) clamp recordings in whole cell configurations were obtained from pyramidal cells. In the first experiment, a current with combined sine waveforms (+/-50pA, f1=7.50Hz and f2=5.45Hz) was injected to the cell at -70mV (subthreshold condition) and at -50mV (suprathrehold condition, that evokes series of

action potentials). In the second experiment, extracellular electrical stimulation was applied at two locations proximal to the cell's apical dendrite. The frequency components of the responses were analyzed. While double spectrum peaks, reflecting the input frequency components (f1, f2), were found in all conditions, extra frequency components were found only in the suprathreshold condition. In addition to the harmonics of f1 and f2, discrete peaks were identified at the frequencies of IMs (most prominently at f1-f2, 2f2-f1, 2f1-2f1, and f1+f2). When only one of the two input frequencies was given at the suprathreshold condition, the power spectrum showed peak at the given frequency and at its harmonics. Hence, at the depolarized state, nonlinear frequency components emerge that are likely the origin of IMs in SSVEP.

Title: 3D appealing: novel nanostructured CNT scaffolds induce three-dimensional neuronal network reconstruction and potentiated signalling

Authors: *D. SCAINI[1], R. RAUTI[1], S. BOSI[1], M. PRATO[1], L. BALLERINI[1,2];
[1]Univ. of Trieste, Trieste, Italy; [2]S.I.S.S.A., Trieste, Italy

Abstract: Modern neuroscience increasingly relies on material science and nanotechnology tools to engineer 3D neuronal network models. *In vitro* recreated 3D neuronal circuits will substantially increase the relevance of results from cultured to whole-brain networks and will promote enabling technologies for neuro-engineering applications. Recently we develop a novel composite materials obtained entrapping carbon nanotubes (CNTs) in an elastomeric porous material able to instruct *genuine* 3D growth and organisation of living neurons inside it. Such system allows investigating the emerging activity, in terms of calcium signals, of small clusters of neurons as a function of the interplay between the 2D or 3D architectures and network dynamics. We observed an intrinsic ability of the 3D geometry to improve functional

organization and synchronization in small neuronal assembly and we propose a mathematical model of network dynamics that supports such a result. Finally, scaffolds nanostructured *via* CNTs insertion remarkably affected network behaviour, allowing for the first time to exploit nanomaterial/cell interfacing in a 3D growth support. Our 3D system represents not only a simple, reliable construct able to improve the complexity of current tissue culture models but opens to the development of new tissue engineering tools and paradigms for unconventional neuroprosthetic and neuromedicine applications. **References:** [1] Cellot G, Cilia E, Cipollone S, Rancic V, Sucapane A, Giordani S, Gambazzi L, Markram H, Grandolfo M, Scaini D, Gelain F, Casalis L, Prato M, Giugliano M, Ballerini L. Title: Spatial motifs in a living engineered hippocampal circuit

Authors: ***G. J. BREWER**[1], A. BHATTACHARYA[1], T. B. DEMARSE[2], B. C. WHEELER[2], H. DESAI[1];
[1]MIND Inst. and Biomed. Engin., UC Irvine, Irvine, CA; [2]Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: To encode memories, the tri-synaptic loop in the mammalian hippocampus exhibits unidirectional feed-forward communication from the dentate gyrus (DG) region to the next region, CA3. The signal provided for these feed-forward connections in functional organization of the different regions is yet to be understood. One way to gain insight is to study the number

and types of functional blocks or patterns of activity (motifs). Here we reconstructed two regions of the hippocampus in a unique cell culture system. Neurons were dissected from the DG and the CA3 regions of P3 rats and cultured in distinct wells or chambers connected by microtunnels carrying only axons for communication between the regions. The system sits on top of an electrode array to be able monitor each subnetwork and the communication between them. Microfabrication (MEMS) technology was used to create two wells connected by micro-scale tunnels. The tunnels facilitate growth of axons between wells loaded with cultured cells from different hippocampal subregions. Spike trains obtained from each electrode were smoothed using a 32-ms Gaussian kernel to yield an activity profile at each electrode. A dendrogram clustering algorithm revealed motifs or patterns of spatial activity. Spike shuffling across electrodes was used to estimate the chance occurrence of such patterns in each of 25 trials as the statistical control. We examined the number of spontaneous spatial motifs in CA3 when CA3 is connected to DG (DG-CA3), when CA3 is connected to other CA3 neurons (CA3-CA3) and in DG connected to DG networks (DG-DG). The higher number of CA3 events identified in DG-CA3 compared to CA3-CA3 and DG-DG suggests longer-range connectivity in the natural configuration. The percentage of CA3 events requiring $\geq$75% of the tunnels active preceded by DG or opposing compartment events was higher in DG-CA3 than CA3-CA3 or DG-DG, suggesting robust wiring of DG to CA3. The percentage of CA3 events preceded by tunnel events (70%) was higher in DG-CA3 networks than for the reverse direction (20%), remarkably different from the percentages for the control CA3-CA3 and DG-DG networks. This shows the connection bias of the natural DG-CA3 network. Overall, motifs in DG-CA3 networks occurred more frequently (3.6 ± 0.9 motifs in 3 min) than expected by chance in shuffles (1.7 ± 0.4) ($p<0.001$) and at only chance frequencies in DG-DG networks. This suggests that the anatomically accurate feed-forward connections result in significant spontaneous spatial configurations of activity at measured times.

Title: Ensemble methods enhance the identification of synaptic connections from multineuronal activity patterns

Authors: *D. Y. LITTLE, B. CHAMBERS, J. DECHERY, J. N. MACLEAN;
Univ. of Chicago, Chicago, IL

Abstract: If we are to mechanistically understand information processing in the neocortex, it is crucial to map synaptic connectivity to cortical circuit dynamics. Circuit spike activity, however, is sparse and diverse in ways that are not easily predicted from connection patterns alone (Barth and Poulet 2012). Functional connectivity maps are an important bridge between static connectivity and dynamic information processing. Previously we have shown that statistical dependencies in the spiking between two neurons have the capacity to reveal a select subset of causal monosynaptic connections. However, the ability to identify a connection is in part determined by the inference algorithm employed. Different inference methods, such as lagged correlation, mutual information, and transfer entropy, capture different statistical correlations in population dynamics and identify distinct, though overlapping, sets of connections. This is the optimal situation in which an ensemble method that combines multiple inference algorithms should obtain better predictive performance than can be achieved using any of the constituent inference algorithms separately. Here, we show that an ensemble of linearly combined inference methods can infer synaptic connectivity with greater precision than any of the underlying methods alone. Using conductance based leaky integrate-and-fire network models we demonstrate that a simple random search algorithm with cyclically annealing step sizes can quickly identify effective ensemble weights that in turn identify synaptic connections. Learned weights show little variance across repeated randomizations supporting the optimality of the resultant ensemble score. Most importantly, we demonstrate that ensemble weights learned for one network can be transferred to improve the prediction accuracy for a novel network. While ensemble learning can be transferred between networks, we find that different weights must be learned for different temporal resolutions. This is not surprising and likely reflects variability in the optimal time-scales of the underlying measures. In developing these ensemble methods, we also introduce new refinements on mutual information and transfer entropy that account for polysynaptic inhibition and heteroskedasticity. These innovations significantly improve inference of synaptic connectivity in neuronal network models.

Title: A small world of synaptic integration

Authors: *B. CHAMBERS, J. N. MACLEAN;
Univ. of Chicago, MacLean Lab., Chicago, IL

Abstract: Linking cortical population activity to the synaptic structure that instantiates and constrains it is a critical goal for neuroscience. A major challenge to understanding structure-function relationships is that they depend on large numbers of synaptic interactions which combine in a complex and non-linear fashion. In this work, rather than focusing on individual connections, we compare the global features of two networks: (1) a functional wiring diagram that summarizes pairwise correlations, and (2) its underlying synaptic network. To study their interrelationship with known ground truth, randomly connected LIF networks were generated with conductance-based synapses and heterogeneous connection strengths. Despite the fact that underlying synaptic connectivity was random, functional wiring diagrams were marked by a global statistical structure: the small-world property. We find that small-worldness is the result of a dramatic elevation in fan-in triangle clustering. Functional wiring diagrams generated from 2-photon imaging of circuit activity in mouse neocortex were similarly marked by an overrepresentation of fan-in triangular clustering, which was not present in rate-matched Poisson nulls. In the LIF model, the clustering of presynaptic activity increased with depolarization in the postsynaptic neuron, linking clustering with effective postsynaptic integration. Synaptic weights in the model were increased to lessen the requirement for integration of multiple inputs to achieve threshold. In these strong-synapse models, functional wiring diagrams were significantly more faithful to the actual underlying connectivity than were models with naturalistic weights. Compared to relationships of simple convergence, activity at fan-in triangle motifs was marked by stereotyped presynaptic timing. Together, our results demonstrate how fan-in triangular clustering improves the reliability of postsynaptic recruitment. As a result, fan-in triangle motifs are especially salient in functional maps, relevant for mapping structure to function in cortical circuits. The integrative properties of individual neurons impose structure in functional maps by

favoring presynaptic coincidence. When applying graph theory to neural data, it is necessary to consider the computational properties of the nodes themselves.

Abstract: Current imaging systems are suitable to functionally image neural tissue elements from the area range down to the synaptic elements, thereby being an indispensable tool to understand brain function. A common drawback of these systems though is the depth limit they all face. The usual working depth of optical imaging systems do not exceed a few hundred micrometers, hardly the width of the rodent cortex. There are engineering approaches to solve this problem, since deeper neural tissue elements also play crucial role in shaping cognition and behavior. So far these solutions all suffer from one or several constraints of being highly invasive, not precise, or of limited scope. Here we describe a possible solution along with *in vivo* test measurements to use with two photon laser scanning imaging of genetically encoded calcium indicators allowing to image deep tissue functions in considerable volumes.

Title: Intrastriatal inhibition by somatostatin expressing neurons

Authors: *M. C. DORST[1], M. ZHOU[2], I. LAZARIDIS[2], S. KIAN TAI[2], K. MELETIS[2], G. SILBERBERG[2];
[2]Dept. of Neurosci., [1]Karolinska Institutet, Stockholm, Sweden

Abstract: A select population of neostriatal interneurons express somatostatin (SOM). These interneurons are tonically active and provide GABA-mediated inhibition onto neighboring projection neurons. Little is known, however, about their connectivity with other types of striatal interneurons. We used a combination of electrophysiological and optogenetic methods to study the synaptic connectivity from SOM neurons to neighboring striatal neurons. Following transduction of AAV DIO ChR2(H134R)-mCherry in SOM-cre mice, we could selectively record from and photostimulate SOM neurons. SOM neurons displayed the electrophysiological characteristics of Low Threshold Spiking interneurons, including high membrane resistance, a long membrane time-constant and a depolarized resting membrane potential resulting in tonic activity. Photostimulation of SOM neurons evoked inhibitory synaptic responses in neighboring projection neurons as well as interneurons, with strongest responses observed in cholinergic interneurons (ChINs). Direct synaptic connections between individual SOM neurons and ChINs were weak and sparse, suggesting that part of the optogenetic response was mediated by axons originating from more distal presynaptic neurons. Bath application of GABAzine (SR-95531) significantly increased the spontaneous firing rate of ChINs, and photostimulation of SOM neurons induced biphasic changes in ChIN firing rate, composed of an immediate pause followed by an increase in discharge frequency. Our results suggest that SOM expressing neurons play an important role in sculpting striatal activity, in particular by regulating the spontaneous activity of ChINs.

Abstract: Agreement between experimental neuroscience and the theory of criticality has been established in terms of observed scale-invariance for neuronal avalanches, which constitute spontaneous activity cascades in the cortex. Pharmacologically-validated optimization of certain aspects of information processing, such as dynamic range, information capacity, and the transient formation of phase-coupled neuronal ensembles, are in line with a balanced critical regime of cortical activity. It is therefore worthwhile to consider how the brain might leverage neuronal avalanches to store, transmit, and process information. A major information aspect introduced by neuronal avalanches is related to their instantaneous spatial spread, e.g. the number of sites visited per time step. From neural network studies, we find that critical dynamics on a network with homogeneous random connectivity generates avalanches with a parabolic spread in time; avalanches will typically initiate at a single site, engage more and more sites as they unfold, and eventually contract spatially and terminate. As reported previously, scale-invariance has been observed for event size and duration probabilities in both simulation and *in vivo* data. However, experimental findings presented here illustrate that not all neuronal avalanches recorded in cortical layers 2/3 of awake Macaque monkeys (n=2) can be described as having a parabolic temporal profile shape. Instead, neuronal avalanches recorded *in vivo* have a flattened spread such that (1) they visit significantly fewer sites during their unfolding than would be expected from homogeneous network architecture, and (2) long-lasting avalanches display considerable variability around a characteristic mean function that is independent of avalanche lifetime. Avalanche data collected *in vivo* did not collapse well, as short-duration avalanches had a steeper curvature than avalanches with long lifetimes (>10ms). Simulated avalanches on homogeneous topology always collapsed well. We altered our network model to capture the *in vivo* profile shape by adding a series of strong directed links to an otherwise random graph. This topological "highway" increased the inhomogeneity in the network and had a flattening effect on the average shape of avalanches of all durations. However, such inhomogeneity did not replicate the poor scaling collapse seen for *in vivo* avalanches. We conclude that additional inhomogeneities beyond network topology (e.g. initiation sites frequency) may contribute to the absence of scaling collapse for avalanche waveforms despite robust power laws in avalanche sizes, a hallmark of neuronal avalanche dynamics.

Title: Neural correlations mediate feature invariant responses

Authors: ***M. G. METZEN**[1], M. J. CHACRON[1,2];
[1]Dept. of Physiol., [2]Dept. of Physics, McGill Univ., Montreal, QC, Canada

Abstract: Feature invariant coding has been observed across sensory modalities and species. Such coding strategies, often associated with sparse coding, are believed to have advantages over more dense responses as they provide a stable perception of behaviorally important stimuli. Invariant responses at the single neuron level to a given feature are generally observed in higher brain areas such as the midbrain and it has been shown that such a global invariance develops in stages by integrating the responses of neurons that display a local invariance. However, the mechanisms that lead to locally feature invariant responses in central neurons are still largely unknown. Here we focused on feature invariant coding of communication signals by electrosensory primary afferents (P-units) in the weakly electric fish, *Apteronotus leptorhynchus*. These fish generate an electric field (electric organ discharge, EOD) surrounding their body. If two fish are in close proximity, their electric fields interfere creating a beat. Furthermore, these fish can produce communication signals (chirps) that can occur on every phase of the beat and thus appear as very heterogeneous stimuli waveforms. We show that correlated activity of P-units can provide a feature invariant representation of small chirp waveforms over a behavioral relevant range of beat frequencies. In contrast, the single neuron activities were not invariant as they faithfully represented the detailed timecourse of the different stimulus waveforms. To understand the mechanisms leading to such responses we used a generic leaky-integrate-and-fire model. By varying model parameters we were able to identify the regimes by which feature invariant responses of P-units are optimum. The model predicts a strong relationship between invariant coding in correlated activity of P-units and stimulus intensity as well as their baseline variability. Correlated activity of the receptors could then be used by downstream neurons such

as ON and OFF cells to generate locally invariant responses. Physiological results will be supplemented with behavioral assays to test whether there is a behavioral correlate to the feature invariant responses seen in correlated activity of P-units. Therefore, this study gives important insights as to how the brain can generate feature invariant responses starting as early as the periphery through correlated activity and how this is decoded by downstream areas to give rise to perception/behavior.

Title: An activity dependent feedback inhibitory loop in mouse presubiculum

Authors: ***J. SIMONNET**[1,2], M. NASSAR[2], B. MATHON[2], I. COHEN[3], C. N. BOCCARA[4], R. MILES[2], D. FRICKER[2];
[1]Bernstein Ctr. for Computat. Neurosci., Humboldt Univ. zu Berlin, Berlin, Germany; [2]INSERM U1127 / CNRS UMR7225, Inst. du Cerveau et de la Moelle Epinière, Paris, France; [3]CNRS UMR 8246 / INSERM U1130, Neurosci. Paris Seine, Paris, France; [4]IST Austria, Am Campus 1, Klosterneuburg, Austria

Abstract: The presubiculum is a cortical region located between the hippocampus and the entorhinal cortex. It contains head direction cells that fire as a function of an animal's directional heading. Presubiculum plays a major role in controlling the accuracy of the head direction signal used for hippocampal-based landmark navigation. The presubicular head direction signal arises mainly from Anterior Thalamic (ATN) inputs but its regulation in presubiculum is poorly understood due to the lack of knowledge of presubicular computation. We used dual patch clamp recordings in the acute slice preparation from adult mice (P20 - P60) to highlight an inhibitory

feedback circuit and some of its functional properties in presubicular superficial layers that are important for the accuracy of the head direction signal. We focused on two neuronal populations, Pyramidal Cells (PC) and Martinotti Cells (MC), using transgenic mice containing fluorescent SST positive interneurons (X98-SST or SST-cre::dtTomato). MC axons target mainly layer 1 and 3, where PC-dendrites receive thalamic inputs. PCs send many axon collaterals to layer 3, where soma and dendrites of MC cells are located. Using stereotaxic viral injections to transduce channerhodopsin2-YFP into ATN, we showed that ATN axons target layers 1 and 3 of the presubiculum and make direct synaptic contacts with PCs but not MCs. The PC-MC connection probability was high: 58% for MC-to-PC, 37% for PC-to-MC and 28% for reciprocally connected pairs. We showed that inhibitory postsynaptic events in PCs were reliable (transfer rate = 0.85 ± 0.05) but small (mean amplitude = 9 ± 1.2 pA), consistent with dendritic inhibition. The efficacy of the PC-to-MC synapse was activity dependent: excitatory post-synaptic events were rarely detected in MCs upon single spike firing of PCs (transfer rate = 0.11 ± 0.02), but synaptic efficacy (initially -2.4 ± 0.6 pA) increased with the duration and frequency of the presynaptic discharge. Several seconds were necessary for this enhanced efficacy to decay down to its initial value. We then showed how these properties conditioned MC recruitment during head directional activity recorded *in vivo*, and injected as spike trains into PCs *in vitro*. The delay of MC recruitment was short, so that self-induced inhibition was time-locked to the PC spike. Time-locked inhibition had little effect on PC firing frequency and even was rather facilitating compared to lateral inhibition, likely to be randomly timed. The PC-MC feedback loop may therefore function as a lateral inhibition process and reinforce the accuracy of specific head direction signals in the presubiculum.

Title: Spike frequency adaptation regulates network sensitivity to synaptic heterogeneities in a cortical model of cholinergic modulation

Authors: *J. P. ROACH[1], L. M. SANDER[2,3], E. BEN-JACOB[5,6], M. ZOCHOWSKI[2,4,3]; [1]Neurosci. Grad. Program, [2]Dept. of Physics, [3]Ctr. for the Study of Complex Systems, [4]Biophysics Program, Univ. of Michigan, Ann Arbor, MI; [5]Sch. of Physics and Astronomy, Tel-Aviv Univ., Tel Aviv, Israel; [6]Ctr. for Theoretical Biol. Physics and Dept. of Biochem. and Cell Biol., Rice Univ., Houston, TX

Abstract: Acetylcholine is a major regulator of cortical network functions such as arousal state and attention. ACh is associated with the transition between slow wave sleep (SWS; where ACh is absent) and rapid eye movement (REM) sleep or waking states (where ACh is high). Patterns of neural activity within the cerebral cortex change drastically when between these states. During bouts of SWS neurons oscillate between high frequency up-states and quiescent down states, which manifest as traveling frequency waves on the macroscopic level. On the other hand, during REM sleep and waking neurons fire tonically and network activity is likely to be organized on a more local scale. Locally driven activity is could underlie working memory and attention dynamics while traveling waves may be needed for synaptic renormalization. The network level mechanisms that translate the cellular effects of ACh into differing activity patterns are not well characterized. In this study we use a model for cholinergic modulation of a network of neurons of the Hodgkin-Huxley type, which recreates the reduction of spike-frequency adaptation (SFA) induced by ACh. During periods of high ACh (SFA is minimal) network activity is localized and highly sensitive to synaptic heterogeneity (i.e. high frequency activity is centered around regions defined by enhanced recurrent excitatory synapses). Increasing the modeled ACh level (SFA is present) leads to traveling waves of activity. Within this activity state ACh level continues to regulate sensitivity to synaptic heterogeneity. At moderate levels of ACh regions defined by synaptic heterogeneity are occupied by frequency wave longer. We show that a mechanism for these divergent states is that the balance of excitation and inhibition (E/I balance) sets the spatial extent of network activity and that SFA defines the temporal scope, which is directly modulated by ACh in the model. Synaptic heterogeneity disrupts E/I balance with decreasing effectiveness as SFA increases. The model simulations give unique insights into the role and significance of ACh in determining patterns of cortical activity and functional differences arising from these patterns.

Title: Optical flow platform for analyzing voltage sensitive dye imaging of evoked and spontaneous activity to quantify velocity and direction, source and sink points, and tracking activity trajectory

Authors: ***N. AFRASHTEH**[1], M. KYWERIGA[2], M. HEIDARI MOHAJERANI[2];
[1]Neuroscience, Canadian Ctr. for Behavioural Neurosci. (CCBN), [2]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The Voltage-Sensitive Dye (VSD) imaging technique is a powerful method to study the subthreshold activity of neuronal depolarizations. The VSD imaging method provides an excellent opportunity to examine the spatiotemporal dynamics of the activity spread over the cortex. However, analysis of these spatiotemporal patterns has been mostly qualitative to date. Plotting fluorescence intensity changes over time was used mainly in previous studies to quantify the dynamics of neural depolarization. The Optical Flow (OF) analysis is a well-known method in computer vision for quantitative motion (velocity and direction) estimation of moving objects. Here we developed an open-source software package to quantify fast local flow patterns of cortical population activation, as measured by VSD imaging. The toolbox can be used to quantify neural depolarization waves in VSD signal in term of their velocity, orientation, localize activity sources and sinks, and track a source to its corresponding sink. Using this toolbox, we analyzed the images to quantify spontaneous and stimulus evoked activity in the isoflurane anesthetized mouse. First, by analyzing VSD signals for stimulus-evoked activity, we found that the global spreading of the neural activity throughout the cortex for whisker stimulation was faster than for forelimb stimulation (n=3). The distributions of velocity and direction throughout the cortex were non-uniform and had multi-modal functions. Second, to assess differences between evoked and spontaneous activity, we compared evoked forelimb activity to forelimb-evoked like pattern in spontaneous activity. We found that the spread of evoked activity was faster than spontaneous activity throughout the cortex. Third, using source and sink analysis we found that the distribution of sources and sinks were constant over time in spontaneous activity. These points were more frequent over the anteromedial and posterolateral regions of the cortex, and along the path connecting them. This result is in line with the results from direction analysis where the majority of activities are traveling along anteromedial posterolateral pathway. We

believe this analysis toolbox will be of broad interest to researchers involved in systems neuroscience, especially those that are interested in the organization of cortical circuits in healthy brain and those that model disease such as Autism or Alzheimer's.

Title: Mechanosensitivity of isolated enteric neuronal networks

Authors: ***G. MAZZUOLI**[1], E. M. KUGLER[1], K. MICHEL[1], F. ZELLER[2], M. SCHEMANN[1]; [1]Technische Univ. München, Freising, Germany; [2]Dept. of Surgery, Klinikum Freising, Freising, Germany

Abstract: The gastrointestinal tract contains a number of neurons comparable to the spinal cord. These neurons are embedded into the gut wall and constitute the enteric nervous system (ENS). The ENS controls gut functions independently from the central nervous system. The wall of gastrointestinal tract is constantly under mechanical stress, which results from the movements of its muscle layers. The enteric neurons, sandwiched between these muscle layers, are the local controller of peristalsis. Direct activation of myenteric neurons by mechanical stimuli has been shown. However, the precise stimulus modalities (shear or normal stress) that excite myenteric mechanosensors are so far unknown. The aim of the present study was to describe the properties of mechanosensitive enteric neurons and to compare them with other first order sensory neurons. Primary cultured myenteric neurons were used to exclude non-neuronal influences. Neuronal activation was recorded with an ultra-fast neuroimaging technique with voltage-sensitive dye that made it possible to record from multiple neurons simultaneously. Normal stress was applied by probing with an ultra-fine von Frey hair. Shear stress was applied by fluid flow through a micro channel. Mechanosensitive myenteric neurons had no specialized regions for mechanotransduction. Instead, this occurred along the entire neurites (45%) and somata (14%). The electrical signal originates at the site of the mechanical stimulation. Neurite signals propagated towards the soma and invaded other neurites. Mechanosensitive neurites not only transmit sensory information but also function as motor neurites spreading the signal to other

cells. This supports the theory of multifunctionality of mechanosensitive myenteric neurons. We proved that the excitability state of the soma is critical for the transduction of mechanical signals. This suggests that neuronal responses can be modulated, which would be crucial to provide appropriate responses to environmental signals. Myenteric neurons share some properties with other sensory neurons but also exhibit specific features, very likely reflecting adaptation to their physiological function in the gut. Mechanosensitive properties are conserved across species as shown for guinea pig and human. Responses to normal stress were reproducible, while shear stress showed only a marginal effect. Thus, normal stress appeared to be the primary stimulus for myenteric mechanosensitive neurons. The present study helps to understand the complex process of neuronal mechanotransduction and to clarify different neuro-motoric patterns involved in the regulation of peristalsis.

Title: Neural network properties can be inferred from electrophysiological power spectral geometry

Authors: *T. J. NOTO, R. GAO, E. PETERSON, B. VOYTEK;
Cognitive Sci., UC San Diego, LA Jolla, CA

Abstract: The study of the biophysical and cognitive role of neural oscillations has become a cornerstone of modern neuroscience. These oscillations are inferred from the power spectral density (PSD) of the neurophysiological signal of interest. The PSD of electrophysiological neural activity assumes a general $1/f^{\chi}$ form. Although changes of power in narrow frequency bands (alpha, beta, etc.) have been related to a variety of cognitive and behavioral states, and the broadband power (the offset) of this process has been shown to reflect aggregate population spiking activity, there is scant evidence for how other global properties of power spectral

geometry relate to the underlying neural network activity. Treating the neural power spectra as a holistic entity affords the application of different analyses that may provide novel insights that would not be evident in narrow bands. Presumably, neural networks produce characteristic changes in the full spectrum (aside from narrowband oscillations) under different operational modes, so it may be possible to estimate certain features of the network from its geometry. Concurrent single cell and local field recordings from rat hippocampus and recordings directly from human cortex allow us to probe these relationships. The slope of the broadband spectrum (10-100 Hz) had a positive correlation with spike count (r=0.35) and a negative correlation with the fano factor of the inter-spike interval (r= -.35). Additionally, the slope of high gamma (80-125 Hz) negatively correlated with phase/amplitude coupling (r = -0.1). These results draw a link between spectral geometry, network properties, and neurobiology, and support the idea that the power spectrum should be considered as a holistic entity that contains a wealth of information about the network that produces it.

Title: Dynamic shifts in large-scale functional connectivity predict transitions in brain state

Authors: ***I. M. STITT**[1], K.-J. HOLLENSTEINER[1], E. GALINDO-LEON[1], F. PIEPER[1], E. FIEDLER[2], T. STIEGLITZ[2], G. ENGLER[1], A. K. ENGEL[1];
[1]Dept. of Neurophysiol. and Pathophysiology, Hamburg, Germany; [2]Dept. of Microsystems Engineering, Univ. of Freiburg, Freiburg, Germany

Abstract: Throughout each day, the brain typically transitions several times between varying states of vigilance and unconsciousness. While the electroencephalographic spectral correlates of brain states have been studied for some time, it remains unclear how large-scale cortico-cortical functional connectivity systematically reorganizes across brain states. In this study, we investigate the time-varying nature of large-scale cortical functional connectivity across brain

states by recording micro-electrocorticographic (μECoG) activity during spontaneous sleep/wake transitions in the ferret. Data were obtained from 64-channel μECoG arrays chronically implanted in 3 female ferrets. Continuous local field potential (LFP) recordings of up to 3 hours duration were made during spontaneous behaviours in the open field. To quantify brain states, we use a data driven approach that projects time-varying LFP spectral properties into lower dimensional state-space. Trajectories of neural data in state space suggest that the temporal evolution of brain state across the sleep/wake cycle resembles a multistable process, defined by a recurring set of neural conditions, with some stages displaying a strong degree of stability (e.g., slow-wave sleep), while others displays a greater dynamical range of freedom (e.g., awake state and rapid eye movement sleep). Distinct brain states displayed markedly different patterns of large-scale functional connectivity, with phase synchronization in slow, theta, and spindle frequencies differing the most across brain states. The largest between-state difference in functional connectivity was observed between presumed slow-wave and rapid eye movement sleep, which were characterized by periods of cortical network fragmentation and global hypersynchronization, respectively. Changes in large-scale functional connectivity at the end of sleep/wake cycles also reliably predicted animal movement associated with waking. We conclude that large-scale cortico-cortical functional connectivity dynamically reorganizes with brain state across the sleep/wake cycle, and suggest that further investigation should focus on the functional connectivity correlates of more subtle state transitions associated with spontaneous drifts in mental activity during resting periods.

Title: Protein arginine methyltransferase1 regulates astrocyte differentiation of neural stem cells through the modification of STAT3

Authors: *M. HONDA, S. KATADA, K. NAKASHIMA;
Grad. Sch. of Med. Science, Kyushu Univers, Fukuoka, Japan

Abstract: Members of the interleukin-6 family of cytokines, such as leukemia inhibitory factor (LIF), induce astrocyte differentiation of neural stem cells (NSCs) by activating the transcription

factor signal transducer and activator of transcription-3 (STAT3). It is well known that the activation of STAT3 is induced by its tyrosine-phosphorylation, however, other posttranslational modifications such as methylation and acetylation are also important. For example, several reports have shown that the phosphorylation and acetylation of STAT3 positively regulate its activity, whereas lysine methylation has the opposite effect. Nevertheless, the effect of STAT3-arginine methylation remains elusive. Arginine methylation is catalyzed by the members of protein arginine methyltransferase (PRMT) family enzymes, yet the role of PRMTs in NSCs is not well understood. Interestingly, our microarray analyses revealed that PRMT1 is highly expressed in mouse embryonic NSCs. To examine whether PRMT1 methylates STAT3, we first transfected STAT3-expressing construct with or without that of PRMT1 to HEK293T cells, and performed western blot using anti-methylated arginine antibody. We found that PRMT1 overexpression enhanced STAT3 arginine methylation. Furthermore, *in vitro* arginine methylation assay using recombinant proteins demonstrated that PRMT1 methylates STAT3. Next, to examine the effect of STAT3 arginine methylation by PRMT1 in NSCs, we performed knockdown experiments of PRMT1 using Prmt1-shRNA in embryonic day (E) 14.5 NSCs. When PRMT1 was knocked-down in E14.5 NSCs, LIF-induced gfap-promoter activation was significantly decreased. Moreover, PRMT1 knocked-down NSCs generated less GFAP-positive astrocytes upon LIF stimulation compared to control. We report here for the first time, the arginine methylation of STAT3 by PRMT1 enhances transcription of a astrocyte specific gene, promoting astrocyte differentiation of NSCs.

Title: Neuroprotective effect of 7,8-dihydroxyflavone on serum deprived C8D1A astrocyte cells

Authors: *V. J. SHUKLA[1], D. PATEL[1], A. TRIPATHI[1], S. MAKAR[1], P. GUDA[1], J. BHUJU[1], C. BEVER[1,2], D. TRISLER[1,2], S. JUDGE[1,2], S. RAY[1];

Abstract: Astrocytes play a major role in the central nervous system (CNS). Astrocytes secrete pro-inflammatory cytokines in different neurodegenerative diseases. Astrocytes grown in serum-deprived (SD) media can cause apoptosis by elevating different apoptotic proteins. Furthermore, when astrocytes are grown in oxygen-,glucose- and serum deprived media apoptosis is induced via endoplasmic reticulum (ER) stress. 7,8-dihydroxyflavone (DHF), a BDNF receptor (Trk-B) agonist is used for neuroprotection in different animal models of neurodegenerative diseases such as Parkinson's, Alzheimer's and Epilepsy. In PC12 cells, it is found that DHF effectively prevented cell death, apoptosis and mitochondrial dysfunction induced by 6-hydroxydopamine. Our objective is to determine out the neuroprotection role of DHF on serum free C8D1A astrocyte cell line where cell death occurs in an apoptotic manner. 50 μM DHF was used in serum free media of C8D1A cell culture. The cells were incubated for 4 hours in SD. Interestingly, we found that level of interleukin1 (IL1), tumor necrosis factor α (TNFα), and Interferon γ (IFN-γ) were significantly increased in serum free media and that cytokine levels were decreased after DHF treatment. We also found that Bax, caspase 3 and caspase 9 were increased in serum deprived cells and that all of these parameters were reduced after DHF treatment. Furthermore, we observed that the ER stress marker Protein kinase R [PKR]-like ER kinase (PERK) expression was significantly increased in SD cells and was suppressed by DHF treatment. In the same experimental condition, Endothelin receptor type A (ETA) receptor expression was upregulated in SD cells whereas DHF treatment suppressed the expression. Pro-inflammatory cytokines are involved in inflammation and causing cell death. In our study we found that IL-1, TNFα and IFN-γ increased in SD media which may cause the induction of different inflammatory proteins that lead to induced ER stress by activating the ETA receptor. As a result, the apoptotic proteins Bax, Caspase3 and caspase-9 were increased. However, DHF showed its neuro-protective activities by down-regulating the above mentioned parameters. Collectively, our findings suggest That DHF can be used for anti-inflammation and neuroprotection.

Title: Effects of hypotonicity on primary rat astrocytes

Authors: S. B. RAO, H. B. BOLDT, D. S. Y. LEUNG, *R. TORP, M. R. AMIRY-MOGHADDAM;
Inst. of Basic Med. Sci. Univ. of Oslo, Oslo, Norway

Abstract: Hyponatremia is associated with a number of clinical conditions and may cause serious consequence such as brain edema with significant mortality rate. Despite several decades of research, there is still no treatment preventing edema formation. Studies in the last decade have shown that Aquaporin-4 (AQP4) water channels anchored to perivascular astrocytic endfeet through an interaction with the dystrophin associated protein complex (DAPC) are involved in development and resolution of hyponatremic brain edema. An earlier study has shown an increased density of the perivascular AQP4 following systemic hyponatremia in rat. However, the increase in AQP4 protein was not accompanied by an increase in mRNA level. The mechanisms involved in the increased AQP4 protein following hyponatremia are still unknown. In this study, we analysed the expression pattern of AQP4 and other members of DAPC in primary rat astrocytes exposed to hyponatremia. The cells were exposed to 1 or 6 hours of hyponatremia, followed by 6 or 12 hours of incubation in the normal media. Our data shows a significant increase in the expression level of DAG1, the gene encoding for the transmembrane proteins alpha- and beta- dystroglycan. Expression levels of the other DAPC members such as AQP4, dystrophin, alpha syntrophin were unchanged. Since dystroglycan link the extracellular matrix to the intracellular cytoskeleton, we hypothesize that it is the gene regulated by the hypotonic stress and its upregulation leads to increased mobilization of AQP4 to the perivascular membrane domains. This hypothesis is currently being tested in animal models.

Title: Microfluidic platform for the study of water transport in astrocytes

Authors: *J. M. LECHOWICZ[1], J. XU[2], S. T. ALFORD[3], A. A. LINNINGER[1];
[1]Bioengineering, [2]Mechanical and Industrial Engin., [3]Biol. Sci., Univ. of Illinois At Chicago, Chicago, IL

Abstract: Recently, the glymphatic system has been proposed as the mechanism for soluble waste clearance in the central nervous system parenchyma. This system facilitates the exchange between cerebrospinal fluid and interstitial fluid. A decreased efficiency or perturbation of this system has been speculated as an etiology of neurodegenerative disorders such as Alzheimer's disease, as well as a major contributor in traumatic brain injuries. Aquaporin-4 is the principal water channel in central nervous system acting as a bidirectional passive conduit. It is expressed by astrocytes and localized to perivascular endfoot processes. Aquaporin-4 appears to be an important component of the glymphatic system as its absence results in more than a 60% reduction of tracer clearance from the parenchyma. Little however is known about the mechanisms at the cellular level. Using soft lithography we have developed a microfluidic platform which enables us to induce rat cortex astrocytes to develop the polarized perivascular endfoot-like processes. This is achieved by developing a nutrient gradient and by patterning of the basal lamina extracellular matrix components, laminin and agrin. We are able to indirectly view and quantify water movement in the cell using calcein quenching and the efflux of water through the use of fluorescence dilution. This allows us to interrogate the water transport in astrocytes and determine whether ion transport plays a role.

Title: Mechanisms responsible for limited astrocytic glutamate release during pathological cell swelling

Authors: A. L. SCHOBER, *A. A. MONGIN;
Ctr. for Neuropharm. and Neurosci., Albany Med. Col., Albany, NY

Abstract: Hyponatremia, epilepsy, stroke, and several other CNS pathologies are associated with substantial swelling of astrocytes. To counteract such swelling, astrocytes engage volume regulated anion channels (VRAC) to release cytosolic ions and small organic molecules, including L-glutamate and taurine. This protective mechanism is problematic because it leads to a buildup of the extracellular levels of the excitotoxic transmitter glutamate. Paradoxically, cultured astrocytes lose disproportionally less intracellular glutamate, as compared to taurine and several other molecules, which share the same VRAC release pathway. In the present study, we explored potential mechanisms that allow astrocytes to conserve intracellular glutamate in a cellular model of hyponatremia. To induce cell swelling, we exposed primary rat astrocytes to hypoosmotic medium (with [NaCl]o reduced by 58 mM). Initial model experiments, revealed fairly similar permeability of VRAC to radiolabeled [14C]taurine and L-[3H]glutamate. However, when we used an HPLC assay to determine the endogenous amino acid content, we found that within 30 min swollen astrocytes lose 54% of the intracellular taurine, but only 19% of the intracellular glutamate. This dramatic difference was eliminated after inhibition of both glutamate reuptake (with the glutamate transporter blocker 300 μM TBOA) and mitochondrial glutamate synthesis (with the inhibitor of aminotransferases 1 mM aminooxyacetic acid, AOA). Treatment with TBOA+AOA made reductions in the intracellular taurine and L-glutamate levels approximately equal. Taken together, these data suggest that swollen astrocytes actively conserve intracellular glutamate via reuptake and de novo synthesis. Our findings also likely explain why in animal models of acute hyponatremia, extracellular levels of taurine are dramatically elevated with minimal impact on extracellular L-glutamate.

Abstract: Edema in the central nervous system develops in a wide range of pathologic conditions, rapidly resulting in life-threatening complications. Vasogenic edema is clinically manageable, but there is no established medical treatment for cytotoxic edema, which affects astrocytes and is a primary trigger of acute post-traumatic neuronal death. To test the hypothesis that adrenergic receptor agonists, including the stress molecule epinephrine protects neural parenchyma from damage, we characterized its effects on hypotonicity-induced cellular edema in cortical astrocytes by *in vivo* and *in vitro* imaging. After epinephrine administration, hypotonicity-induced swelling of cortical astrocytes was markedly reduced and cytosolic 3'-5'-cyclic adenosine monophosphate (cAMP) was increased, as shown by a fluorescence resonance energy transfer nanosensor. Interestingly, in swollen primary cortical astrocytes, the kinetics of cAMP signaling was slowed. To ascertain effects on downstream cytoplasmic processes, we analyzed Ca2+ concentration. We found that epinephrine, via modifying cAMP-signaling, reduced hypotonicity-induced cytosolic Ca2+ excitability, which may be the key to prevent astrocyte swelling. Furthermore, in a rat model of spinal cord injury, epinephrine applied locally markedly reduced neural edema around the contusion epicenter. Together, these findings reveal new targets for the treatment of cellular edema in the central nervous system.

Title: Quantitative evaluation of optogenetically-induced calcium signaling in astrocytes

Authors: *L. BALACHANDAR[1,2], A. RAYMOND[3], A. OROZCO[2], J. RIERA DIAZ[2];
[2]Biomed. Engin., [3]Immunol., [1]Florida Intl. Univ., Miami, FL

Abstract: Optogenetics, a modern technique in neuroscience to control excitable cells with light, has been recently expanded to astrocytes (Figueiredo et-al., 2010). However, the mechanisms by which light-activated channelrhodopsins affect the behavior of such non-excitable cells haven't been clearly identified / quantified. The purpose of this study is to establish a methodology to stimulate astrocytes with light *in vitro*, which included an evaluation of viral parameters for proper cell viability/activity, quantification of experimental parameters for optimal Ca2+ indicator loading and development of a mechanistic biophysical model to predict transient Ca2+ responses in astrocytes. We were able to evoke and quantify Ca2+ signaling in cultured astrocytes (Fig.1.1) and found that Ca2+ signaling is highly dependent on light stimulation parameters. As indicated in Fig. 1.4, after the stimulation laser was switched on astrocytes start firing Ca2+ spikes in a random fashion (Phase B), which trailed off once the laser was turned off (Phase C). As predicted by our biophysical model, low percentage of sustained light was not enough to reach the calcium basal level needed for firing Ca2+ spikes, whereas high percentage brought Ca2+ baseline to a level that blocked Ca2+ activity. We concluded that in order to induce sustained excitability in astrocytes, the overall proportion of sustained light (δ/α %) should be kept within the range of 5-25% (Fig 1.5). These light stimulation parameters are crucial, as it can adversely affect cellular activity by different mechanisms (e.g. phototoxicity, IP3R saturation, ER Ca2+ depletion), if subjected to high frequencies/ time periods of stimulation. We will evaluate this protocol on *in vivo* situations in the near future.

Title: Calcium signaling in astrocytes quantified through experimental measurements and mathematical modeling

Authors: ***M. TAHERI**[1,2], G. HANDY[3], A. BORISYUK[3], J. A. WHITE[4];
[1]Univ. of Utah, Salt Lake City, UT; [2]Dept. of Bioengineering, Univ. of Utah, Salt lake city, UT; [3]Dept. of Mathematics, Univ. of Utah, Salt Lake City, UT; [4]Dept. of Biomed. Engin., Boston Univ., Boston, MA

Abstract: Increasing evidence suggests that astrocytes, through their intracellular calcium signaling, are involved in synaptic plasticity, buffering of extracellular ions, regulation of blood flow in the brain, and several other important physiological functions in the CNS. However, the underlying mechanisms of astrocyte calcium signaling, as well as how calcium signaling contributes to these functions, remain unclear. By pursuing coordinated experimental and modeling studies, our goal is to provide insight into the mechanisms and effects of astrocyte calcium signaling. The resulting mathematical model will allow us to evaluate interpretations from experimental results, test hypotheses, resolve some of the controversies in the field, and make predictions to guide future experiments. Experimentally, we use two-photon microscopy to measure calcium activity in astrocytes from crosses based on our novel PC::G5-tdT transgenic mice (available from JAX labs, stock no. 024477). These crosses express the genetically-encoded calcium indicator GCaMP5G in astrocytes. For *in vivo* preparations, we evoke astrocyte calcium activity with physiological sensory stimulation, such as startling or whisker stimulation. In acute brain slices, we evoke calcium activity through focal application of different GPCR (G-protein coupled receptor) agonists with varying application durations and time intervals. These experiments are being carried out in the absence or presence of blockers for certain calcium dynamic components, such as store-operated calcium channels (SOCCs). Through analyzing

these recordings, we are categorizing the different types of calcium responses and quantifying calcium dynamics in terms of duration, amplitude, latency, as well as rise and decay times. In parallel with experiments, we have developed a mathematical model for astrocyte calcium dynamics. We are currently using the model to make experimentally verifiable predictions and explore causes of apparent inconsistencies in the field.

Title: Calcium regulates mitochondrial mobility and mitochondria regulate calcium signaling in astrocyte processes

Authors: ***J. G. JACKSON**[1], D. A. COULTER[2,4], M. B. ROBINSON[3,5];
[1]Neurosci., [2]Neurol., [3]Pediatrics, Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Neurosci., [5]Systems Pharmacol. and Exptl. Therapeut., Univ. of Pennsylvania, Philadelphia, PA

Abstract: We recently showed that inhibition of neuronal activity, glutamate uptake, or reversed-Na+/Ca2+-exchange increases mitochondrial mobility in astrocytic processes. In neurons, cytosolic Ca2+ decreases mitochondrial mobility in a Miro-dependent fashion, and mitochondria in turn shape Ca2+ signaling. In the present study, we examined the inter-relationships between mitochondrial mobility and Ca2+ signaling in astrocyte processes in organotypic cultures of rat hippocampus. All three treatments that increase mitochondrial mobility (tetrodotoxin, TFB-TBOA, YM-244769) decreased basal Ca2+ as assessed using a genetic Ca2+ indicator (GCaMP). As has been recently reported, we observed spontaneous Ca2+ spikes with half-lives of ~1 sec that spread ~6 µm and are almost abolished by a TRPA1 channel antagonist. Virtually all of these Ca2+ spikes overlap mitochondria (98%), and 62% of mitochondria are overlapped by these spikes. The spread and frequency of these spikes was inversely related to the density of mitochondria in a process. Although tetrodotoxin, TFB-TBOA, or YM-244769 also increased Ca2+ signaling; the specific effects on peak, decay time, and/or

frequency were different. To more specifically manipulate mitochondria, we explored the effects of Miro proteins. We show that Miro1 & Miro2 are both expressed in astrocytes and that exogenous expression of Ca2+-insensitive Miro mutants (KK) nearly doubles the percentage of mobile mitochondria. Expression of Miro1KK had a modest effect on the frequency of these Ca2+ spikes, but nearly doubled the decay half-life. The mitochondrial proton ionophore, FCCP, caused a large prolonged increase in cytosolic Ca2+ followed by an increase in the decay time and the spread of the spontaneous Ca2+ spikes. Photo-ablation of individual mitochondria in astrocyte processes resulted in a large, long-lasting increase in Ca2+ and increased the amplitude, spatial spread, and time constant of individual Ca2+ transients. Together these studies show that Ca2+ regulates mitochondrial mobility and mitochondria in turn regulate Ca2+ signals in astrocyte processes. Positioning of mitochondria at sites of elevated activity within the astrocyte might influence local signaling and energy supply within the astrocyte processes.

Title: Astrocyte calcium dynamics during early and late juvenile periods in the mouse hippocampus

Authors: *R. NAKAYAMA, T. SASAKI, Y. IKEGAYA;
Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Astrocytes generate calcium signals throughout their fine processes, which are assumed to locally regulate neighboring neurotransmission and blood flow. The intercellular morphological relationships mature during juvenile periods when astrocytes elongate highly ramified processes. In this study, we examined how protoplasmic astrocytes in the hippocampus change intracellular calcium activity with development using a transgenic mouse line in which astrocytes selectively express a genetically encoded calcium indicator, Yellow Cameleon-Nano50. Compared with postnatal day 7, astrocytes at postnatal day 30 showed (1) larger

subcellular calcium events, (2) a greater proportion of somatic events, and (3) hotspots of calcium events more largely involved in the somatic region. Such calcium activity in late juvenile astrocytes was not affected by spontaneously occurring sharp waves that trigger a large number of neuronal spikes, implying the independence of astrocyte calcium signals from neuronal synchronization. These inherent features of calcium activity may be crucial for maintaining astrocyte functions during juvenile development.

Title: Astrocyte microdomain Ca^{2+} transients arise from transient opening of the mitochondrial permeability transition pore

Authors: ***A. AGARWAL**[1], P.-H. WU[2], E. G. HUGHES[1], M. FUKAYA[4], M. A. TISCHFIELD[3], J. NATHANS[3], D. WIRTZ[2], D. E. BERGLES[1];

Abstract: Astrocytes exhibit spontaneous increases in intracellular Ca2+ that are spatially confined within their highly ramified processes. However, the cellular mechanisms responsible for triggering these “microdomain” Ca2+ transients and the relevance of this signaling have remained elusive. To facilitate analysis of Ca2+ signaling in astrocyte processes, we generated a knock-In mouse line (ROSA26-lsl-mGCaMP3) in which a membrane-anchored variant of the genetically encoded calcium indicator GCaMP3 (mGCaMP3), can be conditionally expressed. A nested neomycin resistance gene (Neo) cassette flanked by FRT sites was added between loxP sites to lower recombination efficiency and increase specificity. Mice exhibited much higher recombination efficiency when the Neo cassette was removed, demonstrating that this mouse line can be adapted to maintain efficiency and specificity of mGCaMP3 expression with different levels of Cre expression. In GLAST-CreER;ROSA26-lsl-mGCaMP3 mice exposed to tamoxifen, mGCaMP3 was expressed in astrocytes throughout the brain and silver enhanced immunogold electron microscopic analysis showed that mGCaMP3 was localized to the plasma membrane and was abundant in the thinnest astrocyte processes. In acute brain slices from these mice,

spatially restricted, spontaneous fluctuations in Ca2+ levels were observed within astrocyte processes. To identify active microdomains and define the characteristics of their Ca2+ transients we developed a machine-learning based algorithm in MATLAB, called CaSCaDe (Ca2+ Signal Classification and Decoding). Ca2+ transients in microdomains were not coincident, suggesting that these regions are functionally uncoupled, and they persisted in bafilomycin A1, indicating that they do not result from neurotransmitter release. These Ca2+ transients were reduced in mice lacking IP3R2 or after treatment with thapsigargin, but events with similar characteristics (amplitude, duration) were still present, indicating that a proportion of these events do not reflect Ca2+ release from the endoplasmic reticulum. Using mice in which EGFP can be specifically expressed in astrocytic mitochondria, we found that the majority of microdomain Ca2+ transients co-localized with mitochondria. Furthermore, pharmacological inhibition of the mitochondrial permeability transition pore (mPTP) inhibited these events, while enhancing mPTP opening potentiated these events. Thus, transient opening of the mPTP induces spatially restricted Ca2+ transients in astrocytes processes, providing a means to link astrocyte respiration rates and Ca2+ dependent effector pathways.

Title: Specific patterns of synaptic activity alter astrocyte resting calcium

Authors: *E. MEHINA, G. GORDON;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Astrocytes act as important regulators of synaptic function and brain blood vessel tone, carrying out these functions in response to changes in intracellular calcium. While much

research has sought to examine the effects of large, transient increases in astrocyte calcium, the investigation of the role of resting calcium in astrocytes remains untouched. We endeavored to address this deficiency by using two-photon calcium imaging to examine changes in resting astrocyte calcium in acute brain slices of the somatosensory cortex in male Sprague-Dawley rats. Astrocytes were co-loaded with the Ca2+ indicator Rhod-2/AM and the morphological dye calcein-green/AM. A ratio was taken of the two signals to control for any volume or optical changes to the tissue during experiments. In response to electrical theta burst stimulation of neural afferents astrocytes showed a decrease in resting calcium, with these levels becoming reset at a new, lower baseline level. This effect was compounded by subsequent stimulations. Application of a glutamate receptor antagonist cocktail, designed to target metabotropic glutamate receptors (mGluRs), ionotropic N-methyl-D-aspartate receptors (NMDARs) and ionotropic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptors (AMPARs), suppressed the effect suggesting a glutamatergic mechanism. These results indicate that resting astrocyte calcium levels change in response to specific patterns of synaptic activity. This observation is significant because it may have functional consequences to the control of blood vessel tone by astrocytes, as well as their effects at the synapse, providing further insight into the means by which these cells carry out their vascular and synaptic roles.

Title: LPA-LPAR1 signaling modulates astrocyte reactivation in neurodegeneration

Authors: L.-Y. TSAI[1], Y.-H. LEE[2], *C.-Y. WANG[3], J.-J. LIANG[1], P.-C. HSU[2], F.-S. SHIE[1]; [1]Ctr. for Neuropsychiatric Res., Natl. Hlth. Res. Inst., Miaoli County, Taiwan; [2]Inst. of Physiol., Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Chang Gung Univ., Tao-yuan/kwei-Shan, Taiwan

Abstract: Lysophosphatidic acid (LPA) is involved in the regulation of various cellular functions largely mediated through LPA receptor-1 (LPAR1). Here, we show that LPAR1 was increased in reactive astrocytes in the brain of mice with neuroinflammation induced by systemic administration of lipopolysaccharide (LPS) and its expression was in paralleled with the

pathological progression in mice genetically engineered to develop Alzheimer's disease. We also found that genetic silence against LPAR1 mRNA in primary astrocytes led to an increase of LPS-activated immune responses, while overexpression of LPAR1 or treatment of LPA *in vitro* suppressed astrocyte reactivation as evidenced by the reduction of many pro-inflammatory indications. Importantly, the reduction of body temperature and the expression of hippocampal inducible nitric oxide synthase (iNOS) in mice received intraperitoneal injection of LPS can be ameliorated by co-treatment of LPA, which effects were abolished by an LPAR1 inhibitor, Ki16425. These data suggest that LPA-LPAR1 signaling could play an anti-inflammatory role during neuroinflammation. However, our findings also indicate that intraperitoneal injection of LPA promoted LPS-induced GFAP expression and astrocyte IL-6 in the hippocampus in an LPAR1-dependent manner. In summary, LPA-LPAR1 signaling exerts multiple functions in the modulation of astrocyte reactivation under the circumstances of pathological insults. Because of the pivotal roles of astrocyte-mediated neuroinflammation in the pathogenesis of many neurodegenerative diseases, further understanding the impacts of astrocyte LPA-LPAR1 signaling in the diseased brain may confer the molecular basis for the development of the disease therapy.

Title: Neural microcircuit specific astrocyte transcriptomes and proteomes

Authors: *B. DÍAZ CASTRO, H. CHAI, F. GAO, E. MONTE, G. COPPOLA, J. WHITELEGGE, T. M. VONDRISKA, B. S. KHAKH;
UCLA, Los Angeles, CA

Abstract: Astrocytes are found throughout the brain and are involved in diverse processes including synapse formation/removal, ion homeostasis, neurotransmitter uptake, regulation of neuronal function, metabolic support of neurons, and blood flow regulation. In addition, astrocytes respond to all forms of injury and trauma. A common assumption has been that

astrocytes serve identical functions throughout the brain, i.e. that they are a largely homogenous population of cells. However, recent studies raise the possibility that astrocytes may mediate a diverse range of responses in a manner that is tractable and suggestive of astrocyte diversity. In order to systematically compare astrocytes from two different regions of the brain, we performed side-by-side evaluations of astrocyte transcriptomes and proteomes from the hippocampus and striatum. To this end, we refined protocols to enzymatically dissociate brain tissue and then to isolate astrocytes by fluorescence activated cell sorting from P7 and P30 Aldh1L1-eGFP mice, which express eGFP in essentially all astrocytes. We performed basic Western blot analyses to confirm that pure populations of astrocytes were isolated from each area. We used Illumina MouseRef-8 v2.0 Expression BeadChip microarrays and a Thermo LTQ Orbitrap XL mass spectrometer to carefully document RNA and protein expression profiles for hippocampal and striatal astrocytes. Here, we report 70 astrocyte-enriched molecular markers that are common between the hippocampus and striatum, and maintained through postnatal brain development. In addition, our data reveal 89 genes displaying differential expression in astrocytes from striatum and hippocampus at P30 and up to 108 such genes at P7. Finally, we compare results from transcriptomic and proteomic evaluations for astrocytes from hippocampus and striatum at P7. Our data and analyses so far suggest that astrocytes from striatum and hippocampus are largely similar and that most expressed transcripts are common to both cell populations. However, astrocytes from these two regions can be classified as distinct populations based on the expression of several unique genes, supporting the idea that astrocyte function is dependent on the local neuronal microcircuit. Our results will serve as a valuable resource to perform hypothesis-driven experiments to explore astrocyte physiology in the hippocampus and striatum.

Title: Morphologic, phenotypic, and transcriptomic analyses of post-stroke reactive astrocyte heterogeneity: bridging structure and function

Authors: *A. J. GLEICHMAN[1], R. KAWAGUCHI[2], M. V. SOFRONIEW[2], G. COPPOLA[2], S. CARMICHAEL[1];
[1]Neurol., [2]UCLA, Los Angeles, CA

Abstract: It is increasingly clear that astrocytes have diverse and complex roles in both the healthy and injured CNS, such as regulating blood flow, mediating synapse formation and elimination, and responding to and releasing cytokines and chemokines. Many of these functions have clear implications for post-stroke repair, yet little is known about how astrocytes respond to stroke or how these responses may vary. Using both cortical and white matter models of ischemic stroke, we have analyzed the morphologic, phenotypic, and transcriptomic changes astrocytes undergo in these different regions as a function of their distance from the site of injury. The most commonly used marker of reactive astrocytosis is GFAP, which allows only visualization of the main branches of astrocytes. In order to more completely elaborate the fine processes of astrocytic arbors, which comprise the majority of the astrocyte and are crucial for many astrocytic functions, we have developed lentiviral vectors that drive expression of advanced reporters. Using these reporters, we have delineated multiple distinct zones of astrocytes by varying morphology. By developing similar tools for other cell populations, we can obtain a detailed view of the interactions between astrocytes, neurons, and oligodendrocytes. As many important astrocytic functions are dependent on the interaction of astrocytes with other cell types, this detailed morphologic assessment of not only astrocytes but also their position relative to other cell types can yield important clues as to their changing functions post-stroke. Furthermore, morphologically discrete zones have then been further characterized by phenotypic differences, including differences in Ki67, aquaporin-4, glutamate transporters, potassium channels, and others. Together, these data support the existence of multiple discrete zones of reactive astrocytes post-stroke. We have used the morphologic and phenotypic delineation of astrocytic zones to inform transcriptomic analyses of these regions. Using the Ribotag mouse model with a GFAP Cre, we have developed a model in which astrocytic ribosomes express an HA tag, allowing immunoprecipitation of ribosomes and their associated mRNA. Discrete astrocytic zones are specifically isolated using laser capture microdissection, ribosomes are immunoprecipitated, RNA isolated and analyzed by RNAseq. These data provide us a clear view of the differences between these astrocytic populations, which may afford insight into their different roles and the ways in which those roles may be manipulated to promote post-stroke repair. Title: Acute purification and transcriptome profiling of human astrocytes

Authors: *Y. ZHANG, S. A. SLOAN, L. E. CLARKE, C. CANEDA, M. HAYDEN-GEPHART, G. A. GRANT, S. H. CHESHIER, M. S. EDWARDS, G. LI, G. K. STEINBERG, H. VOGEL, P. BLUMENTHAL, B. A. BARRES;
Stanford Univ., Stanford, CA

Abstract: Astrocytes play critical roles in the development and function of the central nervous system. However, our understanding of astrocyte physiology is largely predicated on research in rodent models. Surprisingly, the degree to which rodent and human astrocytes are comparable remains relatively unknown. We developed an immunopanning-based method to acutely purify astrocytes from fetal and postnatal human brains without the need to expand these cells *in vitro* via exposure to serum. Functionally, we found that similar to rodent astrocytes, human astrocytes are capable of promoting neuronal survival, inducing synapse formation, and engulfing synaptosomes. Furthermore, human astrocytes exhibit distinct calcium responses to ATP and glutamate. To uncover the human astrocyte transcriptome, we performed RNA-sequencing of acutely purified astrocytes and compared these data to purified human neurons, oligodendrocytes, microglia and endothelial cells. Our purification method and transcriptome dataset provide new resources for investigating the function of human astrocytes in healthy and diseased brains. Title: Diurnal influences on regional astrocyte morphological functional plasticity

Authors: *S. IRVING[1], M. GILLETTE[2], J. MITCHELL[2];
[1]Mol. and Integrative Physiol., [2]Cell and Developmental Biol., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Astrocytes in the brain are critical to maintaining homeostasis and modulating synaptic signaling and strength. These cellular activities occur in the context of regional differences in brain function that vary with respect to time of day. When challenged osmotically, hypothalamic astrocytes undergo extreme morphological changes that alter relationships with surrounding cells and coordinate neurohormone release. We asked whether under resting physiological conditions morphological change occurs on a daily basis, the period over which brain physiology oscillates normally. To evaluate whether astrocytic morphology varies diurnally, we measured branch complexity of the GFAP cytoskeleton and membrane surface area in two brain regions, the hypothalamic suprachiasmatic nucleus (SCN) and the hippocampal gyrus (DG), throughout the day-night cycle. Unbiased analysis using Imaris software found that GFAP branch complexity and astrocyte surface membrane area of in the SCN are greatest in the early morning (zeitgeber time 2, ZT2) and smallest in the early evening (ZT14). The hippocampal DG showed the opposite changes, with the greatest complexity and surface area in early night and least in early morning. Additionally, utilizing a hyperosmotic challenge via intraperitoneal (IP) injection at ZT2 and ZT14, we identified diurnal differences in GFAP branching changes in response to osmotic stress. In addition to the SCN and DG, we also analyzed GFAP branching in the supraoptic nucleus (SON), a hypothalamic region known to respond to osmotic stress. Results suggest that time-of-day influenced the magnitude of GFAP branching in the SON in response to osmotic stress, with a greater change in early night v*s.* early day, whereas osmotic stress did not change the GFAP branching morphology significantly in either DG or SCN. In conclusion, astrocytes exhibit diurnal regional heterogeneity in GFAP branching complexity and differences in the magnitude of the branching changes, along with differential responses to osmotic challenge. Title: Impact of thyroid hormone on glial function and morphology

Authors: ***M. NODA**, J. LIU, Y. YOSHII, Y. YOSHIOKA;
Kyushu Univ., Fukuoka, Japan

Abstract: L-tri-iodothyronine (3, 3', 5-triiodothyronine; T3) is an active form of the thyroid hormone (TH) essential for the development and function of the central nervous system (CNS). Circulating thyroxine (T4) crosses blood-brain barrier via specific transporters. T4 in the brain is taken up by astrocytes, de-iodinated to produce T3, and then taken by other cells. In adult CNS, both hypo- and hyper-thyroidism may affect psychological condition and potentially increase the risk of cognitive impairment and neurodegeneration including Alzheimer's disease (AD). We have reported non-genomic effects of T3 on microglial functions and its signaling *in vitro* (Mori et al., GLIA, 2015). To investigate whether or not change in THs level affects glial cells *in vivo*, the effects of hyper- and hypothyroidism on microglia and astrocytes were investigated. The morphological changes in microglia and astrocytes in the cerebral cortex and hippocampus in C57/BL6 mice were investigated by immunohistochemical analysis. Hyper- or hypothyroidism were induced by intraperitoneally injecting T4 (0.3 mg/kg) 4 times during 2 weeks or propylthiouracyl (60 mg/kg/day) for 21 days. Interestingly, effects of hyper- and hypothyroidism on glial cells were sex- and age-dependent. Behavioral changes are now under investigation. These results may help to understand physiological and/or pathophysiological functions of THs in the CNS.

Title: Molecular heterogeneous atlas of adult mouse and fly astroglia

Authors: *Y. YANG, L. MOREL, Y. HUANG, S. NG, M. TOLMAN, F. NG, N. BOWENS, S. SENGUPTA, L. IYER, R. JACKSON;
Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: *In vivo* molecular evidence to support astroglia heterogeneity is largely lacking, as is information regarding conservation of astroglia-expressed genes between important biological models. Employing TRAP-mediated isolation of translating mRNAs from adult astroglia of mouse forebrain and subcortical regions, and subsequent RNA-seq analysis, we provide the first *in vivo* evidence for a genome-wide molecular heterogeneity of brain astroglia. Our current study also reveals region-specific expression patterns for genes that are selectively expressed and functionally important in astroglia, providing novel insights about the specificity of their functions. Using similar TRAP-based methods, we identify *Drosophila* genes showing enriched expression in astroglia that are evolutionally conserved between the fly and mouse. A subsequent RNAi-based screen in the fly shows that astroglial AP-2σ expression is required for normal circadian behavior. Overall, our *in vivo* results suggest important functions for certain mouse and fly astroglial genes and provide the first molecular heterogeneous atlas for adult astroglia.

Title: Molecularly defined astrocyte subpopulations in adult CNS and their response to neurodegenerative disease injury

Authors: *S. J. MILLER[1], T. PHILIPS[2], M. ROBINSON[3], R. SATTLER[2], J. D. ROTHSTEIN[1];
[1]Neurology/Cellular & Mol. Med., [2]Neurol., Johns Hopkins Sch. of Med., Baltimore, MD;

Abstract: Astrocytes are the most abundant cell types in the central nervous system. Historically, astrocytes have been considered a homogenous population of cells. However, accumulating evidence has shown that astrocytes are indeed a heterogeneous cell type that exhibits distinct gene and protein expression profiles dependent on their anatomical location. To date, there is a very limited collection of tools available to study different astrocyte populations. This is due to a lack of known markers unique to each subtype. Previously our group has generated a transgenic mouse model containing a genetically encoded fluorescent reporter that labels a specific astrocyte subpopulation in the adult spinal cord and neocortex. We employed this model to study astrocyte subpopulations and show that the distribution of these astrocytes is enriched in Layers II and V of the neocortex and in the ventral horn of the spinal cord grey matter. We also utilized multiphoton *in vivo* imaging and were able to track individual astrocytes over a time period of weeks in the adult mouse neocortex thus establishing that this fluorescent reporter is static. Finally, to understand the role of this astrocyte subpopulation in neurodegenerative disease context, we crossed our transgenic astrocyte reporter mice with G93A SOD1 ALS mouse model. We show that this astrocyte subpopulation and markers enriched in this subpopulation are remarkably affected in both the spinal cord and neocortex of the ALS mouse. Taken together, these results shed light on the heterogeneous population of astrocytes in health and the susceptibility of certain astrocyte subpopulations to disease.

Title: Locally translated proteins in peripheral astrocyte processes

Authors: *K. SAKERS, J. D. DOUGHERTY;
Genet., Washington Univ. Sch. of Med. in St Lou, Saint Louis, MO

Abstract: Within the last two decades, the critical role of peripheral astrocyte processes (PAPs), especially those surrounding synapses, have become increasingly more apparent. Of their many functions, PAPs serve to maintain proper neurotransmission by buffering ions and neurotransmitters in the synaptic cleft. To do so, PAPs must express specific ion channels and solute carrier proteins at their distal ends - at or near the synapse. PAPs are the third component of the “tripartite synapse,” a dynamic structure in which rapid responsiveness to stimuli is critical. Neurons, for example, have adapted to locally synthesize proteins in their dendrites to compensate for the distance from the cell body. This mechanism is important during prolonged periods of activity, such as long-term potentiation, and is required for processes of learning and memory. As a fundamental part of the tripartite synapse, PAPs must have the ability to rapidly adapt to synaptic activity as well. Because PAPs meet, and exceed, length requirements of neuronal dendrites, we hypothesize that PAPs locally synthesize proteins. In order to test this, we have developed PAP-TRAP (peripheral astrocyte processes-translating ribosome affinity purification) in which we can isolate PAPs and purify mRNA bound to ribosomes in order to determine which, if any, mRNAs may be undergoing local translation in these distal processes. Coupling this method to qPCR for candidate mRNAs, we have found evidence for the local translation of the glutamate transporters, Glt1 and Glast, and the inwardly-rectifying potassium channel, Kir4.1.

Title: Novel applications of magnetic sorting to analyze cell-type specific gene and protein expression in a mouse model of Rett Syndrome

Authors: *L. HOLT, N. PACHECO, M. OLSEN;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: The isolation and study of cell-specific populations in the central nervous system (CNS) has gained significant interest in the neuroscience community. The ability to examine cell-specific gene and protein expression patterns in healthy and pathological tissue is critical for our understanding of CNS function. Here we demonstrate that distinct cell populations can be isolated in rodents through adulthood using magnetic bead sorting. We found this technique to be easily amendable to customization using commercially available membrane targeted antibodies, allowing for cell-specific isolation across development and animal species. High quality RNA which can be utilized for downstream applications including quantitative PCR and RNA sequencing was obtained at relatively low cost and without the need for specialized equipment or fluorescently labeled cells. Adding to its utility we demonstrate that cells were isolated largely intact, retaining their processes, enabling analysis of extrasomatic proteins. We used magnetic cell sorting to examine changes in astrocyte gene/protein expression and function in the neurodevelopmental disorder Rett Syndrome. Rett Syndrome, which is caused by mutations in the transcriptional regulator MeCP2, has long been considered a neuronal disease. However, recent work highlights a role for astrocytes in disease pathogenesis. Preliminary data suggests that BDNF is significantly decreased in astrocytes in a mouse model of Rett Syndrome. Work in progress is directed at elucidating both the autonomous and non-autonomous contribution of aberrant astrocytic BDNF regulation in Rett Syndrome.

Title: Defining gene expression and protein secretion signatures in murine primary glia

Authors: *Y. HE[1], N. TAYLOR[1], X. YAO[2], T. LOVENBERG[1], A. BHATTACHARYA[1]; [1]Neurosci., [2]Discovery Sci., Janssen Res. & Develop. LLC., San Diego, CA

Abstract: Growing evidence shows depression involves a complex and bidirectional interaction between the immune system and the central nervous system (CNS). Immune dysfunction plays an important role in the etiology and pathogenesis of major depression by increasing production of pro-inflammatory cytokines. Like peripheral immune cells, glia in the brain are the main source and target cells for cytokines/chemokines (gliotransmitters), which regulate neuronal survival, synaptic plasticity, and neurogenesis. However, the effects of these factors on glia during depression are not clear. To that end, we measured gene expression and protein secretion of isolated glia upon depression-related cytokine stimulation (IL-1b, TNFa, IL-6; 10 ng/ml; 24 hrs). IL-1b was the most sensitive cytokine in the microglia when assessed for upregulation of a panel of genes (iNOS, TSPO, COX-2, P2RX7, CCR2, CSF1R, Arg-1, IL-6, TNFa, IL-1b). Contrary to this, astrocytes were more sensitive than microglia in upregulating expression of iNOS, TSPO, TNFa, IL-6, and CSF-1R upon TNFa stimulation. In conditions that drove M1 (LPS + IFNg) polarization, astrocytes specifically secreted chemokines CXCL1 and CCL2, while microglia secreted CCL3, CXCL2, GCSF, IL-12, TNFa and IL-6. It is apparent that microglia and astrocytes respond to neuroinflammation differentially; the signatures defined at the murine glia will be used to compare and contrast human glial signatures that may shed insight into disease biology and aid in novel target discovery.

Title: The significance and mechanism of differential expression of GDNF splice variants in glioma cells

Authors: H. LI[1], *D. GAO[1,2];
[1]Xuzhou Med. Col., Jiangsu, China; [2]Neurosurg., Affiliated Hosp. of Xuzhou Med. Col., Xuzhou, China

Abstract: Glial cell line-derived neurotrophic factor (GDNF) is highly expressed in glioma cells, and there is evidence that two different GDNF splice variants may be present during transcriptional splicing in eukaryotic cells. It is unclear whether this alternative splicing is related with high GDNF expression in glioma cells or whether different GDNF splice variants produced as a result impact glioma pathogenesis. To shed light on these issues, this study was designed to measure the differential expression of GDNF splicing isoforms in glioma cells, analyze the relationship between these differences and the characteristics of different types of glioma cells, and explore possible mechanisms for these differences. Our results indicate that the two GDNF isoforms, α- and β-pro-GDNF, are expressed in different types of glioma cells, but α-pro-GDNF was preferentially expressed in the most highly invasive glioblastoma tissue. In addition, histone acetylation assays revealed high H3K9 acetylation at the GDNF Δ78 alternative splicing site in glioma cells. Collectively, these results demonstrate differential expression of GDNF alternative splice variants in glioma cells and a possible relationship between preferential expression of α-pro-GDNF and high tumor invasiveness; they also serve as preliminary evidence that differential GDNF expression may be related to changes in histone acetylation in the gene's coding region.

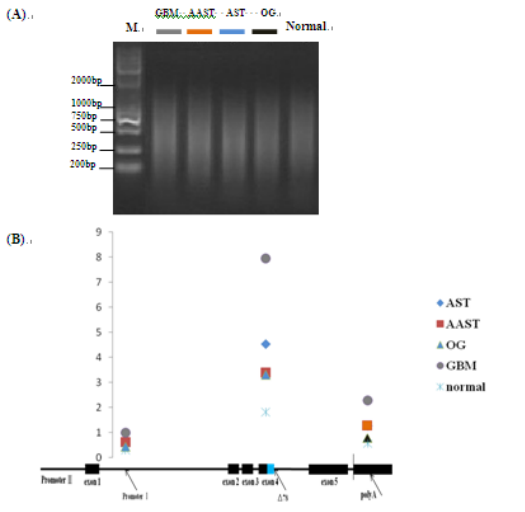

Figure. H3K9 acetylation at the GDNF Δ78 site in gliomas. (A) Electrophoresis of DNA after ultrasonic chromatin shearing. M indicates Marker. (B) H3K9 acetylation at the Δ 78 site compared to the promoter and polyA region. The ordinate indicates the GDNF gene mode, exons are shown as black boxes, and horizontal lines indicate the intron. The corresponding polyA region is behind the vertical bar. The site selected for H3K9 acetylation measurement is denoted with an arrow. Normal represents normal brain tissue. In both panels, AST, OG, AAST, GBM, and Normal indicate the four glioma samples and normal brain tissue, respectively.

Title: Tridimensional culture induces neuronal differentiation in a commercial normal human astrocyte cell line (NHA)

Authors: *V. B. KNIGHT, E. E. SERRANO;
Biol., New Mexico State Univ., Las Cruces, NM

Abstract: Tridimensional environments modulate the fate and morphology of many different cell types. When a primary human cell line derived from embryonic brain tissue was cultured in 3D (Normal Human Astrocytes; NHA; Lonza), its morphology resembled that of mixed neuronal-glial cultures. The characteristic groupings of phase-bright neuronal somata were not visible in monolayer culture where instead, cells assumed the flattened uniform appearance of glial cultures. Next Generation Sequencing technology was used to explore the genetic basis for the observed structural differences. RNA (RIN > 8.9) from replicate NHA samples grown in monolayer or 3D was sequenced at the MIT BioMicro Center using Illumina Tru-Seq protocols. Sequences were mapped to the human genome (UCSC build hg 19; Genome Reference Consortium GRCh37) using TopHat pipeline software running on GenePattern. DeSeq was used to determine whether genes were differentially expressed between tridimensional and monolayer culture conditions. The gene ontology of differentially expressed genes was explored with DAVID (Database for Annotation, Visualization and Integrated Discovery v6.7) and GeneCards. We found significant (enrichment score > 1.3) annotation clusters that included ontological terms such as “neuron development”, “axonogenesis”, “cognition”, and “learning or memory”. Functional analysis suggests that the morphological differences observed in 3D could be due to key genes that include UNC5B and NPTX1. Outcomes may reflect the degree of genetic and cellular variation in primary tissue-derived lines as compared to clonally-derived lines. Results imply that tissue engineering and targeted cellular differentiation can be undertaken with this commercially available cell line. Supported by NIH P50GM068762; NMSU Manasse Endowment.

Title: TAMRA-conjugated spermine is selectively taken up by glial cells in the rodent brain and retina

Authors: *J. BENEDIKT[1], A. ZAYAS-SANTIAGO[2], Y. RIVERA[2], Y. KUCHERYAVYKH[2], L. KUCHERYAVYKH[2], L. CUBANO[2], M. EATON[2], R. VEH[3], C. NICHOLS[4], S. SKATCHKOV[2];

Abstract: The polyamines (PAs) spermine (SPM) and spermidine (SPD) are omnipresent molecules stored predominantly in astrocytes, but not in neurons of the adult rat brain. Because we found no synthesis for SPM and SPD in glial cells, we speculate that PAs are taken up by a yet unknown mechanism. Using RT-PCR we found organic cation transporters (OCT1, OCT2 and OCT3) in rodent brain and using immunocytochemistry we observed OCT3 localization in astrocytes in rat hippocampus and cortex. For the visualization of the uptake of SPM in rodent brain slices, we used covalently tagged SPM with fluorescent 5(6)-carboxytetramethylrhodamine (TAMRA). We perfused rat and mouse hippocampal slices with an extracellular solution containing 10 μM SPM-TAMRA and observed rapid and extensive uptake of fluorescent SPM into astrocytes, but not into neurons or other parenchymal cells. When 10 μM of unconjugated TAMRA was perfused, there was no specific staining of any cell type in the hippocampus, suggesting the presence of a specific mechanism for SPM uptake. Similar experiments performed in isolated retina revealed strong staining of retinal Müller cells, while in corpus callosum, characterized by presence of fibrous astrocytes, only weak uptake of SPM-TAMRA was observed. These findings suggest there is SPM-specific transport mechanism present in protoplasmic astrocytes of the grey matter, but not in fibrous astrocytes. When 10 μM SPM-TAMRA was injected to a single astrocyte via the patch pipette, it spread from one into other astrocytes in the stratum radiatum region of CA1 hippocampus. SPM-TAMRA rapidly diffused through the astroglial syncytium and eventually stained hundreds of astrocytes in a 10 min time interval. The same experiments were performed with 10 μM unconjugated TAMRA as control and this resulted in a low level of dye propagation (33 cells on average). In both cases, pre-application of gap-junction blocker carbenoxolone (200 μM) effectively abolished the propagation of the SPM-TAMRA, implicating a gap-junction mediated mechanism. Altogether, our data suggest that SPM-TAMRA is specifically taken up by hippocampal protoplasmic astrocytes and rapidly propagated through their syncitium.

Title: Differences in resting state functional connectivity between aerobic athletes and sedentary young adults

Authors: *D. RAICHLEN[1], P. K. BHARADWAJ[2,3], M. C. FITZHUGH[2], K. A. HAWS[2,3], G. A. TORRE[2], T. P. TROUARD[4], G. A. ALEXANDER[2,3,5,6];
[1]Anthrop., [2]Psychology, [3]Evelyn F. McKnight Brain Inst., [4]Biomed. Engin., [5]Neurosci., [6]Physiological Sci., Univ. of Arizona, Tucson, AZ

Abstract: Recent studies have shown that aerobic exercise can positively impact brain structure and cognitive function across the lifespan. In older adults, physical activity generates the greatest improvements in executive functions, which some have linked to increased functional connectivity in the fronto-parietal resting state network (FPN). Fewer studies have examined the effects of physical activity on young adult brains, a key sample since exercise at young ages may impact the trajectory of brain aging. Here, we compared resting-state functional connectivity in a sample of adult male collegiate cross-country runners (n=12; mean±SD age = 21.3±2.5) and a sample of healthy, sedentary age-matched male controls (n=11; mean±SD age = 20.6±1.1) to test the hypothesis that aerobic activity affects resting state networks associated with executive control functions in young adults. While subjects did not differ in body mass index ($p=0.60$), the athletes had higher estimated $VO_{2,max}$ ($p<0.000001$) and self-reported physical activity levels ($p<0.000001$) than controls. T1 volumetric and resting-state functional connectivity magnetic resonance imaging (MRI) scans were acquired on a 3.0T GE Signa Excite scanner at rest with eyes open. The subject maps of the correlations between the average of two seed regions in the

FPN (left and right anterior prefrontal cortex) and all voxels of the brain were computed using the CONN functional connectivity toolbox (Whitfield-Gabrieli et al., 2012) with functional images registered to the structural scans and significance for cluster extent taken with FDR, $p < 0.05$. The athletes had greater average connectivity from the two seed regions of the FPN to a region in the left superior frontal gyrus (SFG) compared to controls, who showed an anti-correlation in this area. The controls also showed a region of anti-correlation in the right precentral gyrus (PCG) that was not observed in the athletes. There were significant positive associations between the correlations at these two regions and self-reported physical activity (left SFG $p=0.003$; right PCG $p<0.00004$) and estimates of maximum aerobic capacity (left SFG $p<0.0002$; right PCG $p<0.00002$). Since the SFG has been implicated in working memory and task-switching, and the PCG is associated with motor tasks, our results suggest that differences in aerobic activity observed between endurance athletes and sedentary adults may differentially impact the functional connectivity that link aspects of executive and motor functions. These findings suggest that high intensity physical activity, such as running, stresses cognitive domains in ways that lead to altered functional brain connectivity.

Title: The role of pericytes in cerebrovascular metabolism

Authors: *A. RAMANATHAN, K. KISLER, A. M. NIKOLAKOPOULOU, A. P. SAGARE, B. V. ZLOKOVIC;
USC, Los Angeles, CA

Abstract: At the site of the blood-brain barrier (BBB), pericytes surrounding the cerebral microvessels are known to regulate BBB formation and maintenance, angiogenesis and vascular

architecture. Recently, the key physiological role of pericytes was uncovered; the contractile pericytes modulate cerebral blood flow by regulating capillary diameter in the adult brain. Thus, pericytes may functionally affect the metabolic supply to the brain by acting as the regulatory floodgates surrounding the endothelia. Here, using a mouse model with pericyte deficiency (Pdgfrβ+/-), we examine how the loss of pericyte coverage affects the underlying cerebrovascular metabolism. Using *in vivo* microdialysis, we have observed that in the somatosensory cortex of Pdgfrβ+/- mice, there is a 55% elevation in interstitial fluid (ISF) levels of lactate at baseline, while ISF glucose and serum metabolite levels remain unchanged. Additionally, upon neuronal stimulation via high [K+] aCSF retrodialysis, there was a significant 28% reduction in the ability of the cortical milieu to recruit lactate to maintain the metabolic demands during increased neuronal activity. These early indications of metabolic stress were accompanied by changes in glycolytic capacity in Pdgfrβ+/- microvessels. Using quantitative autoradiography, we observed reduced blood-to-brain uptake of 14C 2-deoxyglucose, suggesting irregular metabolic supply to the brain. Furthermore, electron microscopy studies demonstrate an altered morphology in the endothelial mitochondria of Pdgfrβ+/- mice. Alzheimer's disease (AD) is separately associated with both, a degeneration of pericytes and a hypometabolic brain. These data suggests that pericytes may contribute to the bioenergetic changes observed in AD.

Abstract: In the last two decades several studies have reported different mechanisms that could link type two diabetes mellitus (T2DM) and dementia. Most of the Alzheimer's disease patients show alterations in the glucose metabolism and insulin signal transduction. It is thought that people develop clinical manifestations of dementia many years after the onset of brain deterioration, hindering the establishment of the disease temporality. Due to this fact, we decided to evaluate the cognitive performance in an earlier stage of metabolic dysfunction, i.e. metabolic syndrome (MS). Since MS is a multifactorial complex of signs that increases the probability to develop several types of health problems, cardiovascular processes, diabetes, certain types of cancer and even cognitive deficit among them. We treated young adult Wistar rats during a period of six months with sucrose 20% in drinking water. After the treatment, we performed three different memory tasks (Morris-Water Maze, Object Recognition Memory and Object Location Memory) and several metabolic parameters were monitored (blood glucose levels, insulin levels, body mass index and oral glucose tolerance test). We observed that MS rats showed a selective hippocampus-dependent cognitive impairment, since cortical function seems to be spared at this stage. In addition, we observed decreased levels in the synaptophysin vesicle protein as well as an impaired hippocampal long-term potentiation and increased levels of the Glial Fibrillary Acidic Protein (GFAP). We concluded that the MS rats present a mild hippocampal dysfunction due to the decreased levels of the synapses and the cognitive function performance in the memory tasks.

Title: Transcriptional profiling of deep brain stimulation in an animal model of antidepressant treatment resistance

Authors: *S. MACHLOVI[1], N. KONSTANTOPOULOS[1,3], S. L. SUTOR[2,4], K. O'CONNOR[1], A. J. WALKER[5,2], A. SANIGORSKI[3], Y. KIM[5,2], M. FRYE[2], S. TYE[2];

Abstract: Deep brain stimulation (DBS) is an emerging therapy being evaluated for treatment resistant depression. The current study aimed to identify antidepressant mechanisms of DBS in an animal model of treatment resistant depression. We have investigated the cellular mechanisms mediating antidepressant actions of DBS in an animal model of antidepressant treatment resistance induced via chronic administration of adrenocorticotrophic hormone (ACTH) in male Sprague-Dawley rats. Animals were either stress naïve or were administered the forced swim test (FST) at the end of the treatment. A subset of animals also received DBS of the IL as an anti-depressant treatment. Our goal was to take an unbiased approach to identify the mechanisms through which activity in IL is disrupted in antidepressant resistant state and how it is modified by DBS. The IL was dissected and global gene expression profiles obtained (Agilent). Gene set enrichment analysis was performed (DAVID) following Bonferroni correction and KEGG pathways identified (Fisher exact score $p<0.05$). Pivotal genes were validated in independent groups (n=4-5) by RT-PCR and/or immunoblotting. Significant alterations were observed in key sensors of energy demand, cell division/growth, apoptosis, protein synthesis and glucose/glycogen regulation. Phospho-AMPK and phospho-AKT levels were decreased in ACTH/FST animals compared with ACTH/naïve by 45 and 40% ($p<0.05$), respectively, and not reversed with DBS. Moreover, DBS of IL was shown to effectively reduce immobility time in antidepressant resistant animals and reversing the effects of the genes involved in the control of cellular stressors rather than those involved in energy/glucose regulation.

Title: Anesthesia-induced changes in mouse brain glucose uptake are region-dependent

Authors: *P. BASCUÑANA, J. T. THACKERAY, F. M. BENGEL, J. P. BANKSTAHL; Nuclear Med., Hannover Med. Sch., Hannover, Germany

Abstract: F-18-Fluoro-deoxyglucose (FDG) has been widely used for imaging brain metabolism in both, clinical and animal studies. Due to the fact that preconditioning as well as anesthesia might influence brain FDG levels, this study evaluated how this affects both FDG uptake and kinetics in mice brain. Sixty-minute dynamic PET scans were performed in mice anesthetized with isoflurane [control (n=4), insulin pre-treatment (n=5) and 18h fastening (n=5)], ketamine/xylazine (n=4), sevoflurane (n=6) and chloral hydrate (n=6). These studies were analyzed by comparing standardized uptake values (SUV), FDG influx rate (Slope) and metabolic rate of glucose (MRGlu) calculated by Patlak plot. Ketamine/xylazine and chloral hydrate induced lower uptake of FDG (2.97±0.34, p=0.0017; 4.43±0.11, p=0.022; respectively), whereas, in sevoflurane anesthetized animals uptake was increased (5.58±0.14; p=0.044) compared to the isoflurane group (5.04±0.19). In addition, blood glucose levels showed an inverse correlation to whole brain FDG uptake independently of preconditioning (R2=0.722; p<0.0001). Ketamine/xylazine and chloral hydrate showed a higher uptake in cortex and a lower uptake in cerebellum than isoflurane and sevoflurane animals when normalized to the whole brain uptake. Patlak analysis indicated that use of ketamine/xylazine as anesthetic reduced FDG influx rate in mice brain (0.0135±0.0009 ml/min/g; p<0.005) compared to the isoflurane control group (0.0247±0.0014 ml/min/g). Insulin-treated animals showed a tendency to a higher influx rate than control animals (0.0477±0.0101 ml/min/g; p=0,088). In addition, chloral hydrate animals showed a higher MRGlu (66.72±3.75 mmol/min/100ml; p=0.0014) while pre-treatment with insulin induced a lower MRGlu (21.93±3.12 mmol/min/100ml; p=0.0041) compared to the isoflurane control group (41.55±3.06 mmol/min/100ml). Choice of anesthesia affects not only FDG uptake but also kinetics in mice brain, while an often proposed pre-conditioning, i.e. fastening, did not change any parameter. Total brain uptake is strongly influenced by peripheral blood glucose levels. Interestingly, FDG brain uptake is region-dependently influenced by various anesthesia protocols.

Title: The combination of alcohol and energy drinks contributes to metabolic and neurodegenerative impairment in rats

Authors: *B. VENEGAS MENESES[1], S. TREVIÑO[1], A. HANDAL[1], J. MORAN[1], P. AGUILAR-ALONSO[1], G. FLORES[1], J. GUEVARA[2], A. DÍAZ[1];
[1]Benemerita Univ. Autónoma De Puebla, Puebla, Mexico; [2]Lab. de Neuropsiquiatría, Facultad de Medicina, UNAM, Mexico DF., Mexico

Abstract: Energy drinks (ED), possess high concentration of caffeine and taurine, which often consumed in combination with ethanol, due to the popular belief that caffeine and taurine may counteract some of the intoxicating effects of ethanol. However, scientific research suggests that chronic use of these psychoactive substances in combination with alcohol trigger an inflammatory response mediated by pro-inflammatory cytokines (IL-1β and TNF-α) and iNOS both in the central and peripheral system modifying the behaviour of individuals and causing cell death (apoptosis). Currently, the mechanism of toxicity caused by the ED-ethanol interaction in the brain, are not well known. In the present study we evaluated the effects of chronic alcohol consumption in combination with energy drinks on the inflammatory response and neurodegeneration in rat. We used male Long Evans rats (200-250g). Were formed, 4 experimental groups (n=10 per group): 1) control (water); 2) Ethanol (Vodka, 40%); 3) ED (Red-bull) and 4) Ethanol + ED. Animals were orally administered for 2 months, in the course of treatment was evaluated, motor activity in closed field (day 0, 30 and 60). After treatment, the animals were sacrificed; the brains were removed for immunohistochemistry and fluorescence immunoassay (ELISA) to identify markers of inflammation (GFAP, IL-1β, TNF-α, iNOS, nitric oxide) and neurodegeneration (caspase-3 and -9, synaptophysin) in the temporal cortex and hippocampus, respectively. The results showed a progressive deterioration in motor activity during the administration of ethanol + ED. Biochemical and histological studies revealed that chronic ethanol + ED caused an increase in reactive gliosis, IL-1β, TNF-α, iNOS and nitric oxide, in the temporal cortex and hippocampus, respectively, also show immunoreactivity positive for caspase-3 and 9, and a decreases synaptophysin in temporal cortex and hippocampus. The results suggest that chronic consumption of alcohol in combination, cause an inflammatory response, which induces neurodegeneration in hippocampus and cerebral cortex, which affects the motor behaviour of the rats. Therefore, it is necessary to show caution in the consumption of these drinks combined with ethanol, so it is necessary to report urgently on the risks it is exposed to the health of consumers of these substances, especially young people.

Title: Strain-related modulation of Cu(I)-ATPase in prion protein-deficient mice

Authors: *J. A. NOVAES[1], R. R. H. F. VALVERDE[2], A. VIEYRA[2], J. LOWE[2], R. LINDEN[2]; [1]Neurobio., [2]Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: The prion protein (PrPC) binds copper at multiple sites and is involved in copper metabolism, but mechanisms of such functional interaction are still poorly understood. Much of the data on functional roles of PrPC were obtained in mice deficient of the PrPC-coding gene Prnp, in mixed B6.129Sv genetic background, and potential pitfalls of such an approach are currently a matter of concern. It has been reported that Prnp-null mice have a decreased content of the copper ATPase ATP7A. The aim of this study was to investigate the effect of knocking out Prnp upon functional properties of copper ATPases in differing mouse strains. In both brain and liver, we found diminished activity, and increased catalytic phosphorylation of Cu(I)-ATPase in Prnp-null mice of mixed B6.129Sv background. However, no difference in either parameter was found between Prnp-null and wildtype mice of B10.129Ola background. Activity of Cu(I)-ATPase was reduced and catalytic phosphorylation was selectively increased in brain tissue from mice of the 129/Sv strain, when compared with wildtype of B6, B6.129Sv, or B10.129Ola strains. The results show a strain-dependent effect of the 129/Sv genotype, rather than a Prnp-dependent regulation of the Cu(I)-ATPase catalytic cycle in Prnp-null mice.

Title: Regulatory aspects of exercise in mitochondrial remodeling in t2d diabetes

Authors: A. KALANI[1], P. K. KAMAT[1], P. CHATURVEDI[2], L. W. WINCHESTER[2], S. C. TYAGI[2], *N. TYAGI[3];
[1]Physiol. and Biophysics, [2]Univ. of Louisville, Louisville, KY; [3]Physiology& Biophysics, Univ. Of Louisville, Louisville, KY

Abstract: Abstract: The intense impairment of mitochondrial regulatory functions was suggested to mediate neurodegenerative and cognitive disorders in type-2 diabetes (T2D). Exercise (polypill) has been recommended by clinicians as a secondary protective therapy that exerts myriad beneficial effects against T2D-induced brain pathophysiology; however, exercise effects on diabetic mitochondrial pathology are not well understood. Using mitochondria RT^2 profiler PCR array with exercised and non-exercised db/db (T2D) mice brains, we found that exercise benefit mitochondrial transport, dynamics and regulatory genes. Therefore, we hypothesize that exercise mitigates T2D-induced neurodegeneration and cognitive functions by improving mitochondrial heath. To test this hypothesis, we used 1) db/db mice, 2) db/+ mice as controls, with and without exercise. The mice were exercised at a constant speed of 7 meters/min for 5 days in a week and for the total period of 8 weeks. After that, we investigated different mitochondria-related parameters; ATP production, oxygen consumption, mitochondrial ROS, mitochondrial membrane permeability, mitochondria copy number and mitochondrial dynamics. Interestingly, our results suggest that exercise mitigated almost all mitochondria anomalies in db/db diabetic brains. The intact mitochondria isolated from exercised diabetic db/db brains showed significantly reduced TUNEL positive reactivity as compared to diabetic db/db brains. Furthermore, the loss of neurons was rescued in exercised db/db brains when compared to non-exercised db/db brains, as determined by staining brain coronal sections with Fluoro-Jade C. In addition, exercise significantly mitigated total brain blood flow and memory function, as measured by laser doppler flow and novel object recognition tests, respectively. Taken together after determining gross mitochondrial parameters, these results indicate positive promising results of exercise over mitochondrial pathology in diabetes. Furthermore, our findings suggest regular exercise mitigate neurodegeneration and cognitive disorders thereby improving total mitochondrial health. This work was supported by NIH grant HL107640-NT.

Title: Chocolate and the brain: Cocoa modulates various levels of sensory awareness and increases power spectral density (μV2) of EEG gamma wave band frequency 31-40Hz associated with brain, mental and physiological benefits

Authors: *L. S. BERK[1,2], E. LOHMAN[1], G. BAINS[1], N. DESAI[3], B. MADANE[3], D. MALI[3], J. BRADBURN[3], S. SHAH[3], S. IYER[3], S. JUNEJA[3], R. MOHITE[3], J. LEE[3];

Abstract: Cocoa or dark chocolate are a major source of flavonoids. They are potent antioxidant and anti-inflammatory components, with known mechanisms beneficial to cardiovascular health. However, the correlates of neuroelectric activities that initiate the mechanisms of cocoa's beneficial effects on brain neurocognition, synchronization, memory, recall, mood and behavior are unknown. Studies have shown that absorbed cocoa flavonoids penetrate and accumulate in brain hippocampal regions involved in learning and memory. Neurobiological correlates of cocoa flavonoids cascade the expression of neuroprotective and neuromodulatory proteins that promote neurogenesis, neuronal function, brain connectivity, blood-flow improvement and angiogenesis in brain and sensory systems. However, neuroelectric activity initiation and modulatory control of acute action from cocoa flavanoids on brain state has remained unknown. Purpose: Provide evidence for cocoa initiation of brain state frequency modulation and differentiation (0-40Hz) via electroencephalography (EEG). Methods: Assessment of EEG Power Spectral Density (PSD) of 20 subjects during a sequence of cocoa sensory awareness tasks ranging from: cognition of past experience; imagination of eating; visualization; olfaction; taste; and satiation of cocoa consumption (70% cocoa bar), Parliament Chocolates, Redlands, CA). EEG wave band activity was recorded from 9 cerebral cortical scalp locations F3, Fz, F4, C3, Cz, C4, P3, Pz, and P4 using the EEG B-Alert 10X System™ , Carlsbad, CA. Second by second bandwidth for each subject was recorded and summarized. The PSD band width values (BW) were Z-scored, referenced to the eyes closed baseline task. Results: Z-scores, which represent the distance of raw score from baseline mean in units of standard deviation, were graphed and analyzed for each task and (BW) across 0-40 Hz. The overall respective (BW) were collapsed across all 9 EEG channels. Gamma Band Activity (γBA) (31-40HZ) for PSD was greatest in all 9 brain regions for all 6 sensory tasks ($p<0.01$). The most profound observation was that the composite of sensory tasks (PSD) for (γBA) was greater than any other of the six frequencies ($p<0.01$). Conclusion: This study provides objective evidence that (EEG) (γBA) is initiated by different cocoa sensory awareness tasks ranging from prior conditioned experience to

acute cocoa consumption, with subsequent modulation for brain, behavioral and physiological benefits. We propose this protocol as an assessment tool in determining the efficacy of cocoa dose response modulation of PSD (γBA) 31-40 Hz for optimization of brain health benefits.

Title: A high Calorie diet causes metabolic syndrome and oxidative stress into hippocampus and temporal cortex of rats with impairment memory

Authors: ***A. D. DIAZ**[1], P. AGUILAR-ALONSO[2], J. FLORES-HERNANDEZ[1], V. TOXQUI[1], J. GUEVARA[3], G. FLORES[4], G. LOPEZ-LOPEZ[1], G. MUÑOZ-ARENAS[1], E. BRAMBILA[1], S. TREVIÑO[1];
[1]Facultad De Ciencias Quimicas, BUAP, Puebla, Mexico; [2]Bioquimica, Facultad de Ciencias Químicas, BUAP, Puebla, Mexico; [3]Bioquímica, Facultad de Medicina, UNAM, Mexico DF., Mexico; [4]Lab. de Neuropsiquiatría, Inst. de Fisiologia, BUAP, Puebla, Puebla, Mexico

Abstract: A high calorie intake can induce the appearance of the metabolic syndrome (MS), which is a serious public health problem because it affects glucose levels and triglycerides in the blood. Recently, it has been suggested that MS can cause complications in the brain, since chronic hyperglycemia and insulin resistance are risk factors for triggering neuronal death by inducing a state of oxidative stress and inflammatory response that affect cognitive processes. This process, however, is not clear. In this study, we evaluated the effect of the consumption of a high-calorie diet (HCD) on neurodegeneration and on spatial memory impairment in rats. Our results demonstrate that HCD (90 day consumption) induces an alteration of the main energy metabolism markers, indicating the development of MS in rats. Moreover, an impairment of spatial memory were observed. Subsequently, the brains of these animals showed activation of an inflammatory response (increase in reactive astrocytes and interleukin1-β as well as tumor necrosis factor-α) and oxidative stress (reactive oxygen species and lipid peroxidation), causing a

reduction in the number of neurons in the temporal cortex and hippocampus. Altogether, these results suggest that a high calorie diet promotes the development of MS and contributes to the development of a neurodegenerative process and cognitive failure. In this regard, it is important to understand the relationship between MS and neuronal damage in order to help prevent the onset of neurodegenerative disorders. Furthermore, it will open up the possibility of finding possible treatments to counteract or prevent the occurrence of brain damage caused by metabolic disorders provoked by an excessive calorie intake.

Title: Examining the effects of kale, arugula, and dandelion greens on memory in obese pre-diabetic C57BL/6 mice

Authors: *B. TENG, D. FOSTER, L. BANNER;
California State Univ. Northridge, Northridge, CA

Abstract: The United States is facing a diabetes epidemic. As the 7th leading cause of death and afflicting nearly 10% of the population, diabetes is well studied and its complications are conspicuous, including a battery of neurodegenerative diseases such as Alzheimer's and other cognitive degradation. Diet-induced obesity is an increasingly common occurrence that predisposes individuals to type-2 diabetes and contributes to complications including those of the nervous system and the immune system. Increased body mass is associated with an elevated risk for neurodegeneration and dementia and changes in hippocampal plasticity and spatial learning among others have been documented. While the exact mechanism has yet to be fully understood, neuro-inflammation is thought to be an important factor in impaired cognitive function. Cytokines involved in the inflammatory response are elevated in brains of animals fed a high fat diet (HFD) and a variety of anti-inflammatory/anti-oxidant treatments can reduce this expression and alleviate cognitive changes. What is not well understood is how the progressive nature of

cognitive degradation, as measured by memory loss, manifests itself early in the pre-diabetic stage. Cognitive degradation may be ascribed to neuro-inflammation and differences in diet may either aggrandize or temper its severity. Specifically, we are interested in seeing if adding kale, arugula, or dandelion to an existing obesity inducing diet may taper neuro-inflammation and thus stymie cognitive decline. To address this issue, C57BL/6 mice were fed either a control (10% fat) or high-fat diet (HFD)(60% fat) for 16 weeks until the high-fat group reached a pre-diabetic stage. After 16 weeks, mice on a HFD weighed significantly more than the control mice, displayed elevated blood glucose levels, and showed deficits in spatial learning. During weeks 17 to 25, the diets of all the mice were supplemented daily with 1.0 gram of kale, arugula, or dandelion. Consumption of the greens had no effect on the weights of either groups. During the 8-weeks when the mice are fed their supplemental kale, arugula, or dandelion diets, the mice will be subjected to multiple repetitions of memory tests, such as the Morris Water Maze, Barnes Maze, and Novel Object Recognition, to test for changes in their memory abilities. Furthermore, the brains of the subject animals will also be analyzed for inflammatory and neuronal markers.

Title: Physical fitness in early adulthood: a modifiable risk factor for neurological and psychiatric disorders

Authors: ***G. KUHN**[1,2], J. NYBERG[2], N. D. ABERG[3], M. WAERN[2], A. WALLIN[2], K. TORÉN[3], M. NILSSON[4], M. A. I. ABERG[2,3];
[2]Inst. of Neurosci. and Physiol., [3]Inst. of Med., [1]Univ. of Gothenburg, Gothenburg, Sweden; [4]Hunter Med. Res. Inst., Univ. of Newcastle, Newcastle, Australia

Abstract: Low cardiovascular fitness in mid- and late life represents a risk factor for several neurological diseases. However, the respective effect of aerobic cardiovascular and muscle

fitness in early adulthood is largely unknown. Therefore, we analyzed these in young men with regard to long-term risk depression, bipolar disorders, stroke, and dementia. We performed population-based longitudinal cohort studies of Swedish male conscripts registered in 1968-2005 for mandatory military service (approx. 1,800,000 subjects), representing about 95 % of all Swedish males at age 18 during this time period. Data on cardiovascular fitness (determined by the cycle ergometric test) and muscle strength (isometric contraction) were subdivided into low, medium, high fitness groups. Over a 40-year follow-up, risk of depression, bipolar disorder, stroke and dementia were calculated with Cox proportional hazards models controlling for potential confounders. To identify cases, we used the International Classification of Diseases (ICD) 8-10 in the Hospital Discharge Register. Depression. Adjusted hazard ratios (HRs) with confidence interval (CI) show significant relationships between fitness and severe depression for low compared to high fitness: HR (CI) 1.80 (1.64-1.99) for cardiovascular fitness and 1.43 (1.32-1.55) for muscle strength. Bipolar disorders exhibited a lower, yet significant association with cardiovascular fitness and muscle strength (adjusted hazard ratios (HRs) with confidence interval (CI): 1.35 (1.12-1.63) and 1.22 (1.05-1.42), respectively. Stroke. Adjusted HRs show inverse relationships between fitness and stroke for low compared to high fitness HR (CI) 1.70 (1.50-1.93) for cardiovascular fitness and 1.39 (1.27-1.53) for muscle strength. All three stroke types (subarachnoidal hemorrhage, intracerebral hemorrhage and ischemic stroke displayed similar associations. There were stronger associations for fatal stroke. Dementia. Low compared to high cardiovascular fitness was significantly associated with an increased risk for diagnosis of dementia before age 60: HR (CI) 2.49 (1.87-3.32). Mild cognitive impairment (MCI) showed an even greater association: HR (CI) 3.57 (2.23-5.74). The combination of low cardiovascular fitness and poor cognitive performance in early adulthood was associated with a >8-fold increase in the risk of early-onset MCI and a >7-fold increased risk of early-onset dementia. Overall, this study sheds light on physical fitness as an early-life risk factor for psychiatric and neurological conditions, and underlines the potential for lifestyle modification to reduce the risk of late-life CNS impairments.

Title: The role of epigenetic on mediating the action of diet on brain and body metabolism

Authors: *Z. YING[1], E. TYAGI[1], F. GOMEZ-PINILLA[1,2];
[1]Dept of Integrative Biol. and Physiol., [2]Dept. Neurosurg., UCLA, Los Angeles, CA

Abstract: An increasing body of evidence suggests that a large number of neurological disorders are the result of complex interactions between genetic factors and the environment. In particular, diet is one of the most crucial factors for species survival and adaptation, and seems to have the power to program the epigenome. The strong dependence of the brain on energy implies that metabolic stimuli such as dietary factors have the intrinsic ability to influence brain plasticity (Agrawal, BBA, 2014) and epigenetic variability (Tyagi, Neurob. Dis. 2015). We have examined the effects of a western diet for 7-weeks on central and peripheral markers of metabolism, and the potential role of epigenetic in mediating the effects of the western diet. We investigated the role of DNA methylation on the regulation of molecular systems associated with metabolic control in the brain and peripheral by using the capacity of the DNA methyltransferase inhibitor 5-aza-2'-deoxycytidine to block the effects of the methylation. In the brain, the western diet reduced the mRNA and protein levels of BDNF, and this effect was dependent on the methylation status of the bdnf gene, and could be reversed by the application of 5-aza-2'-deoxycytidine. There also was a reduction in levels of metabolic regulators such as PGC-1a, Sirt1, and NAD/NADH. The exposure to the western diet increased anxiety-like behavior, and these effects were abolished by the DNA methyltransferase inhibitor 5-aza-2'-deoxycytidine. We found that exposure to the western diet increased several metabolic parameters associated with the establishment of the metabolic syndrome such as elevated insulin levels (commensurable to insulin resistance according to the HOMA test), elevated triglyceride levels, cholesterol, LDH, UA, and these effects were abrogated by 5-aza-2'-deoxycytidine. The results indicate that exposure to the western diet concerts a sequel of metabolic disorders in the brain and body, in which methylation plays a role. Our results also indicate that epigenetic regulation via DNA methylation can act in the brain and peripheral organs that regulate glucose metabolism and other features involved with development of metabolic syndrome.

Title: Energetic cost of a running wheel: Implications for exercise-based weight loss interventions

Authors: *T. J. O'NEAL, D. M. FRIEND, A. V. KRAVITZ;
NIDDK/NIH, Bethesda, MD

Abstract: Weight loss interventions often stress the need for increased physical activity to facilitate weight loss, based largely on correlative links between obesity and exercise rates. However, other aspects of energy expenditure can change to compensate for energy expended during exercise, diminishing the efficacy of exercise-based weight loss interventions. Here, we used running wheels to investigate whether increases in physical activity can lead to significant and enduring changes in energy expenditure. In our first experiment, C57BL/6 mice (n = 7) were individually housed and given access to a running wheel for 3 weeks, during which time energy expenditure was measured using an energy balance method (Ravussin et al., 2013). Whereas wheel running significantly increased over the 3 weeks (5000/day in week 1 vs. 20000/day in week 3), both food intake and average daily energy expenditure did not significantly change over time. In our second experiment, C57BL/6 mice (n = 6) were individually housed in indirect calorimeters and given access to a running wheel for 72 hours, during which time energy expenditure was constantly measured. Despite progressive increases in wheel running over 72 hours (2400 in day 1 vs 4100 in day 3), both food intake and energy expenditure again remained unchanged over time. These findings suggest that either (1) the energetic cost of a running wheel is extremely low and negligible in terms of overall energy expenditure or (2) mice can compensate for the slight energetic demand due to wheel running by decreasing other aspects of energy expenditure. If translated to weight loss interventions in humans, these findings allude to the inability of exercise alone to facilitate long-term weight loss. Nevertheless, it is important to consider the robust metabolic, cardiovascular, and neurochemical benefits of exercise which, when paired with dietary changes, can lead to better overall health, rather than simply weight loss.

Title: The Wnt signaling pathways modulates mitochondrial fusion in hippocampal neurons

Authors: *C. SILVA-ALVAREZ[1,2], V. EISNER[1], N. C. INESTROSA[1,2,3];
[1]Pontifical Catholic Univ. of Chile, Santiago, Chile; [2]Cell. and Mol. Biol., Ctr. of Aging and Regeneration (CARE), Santiago, Chile; [3]Ctr. of Excellence in Biomedicine of Magallanes (CEBIMA), Univ. of Magallanes, Punta Arenas, Chile

Abstract: Mitochondria are highly dynamic organelles which can be found as interconnected tubular network or fragmented mitochondria. The control of this dynamic equilibrium is essential for proper neuronal function; its deregulation has become in a hallmark of several pathological conditions such as neurodegenerative diseases. The Wnt signaling pathway is essential for several neuronal functions such as synaptic development and plasticity and its dysfunction is associated to diseases such as Alzheimer´s. The mechanism of regulation of mitochondrial dynamics is not completely understood. We recently demonstrated that the non-canonical Wnt5a ligand has a neuroprotective role against Amyloid-β oligomers exposure, through modulation of mitochondrial dynamics and also was able to modulate the activation state of the principal regulator of mitochondrial fission, the dynamin like protein 1 (Drp1), through activation of Wnt/Ca pathway. However, the effect of Wnt signaling in dynamics processes such as mitochondrial fusion or motility are not clear. To analyze this, in this work neurons were transfected with mitochondrial photoactivable-GFP (mtPA-GFP) and mitoDsRed. The cells were incubated with Wnt5a in the presence and absence of specific Wnt scavengers, and inhibitors of the enzymes activated by the non canonical Wnt pathways. The neurons were studied by photoactivation assays of mtPA-GFP and live-cell imaging, and biochemical assays in order to analyze the mitochondrial fusion and motility proteins Opa1 and Mfns, and Milton, respectively. Our results indicate that Wnt5a is able to modulate mitochondrial fusion frequency rates, and the mitochondrial motility in response to Wnt5a concentration, supporting the idea that this ligand could be an important regulator of mitochondrial function and dynamic under physiological conditions in hippocampal neurons.

Title: Bilingualism prevents cortical surface area reduction during brain aging

Authors: *L. LI[1], J. ABUTALEBI[2], G. GONG[1], L. ZOU[3], X. YAN[1], G. DING[1];
[1]Beijing Normal Univ., Beijing, China; [2]Dept. of Clin. Neurosciences, Univ. Vita Salute San Raffaele, Milan, Italy; [3]Col. of Psychology and Educ., Zaozhuang Univ., Zaozhuang, China

Abstract: Long-term bilingual experience can delay cognitive decline and neurodegeneration with aging. Monolinguals were reported to show decreased gray matter volume (GMV) in several brain regions during aging as compared to age-matched bilinguals, suggesting a neuroprotective effect of bilingualism. However, it is unclear whether this effect reported for unimodal bilinguals also applies to bimodal bilinguals. Furthermore, GMV is a product of surface area and cortical thickness which have distinct neurobiological basis. It is unknown whether the protective effect on GMV for bilinguals can be ascribed to variation in surface area, cortical thickness or both. Here we compared aging effects on GMV, surface area and cortical thickness of proficient bimodal bilinguals to age-matched monolinguals. GMV analysis revealed a significant interaction effect of age × group, in which bilinguals did not show aging effects in the left insula and bilateral anterior temporal lobes while monolinguals did. The analyses on cortical surface-based measures in these regions further revealed surface area showed the same pattern of group difference as GMV did while cortical thickness did not. These novel findings enhance our understanding of the neuroprotective effects of bilingualism on brain aging by showing that the effects are modality-independent and detectable at the surface area level.

Title: A personalized, molecular diagnosis of Lafora disease patient mutations via structural insights

Authors: ***M. S. GENTRY**[1], M. RATHTHAGALA[2], M. K. BREWER[2], C. W. VANDER KOOI[2];
[1]Biochem., [2]Univ. of Kentucky, Lexington, KY

Abstract: Of all the severe and intractable epilepsies, Lafora disease (LD) is among the most severe, and is inevitably fatal. Mutations in two genes have been identified that cause LD, *EPM2A* (laforin) and *EPM2B* (malin). *Identification of the genetic basis for LD has opened up a new era in our understanding of the cause of LD, leading to rapid progress in the field.* Mutations in either of these genes cause glycogen to transform into malformed (starch-like), aggregated inclusions called Lafora bodies (LBs). LBs overtake the cytoplasm of dendrites, and drive the progressive refractory seizure disorder. The human *EPM2A* gene encodes the phosphatase laforin and recessive mutations in *EPM2A* result in Lafora disease (LD). In the absence of laforin activity, glycogen transforms into hyper-phosphorylated, water-insoluble, starch-like Lafora bodies that drive neuronal apoptosis, neurodegeneration, and eventual death of LD patients. We previously defined that the physiological function of laforin is to dephosphorylate glycogen, yet the mechanism of glycogen dephosphorylation by laforin was unknown. Additionally, LD patient missense mutations are dispersed throughout laforin,

bringing to question the structural mechanism(s) of disease. We recently determined the crystal structure of human laforin at 2.4 Å bound to oligosaccharides with a phospho-glucan product at the active site. The structure reveals an integrated tertiary structure of the carbohydrate binding module and dual specificity phosphatase domains as well as an antiparallel dimer mediated by the phosphatase domain that results in a tetramodular architecture, positioning the two active sites ~31 Å from each other. We utilized the crystal structure and three solution-based, biophysical techniques along with biochemical analyses of LD patient mutations and structured guided mutations to probe this unique tertiary and quaternary structure. We define a cooperative mechanism of action for laforin as well as establish the effect of LD disease mutations, thereby providing atomic level insights that connect basic glycogen metabolism to human neurodegenerative disease. Cumulatively, this work allows us to provide a patient specific, molecular diagnosis of each LD laforin mutation. This personalized, molecular diagnosis will prove invaluable as our groups and others move towards a LD therapeutic and/or cure.

Title: Saving Football: using the repulsive force of magnets to reduce impact forces during helmet collisions

Authors: *R. J. COLELLO;
Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: The prevalence of concussions in American football, which is largely the result of helmet-to-helmet collisions, has become a serious health concern for players at all ages. As the average collegiate football player will take over a 1000 hits to the head during one season, and as repeated concussions can lead to severe brain disease, it is imperative to develop better means to

protect the head from impact trauma. Modern football helmets consist of an outer polycarbonate shell that distributes force away from the point of impact and an inner padded liner that can absorb some of that impact energy. Although this general design is acknowledged for reducing mortality on the playing field, the continued prevalence of concussions at all levels of play suggest that further helmet design modifications are required. With this in mind, we have begun to investigate the extent to which repulsive forces, as those generated by the like poles (NN or SS) of neodymium magnets, can be used to reduce impact force generated during helmet-to-helmet collisions. Using a pressure assay we first established that a four ounce N52 magnet can generate 130lbs of repulsive force, which represents a 500:1 repulsive force to weight ratio. We next tested if these magnets can reduce impact energies associated with a wide range of impacts seen on the playing field. Using a weight drop assay, a moving and stationary 10lbs weight were fixed with a pair of four ounce magnets with like poles facing each other and the moving weight was dropped from 6in, 1ft, 2ft, 3ft, 4ft, or 5ft. An accelerometer mounted to the top of the moving weight recorded an 80% reduction in impact forces at the lower drop heights, a 40% reduction at the medium drop heights and a 15-20% reduction at the highest drop heights. Finally, football helmets were custom fitted with N52 arch magnets (magnetized or non-magnetized) that were permanently mounted to the inside polycarbonate shell. These helmets were then tested using a pendulum assay where a helmet is secured to both the stationary and moving component of the pendulum and impacted from varying heights (.6in, 1ft, 2ft, 3ft, 4ft, 5ft). Similar to the weight drop assay, impact forces were reduced by >80% at the lower drop heights, 40% at the medium drop heights and 15-20% at the highest drop heights. Collectively, these studies demonstrate the significant repulsive force of neodymium magnets and suggest that the addition of magnets to the standard football helmet design would complement existing helmet pad lining to dramatically reduce impact forces during helmet-to-helmet collisions. The likely consequence of this novel helmet modification is a reduction in the number of concussions on the playing field.

Title: Appetitive resistance training protocol has an anxiolytic effect on male, Long-Evans rats

Authors: *R. A. COUNTRYMAN, R. C. CROUCH, N. O. V. CUNNINGHAM;
Psychology, Austin Col., Sherman, TX

Abstract: The benefits of aerobic exercise on a variety of issues from metabolism to improvements in learning & memory is well established; however, substantially less research has examined the efficacy of resistance training for modifying behavior and the neuronal changes that result from resistance training. This study created a novel appetitive protocol for resistance exercise modified from previous ladder climbing paradigms (Cassilhas et al., 2012; Hornberger & Farrar, 2004). Male, Long-Evans rats were divided into three treatment groups: Cardiovascular Exercise (voluntary wheel running), Resistance Training (weighted ladder climbs), and Sedentary Controls. After 5 weeks of exercise, rats performed the elevated plus-maze task and novel object discrimination task. Rat were transcardially perfused, and brains were prepared for immunohistochemistry. c-Fos and BDNF were measured in the amygdala and hippocampus while BAX and BCL-2 were only measured in the hippocampus. Additionally, vastus lateralis mass was measured for each rat to verify changes in muscle mass due to exercise. Although we did not see any differences in memory as measured by the object discrimination task, exercise caused an anxiolytic effect as measured by the elevated plus maze. Both the cardiovascular exercise and resistance training rats spent significantly more time in the open arms of the elevated plus-maze and made more overall arms entries in comparisons with sedentary control rats (all ps < .05). In addition, the vastus lateralis of rats in both exercise conditions weighed more than the sedentary control rats. Resistance training rats had increased c-Fos expression in the CA3 region of the hippocampus compared to both cardiovascular exercise and sedentary controls while the cardiovascular exercise rats had significantly fewer Fos-positive cells than those in the resistance training or sedentary control conditions in the basolateral amygdala. BDNF, BAX, and BCL-2 analyses are ongoing. Of particular importance, modifying the resistance training protocol from aversive to appetitive was successful. The current study opens up the opportunity to study resistance exercise training using a protocol that is neither aversive nor forced.

Title: Different types of exercise induce distinct changes in the expression of synaptic proteins in the motor cortex and prefrontal cortex of adult and aged rats

Authors: R. M. S. GUTIERREZ[1], C. R. SCARANSI[2], C. C. REAL[4], S. R. M. ORTIZ[3], L. R. G. BRITTO[4], *R. S. PIRES[5];

Neurobiology, Dept. of Physiol. and Biophysics, Univ. of São Paulo, São Paulo, Brazil; [5]Univ. Cidade De São Paulo, Sao Paulo, Brazil

Abstract: The central nervous system of humans and animals most often respond positively to exercise, inducing an increase in neurogenesis and neuronal activation, an increase of BDNF and dendritic branching. However, little is known of exercise effects on synaptic proteins that mediate transmission synaptic. The objective was to investigate the effect of acrobatic exercise (AC) and treadmill exercise (TE) on the expression of synaptic proteins synapsin I (SYS) and synaptophysin (SYP) in the areas involved in planning and motor learning of adult and aged rats submitted to two months training. Twenty four male Wistar rats, being 12 aged (18 months old) and 12 adults (7 months) were used which were divided into 6 groups: sedentary adult (SED A, n=4), exercise treadmill in adult (TE A, n=4), adult acrobatic exercise (AC A, n=4), sedentary elderly (SED E, n=4), exercise treadmill elderly (TE E, n=4) and acrobatic elderly exercise (AC E, n=4). The rats were trained 3 days/week for 8 weeks. The AC moved through a circuit of obstacles 5 times/day, and TE E speed at 5m/min and the TE A at 8m/min for 40 min.Two months after the training, their brains were removed for Western blotting assay to quantify the SYS and SYP. Statistical analyses were performed using two-way ANOVA with the Tukey post hoc test. Our data revealed that the AC promoted distinct changes in the expression of synaptic proteins in different ages and regions analyzed. In the motor cortex, the AC A induced an increase of SYP (ca. 31%, p=0.005), and SYS relative to the SED A and SED E (ca. 31%, p=0.01). The AC A and AC E promoted an increase in relation to TE E (ca.59%, p=0.0009; ca.51%, p=0.02, respectively). The AC A had a SYS increase in relation to the EE E (ca.57%, p=0.006). In the prefrontal cortex, AC E induced increases in the SYP expression compared to ACA (ac.32%, p=0.01). The SYS in the prefrontal cortex showed no significant difference between groups. We suggest that the AE was able to increase expression of synaptic proteins in the motor cortex of adults and elderly rats, but the prefrontal cortex changes happen only in older animals, suggesting that the learning of a new motor skill can generate neuronal plasticity, but the activated areas can be different in adult and elderly rats.

Title: Reward experience determines the selection of behavioral strategies to maximize foraging efficiency

Authors: ***A. STOLYAROVA**, A. B. THOMPSON, A. IZQUIERDO;
Brain Res. Institute, Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: The adaptive solution to exploration vs. exploitation depends on the current state of the world: stable environments favor exploitation and uncertain environments favor exploration. Any deviations from these behavioral constraints have been interpreted as irrational or maladaptive. However, most investigations are done in primitive environments of the laboratory without much consideration that behavioral adjustments are driven by ancestral evolutionary history in different habitats that are characterized by spatial and temporal heterogeneity and patchy reward sources. In the present investigation, we extend previous computational work (McNamara et al., 2013; Berge-Tal and Avgar, 2012) and develop a model of animal foraging in a naturalistic environment to examine the effects of structured variability on the expression of behavioral strategies. Our model is derived from reports simulating foragers' behavior in a novel landscape of discrete, heterogeneous, and renewable resource patches based on optimal foraging theory, but different in several critical aspects, most importantly the presence of fluctuations in overall environmental quality, closely approximating spatial and seasonal variability in natural environments. We show that variability in the environment encountered early on leads to long-lasting changes in behavioral strategies that determine how an animal samples its environment and produces prolonged misrepresentations of environmental state. Specifically, experience with resource reductions early (when an agent has not yet established a trace of favorable patches to which it can return) favored development of an explorative phenotype, whereas experience with positive resource shifts led to establishment of a narrow preference set, decreasing exploration even when an explorative strategy was dictated by environmental conditions. The present simulation demonstrates that acting according to optimal foraging theory is favorable in

spatially, but even more so temporally, heterogeneous environments as it maximized reward procurement. This solution to temporally structured environmental fluctuations generates a unique behavioral phenotype which is frequently observed in laboratory studies, namely a tendency to persevere rather than adopt an explorative strategy when conditions return to baseline following a rewarding experience. Despite the common interpretation of such responses as maladaptive, we demonstrate that they are on the contrary emergent properties of an evolved endophenotype that likely developed under constraints imposed by a neural mechanism that subserves adaptive foraging behavior.

Title: Maternal obesity alters fetal brain development

Authors: *N. MERABOVA[1], N. DARBINIAN[1], G. TATEVOSIAN[1], R. A. SIMMONS[3], L. GOETZL[2];
[1]Shriners Hosp. Pediatric Res. Ctr., [2]Obstetrics and Gynecology, Temple Univ. Sch. of Med., Philadelphia, PA; [3]Pediatrics; Div. of Neonatology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Maternal obesity is a growing global public health concern. Epidemiologic studies suggest that high maternal BMI is associated with an increased risk of neurodevelopmental and metabolic morbidities in children. Molecular mechanisms underlying this possible link are poorly understood. We hypothesized that fetal exposure to maternal obesity alters gene expression of key neurodevelopmental and metabolic proteins. Study Design: An IRB-approved, matched case-control study was performed in women with singleton fetuses without structural anomalies undergoing elective pregnancy termination in the second trimester (GA 17 - 21 wks). Twelve cases (OBESE) were compared to 12 controls (LEAN). Cases had a BMI >30 (mean 36.7; range 30.2-43.9); controls had a BMI <25 (mean 21.7; range 17.7-24.8). Subjects were matched for gestational age, race and fetal gender. We analyzed CNS-specific genes such as Apolipoprotein D (APOD) and Presynaptic cytomatrix protein (PCLO), as well as Adiponectin (ADIPOQ), a gene regulating metabolism. Total RNAs and samples for FACS were prepared

from snap-frozen fetal brain tissue. Quantitative RT-PCRs were performed, utilizing specific primers and fold change was calculated relative to controls. For FACS analysis samples were incubated with neuronal and astrocyte specific markers (NeuN and GFAP respectively) with subsequent assessment of apoptosis by Guava Nexin assay. Results: Gene expression in the fetal brain was differentially regulated following exposure to maternal obesity. PCLO was significantly down-regulated 3.6 folds (p= 0.0005), and ADIPOQ was significantly upregulated 6.7 folds (p=0.03). FACS analysis suggested a significantly decreased level of apoptosis in the astrocytes of fetuses exposed to maternal obesity *in utero* (8.9% vs 36.8%, p= 0.0004). Assessment of proteins is ongoing. Conclusion: We present novel human data identifying potential molecular mechanisms by which maternal obesity predisposes offspring to neurodevelopmental abnormalities and metabolic complications. Dysregulation of cell death in fetal brain may adversely influence fetal neurodevelopment. Our data suggest that molecular changes may be detected as early as the second trimester (17-21 weeks GA).

Title: Exploring the biological and behavioral effects of methylene blue on a triple transgenic mouse model of Alzheimer’s disease

Authors: *D. A. MITRANO[1], K. JACKSON[1], S. FINK[1], Q. PACE[1], B. GENOVESE[1], N. KHAN[2], H. GRAU[1], L. SMITH WEBB[1];
[1]Mol. Biol. & Chem., [2]Neurosci., Christopher Newport Univ., Newport News, VA

Abstract: Alzheimer’s disease (AD) is a debilitating neurodegenerative disease that is characterized by dementia that increases in severity over time. There are neurological and biological changes that have been shown to accompany, or in some cases precede, the cognitive decline. These changes include the development of amyloid-B plaques and neurofibrillary tangles that lead to cognitive decline, changes in certain markers in the blood, and deficits in olfaction. Currently there are very few diagnostic tools and effective treatments for AD, and no known means of preventing it. Methylene blue (MB) is an FDA approved compound that has been shown to reduce the formation of protein aggregates in AD and other diseases. MB is

currently in clinical trials to determine if it can slow the progression of AD; however, no longitudinal studies have been done using the 3xTg-AD mouse model to determine if MB can effectively prevent, or delay the onset of, the disease in this model. In this study, we use the 3xTg-AD mouse to further determine the validity of the model by examining the effect of MB on the onset and progression of AD; specifically, can MB prevent or delay the accumulation of the amyloid plaques, neurofibrillary tangles, and cognitive and olfactory deficits seen in AD. MB (10mg/kg) or 0.9% saline has been administered intraperitoneally, weekly, to both male and female mice starting at 4 weeks of age. Behavioral and biological tests will be performed on the mice at several time points, starting at 3 months, and continuing to 4.5, 6, 7.5, 9, 12, 15 and 18 months of age. Once mice have reached their set time points we will examine: (1) brain pathology, for the accumulation of plaques and tangles using immunohistochemistry; (2) lipid markers in the blood that have been shown to be associated with, or predictive of AD, through the use of GC-MS; (3) behavioral tests to assess cognitive ability, using the Morris Water Maze; and (4) olfactory deficits through the use of a peanut butter test. This will allow us to determine the extent and progression of AD over the normal life span of these mice and provide further insight into the efficacy of MB as a possible treatment or neuroprotective drug for AD.

Title: Soy flavonoids prevent beta-amyloid-induced degenerative changes of the enteric nervous system of the mouse: relevance to the treatment of Alzheimer’s disease

Authors: ***Y. LIU**[1], G. LIN[2], M. FANG[3], J. A. RUDD[2,4];
[2]Sch. of Biomed. Sci., [1]Chinese Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Inst. of Neurosciences, Zhejiang Univ. Sch. of Med., Hangzhou, China; [4]Brain and Mind Inst., Hong Kong, Hong Kong

Abstract: Late-onset Alzheimer’s disease (AD) accounts for more than 80% of AD cases. It is not known why amyloidogenisis occurs during the aging process in these patients. It is possible that aggregation of soluble beta-amyloid (Aβ) peptide first occurs in the periphery to initiate a cascade of events, which ultimately affects cognition. In this regard, the gastrointestinal (GI)

tract interfaces with the environment and is exposed to chemical and biological stress. In previous studies, we found Aβ and plaques in the GI tract of a transgenic mouse model of AD. We also found that Aβ injected directly into the serosal side of the GI tract of normal ICR mice caused a significant reduction of enteric neurons. Hormonal replacement therapy (HRT) may have beneficial actions to reduce the incidence of AD. Therefore, we investigated the expression of estrogen receptor alpha and beta (ERα/ERβ), and the novel G-protein coupled estrogen receptor, GPR30, in the GI tract of the mouse. We found a high expression of ERβ in the cytoplasm within neuronal cell bodies. GPR30 was also found in neurites, while ERα was expressed in both the nucleus and cytoplasm. Estrogen receptors were only found on enteric neurons, but not enteric glial cells. We also found that Aβ could induce loss of $PGP9.5^{+}$ neurons from a longitudinal muscle and myenteric plexus tissue culture. The soy flavonoids, daidzein, genistein, glycitein, and luteolin, which are known to activate estrogen receptors, antagonized the Aβ-induced toxicity; these protective effects extended to both cholinergic $ChAT^{+}$ and nitrergic $nNOS^{+}$ neurons. Our studies provide evidence that soy flavonoids have neuroprotective effects on the ENS. Further studies are being conducted to identify the estrogen receptor subtypes involved, and if the protective effect on the GI tract can translate to a protective effect on the brain.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder, characterized by formation of neurofibrilary tangles in neurons and amyloid beta plaques formation. Overabundance of amyloid beta 42, promotes neuroinflammation, triggering cascade of detrimental effects, which further aggravate the consequences of the disease. Docohexaenoic acid (DHA) plays an important role in the central nervous system, promoting proper synapse function and neuroprotection. Recent findings revealed that its deficiency is related to cognitive decline in aging and neurodegenerative diseases. Furthermore, it has been shown that treatment with DHA contributes to significant improvement in cognitive abilities and protects from synaptic loss in transgenic mouse AD models. Present study was done on 3-month-old female 5xFAD mice, treated for 3 weeks with fish oil as an abundant natural source of DHA. Immunohistochemical analysis of brain tissue showed decrease in amyloid beta plaque load, accompanied with changes in lipid status in the brain and serum of treated animals. However, recently revealed major blood to brain DHA transporter, mfsd2a, showed no changes, on both RNA and protein levels in the brain cortex, while it significantly decreased in the liver after the treatment. This study reveals a new beneficial aspect of short-term fish oil dietary supplementation on mitigation of Alzheimer's disease pathology.

Title: A western diet exacerbates plaque load and plaque-associated TREM2+ cells in a mouse model of Alzheimer's disease

Authors: *L. C. GRAHAM, J. M. HARDER, I. SOTO, W. N. DE VRIES, S. W. M. JOHN, G. R. HOWELL;
The Jackson Lab., Bar Harbor, ME

Abstract: Alzheimer's disease (AD) is caused by a combination of genetic and environmental risk factors such as diet. In particular, components of food commonly consumed in the westernized world, including high levels of fat and simple carbohydrates that are sourced from animal-based rather than plant-based products, are considered to contribute to an increased risk for AD. However, the mechanisms by which these dietary components influence AD

susceptibility and progression are not clear. A western diet was developed that mimicked the average fat, carbohydrate, protein, vitamin and mineral levels of diets in western societies. The western diet, along with a standard mouse chow was fed to APP/PS1 mice, a widely used mouse model of AD, and C57BL/6J control mice, for eight months. After long-term consumption of the western diet, mice were assessed for metabolic and AD-relevant phenotypes. The western diet caused both AD and control mice to become obese but not diabetic. Astrocytosis and microglia/monocyte activation were dramatically increased in multiple brain regions in both control and AD mice fed the western diet, compared to mice fed the standard chow. Consumption of the western diet also resulted in a small but significant loss of cortical neurons in both AD and control mice. Amyloid plaques significantly increased in the hippocampus, but not the cortex, of AD mice fed the western diet suggesting region-specific outcomes in response to the western diet. AD mice fed the western diet also showed a significant increase in the number of TREM2+ microglia/monocytes surrounding plaques compared to AD mice fed the control diet. These data suggest that a western diet induces neuroinflammation, possibly mediated by TREM2+ microglia/monocytes, that increases severity of AD. These findings further support modulating diet or specific neuroinflammatory processes to reduce risk for AD.

Title: Near infrared light treatment reduces amyloid beta oligomer binding to synapses in a transgenic mouse model of Alzheimer’s disease

Authors: *M. M. COMEROTA[1], G. TAGLIALATELA[2];
[2]Dept. of Neurol., [1]Univ. of Texas Med. Br., Galveston, TX

Abstract: The neuropathological characterization of Alzheimer’s disease, the most common neurodegenerative dementia, includes deposits of aggregated amyloid beta (Aβ) and hyper-

phosphorylated tau protein neurofibrillary tangles. The cognitive decline that is associated with AD is believed to be driven by the dysfunction of synapses due to the binding of small toxic Aβ oligomers on the post-synaptic density (PSD). Despite the growing prevalence of AD, current treatment options do not address the underlying causes of the disease, providing limited alleviation of symptoms. Near infrared (NIR, 600-1000 nm) light therapy has previously been used in pain management and to accelerate wound healing. NIR light is believed to target mitochondria through photostimulation of cytochrome c oxidase that results in an increase in ATP. Recent studies have suggested that the application of NIR light treatment can be expanded to include neurodegenerative disorders such as AD and Parkinson's disease (PD). Notably, it has been reported that NIR light treatment on APP/PS-1 transgenic mice induced a reduction of amyloid β plaque load and improved memory function; however, the mechanism contributing to this effect remains unresolved. In the present study, we focused on mechanistic changes that occur at the synaptosome after NIR light treatment that may lead to the restoration of cognitive integrity. Specifically, we investigated the susceptibility of amyloid β binding to the synaptosome (an important event linked to amyloid beta-driven synaptic disruption and memory deficits) and found that after a treatment with NIR at 670 nm (90 sec a day for 4 weeks), the amount of amyloid β was significantly reduced at synapses from various brain areas of 6 month old APP transgenic mice (Tg2576). This study provides evidence that NIR can effectively reduce the amount of damaging amyloid beta at synapses, thus furthering light therapy as a viable treatment for AD.

Title: Neuro-EPO, an intranasally deliverable low sialic acid formulation of erythropoietin, is neuroprotective in the APPSwe mouse model of Alzheimer's disease

Authors: ***T. MAURICE**[1], Y. RODRIGUEZ CRUZ[2], M. STREHAIANO[1], J. C. GARCIA RODRIGUEZ[3];
[1]INSERM U 1198, Montpellier, France; [2]Histology Dept., Preclinical and Basic Sci. Institute; Havana Med. Univ., Havana, Cuba; [3]Havan Med. School, Fac. Victoria de Giron, Havana, Cuba

Abstract: Besides its role in erythropoiesis, the cytokine erythopoietin (EPO) is a potent cell protectant and it showed a strong potential in protecting brain cells from ischemic injury or from toxicity observed in neurodegenerative pathologies, including Alzheimer's disease (AD). Different types of EPO without erythropoiesis-stimulating activity have been developed, including carbamylated-EPO, erythro-EPO and Neuro-EPO with low sialic acid content (Garcia Rodriguez & Sosa Teste, WorldScientificJournal 2009). This latter form allows efficient intranasal (IN) delivery, thus avoiding systemic administration related potential side effects, and showed effective neuroprotective activity in the nontransgenic AD model induced in mice by intracerebroventricular injection of Aß25-35 oligomers (Maurice et al., J Psychopharmacol 2013). In the present study, we analyzed the neuroprotective effect of Neuro-EPO in APPSwe mice. Twelve-month old animals were treated IN, 3 times a week during two months with Neuro-EPO (0, 125, 250 µg/kg). Animal weight, attrition, motor impairments and general activity of the animals (open-field) were checked after treatment. Animals were submitted to memory procedures (spontaneous alternation, place learning in the water-maze and novel object recognition) and we observed that Neuro-EPO, at the lowest or both doses, alleviated the learning impairments measured in APPSwe animals. After the behavioral observations, animals were sacrificed and biochemical and histological analyses were performed. Oxidative stress (increase in lipid peroxidation), neuroinflammation (increases in GFAP and Iba-1 expression), induction of apoptosis markers (increases in Bax expression, Bax/Bcl2 ratio, TNFalpha expression...) measured in hippocampus extracts of APPSwe mice were significantly restored by Neuro-EPO. The cytokine had however marginal effects on decreased BDNF levels and synaptophysin expression in APPSwe. Finally, brain insoluble Aß1-42 content was significantly decreased with Neuro-EPO (125 µg/kg). These data are the first evidence for a neuroprotective efficacy of Neuro-EPO in a transgenic mouse model of AD and confirmed the benefits of the IN route in this disease.

Title: Inhibition of Amyloid beta accumulation by SAK3 as an Alzheimer's disease drug candidate

Authors: *H. IZUMI, Y. SHINODA, Y. YABUKI, K. FUKUNAGA;
pharmacology, Tohoku Univ. Grad Sch. Pharm Sci., Sendai, Japan

Abstract: As Alzheimer disease therapeutics candidate, we introduced SAK3 (Ethyl 2',3'-dyhydro-8-methyl-2',4-dioxo-2-peperidinospiro[2-cyclopentene-1,3'-imidazo[1,2-a]-pyridine]-3-carboxylates) which stimulates T-type voltage-gated Ca2+ channels (T-VGCC) in mouse cortical slices and neuro2A cells over-expressed T-type calcium channel, Cav3.1 (Moriguchi et al., J Neurochem 2012;121:44-53) (PCT/JP2013/051388). We also reported that SAK3 stimulates acetylcholine release and promotes long-term potentiation in mouse hippocampus (Neuroscience 2014 abstract 265.21). We here tested whether SAK3 reduced amyliod beta (1-42) accumulation in Alzheimer model mice. Female mice aged 6-8 months were treated for two month with SAK3 (0.5mg/kg, p.o.) and measured amyliod beta (1-42) levels in both soluble and insoluble fraction from the cortex. The chronic administration significantly reduced amyliod beta (1-42) levels in both soluble and insoluble fractions from the cortex. Consistent with reduced amyliod beta (1-42) levels, the numbers of amyloid plaques assessed by thioflavin staining were significantly reduced by the chronic SAK3 treatment. Furthermore, the cognition assessed by novel object recognition task was improved by the chronic administration. Taken together, novel T-type calcium channel stimulator SAK3 possibly elicits the improvement of cognitive impairment in Alzheimer disease model mice and reduction of amyliod beta (1-42) accumulation/aggregation. However, further extensive studies are required to elucidate the mechanism underlying inhibition of amyliod beta (1-42) accumulation/aggregation. This work is supported by Translational Research Network Program (JST).

Title: Neuroprotection of medial septal cholinergic neurons by memantine after intralateral septal injection of aβ1-40

Authors: *M. T. CASTANEDA[1,2], E. LOPEZ[2], H. RODRIGUEZ[2], A. TOUHAMI[3], J. RODRIGUEZ[2], M. ORTEGA[2], R. TOVAR[2];

Abstract: Alzheimer's Disease (AD) is a progressive disorder of the brain that leads to memory loss, dementia and death. Several lines of evidence suggest that the accumulation of amyloid beta peptides (Aβ) may trigger the dysfunction and degeneration observed in the AD brain. The basal forebrain, including the septal region which regulates the excitability of the hippocampus and neocortex, is early affected in AD because its neurons are vulnerable to the Aβ peptides. In addition, the connections between lateral and medial septal region (medial septum and diagonal band of Broca, MS/DB) have been demonstrated in previous studies. In order to demonstrate the presence of excitotoxicity in Aβ-induced septal damage, we compared rats injected with Aβ1-40 into the lateral septal region structure with rats treated with memantine (a non-competitive NMDA receptor antagonist), prior, during, and after Aβ1-40 injections. Medial septal cholinergic neurons were immunochemically identified and their numbers were estimated using Image J cell count. Our results show that Aβ1-40 treated animals have significantly a low number of MS/DB cholinergic neurons compared to Aβ/memantine treated group.

Abstract: Emerging evidence suggests that β-amyloid (Abeta) has a detrimental effect on short-term and long-term memory that is the initial and major symptom of Alzheimer's disease (AD) via inhibition of both cAMP/cGMP-dependent neuroprotective pathway. Microinfusion of Abeta in animal models results in Abeta deposition, neuroinflammation, apoptosis and cognitive impairment. However, whether the neuroinflammation and apoptosis are required for the Abeta-induced learning deficits and whether phosphodiesterase 2 related cAMP and/or cGMP pathway is involved in the progression of AD is unclear. In the studies reported here we investigated that intraventricular infusion of Abeta1-42 into bilateral CA1 subregions led to deficits in learning and memory, as evidenced by an increased latency to find the platform and decreased number of platform crossing in the probe trial of the water maze task and decreased 24-h retention in the step-down passive avoidance test. These effects were blocked by treatment with increasing doses of phosphodiesterase 2 (PDE2) inhibitor Bay 60-7550 (0.5, 1 and 3 mg/kg every day for 21 days, i.p.). Abeta-treated mice were also found to increase in the expression of IL-6, IL-10 and Bax; while decrease in the expression of BCl-2, PKA, PKG and brain-derived neurotrophic factor (BDNF) in the hippocampus. These effects were also reversed by treatment with Bay 60-7550 in a dose-dependent manner. The findings suggest that inhibition of PDE2, such as Bay 60-7550, would reverse Abeta-induced learning and memory impairment at least in part by its regulation of neuroinflammatory and apoptotic processes, which are involved in cAMP/cGMP-BDNF signaling.

Title: Sodium butyrate ameliorates memory deficit,increases neurogenesis and reduces inflammation in presenilins-deficient mice

Authors: *C. LI[1], X. ZHOU[2], T. CAO[2], Y. CUI[2], H. WANG[2];
[1]Sch. of Psychology and Cognitive Science, East China Normal Univ., Inst. of Cognitive Neurosci., Shanghai, China; [2]Sch. of Psychology and Cognitive Neurosicence, East China Normal Univ., Shanghai, China

Abstract: Histone acetylation has been shown to play a crucial role in memory formation and histone deacetylase inhibitor sodium butyrate (NaB) can improve memory performance as well as rescue the neurodegeneration of several Alzheimer's disease (AD) mouse models. Presenilin-1 and presenilin-2 double knockout (cDKO) mice showed memory decline, forebrain degeneration, tau hyperphosphorylation and inflammation that closely mimics phenotypes in AD patients. Here we have investigated the effects of systemic administration of NaB on different phenotypes in cDKO mice. We found that chronic NaB treatment (3weeks) significantly restored the deficit of hippocampus- dependent contextual memory, but didn't alter amygdala- dependent memory in cDKO mice. Biochemical analysis showed that tau hyperphosphorylation and inflammation related protein GFAP level were decreased in the forebrain of cDKO mice after NaB treatment. In addition, NaB treatment increased neurogenesis in SGZ of cDKO mice. Although we found synaptic numbers were dramatically decreased in cDKO mice,NaB treatment didn't increase synaptic numbers, nor did it attenuate forebrain neurodegeneration. Furthermore, mRNA-Seq analysis demonstrated that not only did NaB decrease the expression of inflammation related genes, but also increased the expression of genes involved in homeostasis and neural activity in the forebrain of cDKO mice. These results may shed some lights on the possible molecular mechanisms of HDAC inhibitor in alleviating the neurodegenerative phenotypes of cDKO mice.

Title: Treatment with the diabetic medication, glibenclamide, improves disease pathology in the APPswe/PSEN1dE9 mouse model of Alzheimer's disease

Authors: E. E. CAESAR[1], *S. L. MACAULEY[2], M. STANLEY[1], T. E. MAHAN[1], D. M. HOLTZMAN[1];
[2]Neurol., [1]Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Epidemiological studies demonstrate that type-2-diabetes mellitus (T2DM) patients have a 2-4 fold increased risk for developing Alzheimer's disease (AD). Although studies suggest that pathological changes associated with T2DM exacerbate AD pathology, it is unclear how diabetic therapies affect AD pathogenesis. A recent study from our laboratory indicated that systemic hyperglycemia increased amyloid-beta (Aβ) levels within the hippocampal interstitial fluid (ISF) in conjunction with increased neuronal activity. We identified inward rectifying, ATP-sensitive potassium (KATP) channels within the brain as a mechanistic link between elevated glucose levels, neuronal excitability, and Aβ metabolism. By altering the open probability of brain KATP channels, changes in cellular metabolism result in altered neuronal activity and Aβ production. Therefore, KATP channels are one mechanism by which neurons respond to hyperglycemia and couple cellular metabolism with neuronal firing. Therefore, investigating the role of KATP channels in both the pathogenesis and treatment of AD warrants further study. Recent studies suggest T2DM medications differentially alter risk for developing AD. Monotherapy with sulfonylureas, a class of drugs that modulate KATP channels, may reduce AD risk; while insulin therapy increased risk. These data suggest that T2DM medications might be a novel therapeutic approach for the treatment of some aspects of AD. To investigate the effects of the KATP channel antagonist, glibenclamide (i.e. glyburide), on AD pathology, 4-month-old female APP/PS1 mice were treated systemically with glibenclamide or placebo for 3 months via the implantation of a slow release, subcutaneous pellet. Initially, glibenclamide-treated APP/PS1 mice experienced decreased blood glucose levels that rebounded within 2 weeks of implantation. At 7 months, glibenclamide-treated mice weighed more than placebo and had an observable increase in visceral fat. However, both blood glucose levels and serum insulin levels were comparable in treated and untreated mice at 7 months. There was a significant reduction in Aβ deposition in the brains of glibenclamide-treated mice. Interestingly, there was no difference between the levels of microglial or astrocyte activation, suggesting neuroinflammation was unaffected in treated mice. These data suggest that KATP channel antagonists can reduce Aβ deposition in APP/PS1 mice and the pathway it is affecting may be a potential therapeutic area for further investigation. Autònoma de Barcelona (UAB),, Barcelona, Spain

Abstract: The C-terminal domain of tetanus toxin (Hc-TeTx) is new nontoxic peptide of the tetanus toxin that has a protective action against glutamate excitotoxicity. Moreover its efficacy as a neuroprotective agent has demonstrated in several animal models of neurodegeneration. The Aβ(25-35) fraction mimics the toxic effects of the full complete peptide Aβ. This fraction modify the cholinergic system in medial septum (MS) leading alterations of septo-hippocampal pathway, and results in cognitive impairments. The aim of this study was examined the neuroprotective effects of Hc-TeTx fragment against neurotoxicity of Aβ(25-35) fraction into MS in rats. Rats received an injection of Hc-TeTx fragment 2μL at 2μM, and later with Aβ(25-35) (2μg/2 μL) into MS. Animals were tested for spatial learning and memory in the eight-arm radial maze. The

brains were obtained to assess cholinergic markers such as choline acetyltransferase (ChAT) and acetylcholinesterase (AChE), even to explore the neurodegeneration in MS and hippocampus, by the amino-cupric silver and H&E staining. We found that Hc-TeTx protects against cholinergic markers (ChAT and AChE) loss, and neurodegeneration by Aβ(25-35) in MS, CA1 and CA3 subfields of hippocampus. All these improvements could be reflected on spatial learning and memory performances. In summary, our findings suggest that Hc-TeTx fragment protects the septo-hippocampal pathway, since Hc-TeTx reduces the neurodegeneration by Aβ(25-35) and improves learning and memory process.

Title: Amyloid beta toxicity induces autophagic flux via sequestosome-1 mediated alpha-7 nicotinic acetylcholine receptor activation; Role of resveratrol as homeostatic regulator

Authors: *C. KARTHICK[1], S. PERIYASAMY[3], K. JAYACHANDRAN[4], M. ANUSUYADEVI[2];
[2]Biochem., [1]Bharathidasan Univ., Tiruchirappalli, India; [3]Biochem., [4]Bioinformatics, Bharathidasan Univ., Tiruchirappalli, India

Abstract: Objective: Abnormal accumulation of aggregated protein amyloid beta (Aβ) in selectively vulnerable region is a key event in Alzheimer's disease (AD) pathology, while resveratrol (RSV) is very promising against Aβ induced neurodegenerative disorders. However, the more precise mechanism of how RSV renders neuroprotection remains elusive. More highlights demonstrate autophagy defect and deterioration of the hippocampal cholinergic system as a leading neurochemical feature of Alzheimer's disease. Loss of homeostatic regulators is suspected to alter autophagic response by disturbing the expression of autophagosome enhancing factors. Our previous studies showed that RSV could effectively

normalize the expression of nicotinic acetylcholine receptor alpha-7 (α7nAchR) in Ibotenic acid induced AD models. The current study thus aim at understanding whether the neuroprotective effect of reseravatrol in α7nAchR activation is facilitated via autophagy regulatory factors in Aβ (1-42) induced AD male Rattus novergicus. Methodology: Current study utilizes Aβ (1-42) induced experimental animals with or without trans-resveratrol, studying the spatial learning memory and expression profile of various factors like Atg5, Atg6, Atg7, Atg12, USP10/13 and SQSTM1 regulating autophagic response using RT-qPCR analysis. Results: A stereotactic intrahippocampal infusion of 500nmol/µl of aggregated Aβ (1-42) revealed working memory and reference memory errors during 8-arm Radial Arm Maze (RAM) and spontaneous alterations percentage within Y-maze task. RSV (20mg/kg bodyweight for 21 days) administration significantly ($p<0.05$) improved RAM task performance and spatial working memory in Aβ (1-42) induced experimental animals. mRNA expression profile for Atg5, Atg6, Atg7, Atg12, USP10/13 and SQSTM1 in control and experimental animals demonstrated that RSV mediated autophagic activation is regulated by upregulating α7nAchR protein expression via SQSTM1 in Aβ induced Alzheimer's disease. Conclusion: Resveratrol could protect neurons by enhancing autophagic response via SQSTM1 upregulation thereby maintaining homeostasis invivo favoring clearance of beta-amyloid and reducing the stress in neurons.

Abstract: Aging is the major risk factor associated with Alzheimer's disease (AD); however, the molecular mechanisms linking aging to AD remain unclear. Suppression of the ribosomal protein S6 kinase 1 (S6K1) increases healthspan and lifespan in several organisms, from nematodes to mammals. Here we show that S6K1 expression is upregulated in the brains of AD patients. Using a mouse model of AD, we found that genetic reduction of S6K1 improved synaptic plasticity and spatial memory deficits, and reduced the accumulation of amyloid-β and tau, the two neuropathological hallmarks of AD. Mechanistically, these changes were linked to reduced translation of tau and the *beta-site APP cleaving enzyme 1, a key enzyme in the generation of amyloid-β. Our results* implicate S6K1 dysregulation as a previously unidentified molecular mechanism underlying synaptic and memory deficits in AD. These findings further suggest that therapeutic manipulation of S6K1 could be a valid approach to mitigate AD pathology.

Title: PRAS40 as a novel therapeutic target for Alzheimer's disease

Authors: *R. VELAZQUEZ[1], D. M. SHAW[1], J. S. TALBOOM[1], S. ODDO[1,2];

Abstract: Clinically, Alzheimer's disease (AD) is characterized by impairments of memory and cognitive functions. Amyloid-β (Aβ), neurofibrillary tangles and synaptic loss are the prominent neuropatholgies in patients with AD. Strong evidence indicates that an imbalance between production and degradation of key proteins contributes to the pathogenesis of AD. The mammalian target of rapamycin (mTOR) plays a key role in maintaining protein homeostasis as it regulates both protein synthesis and degradation. In human AD brains, mTOR signaling is

hyperactive and negatively correlates with cognitive function. A key regulator of mTOR activity is the proline-rich AKT substrate 40 kDa (PRAS40), which directly binds to mTOR and reduces its activity. Phosphorylation of PRAS40 reduces its ability to bind to mTOR thereby removing the inhibitory constrain on mTOR activity. Our preliminary data of human AD brains show a significant increase in the phosphorylated levels of PRAS40 confirming hyperactive mTOR activity. Physiologically, PRAS40 phosphorylation is regulated by Pim-1, a protein kinases of the protoconcogene family. We have identified a Pim-1 inhibitor (Pim-1i) that crosses the blood brain barrier, reduces PRAS40 phosphorylation, and thereby reduces mTOR signaling. The main objective of the present experiment was to test the effects of the selective Pim-1i on learning and memory in 3xTg-AD mice, a widely used mouse model of AD. We found that daily intraperitoneal injections of the Pim-1i for 4 weeks dramatically improved spatial and working memory deficits in 3xTg-AD mice. Specifically, Pim-1i-treated 3xTg-AD mice performed significantly better than their vehicle treated counterparts, and as well as non-transgenic mice. These findings suggest that reductions of mTOR by decreasing phosphorylated PRAS40 is sufficient to ameliorate the cognitive deficits in ~8 month old 3xTg-AD mice. These results set the stage for the development of clinical trials aimed at using Pim-1 inhibitors for AD. Given that Pim-1 inhibitors are already being tested in ongoing human clinical trials for cancer, these findings may open a new venue of drug discovery for AD by developing more Pim-1 inhibitors. Furthermore, given the role of mTOR/PRAS40 in aging, our results may unveil new mechanisms by which age-associated risk factors contribute to the development of AD.

Title: Effects of NPT088, a novel fusion protein bivalent for a General Amyloid Interaction Motif (GAIM), on behavior, neuropathology and CSF biomarkers in transgenic mice

Authors: *J. C. CARROLL[1], J. M. LEVENSON[1], S. SCHROETER[1], E. ASP[1], M. PROSCHITSKY[1], V. CULLEN[1], C. CHUNG[1], H. TSUBERY[1], R. KRISHNAN[1], B. SOLOMON[2], R. FISHER[1], K. GANNON[1];
[1]NeuroPhage Pharmaceuticals, Cambridge, MA; [2]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Alzheimer's disease (AD) is characterized by both amyloid-β (Aβ) plaque deposition and intracellular neurofibrillary tau tangles accompanied by progressive cognitive decline. We isolated a protein motif from bacteriophage M13 that binds and disaggregates multiple amyloids including those formed by Aβ, tau, prion protein, huntingtin and α-synuclein (Krishnan et al., 2014). We call this motif the General Amyloid Interaction Motif (GAIM). The present studies were conducted to evaluate whether systemic administration of NPT088, a Hu-IgG_1-Fc fusion protein bivalent for GAIM, could alter disease-relevant CSF biomarkers, neuropathology and functional endpoints in transgenic AD mouse models. NPT088 (2 or 20 mg/kg) or PBS was administered weekly via intraperitoneal injection for ~14 weeks. Transgenic mice burdened with either Aβ (Tg2576; ~22 mo at last dose) or tau (rTg4510; ~9 mo at last dose) were used. Behavior (locomotor activity and object recognition) was assessed at various times throughout experiments. In Tg2576 mice, Aβ in CSF was measured by MSD ELISA for $Aβ_{38}$, $Aβ_{40}$, $Aβ_{42}$. Brain levels of $Aβ_{42}$ were measured by Innotest ELISA in RIPA soluble and formic acid soluble fractions of frontal cortex and hippocampus. In rTg4510 mice, CSF tau was measured with MSD ELISA. Levels of pTau in brain were measured by ELISA and western blot. Administration of NPT088 to Tg2576 mice reduced levels of Aβ in both CSF and brain. The reduction in levels of Aβ was associated with significant reductions in hyperactivity, and modest improvements in novel object recognition. In rTg4510 mice, 14 weeks of NPT088 treatment resulted in less brain weight loss relative to rTg4510 mice dosed with PBS. In addition, reduced levels of tau in CSF and brain, and a significant reduction of hyperactivity and a significant improvement in novel object recognition were present. Collectively, these results indicate that NPT088 reduces Aβ and tau neuropathology, improves functional endpoints and affects disease-relevant biomarkers in both Aβ and Tau transgenic mouse models. These data support clinical studies with NPT088 as a unique therapeutic approach to AD that targets multiple misfolded proteins. An IND is planned for 4Q2015 with initiation of clinical trials in 1Q2016.

Title: Docosahexaenoic acid intake improve visual memory and decreases the lipolysis-lipoprotein stimulated receptor (LSR) in mice knock-in for human APOE

Authors: *A. G. PINÇON[1], J.-D. COULOMBE[2], R. CHOUINARD-WATKINS[2], M. PLOURDE[2];
[1]Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: Dyslipidemias are significant risk factors for Alzheimer's disease (AD) and remain an important health concern. Individuals with elevated levels of plasma cholesterol in mid-life have an increased susceptibility to AD. ApoE is one of the major apolipoproteins in the plasma and the principal cholesterol carrier protein in the brain. The 4 allele of APOE is the most important genetic risk factor for AD. A number of epidemiological and *in vivo* studies suggest that a higher intake of fatty fish containing docosahexaenoic acid (DHA) is associated with a reduced risk of AD and might improve cognitive functions. Whether DHA intake has a role in maintaining cholesterol homeostasis is yet unknown. Hence, we explored the potential mechanisms focusing on DHA intake on the regulation of cholesterol homeostasis in model of mice expressing human APOE isoforms. Four months old APOE3 and APOE4 mice were fed an isocaloric control diet or a diet containing DHA (n = between 8 and 10 /genotype/diet) for 8 months. At 12 months, animals were tested for visual memory using the object recognition (OR) test. A recognition index (RI) was calculated in the OR test. There were independent significant diet and genotype effects. Mice fed the DHA diet recognized the new object compared to the control diet ($P < 0.0001$). The lipolysis-lipoprotein stimulated receptor (LSR) is involved in the clearance of triglyceride-rich lipoproteins and low-density lipoproteins, and also acts as an apolipoprotein B/E-containing lipoprotein receptor. DHA supplementation decreased by two fold LSR protein levels in the liver of APOE3 and APOE4 mice ($p < 0.01$). The low density lipoprotein receptor-related protein-1 (LRP1), a chylomicron remnant receptor in the liver was not modified by dietary DHA intake neither by APOE genotype. Therefore, a diet rich in DHA seems to modify

LSR and this in independent of APOE genotype. It is however premature to conclude that modifications in the expression of lipoprotein receptor are involved in cognition in this mouse model.

Title: Combined secretase modulation therapy provides cognitive benefit and ameliorates cerebral amyloid pathology in transgenic mice

Authors: *T. MORI[1], N. KOYAMA[1], J. TAN[2], T. TOWN[3];
[1]Saitama Med. Ctr./Univ., Kawagoe, Japan; [2]Dept. of Psychiatry and Behavioral Neurosciences, Univ. of South Florida, Silver Child Develop. Ctr., Tampa, FL; [3]Dept. of Physiol. & Biophysics, Keck Sch. of Med. of Univ. of Southern California, Zilkha Neurogenetic Inst., Los Angeles, CA

Abstract: Alzheimer disease (AD) is the most common progressive age-related neurodegenerative disorder. While pharmacological targets have been identified, to date there has not been a successful disease-modifying therapy. We screened a class of naturally-occurring dietary substances (‘nutraceuticals’) and have focused on two promising compounds [ferulic acid (FA), a β-secretase inhibitor and octyl gallate (OG), an enhancer of α-secretase activity] that inhibit amyloidogenesis. Here, we examined whether FA plus OG combination therapy might synergistically improve cognitive impairment and mitigate amyloid-β (Aβ)/β-amyloid pathology in the PSAPP transgenic mouse model of cerebral amyloidosis. Beginning at 12 months of age, PSAPP mice were orally administered (via gavage) FA plus OG, FA, OG (all at 30 mg/kg), or vehicle once daily for 3 months. At 15 months of age, each treatment improved PSAPP transgene-associated behavioral impairment of activity, novel object recognition, working memory, and spatial reference memory, but left non-transgenic mouse behavior unaltered. Notably, combination therapy synergistically improved most behavioral outcome measures. Moreover, brain parenchymal and cerebral vascular β-amyloid deposits as well as levels of various Aβ species including oligomers were synergistically decreased in FA plus OG-treated versus singly-treated PSAPP mice. These effects were due to a shift toward non-amyloidogenic amyloid precursor protein (APP) cleavage via β-secretase inhibition and α-secretase

enhancement. Notably, β-carboxyl-terminal APP fragment and β-site APP cleaving enzyme 1 (BACE1) protein expressions were decreased, whereas soluble APP-α and tumor necrosis factor α-converting enzyme (TACE; a primary candidate α-secretase protein) expression were increased. Together, these data provide pre-clinical proof-of-concept that secretase modulation via combination therapy is a promising avenue for AD treatment.

Title: Repeated intravenous administration of human adult ischemia-tolerant mesenchymal stem cells reduces Abeta amyloid pathology in a mouse model of Alzheimer's disease

Authors: *T. BOLMONT[1], T. HARACH[1], T. LASSER[1], A. LUKASHEV[2];
[1]EPFL STI IMT LOB, Lausanne, Switzerland; [2]Stemedica Intl., Epalinges, Switzerland

Abstract: The impact of a repeated intravenous administration of adult ischemia-tolerant mesenchymal stem cells (hMSC) on cerebral Abeta amyloid pathology was investigated in a transgenic mouse model of Alzheimer's disease. To this end, hMSC were administered to aged and young transgenic mice that co-express human mutated amyloid precursor protein (APP) with presenilin 1 (PS1) and develop age-dependent cerebral Abeta amyloidosis. Ten weeks of intravenous hMSC treatment (one injection / week) safely reduced cerebral amyloid plaques in both aged and young amyloid-depositing transgenic mice (-44% and -35%, respectively), while significantly reducing neuroinflammation (-35% and -39%, respectively) without increasing cerebral amyloid angiopathy or microhemorhages. Quantitative RT-PCR biodistribution analysis demonstrated that intravenously-delivered hMSC were readily detected in transgenic brains at 1 hour post-delivery. We next investigated if hMSC migration to the brain was necessary for reducing cerebral Abeta amyloidosis, or whether one or several soluble factors released by hMSC in the periphery would subsequently alter cerebral Abeta amyloidosis. Daily intranasal application for a total of three weeks of soluble hMSC factors, which are secreted by hMSC in culture, reduced cerebral Abeta amyloid plaques (-25%) in the absence of intravenous hMSC delivery. Altogether, our pre-clinical results demonstrate that intravenously-delivered hMSC

lower Abeta amyloid pathology in a mouse model of Alzheimer's disease. They also suggest that intranasal application of hMSC factors may be used as a maintenance therapy to accompany intravenous delivery of hMSC, paving the way for a next clinical trial in Alzheimer patients.

Title: APPSweDI mice have severe olfactory deficits and olfactory bulb pathology, treatment with Dpeptide improves outcome

Authors: *T. VAN GROEN[1], I. KADISH[1], A. KUMAR[1], D. WILLBOLD[2];
[1]Cell, Developmental and Integrative Biol., Univ. Alabama-Birmingham, Birmingham, AL;
[2]ICS-6, Forschungszentrum Juelich, Juelich, Germany

Abstract: The transgenic AD model mice we use express three AD-related mutations in APP, i.e., with the APP_{SDI} (Swedish, Dutch and Iowa) mutations, they develop plaques at about five months of age, and we have described that three types of deposits are present, i.e., plaques (with a thioflavine S positive core), and, especially, cerebral amyloid angiopathy (CAA). We tested the olfactory capabilities of these mice at 9 months of age, since we hypothesized that Aβ pathology would result in decreased olfaction. Thus, in this study we investigated the effects on amyloid deposition on olfaction. Further we tested whether treatment with an Aβ42-binding D-peptide (i.e., consisting of D-amino acids), RD2RD2 would improve outcome. We used groups of C57BL/6J mice and APP_{SDI} mice to test olfactory sensitivity, and a group of female, Tg AD model mice for treatment; these animals received ip infusions using Alzet minipumps with either saline, or the RD2RD2 peptide for one month, i.e., from 9 to 10 months of age. Following behavioral analysis, the treated animals were perfused transcardially with a saline solution followed by a 4% paraformaldehyde solution. The brain was cut in 6 series of 35 µm sections, and these were stained with 1) amyloid β, 2) GFAP, 3) CD11b, series 4-6 were stored for later analysis. The density of labeling in the stained sections was quantificated with densitometric

analysis. Whereas C57 mice can smell urine at dilutions of 1:1000, but not at 1:2000, in contrast the Tg AD model mice clearly distinguish urine only at 1:100. The treatment with the amyloidβ42-binding peptides significantly improves olfactory functioning, mice could distinguish urine at 1:250. Further the treatment significantly reduces amyloid β pathology in the olfactory bulb in this mouse model of AD compared to the saline control. Together this suggests that this mouse model of AD has significant olfactory deficits (and olfactory bulb pathology), and that treatment with amyloid-binding peptides decreases the amyloid β pathology, likely by improvement of clearance of amyloid β, leading to improved olfactory cognition.

Title: Potential memory restorative effects of a neurotrophic factor mimetic in an aged, transgenic mouse model of Alzheimer’s disease

Authors: *L. S. HONICAN[1], J. BURRILL[2], A. E. CASLER[1], J. E. GEORGAKAS[1], D. S. ADAMS[2], M. D. SPRITZER[1];
[1]Dept. of Biology, Program in Neurosci., Middlebury Col., Middlebury, VT; [2]Dept. of Biol. and Biotech., Worcester Polytechnic Inst., Worcester, MA

Abstract: Alzheimer’s disease (AD) is associated with an increased accumulation of amyloid beta (Aβ) peptide in the brain, which is believed to lead to cognitive impairment. Neurotrophic factors, which aid neuronal growth and survival, have shown promise for treating AD symptoms. We tested the effectiveness of a growth factor mimetic (BTX-1039) in the treatment of spatial memory deficits. The transgenic mice used in this study have three mutations that lead to over-production of the 770 isoform of the human amyloid beta-precursor protein and associated Aβ in a C57BL/6J background strain. We conducted separate experiments with 6-month-old and 9-month-old mice. Our four treatment groups were: AD mouse/drug, AD mouse/vehicle, wild type mouse/drug, and wild type mouse/vehicle. Mice received daily i.p. injections of 0.20 ml saline or BTX-1039 (60mg/kg) in saline for 14 consecutive days prior to starting behavioral testing, with the researcher blind to treatment. We used a Morris water maze protocol that consisted of 6 days

of place learning, 1 day of probe trials, and 3 days of cued learning. For both experiments, the transgenic mice given saline had significantly longer paths to the target platform during place learning than did all other groups, indicating that the drug restored some memory function. The groups showed no differences in learning during the cued trials, indicating no effect of the transgenes or the drug on stimulus-response learning for the ages tested. For the probe trials, we observed significant impairment in memory retention in the transgenic mice relative to the wild type mice at 6 months of age, but we observed no differences between the strains at 9 months of age and no effects of the drug in either age class. This indicates that mice of this strain under 9 months of age should be used to test memory retention, but also suggests that our drug mainly impacts spatial learning rather than memory retention. In a pilot study, we tested mice of an intermediate age (8 months) using a higher dose of the drug (100 mg/kg), and these results suggest even stronger effectiveness for the drug in restoring spatial learning. We also quantified cell proliferation (Ki67 expression) within the dentate gyrus of the 9-month-old mice, as some studies indicate AD causes dysregulation of the cell cycle. Preliminary results indicate that the transgenes cause a decrease in cell proliferation within the granule cell layer and a significant increase in cell proliferation in the hilus. The drug had no effect on cell proliferation. Together, the results indicate some memory restorative effects of a neurotrophic factor mimetic that were not associated with changes in hippocampal cell proliferation.

Title: Increased APP intracellular domain (AICD) production perturbs synaptic signal integration via increased NMDAR function

Authors: *P. A. POUSINHA[1], E. RAYMOND[1], X. MOUSKA[1], M. WILLEM[2], H. MARIE[1]; [1]660 Route de Lucioles, CNRS IPMC UMR 7275, Valbonne, France; [2]Ludwig-Maximilians-University Munich, Munich, Germany

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease that begins as mild short-term memory deficits and culminates in total loss of cognition and executive functions. The main culprit of the disease, resulting from Amyloid-Precursor Protein (APP) processing, has been thought to be amyloid-b peptide (Ab). However, despite the genetic and cell biological evidence that supports the amyloid cascade hypothesis, it is becoming clear that AD etiology is complex and that Ab alone is unable to account for all aspects of AD [Pimplikar et al. J Neurosci.30: 14946. 2010]. Gamma-secretase not only liberates Ab, but also its C-terminal intracellular counterpart called APP intracellular domain (AICD) [Passer. et al. JAlzheimers Dis.2: 289-301. 2000], which is known to also accumulate in AD patient's brain [Ghosal et al. PNAS.106:18367. 2009], but surprisingly little is known about its functions in the hippocampus. To address this crucial issue, we increased AICD production *in vivo* in adult CA1 pyramidal neurons, mimicking the human pathological condition. Different ex-vivo electrophysiological and pharmacological approaches, including double- patch of neighbor neurons were used. We clearly demonstrate that *in vivo* AICD production increases synaptic NMDA receptor currents. This causes a frequency-dependent disruption of synaptic signal integration, leading to impaired long-term potentiation, which we were able to rescue by different pharmacological approaches. Our results provide convincing and entirely novel evidence that increased *in vivo* production of AICD is enough, per se, to cause synaptic dysfunction in CA1 hippocampal neurons.

Title: CREB is a target for the physiological signaling pathway activated by beta-amyloid monomers

Authors: M. GIUFFRIDA[1], G. PANDINI[1], *A. G. COPANI[3,2], E. RIZZARELLI[1];
[1]IBB, [2]Ibb, CNR-IBB, Catania, Italy; [3]Univ. of Catania, Catania, Italy

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder associated with synaptic dysfunction, pathological accumulation of ß-amyloid (Aß) in plaques, and neuronal loss. The self-association of Aß monomers into soluble oligomers seems to be crucial for the development of neurotoxicity (Walsh and Selkoe, J Neurochem 2007). Different from oligomers, Aß monomers activate IGF-1-like surviving and metabolic pathways. Specifically, Aß monomers act at type I IGF-1 receptors and stimulate PI-3-K/AKT-dependent responses (this presentation and Giuffrida et al, J. Neurosci 2009). We now provide the evidence that, in cultured neurons, Aß monomers induce the activation of the transcription factor CREB in a ser/thr kinase-dependent manner. The results of our study will be presented and discussed in light of the evidence that CREB dysfunctions occur in the brain of transgenic AD mice (Gong B et al., J. Clin Invest., 2004) and in the human AD brain (Yamamoto-Sasaki M et al , Brain Res., 1999; Pugazhenthi S. et al., Mol Neurod., 2011)

Title: The effect of the mitochondria-targeted antioxidant MitoQ on memory retention and neuropathology in aged 3xTg-AD mice

Authors: M. L. YOUNG[1,2], M. PATEL[1,2], *J. L. FRANKLIN[2];
[1]Pharmaceut. and Biomed. Sci., [2]Univ. Georgia, Athens, GA

Abstract: Considerable evidence suggests that oxidative stress is a major mediator of Alzheimer's disease (AD) pathology. Malfunctioning mitochondria, the likely source of reactive oxygen species (ROS) responsible for the oxidative stress, are among the earliest pathologies of

the disease preceding β-Amyloid plaque formation, neurofibrillary tangles, and memory loss. To further understand the role of oxidative stress originating from the mitochondria, we took advantage of a novel mitochondria-targeted antioxidant mitoquinone mesylate (MitoQ). Our previous studies show that treatment of the 3xTg-AD mouse model of AD with MitoQ prevents development of pathologies that occur from 2-7 months after birth including cognitive decline, β-Amyloid deposition, synaptic loss, astrogliosis, and increased caspase-3 activity. In this continuation study, we explore the effects of MitoQ with mice that were well into disease progression. Twelve-month-old female 3xTg-AD mice were administered MitoQ (100 μM) continuously in their drinking water until seventeen months after birth. Following the treatment period, behavioral assessments and biochemical assays were conducted to evaluate the effect of MitoQ on known Alzheimer's disease-like pathologies present in 3xTg-AD mice. Morris water maze training, a measure of spatial memory retention, showed that mice treated with MitoQ were able to learn spatial cues 3 days before littermate controls and were also able to retain memory better in both short-term and long-term probe trials. Sensorimotor deficiencies and escape motivation from the water maze were evaluated and did not prove to be significantly different between treatment groups. These findings suggest that MitoQ improved cognitive abilities rather than physical abilities such as swim speed or eyesight. In support of our behavioral studies, synaptophysin, a marker of synapse loss, was significantly increased after treatment. Glial fibrillary acidic protein, a measure of reactive astrocytes that are normally increased in aged 3xTg-AD mice, was reduced by 50%. β-Amyloid (1-42) deposition measured by ELISA was not significantly different from littermate controls. However, caspase-3 activity, implicated in tau pathology, was significantly reduced by treatment. Our behavioral studies suggest that MitoQ may prevent further cognitive decline when administered after disease progression has begun. Interestingly, MitoQ did not have an effect β-Amyloid deposition. We are currently exploring the effects of MitoQ on tau pathology.

Title: Mitochondrial dysfunction and cellular toxicity by mitochondria-targeted amyloid β

Authors: *D. KIM, M.-Y. CHA, H. SONG, I. MOOK-JUNG;
Seoul Natl. University, Grad. Sch., Seoul City, Chongno-Gu, Korea, Republic of

Abstract: Amyloid β (Aβ) peptide is the key molecule in Alzheimer's disease (AD) pathogenesis and also implicated in mitochondrial abnormality during disease progress. Several studies reported that cellular toxicity, mitochondrial dysfunction, and mitochondrial accumulation of Aβ have been shown in the brain of patients with AD and AD model mice. However, the direct correlations among those triangular phenomena remain unclear. Here, we constructed mitochondria-targeted amyloid β sequence, containing a mitochondrial targeting sequence. We demonstrated that mitochondrial dysfunction and cellular toxicity was induced by mitochondria-targeted amyloid β in transfected mouse hippocampal HT22 cells. Furthermore, we constructed the lentiviral system which contain mitochondria-targeted amyloid β sequence. We infected mouse hippocampus with this system to investigate whether accumulation of Aβ only in mitochondria causes memory impairment. In addition, proteomic analysis of the hippocampus indicated that pathological events appeared in the hippocampus matched to partial AD database. These results indicated that mitochondrial Aβ accumulation is sufficient to cause memory impairment *in vivo* system.

Title: O-GlcNAcylation of amyloid-b precursor protein at T576 regulates trafficking and processing

Authors: *O. KWON, Y. CHUN, Y. PARK, H. OH, S. CHUNG;

Abstract: Deposition of amyloid-b (Ab) in the brain is the main culprit of Alzheimer's disease (AD). Ab is derived from sequential proteolytic cleavage of amyloid-b precursor protein (AbPP). AbPP undergoes post-translational modification including N- and O-glycosylation. O-GlcNAcylation is a novel type of O-glycosylation, mediated by O-GlcNAc transferase (OGT) attaching O-β-N-acetylglucosamine (O-GlcNAc) to serine/threonine residues of the target proteins. O-GlcNAc is removed by O-GlcNAcase. We have previously reported that increasing

O-GlcNAcylated AbPP using the O-GlcNAcase inhibitor, PUGNAc, increases its trafficking rate to the plasma membrane and decreases its endocytosis rate, resulting in decreased Aβ production. However, O-GlcNAc modification sites in AβPP are unknown. In this study, we mutated three predicted O-GlcNAc modification threonine residues of AbPP695 into alanines (T291A, T292A, and T576A) and expressed them in HeLa cells. These AbPP mutants showed reduced O-GlcNAcylation levels, indicating that these sites were endogenously O-GlcNAcylated. Thr 576 was the major O-GlcNAcylation site when AbPP was treated with PUGNAc. Surface levels and trafficking to the plasma membrane were decreased in the T576A mutant. Consistent with these observations, T576A mutant accumulated in the early endosomes. In the T576A mutant, the level of secreted Ab was increased and the inhibitory effect of PUGNAc on Ab production was prevented. These results implicate Thr 576 as the major O-GlcNAcylation site in AβPP and indicate that O-GlcNAcylation of this residue regulates its trafficking and processing. Thus, specific O-GlcNAcylation of AbPP at Thr 576 may be a novel and promising drug target for AD therapeutics.

Title: Direct *in vivo* assessment of glutamate dysfunction in APPPS1 transgenic mice

Authors: ***J. K. HEFENDEHL**[1], J. LEDUE[1], R. KO[1], T. MURPHY[2], B. A. MACVICAR[1]; [1]Djavad Mowafaghian Ctr. For Brain Health, UBC, Vancouver, BC, Canada; [2]Dept. of Psychiatry, UBC, Vancouver, BC, Canada

Abstract: Extracellular deposition of the amyloid-β peptide (Aβ) are a hallmark lesion of Alzheimer's disease (AD) and are surrounded by regions of neuronal and glial hyperactivity. Used as a predictive marker for the progression of preclinical to symptomatic AD we examined the close surroundings of Aβ deposits for pathological alterations of glutamate dynamics in APPPS1 transgenic mice. Using *in vivo* two-photon imaging of the glutamate sensor iGluSnFR we examined evoked and spontaneous glutamate dynamics in awake and anaesthetized mice in two cortical brain areas. Timing characteristics characteristics of glutamate changes in an Aβ-

plaque dependent manner. Decay rates of glutamate increase when analysed in close proximity to amyloid deposits and a chronic state of high glutamate fluctuation was found in the direct vicinity of Aβ-plaques. The upregulation of GLT-1 by ceftriaxone was able to partially restore the pathologically altered glutamate dynamics. Together, our results identify a new component of the toxic microenvironment in the close surrounding of Aβ-plaques and a potential new target for early intervention strategies.

Title: Neuronal activity enhances APP processing in cultured neurons

Authors: K. SAITO, K. KASUGA, *T. IKEUCHI;
Niigata University, Brain Res. Inst., Niigata, Japan

Abstract: Alzheimer’s disease (AD) is the most common cause of dementia, which is pathologically characterized by extracellular deposits of β-amyloid (Aβ) and intracellular accumulation of hyperphosphorylated tau. Aβ is derived from amyloid precursor protein (APP) by sequential cleavages. It has been reported that Aβ production is enhanced by neuronal activation. Early in the disease course, hippocampal neurons showing hyperactivity send those axons to the default-mode network where Aβ accumulates remarkably in the AD brain. It has been suggested that Aβis released from an axonal terminal of the hippocampal neuron, subsequently accumulated in the default-mode network. However, it is unclear whether neuronal activity dependent Aβ release affects phosphorylation of tau within the network. Here we performed *in vitro* assay with rat cortical neuron primary cultures. After glutamatergic stimulation, we found that full length APP was reduced and this reduction was preceded by Egr-1 activation. In addition, C-terminal fragments of APP were increased after the stimulation, suggesting that the stimulation enhanced β-cleavage. We previously showed Aβ-dependent tau

phosphorylation by using the coculture system. Taken together, neuronal activity may affect APP processing and tau phosphorylation in neuronal network.

Title: The analysis of endosomal proteins, which specifically interact with APP-βCTF

Authors: *N. TAKASUGI, T. SAKURAI;
Juntendo Univ. Sch. of Med., Tokyo, Japan

Abstract: Alzheimer disease (AD) is a progressive neurodegenerative disorder neuropathologically characterized by senile plaques (SP) and neurofibrillary tangles. Amyloid β peptide (Aβ) is the major component of SP, and produced from sequential cleavage of Aβ precursor proteins (APP) by β-site APP cleaving enzyme 1 (BACE1) and γ-secretase. Numerous studies support the hypothesis that AD pathology is associated with aggregation of Aβ in patient brain. However, the growing evidence suggests Aβ independent abnormality in AD brain precedes Aβ deposition. Intriguingly, abnormally enlarged neuronal endosomes, which is considered to be the reminiscent of the impairment of endosomal-lysosomal systems, have been observed in the early phase of AD. Further study suggests the accumulation of β-carboxy terminal fragment of APP (βCTF), which is the biproduct of Aβ, is a causative molecule for endosomal dysfunction. However, the mechanisms of βCTF accumulation and the effect on endosomal-lysosomal systems are largely unknown.To gain an insight into the molecular

mechanisms, we screened endosomal proteins that interact with βCTF. We will report the analysis of the interaction between these candidates and βCTF, and the impact of the interaction on endosomal-lysosomal systems.

Abstract: BACKGROUND Increasing evidence suggests that phosphorylated tau (pTau) and mitochondrial (mt.) abnormalities are involved in the loss of synapses, defective axonal transport and cognitive decline, in patients with Alzheimer's disease (AD). Molecular, biochemical studies revealed pTau is capable of reducing anterograde transport of vesicles and subcellular organelles such as mt. by blocking microtubule tracks in AD neurons, suggesting that dysregulation of tau causes starvation of synapses, oxidative stress and mt. dysfunction in AD. Further, our co-IP and IHC analysis revealed mt. fission Drp1 interacted with pTau, and this interaction increased as AD progressed. Based on these, we hypothesize that a partial deficiency of Drp1 inhibits Drp1-pTau interactions and protects neurons from pTau induced mt. and synaptic toxicities, and maintains mt. and neuronal functions in AD progression. METHODS We crossed dynamin-related protein heterozygote knockout (Drp1+/-) mice with tau transgenic mice (P301L line) and created double mutant mice - Drp1+/-xTau (DT). Using real time RT-PCR and immunoblotting analyses, we measured mRNA expressions and protein levels of genes related to the mt.

dynamics - Drp1 and Fis1 (fission), Mfn1, Mfn2 and Opa1 (fusion), CypD (Matrix), biogenesis - Nrf1, Nrf2, PGC1α and TFAM and synaptic - synaptophysin, PSD95, synapsin 1, synaptobrevin 1, neurogranin, GAP43 and synaptopodin in brain tissues from 6-mo. Drp1+/-, Tau, DT and WT mice. Using biochemical assay, we also studied mt. function and measured soluble Tau & pTau in brain tissues from all lines of mice in this study. RESULTS Decreased mRNA expressions and protein levels of Drp1 and Fis1, and CypD, and increased levels of Mfn1, Mfn2 and Opa1, Nrf1, Nrf2, PGC1α, TFAM, and synaptophysin, PSD95, synapsin 1, synaptobrevin 1, neurogranin, GAP43 and synaptopodin genes were found in 6 mo. old DT mice relative to AβPP mice. Mitochondrial functional assays revealed that mt. dysfunction is reduced in Drp1+/-xTau mice relative to tau mice, suggesting that reduced Drp1 enhances mitochondrial function in AD neurons. Measurement of pTau studies revealed that soluble and pTau levels were significantly reduced in DT mice relative to Tau mice, indicating that reduced Drp1 decreases soluble and pTau production in AD progression. CONCLUSIONS These findings suggest that partial reduction of Drp1 decreases soluble tau and pTau, reduces mt. dysfunction, maintains mt. dynamics, and enhances mt. biogenesis and synaptic activity in tau mice. These findings may have implications for the development of Drp1 based therapeutics for patients with AD and tauopathies.

Abstract: BACKGROUND The Garrison Institute on Aging (GIA) Brain Bank was created in 2007 and brains have been primarily donated in the State of Texas, and neighboring states in the United States. The objectives of GIA Brain Bank are provide a free brain autopsy and to confirm clinical diagnosis of dementia and to provide brain tissues to qualified researchers studying diseases related to Alzheimer's disease (AD), related dementias and other neurodegenerative diseases. The measurement of synaptic and mitochondrial gene expressions in autopsy brains with a long-term postmortem interval is a challenging and major area of brain research. The objective of our research was to compare messenger RNA (mRNA) expressions of synaptic genes using Eva-Green and Sybr-Green biochemistry based quantitative real-time RT-PCR in autopsy AD brains with a long postmortem interval. METHOD Using Eva-Green and Sybr-Green biochemistry based quantitative real-time RT-PCR, we measured mRNA expressions of a large number of postmortem brains from AD patients and non-demented control subjects. We measured mRNA levels of several synaptic genes, including - synaptophysin, PSD95, GAP43 and others after normalizing cycle threshold values with commonly used reference genes - beta-actin and GAPDH. In addition, we also assessed whether post-mortem interval influences mRNA expressions using Eva-Green and Sybr-Green chemicals. RESULTS Our real-time PCR analysis results indicate that mRNA expression can be detected in all brain specimens for beta-actin and GAPDH. The cycle threshold values of reference gene GAPDH is similar in AD patients and control specimens. Further, the cycle threshold values are lower in Eva-Green compared to Sybr-Green in AD patients with a long postmortem interval, indicating that Eva-Green is a better chemical to measure mRNA levels in brain specimens with a long postmortem interval. CONCLUSIONS These findings suggest that Eva-Green can be used as a better chemical to detect mRNA expressions using real-time RT-PCR in AD postmortem brains with a long postmortem interval. ACKNOWLEDGEMENTS The present study was supported by NIH grants AG042178 and AG047812 and the Garrison Family Foundation.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disease in humans that leads to dementia. The disease process is associated with Aβ plaques and pTau neurofibrillary tangles in the brain. Electroencephalographic (EEG) changes have been reported in AD patients, some of which include slowing of delta waves, increased theta power, seizure activity and evoked potential deficits. TG-2576 mice (129.Cg-Tg(APPSWE)2576), a pre-clinical model of Alzheimer's disease, over express the amyloid precursor protein (APP) with the Swedish mutation, the precursor to beta amyloid found in amyloid plaques. Increased beta amyloid levels in the TG-2576 mice have been reported in literature beginning at approximately 6 months of age. Transgenic AD mouse models are reported to have EEG changes that can include changes in frequency bands and sleep, hippocampal hyper-synchrony, and seizures. Here we longitudinally profile EEG in theTG-2576 mouse model of AD across 5 months. Spontaneous EEG recordings from frontal and parietal cortex over CA1 in freely-moving male TG-2576 and wildtype (WT) mice began at 4 months of age. Analysis of the EEG spectrum up to 30 Hz demonstrated an increase in power across theta/alpha frequencies in TG-2576 mice compared to wildtypes for both frontal and parietal cortex. When compared to frontal cortex, there was prominent theta activity recorded from the parietal cortex from both TG-2576 and WT mice. An increase in theta power in the parietal cortex from TG-2576 mice demonstrated a hippocampal hyper-synchrony. The spectral analysis findings were maintained for the duration of the longitudinal experiment. Also, there were no signs of spontaneous seizure or spike wave discharge (SWD) activity noted at any time during the course of the investigation. These data indicate that there are marked changes in the spontaneous EEG profile in APP-overexpressing TG-2576 mice compared to WT mice, and that these changes remain consistent across time. Future studies include assessing the potential impact of progression of pathology, i.e., Abeta plaque deposition, on spontaneous EEG in TG2576 mice. Title: Synaptic hyperactivity and BDNF induction are early neuronal responses to sub-lethal beta-amyloid concentrations in organotypic hippocampal cultures

Authors: S. MERLO[1], S. F. SPAMPINATO[1], *M.-A. SORTINO[2];
[1]Biomed Biotechnol Sci., [2]Univ. of Catania, Catania, Italy

Abstract: The β-amyloid peptide (Aβ) has been identified as a key molecular factor in the etiology of AD. Aβ overproduction leads to protein build-up and abnormal aggregation into toxic oligomers which progressively assemble into fibrils. This process is slow and the culminating events are neuronal death and formation of extensive extracellular brain deposits. Aβ toxicity is directed to synaptic function with significant synaptic loss when neuronal degeneration is ongoing. Little is yet known on the exact mechanisms preceding synaptic dysfunction coinciding with pre-symptomatic stages of AD. As these events likely represent a critical time span for preventive intervention, further studies are needed. To this end we used an *in vitro* model of organotypic hippocampal slice cultures (OHC) exposed to low, sub-lethal concentrations of Aβ in order to re-create a condition of slow maturation of neuronal damage in the hippocampus. Treatment of OHC with Aβ leads to early and transient (16-72 h for 2 μM A Aβ(25-35) and 7 d for 500 nM Aβ(1-42)) increase of synaptic proteins synaptophysin, synapsin and PSD95, followed by their decrease coincident with neuronal death (7d or 14d). At 72 h of Aβ(25-35) (2 μM) exposure, higher levels of released glutamate and increased loading and unloading of FM 1-43-labeled synaptic vesicles point to increased synaptic activity. All these effects are prevented when OHC are pre-exposed to neuroprotective agent 17-β-estradiol (10 nM). BDNF is an important neurotrophic factor expressed at high levels by neuronal and glial cells in the brain. Recently, a biphasic pattern of expression similar to that we observed for synaptic proteins has been shown for BDNF in AD, with an increase in early stages and reduction in advanced stages of disease. Also, BDNF up-regulation has been linked to sustained microglial activation and release of TNFalfa. In order to test the involvement of BDNF in early synaptic changes induced by Aβ, BDNF levels were evaluated by Western blot. A significant increase of BDNF was detected in OHC exposed to Aβ(25-35) for 72 h or Aβ(1-42) for 7 d. To assess the contribution of each cell type to BDNF increase, its levels were also assessed in primary neurons, astrocytes and microglia treated with Aβ(25-35) 25 μM for 18 h. Early increase of synaptic components and activity, likely mediated by BDNF, may represent an initial step that precedes synaptic loss and neuronal death and may be interpreted as an attempted neuronal response to Aβ toxicity appearing as a new potential target for intervention in AD.

Abstract: BACKGROUND Mounting evidence suggests that amyloid beta (Aβ) and mitochondrial (mt.) structural and functional abnormalities are critically involved in the loss of synapses and cognitive decline, in patients with Alzheimer's disease (AD).Molecular and biochemical studies revealed that impaired mt. dynamics - increased mt. fragmentation and decreased fusion - in neurons from autopsy brains of AD patients, and from transgenic AD mice and neurons expressing Aβ, suggesting that Aβ causes mitochondrial fragmentation in AD. Further, our co-IP and IHC analysis revealed that the mt. fission protein Drp1 interacted with Aβ, and this interaction increased as AD progressed. Based on these, we hypothesize that a partial deficiency of Drp1 inhibits Drp1-Aβ interactions and protects Aβ-induced mitochondrial and synaptic toxicities, and maintains mt. dynamics and neuronal function in AD neurons. METHODS We crossed dynamin-related protein heterozygote knockout (Drp1+/-) mice with AβPP transgenic mice (Tg2576 line) and created double mutant mice - Drp1+/-xAβPP (DAβ). Using real-time RT-PCR and immunoblotting analyses, we measured mRNA expressions and protein levels of genes related to the mt. dynamics - Drp1 and Fis1 (fission), Mfn1, Mfn2 and Opa1 (fusion), CypD (Matrix), mt. biogenesis - Nrf1, Nrf2, PGC1α and TFAM and synaptic - synaptophysin, PSD95, synapsin 1, synaptobrevin 1, neurogranin, GAP43 and synaptopodin in brain tissues from 6-month-old Drp1+/-, AβPP, Drp1+/-xAβPP and wild-type mice. Using biochemical methods, we also studied mitochondrial function and measured soluble Aβ in brain tissues from all lines of mice in our study. RESULTS Decreased mRNA expressions and protein levels of Drp1 and Fis and CypD genes, and increased levels of Mfn1, Mfn2 and Opa1, Nrf1,

Nrf2, PGC1α, TFAM and synaptophysin, PSD95, synapsin 1, synaptobrevin 1, neurogranin, GAP43 and synaptopodin were found in 6-month-old DAβ mice relative to AβPP mice. Mitochondrial functional assays revealed that mt. dysfunction is reduced in DAβ mice relative to AβPP mice, suggesting that reduced Drp1 enhances mt. function in AD neurons. Sandwich ELISA assay revealed that soluble Aβ levels were significantly reduced in DAβ mice relative to AβPP mice, indicating that reduced Drp1 decreases soluble Aβ production in AD progression CONCLUSIONS These findings suggest that partial reduction of Drp1 reduces Aβ production, reduces mt. dysfunction, and maintains mt.dynamics, enhances mt. biogenesis and synaptic activity in AβPP mice. These findings may have implications for the development of Drp1 based therapeutics for AD patients.

Title: Induction of phosphorylated tau in synapse from AD model mice

Authors: *T. KAWARABAYASHI[1], T. NAKAMURA[2], T. NAKATA[2], Y. WAKASAYA[2], N. NAKAHATA[2], M. SHOJI[2];
[2]Neurol., [1]Hirosaki Univ. Grad. Sch. of Med., Hirosaki, Japan

Abstract: Oligomers of amyloid β protein (Aβ) are supposed to exert neurotoxicity in synapse in Alzheimer's disease (AD). Tau is recently considered an executor of neuronal damage and cognitive dysfunction in AD. Aβ oligomers are suggested to induce phosphorylated tau, however, the relationship between Aβ oligomers and tau and the mechanism of neurotoxicity are not obvious. Recently presynaptic localization of tau and increased release of tau from presynaptic terminals from AD are shown. We prepared synaptosomes from brains of AD model, Tg2576 mice (Tg n=33, NonTg n=33). Aβ monomer and oligomers were localized in synaptosomes. Phosphorylated tau was increased in synaptosomes from Tg2576 mice compared to NonTg mice. Tau fragments were also increased in synaptosomes from Tg2576 mice. These findings suggest that Aβ oligomers may induce phosphorylated tau in presynaptic compartment.

Title: NMDA receptor regulation by endogenous ceramide in the hippocampus

Authors: *S. ATTIORI ESSIS[1], M.-E. LAURIER-LAURIN[2], M. CYR[2], G. MASSICOTTE[2];
[1]Biologie Médicale, Univ. Du Québec À Trois-Rivières, Trois-Rivières, QC, Canada; [2]Med. Biol., Univ. Du Quebec a Trois-Rivieres, Trois-Rivières, QC, Canada

Abstract: The lysosomal acid ceramidase, an enzyme known to limit intracellular ceramide accumulation, has been reported to be defective in neurodegenerative disorders associated with high ceramide levels. We show here that rat hippocampal slices preincubated with an acid ceramidase inhibitor (ACI) exhibit increased NMDA receptor-mediated field excitatory postsynaptic potentials (fEPSPs) in CA1 synapses. The ACI by itself did not interfere with either paired pulse facilitation or AMPA receptor-mediated fEPSPs; indicating that its influence on synaptic transmission is postsynaptic in origin and specific to the NMDA subtype of glutamate receptors. From a biochemical perspective, we observed that Tau phosphorylation at the Ser262

epitope was highly increased in hippocampal slices preincubated with the ACI, an effect totally prevented by the global NMDA receptor antagonist AP-5, the calcium chelator BAPTA and the GluN2B receptor antagonist RO25-6981. Preincubation of hippocampal slices with the compound KN-62, an inhibitor known to interfere with calcium/calmodulin-dependent protein kinase II (CaMKII), also totally abolished the effect of ACI on Tau phosphorylation at Ser262 epitopes. Collectively, these results provide experimental evidence that production of endogenous ceramide, resulting from acid ceramidase inhibition, play an important role in regulating Tau phosphorylation via a pathway dependent on GluN2B receptors and CaMKII.

Title: Mitochondrial dysfunction in 3xTg mouse brain is accompanied by deficits in Complex I

Authors: *J. DJORDJEVIC[1], S. ROY CHOWDHURY[2], W. M. SNOW[2,3], D. MCALLISTER[2], C. CADONIC[2,4], E. THOMSON[2], P. FERNYHOUGH[2,3], B. C. ALBENSI[2,3,4];

Abstract: Objective: Alzheimer’s disease (AD), the most common late onset neurodegenerative dementing disorder, affects almost 800 000 elderly in Canada. AD disproportionately affects women in both prevalence and severity; 72% of AD sufferers in Canada are women. AD is characterized by progressive neuronal loss, especially in the hippocampus and cortex. While plaques and tangles are hallmarks of the disease, emerging evidence strongly support the idea that mitochondrial dysfunction is an early event in the onset and progression of AD. Although mitochondrial dysfunction was reported in AD cases, the origin(s) of the mitochondrial dysfunction, its causal relationship to oxidative stress and the mechanisms of downstream effects

to yield synaptic dysfunction and neuronal death are not clear. These experiments characterize dysfunctional processes in brain mitochondria that contribute to AD at different points in disease progression in 3xTg AD mice. Methods: Hippocampus and cortex of 3xTg and control male and female mice (2, 6 and 14 month-old) were analyzed for mitochondrial function by measuring oxygen consumption rates (OCR) on the XF24 Analyzer, (Seahorse Bioscience) and Oxygraph 2K (Oroboros) instruments. Western blot experiments were used to determine protein levels of selected Complex I-V subunits in cortical and hippocampal mitochondria. Results: Our data showed significantly decreased OCR, maximal respiration, spare respiratory capacity, basal and coupled respiration in cortical mitochondria from both male and female 3xTg mice ($*p < 0.05$, n=4) compared to their age-matched controls (14 month old). However, hippocampal mitochondria showed decreased maximal respiration and spare respiratory capacity only in 3xTg females. Western blot results of Complex I-V subunits revealed significant decrease in Complex I protein level (almost 50%) in both brain structures in female 3xTg ($*p < 0.05$). Experiments to determine mitochondrial function and Complex I-V protein levels at younger ages are ongoing. Conclusion: Our preliminary data confirm compromised mitochondrial function in hippocampus and cortex of 14 month-old 3xTg mice and suggest that deficits in Complex I are mitigating factors. Title: CRTC1 activates a memory-related transcriptional program deregulated at early Alzheimer's disease pathological stages

Authors: ***A. J. PARRA-DAMAS**, J. VALERO, M. CHEN, J. ESPAÑA, E. MARTIN, J. RODRÍGUEZ-ALVAREZ, C. A. SAURA;
Inst. De Neurociències, Universitat Autònoma De Barcelona, Spain

Abstract: Cognitive decline is associated with gene expression changes in the brain, but the transcriptional mechanisms underlying memory impairments in cognitive disorders, such as Alzheimer's disease (AD), remain largely unknown. In this study, we aimed to elucidate relevant mechanisms responsible for transcriptional changes underlying early memory loss in AD by examining pathological, behavioral, and transcriptome changes in control and mutant β-amyloid precursor protein (APP Sw,Ind) transgenic mice during aging. Genome-wide transcriptome analysis using mouse microarrays revealed deregulation of a gene network related with neurotransmission, synaptic plasticity, and learning/memory in the hippocampus of APP Sw,Ind mice after spatial memory training. APP Sw,Ind mice show changes on a transcriptional program dependent on the CREB-regulated transcription coactivator-1 (CRTC1). Importantly, we found that synaptic activity and spatial memory induces CRTC1 dephosphorylation and activation leading to CRTC1-dependent transcription in the hippocampus, and these events are impaired in APP Sw,Ind mice at early pathological and memory decline stages. Furthermore, CRTC1 overexpression in the hippocampus of APP Sw,Ind mice efficiently reverses Aβ -induced spatial learning and memory deficits by restoring a specific subset of CREB/CRTC1 target genes. Our results reveal a critical role for CRTC1-dependent transcription on spatial memory and provide evidence that targeting CRTC1 can ameliorate memory deficits in AD.

Title: Visual system dysfunction in a murine model of Alzheimer's disease

Authors: *L. DOMENICI[1,2], C. CRISCUOLO[1,2], S. CAPSONI[3,4], E. CERRI[1], A. CATTANEO[3,4];

Abstract: In addition to progressive cognitive disorder, there is increasing evidence of visual involvement in Alzheimer's disease (AD). Indeed, a wide range of visual disturbances is reported in AD patients, including a decrease in visual acuity. As well, there is evidence of amyloid beta (Aβ) deposits and cell death in the retinas of AD patients and these, together with an Aβ deposition found in the lens fiber cells, may be responsible for some of the visual deficits seen in AD. Moreover, these visual deficits are strongly correlated with cognitive ability. In particular, visual spatial impairment and thinning of the retinal ganglion fiber layer may be one of the earliest symptoms of AD-type neurodegenerative change. The opportunity to study microscopic functional cellular changes in the eye non-invasively may be used as a window to facilitate early diagnosis of AD and monitor treatment efficacy. We used a familial AD mouse model, 5xFAD, which most closely approximates the human Aβ40 or Aβ42 peptide load in the retina, besides showing the highest concentration of Aβ peptides in the brain compared with other murine models. These characteristics make 5xFAD mouse a suitable in-vivo model for studying the mechanism of amyloidogenic neurodegeneration in the retina and the pathogenic signals that may progressively spread across the antero-posterior axis of the visual circuitry. In our work, visual retinal function was monitored using Pattern Electroretinogram (P-ERG), whose source is in the inner retina at the level of retinal ganglion cells, and visual cortical evoked potential (VEP). We found P-ERG significant alteration in 6 months old 5xFAD, when cognitive impairment is well shown; preliminary data showed VEP lower amplitude. These data highlight a first involvement of the retinal ganglion cells in the AD progression. In ongoing experiments we are monitoring the visual function at earlier stages of neurodegeneration, in order to describe the time course of the visual dysfunction in relationship with the cognitive impairment.

Title: Aberrant dynamics of hippocampal neural stem cells in Alzheimer's disease transgenic mice

Authors: *C. H. FU, D. IASCONE, A. HAZRA, M. PYFER, X. ZHANG, J. CHIN; Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Alzheimer's disease (AD) is associated with impaired hippocampal function in both human patients as well as in transgenic mouse models of disease. Because adult neurogenesis in the dentate gyrus is critical to normal hippocampal function, alterations in neurogenesis may contribute to hippocampal impairments in AD patients and mice. Hippocampal neural stem cells appear to undergo a finite number of divisions, which could limit the stem cell pool's capacity for neurogenesis with aging. Seizure activity, exhibited by both AD patients and mice, aberrantly accelerates neurogenesis and may drive premature depletion of the hippocampal neural stem cell pool, thus contributing to functional deficits. We found that alterations in the rates and levels of neurogenesis in AD mice throughout disease progression are associated with seizure activity, correspond to the development of impairments in dentate function, and are normalized by treatment with an antiepileptic drug. Current studies in the lab investigate the dynamics of depletion of the hippocampal neural stem cell pool in AD mice. Our findings are consistent with the hypothesis that seizures induce aberrant neurogenesis and drive premature depletion of the hippocampal neural stem cell pool, which may contribute to cognitive deficits in AD mice.

Abstract: The glucose transporter GLUT1, encoded by *SLC2A1*, mediates glucose transport into the brain. GLUT1 is expressed at the blood-brain barrier (BBB), but not in neurons. Brain glucose uptake correlates with GLUT1 levels in cerebral microvessels. Alzheimer's disease (AD) is characterized by early reductions in glucose transport associated with diminished GLUT1 expression at the BBB. Whether GLUT1 reductions can lead to cerebrovascular damage contributing to and/or accelerating AD-like neurodegeneration remains, however, elusive. To address this question, we crossed transgenic mice overexpressing human amyloid β-peptide (Aβ) precursor protein ($APP^{Sw/0}$) with GLUT1-deficient $Slc2a1^{+/-}$ mice. We also utilized conditional $Slc2a1^{lox/lox}$ mice to determine the effects of cell-specific GLUT1 deletions from endothelium and astrocytes on the BBB phenotype. We show that GLUT1 deficiency in $APP^{Sw/0}$ mice leads to early cerebral microvascular degeneration, cerebral blood flow reductions, and BBB breakdown, and to reductions in Aβ clearance, via reduced expression of LRP1 in the microvasculature, accelerated Aβ pathology, diminished neuronal activity, behavioural deficits, and progressive neuronal loss and neurodegeneration that develop after initial cerebrovascular degenerative changes. Our data suggest that GLUT1 reductions at the BBB play an early pathogenic role in neuronal demise in an AD-like neurodegenerative process and may represent a novel therapeutic target for Alzheimer's disease vasculo-neuronal dysfunction and degeneration.

Title: P2X2R-FE65 interaction induces synaptic failure and neuronal dyshomeostasis after treatments with soluble oligomers of amyloid beta peptide

Authors: *J. FUENTEALBA[1,3], P. A. GODOY[2], T. SILVA-GRECCHI[2], K. M. BARRA[2], T. CELIS[2], J. D. PANES[2];
[2]Physiol., [1]Univ. de Concepcion, Concepcion, Chile; [3]Physiol., Ctr. for Advanced Res. on Biomedicine (CIAB-UdeC), Concepcion, Chile

Abstract: Alzheimer´s Disease (AD) is mainly caused by soluble oligomers of amyloid β peptide (SO-Aβ) toxicity. Aβ is generated from APP proteolytic processing, given by β and γ-secretases cleavage, releasing as well the Amyloid Intracellular domain of APP (AICD) to the cytoplasm. On the other hand, Fe65 a multidomain adaptor protein which is able to interact with different proteins from the intracellular milieu and membrane, one if the most important interactions is with AICD, these proteins form a transcriptional complex which accomplishes many fundamental roles in the cell normal function; furthermore, impairment in the formation of this complex could generate neuronal dyshomeostasis, mitochondrial dysfunction, and synaptic failure. Besides, it has been reported that Fe65 can interact with the purinergic receptor P2X2 (P2X2R), whose family has been described to have an important role in neurodegenerative diseases. The aim of this work is to study the effects of the treatment with the SOAβ1-40 on the P2X2R, Fe65 and APP expression on two different models to evaluate the role of these proteins on the mechanism underlying the onset of AD. We have demonstrated that treatments with SOAβ1-40 (0,5 μM) enhance the P2X2R expression (control: 100±8%, Aβ: 143±16%) in PC12 cells without significant changes on Fe65 levels (control: 100±10%, Aβ: 134±18); additionally, our results reinforce the idea of an active interaction between P2X2R and Fe65 which has been demonstrated by coimmunoprecipitation. The increase of P2X2R expression could suggest a possible sequestration of Fe65 which may induce deterioration in other key functions of Fe65, like interaction with AICD. Searching for another approach, we used mice hippocampal slices treated with SO-Aβ1-40 (0,5 uM), where we were able to see a fast and acute increase on Fe65 protein immunoreactivity on the dentate gyrus and also an increase of APP immunoreactivity in CA3 region after subchronic treatments. On slices treated with SOAβ1-40 (1 uM) it was possible to see changes in the APP signal localization, from cytosol to the nucleus on dentate gyrus and CA1 areas. Concerning Fe65, we were able to see a fast and significant increase of the immunoreactivity in the mossy fibers region near the CA3 area of the hippocampus. Moreover we evaluated P2X2R after said treatments, and we observed a fast and significant increase of its immunoreactivity in all hippocampal areas that were studied. In conclusion, Aβ toxicity promote

acute and chronic changes on key protein redistributions an expression, enhancing P2X2R-FE65 interaction, inducing alterations on mitochondrial dynamics.

Title: Amyloid β-protein from aqueous extracts of Alzheimer's disease brain disrupts excitatory-inhibitory tone and impairs synaptic plasticity

Authors: *Z. WANG[1,2], T. T. O'MALLEY[1], W. HONG[2], W. LIU[2], S. LI[2], D. M. WALSH[2]; [1]Brigham and Women's Hosp., Boston, MA; [2]Ann Romney Ctr. for Neurologic Diseases, Harvard Inst. of Med., Boston, MA

Abstract: Alzheimer's disease (AD) is a progressive and fatal neurodegenerative disease that mostly affects persons over the age of 65 years. Genetic studies on familial AD indicate that APP and its metabolites, including the amyloid β-protein (Aβ), play a central role in AD. Recent studies found that Aβ can exist in multiple different forms that differ both in terms of primary structure and aggregation state. This heterogeneity makes modeling Aβ *in vitro* very complex. Given that significant data suggest that Aβ plays an initiating in role in AD, we focus on brain tissue of individuals who died with very mild forms of disease, studying a region of temporal cortex implicated in the early stages of the disease. So far we have prepared extracts from entire temporal cortices of 3 mild AD cases. In each case tissue was homogenized in artificial cerebrospinal fluid and a portion of these treated with a pan anti-Aβ polyclonal antibody to remove all detectable forms of Aβ. The effect of AD brain extracts (+/- immunodepletion) on excitatory-inhibitory (E/I) tone and long-term potentiation (LTP) were then investigated. Extracts from all 3 brains suppressed LTP in the hippocampal CA1 area of mouse brain slices in an Aβ-dependent manner, i.e. samples immunodepleted of Aβ did not disrupt synaptic plasticity. However, the extent of LTP inhibition varied between extracts. This variation was not attributable to a simple difference in the total amount of Aβ since the sample which contained the highest levels of Aβ as measured by Western blotting and 3 different ELISAs actually produced

the weakest impairment of synaptic plasticity. We are currently investigating the basis of the apparent differences in potency of extracts. Simultaneously, we are also seeking to understand the underlying mechanism of inhibition of Aβ on LTP. We have used whole cell voltage clamp recording and measured E/I balance on individual pyramidal neurons of the CA1 area. Our results show that extracts of AD brain decrease inhibitory activity without altering excitatory input on pyramidal neuron. These findings suggest that certain (as yet undisclosed) forms of Aβ act by disrupting GABA release and that the subsequent increase in excitability leads to disruption of LTP. Interestingly, conditioned medium (CM) from a cell line (referred to as 7PA2) which contains significant amounts of N-terminal extended Aβ (NTE-Aβ) species also blocks LTP and disrupts E/I balance. However, 7PA2 CM disturbs the E/I balance by increasing excitatory input without altering inhibitory input. These results indicate that human brain extracts (which contain little or no NTE-Aβ) act by a mechanism distinct from the NTE-rich 7PA2 CM.

Title: An anatomical correlate of the mouse default mode network

Authors: *J. D. WHITESELL, P. BOHN, M. T. MORTRUD, K. E. HIROKAWA, S. W. OH, S. MIHALAS, H. ZENG, J. A. HARRIS;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The default mode network (DMN) is a group of brain regions that are active when individuals are in a state of internal focus or "alert rest" and deactivated during goal-directed tasks. The DMN is defined in humans and nonhuman primates on the basis of correlated activity during resting state functional MRI (fMRI), and analogous networks in rodents have recently been observed using fMRI in anesthetized rats and mice. Several neurodegenerative disorders affect the DMN, including Alzheimer's disease (AD). In AD, network activity persists during task-oriented activities and DMN regions show early and extensive deposition of amyloid-beta plaques. We hypothesize that brain regions comprising the DMN are preferentially linked by a

class of cells selectively vulnerable to neurodegeneration in AD, while a separate group of cells links these regions to non-DMN brain areas. To examine the structural connectivity underlying the functionally-defined rodent DMN, we first performed graph-theoretical analysis on our large dataset of stereotaxic anterograde viral tracing experiments (the Allen Mouse Brain Connectivity Atlas) to identify a group of anatomically connected regions which closely resemble the putative mouse DMN. We further probed the connectivity of this network with dual stereotaxic injections of retrograde CAV2-Cre virus and anterograde rAAV expressing Cre-dependent fluorescent protein (e.g. rAAV2/1.pCAG.FLEX.EGFP.WPRE.bGH) in pairs of connected regions inside and outside the DMN. For a given DMN source, retrograde Cre expression was produced by CAV2-Cre injections into both DMN and non-DMN targets. Whole brain projections from these target-defined neuron populations were labeled by injecting Cre-dependent rAAV-eGFP in the source area. Projections to targets within the DMN were compared with projections to outside-DMN targets and with interareal connectivity datasets obtained as part of the Allen Mouse Connectivity Atlas. When completed, this collection of target-defined projection patterns from DMN sources will provide a detailed map of cell type-specific anatomical circuit architecture that may in part explain the functional rodent DMN, and also help identify neuron types selectively vulnerable to AD. Future experiments will test the vulnerability of the DMN to AD pathology in mouse models. These experiments may provide important insight into the spread of pathology through neural networks in AD.

Abstract: A growing number of human post-mortem and animal studies indicate that neuroinflammation contributes to the nigrostriatal degeneration observed in Parkinson's disease (PD). Microglial cells, the resident immune cells of the central nervous system, are present in an activated state in the substantia nigra (SN) of PD patients and in animal models. In this state, they release pro-inflammatory cytokines, nitric oxide, and reactive oxygen species, all of which are toxic to the local dopaminergic neurons. Previous work has shown that the catecholamine-specific neurotoxin 6-hydroxydopamine (6-OHDA) can activate microglia. In this study, we sought to determine if systemic administration of an anti-inflammatory agent, concurrent with a 6-OHDA lesion, would abrogate the behavioral dysfunction and degeneration of nigral dopaminergic neurons found in the unilateral 6-OHDA striatal-lesion model of PD. In a flanked paradigm, rats received the broad-spectrum antibiotic minocycline dissolved in drinking water for two weeks before and four weeks following unilateral striatal injection of 6-OHDA. The rats received a minocycline dosage of 30-40 mg/kg/day. Motor deficits were assessed as a measure of forelimb asymmetry (cylinder test) at two- and four-weeks post-lesion. Following the final cylinder test, the rats were sacrificed and the brains were sectioned and processed for Iba-1 and tyrosine hydroxylase (TH) immunohistochemistry for markers of microglia and dopaminergic neurons, respectively, in the ventral midbrain. Morphological analysis of microglia in the SN was performed using ImageJ and unbiased stereology was used to count the number of TH-positive (TH+) neurons and Iba-1-positive (Iba-1+) microglia in the SN. Initial results demonstrate a strong trending interaction effect of minocycline and 6-OHDA in both the cylinder test and the TH+ cell counts in animals receiving both minocycline treatment and 6-OHDA lesion compared to animals receiving regular water and 6-OHDA lesion (P=0.0553 and 0.0832, respectively). Morphological analysis of the microglial perikarya indicated no differences in somal area at the four-week post-lesion time point; counts of Iba-1+ cells in the SN are ongoing. Overall, the results suggest that minocycline treatment may prevent both TH+ cell loss and motor dysfunction in the 6-OHDA rat model of PD, presumably by preventing activation of microglia.

Title: Analysis of sumoylation mutants of alpha-synuclein in yeast models

Authors: *A. N. ROMAN, G. LIPKIN, S. BELLO-ROJAS, R. THOMAS, S. K. DEBBURMAN;
Neurosci. Dept., Lake Forest Col., Lake Forest, IL

Abstract: Parkinson's disease (PD) is a hypokinetic neurodegenerative disorder linked to the death of midbrain dopaminergic neurons. Within affected cells are Lewy bodies composed primarily of insoluble aggregates of the protein alpha-synuclein. PD can be genetic or sporadic; genetic forms account for 10% of cases and thus far, seven mutant genes have been identified, including alpha-synuclein. Six mutations on alpha-synuclein cause PD (A30P, E46K, H50Q, G51D, A53E, A53T). Alpha-synuclein is also a highly post-translationally modified protein and it exists in full length and three alternatively spliced isoforms (Syn-126, Syn-112, Syn-98). Unlike regulation by phosphorylation, less is known about alpha-synuclein sumoylation, which is proposed to be neuroprotective based on limited studies. Sumoylation influence on familial mutants and splice variants of alpha-synuclein are also not well understood. The majority of sumoylation takes place on lysine-96 and lysine-102 in alpha-synuclein. Our goal was to test these related hypotheses: 1) sumoylation will protect against wild-type alpha-synuclein toxicity; 2) sumoylation will also protect against toxicity of familial mutant and spice variants; 3) phosphorylation will regulate sumoylation-dependent properties. First, we have created and expressed sumoylation-blocking variants (K96R, K102R, K96R/K102R) on wild-type and familial mutant backgrounds in our well-established budding and fission yeast models through site-directed mutagenesis. We found that reducing alpha-synuclein sumoylation not only increases its aggregation, but also reduces its association with the plasma membrane. We believe this is the first description of sumoylation effects on alpha-synuclein membrane association. We are currently studying the effects of sumoylation mutants on splice variants and phosphorylation-modified variants of alpha-synuclein. Together, these studies will add insight into alpha-synuclein based pathogenesis in both sporadic and familial forms of PD.

Title: Mutated α-Synuclein(A30P) transgenic marmosets for the pathological research on Parkinson's disease

Authors: *R. KOBAYASHI[1], C. HARA-MIYAUCHI[1,2], J. OKAHARA[4], J. TAKAHASHI-FUJIGASAKI[3], F. OZAWA[1], T. MAEDA[1], H. J. OKANO[1,2], E. SASAKI[1,4], H. OKANO[1]; [1]Keio Univ. Sch. of Med., Tokyo, Japan; [2]Div. of Regenerative Med., [3]Div. of Neuropathology, Jikei Univ. Sch. of Med., Tokyo, Japan; [4]Central Inst. for Exptl. Animals, Kanagawa, Japan

Abstract: α -Synuclein which mainly expressed at presynaptic terminals is implicated in Parkinson's disease (PD), dementia with Lewy body (DLB) and multiple system atrophy (MSA). Actually, mutations in α-Synuclein gene were identified in PD family lines. In neurons of PD patients, α-Synuclein forms aggregations and most of them is modified such as ubiquitination and phosphorylation. This aggregation is thought to cause the Lewy body formation, however, its function is not well understood. To identify the initial pathological change of PD, it is necessary to establish the non-human primate model. We established a novel non-human primate model of PD using mutated α-Synuclein (A30P) to explore the pathology of α-Synucleinopathy. As for the common marmoset (Callithrix jacchus), a small New World primate, its structure of the brain evolves in comparison with rodents. Therefore, we expected that it is possible to link between an exercise or non-exercise dysfunction and a lesion part because the structure of the basal nuclei is clear in marmoset. In the transgenic (Tg) marmoset, the transgene of mutated α-Synuclein (A30P) expression was evident. Moreover some proteins which are component of Lewy body showed higher expression in Tg than in wild-type marmoset. We investigated for pathological changes in tissues of Tg marmoset. In this presentation, we will show the recent results of pathological and exercise functional analysis.

Title: The lipase activity of phospholipase D2 is responsible for nigral neurodegeneration in a rat model of Parkinson's disease

Authors: H. MENDEZ-GOMEZ[1,2], J. SINGH[2], O. GORBATYUK[3], C. MEYERS[2], W. CHEN[2], *N. MUZYCZKA[1,2];
[1]Dept Mol Gen & Microbiol, Powell Gene Therapy Ctr., Gainesville, FL; [2]Univ. of Florida, Gainesville, FL; [3]Univ. of Alabama, Birmingham, AL

Abstract: Phospholipase D2 (PLD2), an enzyme involved in vesicle trafficking and membrane signaling, interacts with α-synuclein, a protein that it is involved in Parkinson's disease. We previously reported that PLD2 overexpression in rat substantia nigra pars compacta (SNc) caused a rapid neurodegeneration of dopamine neurons and that α-synuclein suppressed PLD2 neurodegeneration. Here, we show that PLD2 toxicity is due to its lipase activity. Overexpression of a catalytically inactive mutant (K758R) of PLD2 prevents the early loss of dopaminergic neurons in the SNc and does not show signs of toxicity after 10 weeks of overexpression. Further, mutant K758R does not affect dopamine levels in the striatum. In contrast, mutants that prevent PLD2 interaction with dynamin or Grb2 (a tyrosine kinase receptor scaffold protein) but retained lipase activity, continued to show rapid neurodegeneration. Our findings rule out the interaction of PLD2 with dynamin and a potential role in vesicle trafficking, and the interaction with tryrosine kinase complexes and their associated downstream signal transduction as the cause of PLD2 induced neurodegeneration. Instead, the synthesis of phosphatidic acid, the product of PLD2, which is a second messenger in multiple cellular pathways appears to be the key to PLD2 induced neurodegeneration. The fact that α-synuclein is a regulator of PLD2 activity suggests that regulation of PLD2 activity could be important in the progression of Parkinson disease.

Title: Attempts to measure cognitive function of the common marmoset for the purpose of detecting its impairment in Parkinson's disease model

Authors: *K. ANDO, R. INOUE, C. NISHIME, E. NISHINAKA, H. TSUTSUMI;
Central Inst. for Exptl. Animals, Kawasaki, Japan

Abstract: Cognitive impairment is one of the main syndromes of Alzheimer's disease and other neuropsychiatric diseases although pathophysiology is not well known. The impairment is also reported in patients of Parkinson's disease (PD) of which primary syndrome is progressive impairment of movement derived from degeneration of dopaminergic neurons at the substantia nigra. Preclinical studies using marmosets treated with 1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine (MPTP) or 6-hydroxydopamine (6-OHDA) as PD models have been reported on movement impairments by us in SfN. The present report briefly reviews on our attempts to establish methods measuring cognitive function for the future and final purpose of evaluating its impairment in PD model marmosets. In our earlier attempts, lever-pressing behavior was established in intact marmosets by reinforcing with sweetened liquid using operant chambers originally designed for the rat. Furthermore, pressing on the lighting side of either of 2 levers was reinforced. This discrimination behavior, however, was not stably established owing to weak motivation due to limited water deprivation and restlessness of the behavioral trait of this monkey species. Apart from operant chambers, mailbox-type equipment consisting of 10 compartments was used. A food pellet was placed in each compartment through an opaque door. By repeated training, marmosets opened up each door with knob and took all pellets within 5 min. Then, MPTP (2, 2 and 1 mg/kg, SC on the 1st, 2nd and 3rd consecutive days, respectively) was given to these marmosets. Door opening behavior was tested in 4 months thereafter. Both of the percent correct opening responses and the response rate significantly decreased compared with the levels before MPTP administration and with those of the intact control marmosets. The results indicated that MPTP-treated marmosets of PD model showed cognitive impairment along with movement impairment. Minimizing movement factor, touch response of marmosets on iPad

screen was measured. Touching either of 9 moving stimuli was reinforced with enlarging the touched stimulus and giving music sound. By training, responses were stably maintained and were sensitively affected by some dopaminergic drugs such as methamphetamine. Sensory reinforced touch behavior may be used for testing impairment of cognitive function in PD model marmosets with less involvement of motor impairment. In conclusion, test system measuring cognitive impairment in the PD model marmosets may be useful and important in preclinical studies as well as evaluation of movement impairment.

Title: The effect of sodium metabisulfite on locomotor activity in experimental Parkinson’s model: the role of cyclooxygenase and nuclear factor kappa B

Authors: *A. AGAR[1], A. OZKAN[1], H. PARLAK[1], O. OZSOY[2];
[1]Akdeniz Univ., Antalya, Turkey; [2]Akdeniz Üniversitesi, Antalya, Turkey

Abstract: Sulfite commonly used as preservative in food,beverages and pharmaceuticals ,is a very reactive and potentially toxic molecule.The aim of this study was to investigated the possible effects of sulfite on neuron toxicity by measuring locomotor activity in normal and 6-hydroxydopamine (6-OHDA)induced experimental Parkinson model(PA) rats.The changes were determined by levels of activities of cyclooxygenase (COX) ,Prostaglandine E2 (PGE2),Nuclear factor Kappa B(NF-ƙB) ,caspase-3 and locomotor activity. Male Wistar rats were divided into four groups as follows: control (Control), sulfite treated (Sulfite), (6-OHDA) injected (6-OHDA), sulfite treated and 6-OHDA injected (6-OHDA+Sulfite).Sodium metabisulfite was administered at dose 100mg/kg/day for 45 days by gavage in sulfite and 6-OHDA group +sulfite. Experimental PD was created stereotactically via unilateral infusion of 6-OHDA into the medial forebrain bundle (MFB).In sulfit +6-OHDA group experimental PD was created on 38 rd day of sulfite treatment and continued for remaining 7 days. Locomotor performance decreased in 6-

OHDA group compared to kontrol.Additional effect of sulfite treatment did not induced this impairment.COX and PGE2 activities of substantia nigra(SN) were significantly increased in 6-OHDA group compared with control group.COX and PGE-2 activities significantly elevated in 6-OHDA+sulfite group compared with control and sulfite groups. COX and PGE2 activities of SN of 6-OHDA +S group were not changed compared with the 6-OHDA group. Caspase-3 activity and NF ƙ B p 65 of SN were increased in 6-OHDA and 6-OHDA+Sulfite groups compared with Control group. The tyrosine hydroxylase (TH)-positive neuron number in substantia nigra was reduced in the animals treated with 6-OHDA and 6-OHDA+Sulfite compared with control. In conclusion : Sulfite treatment is not potentially effective for activities of COX,PGE2 ,caspase-3, NF ƙ B p 65 in 6-OHDA induced by experimental Parkinson model.

Title: Differential cortical oscillation activities in hemiParkinsonian rats under apomorphine and L-DOPA treatments

Authors: *B. POUYATOS, R. MAURY, C. BOUYSSIÈRES, C. ROUCARD, Y. ROCHE, V. DUVEAU;
Synapcell, La Tronche, France

Abstract: Motor symptoms observed in Parkinson’s disease result from a dysfunction of the cortico-basal ganglia circuits mainly due to the death of dopaminergic neurons in the substantia nigra pars compacta. A hyper synchronization of beta frequency oscillatory activity in the cortico-basal ganglia circuit has been well characterized in both parkinsonian patients and animal models of the disease. This abnormal beta oscillation is positively correlated to motor symptoms and can be suppressed by dopaminergic treatment. Moreover, a recent study has demonstrated an increase of gamma power oscillation in the motor cortex of both hemiparkinsonian rats (Halje et al. 2012) and patients (Oswal et al. 2013) after chronic injection of L-DOPA. The aim of this work was to further explore oscillatory activities in the motor cortex of hemiparkinsonian rats under normal behaving conditions and after treatment with the dopamine agonist apomorphine

and the dopamine precursor levodopa (L-DOPA) in order to develop a powerful and predictive tool for drug discovery and development. Using the 6-hydroxydopamine-lesioned rat model of PD, we found a significant increase of the beta band power (30Hz) in the cortex compared to controls. Acute injection of apomorphine or L-DOPA alleviated the beta band peak previously observed in the motor cortex. Concomitantly to this reduction, we observed an increase of the gamma power (80-100Hz). Altogether these data suggest that dopaminergic treatments in hemiparkinsonian rats induce a switch of EEG activities from beta to gamma resonant oscillations. One can hypothesize that the abnormal cortical beta oscillation is correlated to the motor symptoms of PD whereas the gamma band would be correlated to the levodopa-induced dyskinesia. We discuss here how these two distinct oscillatory activities could be used as predictive biomarkers for the development of new treatments in Parkinson's disease. ref: Oswal A, Brown P, Litvak V. Title: Behavioral and histological effects of adeno-associated viral vectors (AAV2 and AAV5) for alpha-synuclein overexpression in rats

Authors: *K. B. COSTA, J. NUNES, M. FREIRE, M. ARAÚJO;
Edmond and Lily Safra Intl. Inst. of Neurosci., Santos Dumont Inst., Macaiba, Brazil

Abstract: Parkinson's disease (PD) is the second most prevalent neurodegenerative disorder worldwide, characterized by the progressive loss of dopaminergic neurons in the nigrostriatal pathway. The injection of adeno-associated viral vectors for overexpression of alphasynuclein (AAV-αsyn) in the substantia nigra (SN) is a promising model for studying this pathophysiology since it reproduces the pathologic and neurochemical features found in the human disease. However, many factors such as the serotype of the AAV or the amount injected can affect both the transfection and the alpha-synuclein expression in transfected cells. In this study, we evaluated the behavioral and histological profiles after injection of different volumes of two types of viral vectors in the SN of rats. Twelve Sprague-Dawley rats housed at the Edmond and Lily Safra International Institute of Neuroscience's (ELS-IIN) animal facility were used. All procedures were approved by the institution's Ethics Committee for the Use of Animals (protocol 05/2014) and under the knowledge and agreement of scientific direction of ELS-IIN. AAV-αsyn was injected in the left SN of all animals, which were divided in 4 groups according to the amount and serotype injected (4µl or 2µl of AAV2 and 4µl or 2µl of AAV5). Animals were tested for forepaw asymmetry use in the cylinder test one week before and for 8 weeks after injection. After this period the rats were perfused and their brains were processed for TH immunohistochemical assessment. For each animal, we analyzed 3 sections in which the striatum and 3 sections in which SN could be easily identified. Striatal dopaminergic degeneration was assessed by optical densitometry of TH immunoreactivity in both injected and contralateral sides using ImageJ software. Striatal denervation and neuronal cell loss in the SN was observed in the injected hemisphere of all animals. The denervation was higher in the groups injected with 4µL, regardless of viral serotype. Preliminary analysis suggests that animals in the group injected with 4 µl of AAV2 tended to decrease the use of their right paw in the cylinder test over the weeks. These results contribute to the standardization of an animal model to investigate the histological changes observed in PD and the mechanisms involved in the causes of the human disease

Title: Intracranial chronic administration of prolyl oligopeptidase inhibitor, KYP-2047, counters the behavioural effects and alpha-synuclein overexpression after nigral AAV-alpha-synuclein injection

Authors: *R. SVARCBAHS, U. JULKU, T. MYÖHÄNEN;
Univ. of Helsinki, Helsinki, Finland

Abstract: Prolyl oligopeptidase (PREP) is a serine protease able to hydrolyse small (less than 30 amino acid) proline containing neuropeptides. Recently, it has been recognised that PREP non-enzymatic interaction with alpha-synuclein (aSyn) leads to aSyn aggregation. Our previous results have shown that interaction of PREP with aSyn can be modulated with PREP inhibitors, leading to decreased aggregation process. Moreover, our findings showed that PREP inhibitors enhance autophagy. However, the extent of PREP's involvement in aSyn aggregation processes, clearance from neurons, and aSyn mediated neuronal toxicity is still vaguely understood. In this study, we injected AAV2-CBA-aSyn in a stereotaxic surgery into the mouse (C57Bl/6RccHsd) substantia nigra, and AAV2-CBA-GFP served as a control. Intracranial KYP-2047 treatment with Alzet minipump was initiated one month after the virus administration and continued for 2 weeks. We observed that KYP-2047 administration cleared aSyn from the mice brains and partially reversed aSyn caused motor impairment. Immunohistochemical staining showed a decrease in aSyn immunostaining and an increase in tyrosine hydroxylase (TH) positive staining in the KYP-2047 treated animals compared to the vehicle group. Behavioural scores for the cylinder test paw preference showed improvements in KYP-2047 treated animals. Prior to the study, aSyn and GFP virus vectors were evaluated to establish their activity. AAV-aSyn gave rise to the robust aSyn expression and loss in the TH positive staining with moderate behavioural effects while the GFP control vector did not cause observable neurotoxicity. Our results suggest that PREP inhibitors could be of the therapeutic use in the clearance of accumulated aSyn in synucleinopathies.

Title: A non-human primate model of Parkinson's disease based on viral vector mediated overexpression of alpha-synuclein

Authors: *J. B. KOPRICH[1], T. H. JOHNSTON[1], J. SEIBYL[2], K. MAREK[2], Y. MA[3], D. EIDELBERG[3], C. ZUO[4], Y. GUAN[4], J. H. KORDOWER[5], S. H. FOX[6], J. M. BROTCHIE[1]; [1]Atuka Inc., Toronto, ON, Canada; [2]Mol. Neuroimaging, New Haven, CT; [3]Feinstein Inst. for Med. Res., Manhasset, NY; [4]PET Ctr., Huashan Hospital, Fudan Univ., Shanghai, China; [5]Neurolog. Sci., Rush Univ. Med. Ctr., Chiacago, IL; [6]Movement Disorders Clin., Toronto Western Hosp., Toronto, ON, Canada

Abstract: Rodent models of Parkinson's disease based on the viral overexpression of alpha synuclein (aSyn) have proven useful in better understanding aSyn function. However, the field currently lacks a robust, well-characterized primate model. In this study, 12 cynomolgus macaques each received monthly baseline assessments on motor activity, a functional rating scale (MPPrs) and were trained to conduct a fine motor task (mMAP test). Baseline PET scans were obtained bimonthly to visualize VMAT-2 and FDG fluorodeoxyglucose (FDG). Animals were injected with either AAV1/2 A53T aSyn or empty vector (EV) (both, 1.7 x 10exp12 gp/ml) bilaterally into the substantia nigra (SN) and killed 8 months post surgery. In an independent study (validation study), another 4 macaques were injected unilaterally with the same vector and pathology was characterized at 4 months. In the first study, postmortem analyses, showed that at 8 months, there was a 42% and a 39% reduction in putaminal DA and DAT, respectively, compared to controls (all, $P<0.05$), along with a reduction in TH positive neurons in the SN. Neurites also showed transgene expression throughout the striatum and had a dystrophic Lewy morphology. Remaining neurons showed overexpression of aSyn, however, pS129 aSyn and thioflavin-S positive inclusions were absent. By 5 months post surgery, A53T aSyn macaques showed 45% less motor activity in the 2-4 hr period of a 4 hr observation, compared to EV controls ($P<0.05$). This deficit persisted through to the final month (53%, 56% and 60%, respectively, to month 8, [all, $P<0.05$]). No significant effects were observed on mMAP performance. PET imaging showed no significant change in striatal VMAT-2 to assess dopaminergic activity or change in FDG uptake evaluated to derive the Parkinson related pattern

(PrP). In the validation study, we found that, at 4 months, aSyn aggregates were positive for p129 aSyn and thioflavin-S. Relative to the contralateral side, there were reductions in the number of remaining TH positive neurons (reduced by 30%), TH optical density in the putamen and caudate nucleus (reduced by 26 and 20%, respectively), and striatal dopamine as measured by HPLC (reduced by 34%). The presence of pathological aSyn (pS129 and thioflavin-S positivity) observed at 4 months and the absence of such, despite continued overexpression of the aSyn transgene, at 8 months, may be evidence of more vulnerable neurons degenerating over the period of 4-8 months. In conclusion, the macaque model of PD alpha-synucleinopathy produced here is in a position to assess therapeutics aimed at reducing or preventing aSyn accumulation and concomitant neurodegeneration in the nigrostriatal system.

Title: Kinetics of MPTP elimination in non-human primate’s urine intoxicated by MPTP: study by a new nano-interface based Matrix-Assisted Laser Desorption / Ionization Mass Spectrometry approach

Authors: *F. DARLOT[1,2,3], C. YEROMONAHOS[4,3], A. MOMBRUN[2,3], F. REINHART[2,3], D. AGAY[2,3], N. TORRES-MARTINEZ[2,3], V. JOUSSEAUME[4,3], C. MORO[2,3], F. BERGER[2,3], A.-L. BENABID[2,3], A. BOUAMRANI[2,3];

Abstract: Parkinson's disease is a progressive neurodegenerative disease that leads to dopaminergic neurons death and induces motor disorders such as resting tremor, rigidity, and akinesia. This disease has a significant socioeconomic impact and, currently, only symptomatic treatments exist and there is no curative treatment. In this context, research on this disease is a main health concern. Several experimental models exist, including models by injecting toxins or genetic models. Here we focus on MPTP non-human primate model. The use of MPTP involves the use of health protections for user in order to protect from contamination. Indeed, MPTP is a neurotoxin that crosses the blood-brain barrier and after transformation into MPP+ induces oxidative stress and mitochondrial dysfunction leading to dopaminergic neurons death. In animal experiments, there are many risks of contamination to the user: during MPTP administration, in the case of a bite, and during contact with the excreta of animals (blood, saliva, urine, feces). The major risk highlighted here is the risk of contact with urine. We study the elimination kinetics of MPTP in the urine in order to adapt the means of protection and facilitate experiments. In our laboratory, we have developed new biochips from nanoporous SiOCH thin films that allow the selective detection of low concentrated low molecular weigth molecules by Matrix-Assisted Laser Desorption / Ionization Mass Spectrometry (MALDI MS) in complex biological fluids such as urine. We used this technique to determine when MPTP is completely metabolized, it means when there is no significant detectable MPTP remaining in urine. Monkeys (5-7kg) are injected (intramuscular injection) with 0.3mg MPTP/kg daily for several days, and urine was collected daily for measure processing. Results show that we no longer detect MPTP in urine beyond 48 hours after last MPTP injection. In addition, the number of repetition of daily injection has no cumulative effect on the detection time of MPTP in urine. We detect MPP+ up to 6 days after the last injection of MPTP, but as this molecule does not go through the blood-brain barrier, it induces minor risk to the user. Results of this study can be used as a scientific basis for MPTP protocols on non-human primate to adapt user protection measures.

Title: Chronic variable stress increases the neuroimmune response in an experimental Parkinson's model

Authors: *A. M. HEMMERLE[1], S. N. CASSELLA[1], K. H. LUNDGREN[2], J. P. HERMAN[3], K. B. SEROOGY[1];
[1]Dept of Neurol. and Neurosci. Grad. Program, [2]Dept of Neurol., [3]Dept of Psychiatry and Neurosci. Grad. Program, Univ. Cincinnati, Cincinnati, OH

Abstract: There is an increasing realization that the non-motor symptoms of Parkinson's disease (PD) affect the quality of life of patients as much, if not more, than the motor symptoms. In particular, there is high comorbidity with the psychiatric disorder of depression, but few good animal models exist with which to investigate the potential convergence of pathologies. To address this issue, we have developed a novel paradigm in which a neurotoxic lesion model of PD is combined with the chronic variable stress (CVS) model of depression. Previously we found that administration of the catecholaminergic neurotoxin 6-hydroxydopamine (6-OHDA) concurrently with chronic unpredictable stress resulted in the worsening of both the motor deficits and nigral cell loss normally present in the 6-OHDA model (Hemmerle et al., Mol. Psychiatry, 2014). In the current study, we sought to examine a potential mechanism underlying the enhanced dysfunction by exploring the neuroinflammatory environment of the substantia nigra (SN). Inflammation is thought to underlie, at least in part, the pathogenesis of both PD and depression. Adult male Sprague Dawley rats were subjected to CVS for two weeks both prior to and after receiving 6-OHDA. Two weeks after the cessation of stressors, animals were sacrificed, processed for immunohistochemistry of the microglia marker Iba-1, and labeled cells counted using unbiased stereological techniques. Cell counts in the SN pars compacta (SNpc) revealed that animals exposed to both the stress regimen and 6-OHDA displayed significantly higher numbers of Iba-1+ cells compared to lesioned-only animals. Determination of immune cell activation by examination of microglial soma size and process length remains ongoing. These results indicate that the exacerbated deficits found in the combined chronic stress/PD model may be a response to increased neuroinflammation within the SNpc and has implications for the optimal therapeutic treatments for comorbid depression and PD.

SORTWELL[1]; [1]Translational Sci. and Mol. Med., Michigan State Univ., Grand Rapids, MI; [2]Ctr. for Neurodegenerative Dis. Research, Dept. of Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Our lab has recently characterized the accumulation of phosphorylated alpha-synuclein (a-syn) intraneuronal inclusions and bilateral nigrostriatal degeneration that results from intrastriatal injection of a-syn preformed fibrils (PFFs) into rats, extending previous work done in mice (Luk et al., Science, PMID: 23161999). Recent evidence has implicated a-syn as an initiator of neuroinflammation in Parkinson's disease with neuron-released a-syn activating toll-like receptor 2 (TLR2) on microglia. The present study examined the neuroinflammatory signature resulting from intrastriatal a-syn PFF injections and its temporal relationship to nigrostriatal degeneration. Young adult, male F344 rats received 2 x 2.0 µl unilateral intrastriatal injections of mouse a-syn PFFs (8 µg protein total) or saline. Rats were euthanized 2, 3, 4 or 6 months post-injection. To differentiate the contribution of nigrostriatal degeneration from the accumulation of phosphorylated a-syn on neuroinflammation, rats in which nigrostriatal degeneration was induced by 6-hydroxydopamine (6-OHDA) were used as comparators. This cohort of young-adult, male, F344 rats received 2 x 2.0 µl unilateral, intrastriatal injections of 6-OHDA or vehicle and were euthanized at multiple time points corresponding with increasing nigrostriatal degeneration. Immunohistochemical analysis and stereological quantification is ongoing. The focus of our analysis will be on the magnitude of nigrostriatal degeneration (tyrosine hydroxylase), phosphorylated a-syn and neuroinflammation (ionized calcium binding adaptor molecule 1, major histocompatibility complex-II). We will examine the temporal relationship between a-syn aggregation, microglia-mediated neuroinflammation and nigrostriatal

degeneration. Results from this study will provide new insight into neuroinflammatory dynamics and mechanisms in relation to a-syn aggregation and nigral degeneration and could establish the use of the a-syn PFF rat model as a platform for testing anti-inflammatory therapeutics.

Abstract: Alpha synuclein (αsyn) aggregates are associated with the pathogenesis of Parkinson's disease and others related disorders. The mechanism of αsyn accumulation is not well understood, but a large body of evidence points to αsyn oligomers as a species contributing to neurodegeneration. Although modulation of αsyn aggregation is an attractive therapeutic target, new powerful methodologies are desperately needed to facilitate *in vivo* screening of novel therapeutics. Here we report a novel *in vivo* rodent model with the unique ability to rapidly track αsyn oligomers using a bioluminescent protein complementation strategy that monitors spatial and temporal αsyn oligomers formation *ex vivo*. We find that αsyn forms oligomers *in vivo* as early as 1 week after stereotactic AAV injection into rat substantia nigra (SN). Strikingly, although abundant αsyn expression is also detected in striatum (STR) at 1 week, no αsyn oligomers are detected at this time point. By 4 weeks, oligomerization of αsyn is detected in both STR and SN homogenates giving insight into the kinetics of oligomers formation *in vivo*. Moreover, the effect of a de novo Hsp90 inhibitor, known to prevent αsyn oligomers formation, dramatically reduced αsyn oligomerization. Taken together, we demonstrate that this de novo viral-vector rodent model, that uses Gaussia princeps luciferase as a surrogate reporter of αsyn oligomerization, can be utilized to track the dynamics of oligomers formation *in vivo*. We also

show that αsyn oligomers formation may not necessarily be concentration-dependent as previously thought. We believe this model will be useful rapid and sensitive animal model for future testing of novel therapeutics.

Title: Identification of PP2A as a novel modulator of LRRK2 G2019S-mediated toxicity

Authors: ***J. P. SIM**[1], S. LIN[1], C. NG[1], K. LIM[1,2,3];
[1]Res., Natl. Neurosci. Inst., Singapore, Singapore; [2]Duke-NUS Grad. Med. Sch., Singapore, Singapore; [3]Physiol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Parkinson's disease (PD) is the second most prevalent neurodegenerative disease, affecting millions of people worldwide. Although the etiology of PD remains poorly understood, a subset of PD cases is inheritable and attributable to mutations in specific genes. Among these, mutations in the Leucine-Rich Repeat Kinase 2 (LRRK2) gene is currently recognized to be the most common genetic cause of PD, of which the G2019S substitution accounts up to 4% of familial PD and 1% of sporadic PD. It is widely accepted that G2019S mutation enhances the kinase activity of LRRK2, leading to neurotoxicity. Based on the hypothesis that antagonizing kinase activity will be neuro-protective, we hypothesized that the cognate phosphatase(s) that reverses LRRK2-mediated phosphorylation would also be neuro-protective. Accordingly, we performed a genetic screen using a phosphatase library in *Drosophila* melanogaster LRRK2 model. One of the phosphatases that we have identified to rescue G2019S-induced neurotoxicity is the serine-threonine phosphatase PP2A. We found that over-expression of PP2A ameliorates the climbing defects of G2019S transgenic flies and restores dopaminergic neuronal function. In addition, PP2A over-expression mitigates the mitochondrial pathology induced by LRRK2 G2019S. Similarly, pharmacological activation of PP2A also rescues the parkinsonian

phenotypes of G2019S flies. Collectively, these results suggest that PP2A has an antagonistic role to LRRK2 possibly via the modulation of its downstream substrate phosphorylation. In conclusion, we found that pharmacological or genetic activation of PP2A reduces LRRK2-mediated toxicity, suggesting that the reversal of G2019S kinase activity by PP2A may be a therapeutic strategy for LRRK-related PD.

Title: Octodon degus: a model for the study of age-associated synucleinopathy?

Authors: *S. DOVERO, M. BOURDENX, E. BEZARD, B. DEHAY;
Inst. of Neurodegenerative Dis., Bordeaux, France

Abstract: Animal models are an essential tool for basic pathophysiological research, age-related research as well as drug development and compound testing in neurodegenerative diseases. So far, most of animal studies on neurodegenerative disorders are based on transgenic mice or rats. Although very useful to unravel cellular mechanisms associated to neuronal cell death during the time course of the disease, no mammalian model recapitulates the required age-dependent neurodegeneration, especially in Parkinson’s disease (PD). Of interest, these models failed to replicate the combination of features characterizing PD: α-synucleinopathy associated with dopaminergic cell loss and both motor and non-motor dysfunctions. The absence of adequate *in vivo* experimental models of Parkinson’s disease has severe repercussions for therapeutic intervention success. Natural or ecological models would be an alternative to model PD. Of

interest, among rodent models, *Octodon degus,* a diurnal and highly social South American rodent, might be a very good candidate to study age-associated PD neurodegeneration. Since age-dependent deposition of Aβ-amyloid has been reported in the *Octodon degus*, we posited that this animal could as well be a model of age-related synucleinopathy, and more broadly proteinopathies. No exploratory studies have been undertaken on PD to date. To study this hypothesis, we used a statistically significant group of animals of one, two, three, five and six years old. We thus explored the age-related neurodegeneration observed in the *O. degus* brain by evaluating the progression of pathological markers known to be affected in PD. Analyses have been carried out using biochemical and histochemical techniques in the whole brain. We characterized the pattern of dopaminergic loss in the striatum and in the substantia nigra, the regional distribution of α-synuclein immunoreactivity in several brain structures (i.e. within hippocampus, striatum, substantia nigra, and cortex), as well as its pathological state (i.e. S129 phosphorylation) and occurrence of intracellular inclusion formation. Overall, we observed age-related differences in several brain areas related to PD pathophysiology.

Title: Alpha-Synuclein splice variant and C-terminal truncation analysis in yeast: Implications for sporadic and familial PD

Authors: *S. BELLO ROJAS[1], K. HAMID[2], N. KUKULKA[2], K. CAMPBELL[2], P. SCHRAG[2], L. GRAHAM[2], M. MUNOZ[2], C. ALVARADO[2], S. CHIREN[2], J. JAMES[2], A. ROMAN[2], S. K. DEBBURMAN[2];
[1]Neurosci. Program, Lake Forest Col., [2]Lake Forest Col., Lake Forest, IL

Abstract: Parkinson's disease (PD) is a neurodegenerative disease caused by the death of midbrain dopaminergic neurons linked to misfolding and aggregation of the protein alpha-synuclein. Familial PD accounts for 10% cases and is linked to at least seven genes. Six different mutations on alpha-synuclein itself cause PD. While the full-length alpha-synuclein (which is 140 amino acids long) is the major misfolded form in all PD forms, smaller versions of alpha-synuclein were recently discovered, including three alternatively spliced variants (syn126, syn112, and syn98) and several carboxyl-terminal truncation variants (syn103, syn110, syn120, and syn123). Truncation variants are better studied, but in the wild-type alpha-synuclein background only, and in cell culture and *in vitro* systems; current splice variants studies are limited to just one report. Evaluation of both variant types needs to be extended to additional model systems. Furthermore, properties of neither type of variants are known for the six familial mutant alpha-synuclein backgrounds. We tested the hypotheses that both types of variants would possess a higher pathogenic potential compared to the full-length form, and that this increased pathogenicity would be further potentiated on the six familial mutant backgrounds. We used our well-developed budding yeast model to test our hypotheses. Here, we firstly describe the creation, subcloning, and yeast transformation of all splice variant forms of alpha-synuclein and familial splice variants needed for this study. Thus far, we have examined both types of variants in the wild-type alpha-synuclein background. With them, we describe evidence that the truncation variants have altered solubility, membrane association and aggregation potential; the degree of change depends on how much of the C-terminus is removed. Finally, we show that splice variants possess reduced membrane association and increased aggregation, depending on the variant. We are currently comparing truncation and splice variant properties in familial mutant backgrounds. Our longer-term expectation is that our completed studies will provide a fuller picture of the contributions of the diversity of naturally occurring alpha-synuclein variants in familial and sporadic PD pathogenesis.

Title: Effects of α-synuclein on behavioral dysfunction in the Parkinson's disease model *Drosophila* melanogaster

Authors: *D. HWANG;
California State University, Fresno, Fresno, CA

Abstract: The present study involves using *Drosophila melanogaster* to look at behavioral dysfunction associated with specific genes linked to Parkinson's Disease (PD) known as A30P and A53T genes. The genes promote the formation of protein α-synuclein and the overexpression of this protein promotes the formation of toxic filamentous inclusions. Ultimately, the build up of inclusions leads motor dysfunction due to severe loss of dopaminergic neurons. Research has suggested a deep homology of the arthropod and vertebrate brain structures that have similar functions. Particularly, the arthropod central complex and vertebrate basal ganglia are the homologous structures that mediate the selection and maintenance of behavioral actions. Testing *Drosophila* that overexpress this protein can inform us about how abnormalities in human A30P and A53P genes account for behavioral deficits. Currently, the assay that has been used to investigate motor dysfunction in flies is a simple negative geotaxis climbing assay. However, geotaxis climb may not fully represent the movement dysfunction observed in PD patients. PD patients have difficulty negotiating obstacles due to impairment of voluntary motor control. For this reason we developed a gap negotiation and an obstacle avoidance assay that may be better suited to study PD in the fruit fly model and allow for investigation into more complex motor control. Using GAL4 lines targeting the ellipsoid body or mushroom bodies and UAS lines carrying A30P or A53T, *Drosophila* were genetically altered to express α-synuclein protein in specific brain regions known to be associated with sensory integration and locomotor abilities in insects. In this study, gap-crossing and visually guided obstacle avoidance tests were examined in flies using a high-speed camera and tracking system. We quantified the locomotor abilities of control and mutant flies expressing α-synuclein in terms of the changes in approach speed towards the gap or obstacle, the speed of negotiating the gap or obstacle and the changes in success of negotiating the gap or obstacle on repeated trials. Our results suggest that flies expressing α-synuclein had significantly reduced locomotor ability, resulting in low success rate in gap crossing and impaired obstacle avoidance. Our behavioral assays and results provide new insight into our understanding of behavioral deficits and α-synuclein pathology associated with human neurological diseases, such as PD.

Title: Evaluation of alpha-synuclein nitration in yeast models

Authors: *M. N. MARSHALL, C. ALVARADO, K. SOLVANG, Y. ZAYATS, S. K. DEBBURMAN;
Neurosci. Program, Lake Forest Col., Lake Forest, IL

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder linked to the death of midbrain dopaminergic neurons and alpha-synuclein misfolding and aggregation. Alpha-synuclein is a highly post-translationally modified protein, including phosphorylation, sumoylation, and nitration. Nitration sites on alpha-synuclein occur on tyrosine residues -39, -125, -133, and -136. To add to the growing literature on alpha-synuclein nitration contributions to PD pathogenesis, we created nitration-mimic (Y39C, Y125C, Y133C, Y136C) and nitration-deficient (Y39F, Y125F, Y133F, Y136F) mutants of alpha-synuclein to test the hypothesis that nitration of alpha-synuclein will increase aggregation and cell toxicity, and decrease membrane binding. We evaluated these eight mutants in budding and fission yeast models. Our results demonstrate that nitration does regulate alpha-synuclein localization, aggregation and toxicity. In budding yeast, nitration at Y133 affected toxicity the most, while nitration at Y39 regulated membrane localization. In fission yeast, alpha-synuclein nitration at Y39 and Y125 most affected its toxicity, while nitration on all four sites altered intracellular localization. We are currently evaluating double/triple/quartet combination mutants in our budding and fission yeast models, and also in yeast genetically altered for nitrative stress. Our assessment of nitration supplements our insight into the effects of alpha-synuclein post-translational modifications as they relate to PD.

Title: GDNF gene containing cells and sleep-wake cycle in a mouse model of Parkinson's disease

Authors: *V. M. KOVALZON[1], G. V. PAVLOVA[2], A. V. REVISHCHIN[2], Y. V. UKRAINTSEVA[3], V. B. DOROKHOV[3], L. S. MOISEENKO[4];

Higher Nervous Activity Neurophysiology, Acad. Sci., Moscow, Russian Federation; [4]Innovation Technol. Lab., Severtsov Inst. Ecology/Evolution, Acad. Sci., Moscow, Russian Federation

Abstract: We found that transgenic GDNF containing HEK cells implanted into striatum of C57Bl/6 mice can effectively smooth changes in the characteristics of sleep-wake cycle induced by injection of proneurotoxin MPTP. HEK293 cells transfected by plasmid constructions containing an isoform of human GDNF gene without pre- and pro-sites were implanted (under chloral-hydrate anaesthesia) into caudatum/putamen area of C57Bl/6 mice preliminary adapted to 12/12 LD circadian rhythm. Simultaneously, the epidural electrodes for EEG registration were implanted to the same mice. Three days later animals were subjected to subcutaneous injection of 40 mg/kg dopaminergic proneurotoxin MPTP. Just before the injection, 7 and 14 days after it the 24-hr continuous recording of sleep-wake EEG and motor activity have been performed. After the completion of the experiment animals were tested in Rotarod. Then the animals were narcotised, perfused, brains were extracted and fixed. The amount of dopaminergic neurons of substantia nigra/pars compacta and ventral tegmentum area was studied in brain slices. Our previous studies revealed an increase in motor activity and percentage of waking state during the dark period of nychthemeron at the 7th and especially 14th day since MPTP administration as compared to the controls. Consequently, there was a decrease in percentage of NREM and REM sleep at the 12-hr dark period. Now we have found that preliminary implantation of transgene HEK293/mGDNF cells in amount of about 200000 cell bodies in 1 microliter of solution into striatum of mice results in smoothing of above-mentioned behavioral and EEG effects of MPTP. These data were also confirmed by histochemical studies. We can suppose that the transgenic cells developed and used in our experiments might be regarded as neuroprotective ones also in *in vivo* situation. Supported by RFFI #13-04-00327a and RSF #14-15-00942.

Title: traumatic brain injury leads to development of Parkinson's disease in mice

Authors: ***E. ESPOSITO**, D. IMPELLIZZERI, M. CORDARO, G. BRUSCHETTA, R. CRUPI, S. CUZZOCREA;
Univ. of Messina, Messina, Italy

Abstract: Central nervous insults, such as traumatic brain injury (TBI), are among the leading causes of mortality and morbidity worldwide. TBI is an insult to the brain from the application of external physical force that leads to temporary or permanent structural and functional impairment of the brain. Traumatic brain injuries are reported as risk factors for sporadic neurodegenerative diseases. Parkinson's disease (PD) is a late-onset neurodegenerative disorder caused by degeneration of dopaminergic neurons in the substantia nigra (SNc). In that regard, the aim of this study was to investigate the possible development of PD following experimental model of TBI. Specifically, TBI was induced in mice by controlled cortical impactor. At different time points behavioral tests (Open field, Elevated plus maze tests and Barnes maze) were performed; the animals were sacrificed 30 days after TBI (corresponding to 5-6 years in human) and the brains were collected. Our results showed that following TBI there was decreased expression of tyrosine hydroxylase (TH) and dopamine transporter (DAT) in the SNc, which are specific markers of PD, and significant behavioral alterations. In addition, a strong increase in neuroinflammation evaluated as GFAP, TNF-α, COX-2, iNOS expressions, IκB-α degradation, and NF-κB translocation, was evident. Also, neurotrophic factors such as BDNF, NT3, NGF, GDNF were also decreased at 30 days after TBI. Interestingly, our results showed a significant accumulation of αsynuclein (αsyn) in microglia compared to astrocytes, where we couldn't find any difference; the same situation was found in TH expression. In conclusion, in this study, we suggested that there are currently under-appreciated biological mechanisms linking brain injury and neurodegenerative diseases.

Title: The antioxidant N-acetyl-L-cysteine exerts strong neuroprotective effects in both *in vitro* and *in vivo* models of Parkinson’s disease

Authors: *E. ANDRIAMBELOSON, C. NEVEU, N. KADOUCI, F. LAUGA, E. POIRAUD, B. HUYARD, S. WAGNER;
NEUROFIT, ILLKIRCH, France

Abstract: Parkinson's disease (PD) is a devastating neurodegenerative disorder for which there is no cure. It is caused by the loss of dopaminergic (DA) neurons in the striatum, producing disabling motor symptoms. In the present study, the neurotoxin 6-hydroxydopamine (6-OHDA) was used for the modeling of Parkinson's disease in both *in vitro* and in-vivo experiments. In primary culture of mesencephalic neurons, 15µM of 6-OHDA induced selective death of the DA neuron population. Unilateral injection of 6-OHDA in the medial forebrain of the rat induced ipsilateral depletion (90% reduction) of nigrostriatal dopamine along with ipsilateral rotation of rat following injection of apomorphine. In addition, 6-OHDA-injected rats showed marked motor deficit in different behavioral tests such as beam walking and forelimb use asymmetry tests. *In vitro*, Baclofen ($GABA_B$ receptor agonist), Z-vad-fmk (caspases inhibitor) and PD150606 (calpain inhibitor) elicited 30, 50 and 55% inhibition of the death of DA neurons, respectively. Complete inhibition of cell death was observed with the antioxidant N-acetyl-L-cysteine (NAC). Furthermore, treatment of 6-OHDA rats with NAC prevented the loss of nigrostriatal dopamine and markedly reduced apomorphine-induced rotation. These rats showed improved performance in beam walking and in the forelimb use asymmetry tests. The above data underline the pivotal role of the oxidative stress pathway in 6-OHDA -mediated death of DA neurons. In addition, they indicate the relevance of an *in vitro* model to predict in-vivo neuroprotection.

Title: Knockdown of ESCRT-0 disrupts protein quality control and promotes ER stress-mediated neuronal cell death

Authors: *T. HASEGAWA[1], R. OSHIMA[1], N. SUGENO[1], K. TAMAI[2], S. YOSHIDA[1], J. KOBAYASHI[1], A. KIKUCHI[1], A. TAKEDA[3], N. TANAKA[2], M. AOKI[1];
[1]Tohoku Univ., Sendai, Miyagi, Japan; [2]Miyagi Cancer Ctr. Res. Inst., Natori, Japan; [3]Sendai-Nishitaga Hosp., Sendai, Japan

Abstract: Objectives: ESCRT (endosomal sorting complex required for transport) plays a key role in the later step of the autophagosome, amphisome, and endosome maturation. The aim of this study is to investigate as to whether the ESCRT dysfunction is associated with the abnormal accumulation of protein aggregates and subsequent neurodegeneration in animal model. Methods: We specifically deleted the ESCRT-0 component, hepatocyte growth factor-regulated tyrosine kinase substrate (hrs), in neurons of the adult forebrain by using conditional knockout mice on calcium/calmodulin-dependent protein kinase II alpha (CaMKII)-Cre-expressing background. The locomotor activity was evaluated by footprint analysis, hind-limb extension and hanging wire tests. The neuronal cell loss was determined by hematoxyline-eosin staining. The intraneuronal accumulation of ubiquitinated proteins, p62, and neurodegenerative disease-related proteins such as α-synuclein, TDP-43, tau, and huntingtin was examined by immunostaining and Western blot analyses. In parallel with *in vivo* studies, RNAi-mediated silencing of Hrs was conducted in HEK293 and PC12 cells to validate the autophagic function, involvement of ER stress and its downstream MAPKs pathway. Results: The locomotor performance in the hrsflox/flox; CaMKII-Cre mice was significantly impaired compared to that in hrs+/+; CaMKII-Cre mice. Histological analysis showed the prominent neuronal loss in CA1/CA3 regions of the hippocampus. Furthermore, we observed a striking accumulation of detergent-insoluble α-synuclein, TDP-43, tau, and huntingtin as well as ubiquitinated proteins and p62 in the brain of hrsflox/flox; CaMKII-Cre mice. Tracking of autophagy in RFP-GFP-LC3B-expressing HEK293 cells revealed the impairment of autophagic flux at later stage. The neuronal cell death induced by Hrs knockdown was accompanied by the striking induction of ER stress markers and the

activation of SAPK/JNK signaling pathway. Conclusions: These findings suggest that the neuron-specific disruption of ESCRT-0 compromises autophagic/lysosomal degradation of aggregate-prone proteins and acquires ER stress-mediated neuronal cell death.

Title: Mechanisms of nigral neuron loss in PINK1 knockout rat models of Parkinson's disease

Authors: ***S. K. BARODIA**, J. WATSON, R. B. CREED, V. M. TAPIAS, M. S. GOLDBERG; Dept. of Neurology, Ctr. for Neurodegeneration and Exptl. Therapeut, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Parkinson's disease (PD) is characterized by motor symptoms caused by selective, progressive and robust loss of dopaminergic neurons in the substantia nigra. Mutations in genes including Parkin, DJ-1, PINK1, LRRK2 and alpha-Synuclein are causally linked to inherited forms of PD. PINK1 is a serine/threonine kinase with a mitochondrial targeting motif at its N-terminus. Recent studies indicate that PINK1 normally functions by recruiting Parkin to selectively target dysfunctional mitochondria for clearance by autophagy. PD-linked mutations in PINK1 are recessively inherited and result in the loss of functional PINK1 protein, consistent with a loss-of-function mechanism. We used PINK1 knockout rats and neurons cultured from wild-type and PINK1 knockout rats to test potential mechanisms by which PINK1 mutations cause early onset PD. We hypothesized that PINK1 deficiency causes an accumulation of dysfunctional mitochondria due to impairment of mitochondrial autophagy (mitophagy) resulting in enhanced oxidative stress. PINK1 knockout rats show age-dependent loss of greater than 50% of nigral dopamine neurons by age 8 months. We observed mitochondrial abnormalities in PINK1 knockout rats, suggesting that this might be the mechanism underlying the loss of nigral dopamine neurons caused by PINK1 mutations. Analysis of susceptibility of wild-type and

PINK1 knockout neurons to PD-relevant stresses may further define the mechanisms of neurodegeneration in familial and sporadic PD.

Title: Partial neurorestorative action of DHA after a lesion of the mouse dopaminergic system

Authors: *K. COULOMBE[1,2], M. SAINT-PIERRE[1], G. CISBANI[1,3], I. ST-AMOUR[1,3], C. GIBRAT[1,3], A. GIGUÈRE-RANCOURT[1,2], F. CALON[1,2], F. CICCHETTI[1,3];

Abstract: BACKGROUND: Parkinson disease (PD) is characterized by a massive loss of dopaminergic (DAergic) projections from the substantia nigra pars compacta (SNpc) to the striatum, which is responsible for motors symptoms. The underlying causes of the diseases have not been clearly identified. Although symptomatic treatments exist, curative therapy is yet to be found. Recent data from our team in the MPTP mouse model of PD support the use of omega-3 polyunsaturated fatty acids (n-3 PUFA)-enriched diet as a neuroprotective intervention. However, the usefulness of n-3 PUFA in diagnosed symptomatic patients, after the 70-80% DAergic neuronal death, remains to be evaluated. OBJECTIF: In this study, we investigated the effects of a n-3 PUFA rich diet using a neurorestorative paradigm METHODOLOGY: C57Bl6 mice fed a control diet were submitted to a striatal stereotaxic injection of the neurotoxin 6-hydroxydopamine (6-OHDA) to induce DAergic denervation. Three weeks post-lesion, the mice received either an n-3 PUFA rich or a control diet for a period of 6 weeks. We investigated the effect of dietary intake on the motor phenotype and DAergic nigrostriatal system. RESULTS: Although no improvement in the motor behavior was observed, HPLC analyses revealed a 39% increase of striatal dopamine levels in the n-3 PUFA group compared to ctrl ($P<0.05$). Furthermore, the n-3 PUFA diet led to a 52% rise of tyrosine-hydroxylase (TH) - positive terminals in the striatum ($P<0.05$). Interestingly, despite the fact that n-3 PUFA did not restore

the number of TH-positive neurons in the SNpc, morphological analyses uncovered increased perimeters (+ 21% vs ctrl) and areas (+ 7 % vs ctrl) of DAergic cell bodies. CONCLUSION: Collectively, our results suggest a mild neurorestorative effects or a potentiation of DAergic neurorecovery mechanisms following a n-3 PUFA - enriched diet, and support further studies to investigate the potential of a diet-based intervention in PD.

Title: Mutant alpha-synuclein causes age-dependent neuropathology in monkey brain

Authors: *W. YANG[1], G. WANG[1,2], C.-E. WANG[2], X. GUO[1], P. YIN[1], J. GAO[1], Z. TU[1], Z. WANG[3], J. WU[3], X. HU[3], S. LI[2], X. LI[1,2];

Abstract: Parkinson's disease (PD) is an age-dependent neurodegenerative disease that often occurs in those over age 60. Although rodents and small animals have been used widely to model PD and investigate its pathology, their short life span makes it difficult to assess the aging-related pathology that is likely to occur in PD patient brains. Our recent work has established transgenic PD monkey model that expresses mutant alpha-synuclein and shows early non-motor symptoms. Because the neuropathology of PD is age-dependent, we want to investigate how aging influences PD neuropathology. We first examined the expression of Parkin, PINK1, and alpha-synuclein, which are known to cause PD via loss- or gain-of-function mechanisms, in the brain tissues of monkeys at 2-3, 7-8, and >15 years of age. We found that alpha-synuclein is

increased in the older monkey brains, whereas Parkin and PINK1 are decreased or remain unchanged. Stereotaxic injection of lentiviral vectors expressing mutant alpha-synuclein (A53T) into the substantia nigra of monkeys revealed that aging increases the accumulation of A53T in neurites and its associated neuropathology. A53T also causes more extensive reactive astrocytes and axonal degeneration in monkey brain than in mouse brain. We also found that A53T interacts with neurofascin, an adhesion molecule involved in axon subcellular targeting and neurite outgrowth, and that aged monkey brain tissues show an increased interaction of neurofascin with A53T. Overexpression of A53T causes neuritic toxicity in cultured neuronal cells, which can be attenuated by transfected neurofascin. These findings from non-human primate brains reveal age-dependent pathological and molecular changes that could contribute to the age-dependent neuropathology in PD.

Title: Non invasive imaging of retinal morphology and mitochondrial dysfunction by optical coherence tomography during progression of Parkinsonism in a nonhuman primate model

Authors: *D. W. ANDERSON, M. E. AULT, J. S. SCHNEIDER;
Dept Pathol, Anat & Cell Biol, Thomas Jefferson Univ., Philadelphia, PA

Abstract: Optical coherence tomography (OCT), a non-invasive procedure for analysis of retinal morphology, has been effectively used as a measure of disease progression in multiple sclerosis

(MS) and may be a surrogate measure for brain damage. OCT may also be a valuable tool for longitudinally following other neurodegenerative conditions such as Parkinson's disease (PD) and potentially for monitoring disease progression as well as assessing efficacy of neuroprotective treatments. Studies using OCT to assess retinal histology *in vivo* in PD patients have reported significant inverse correlations between foveal or peripapillary retinal nerve fiber layer (RNFL) thickness and Unified Parkinson's Disease Rating Scale scores, and have even suggested the possibility of differentiating between rigid/akinetic and tremor dominant PD patients by differences in retinal morphology between these subgroups. In a recent study using a non-human primate model of Parkinsonism, we identified statistically significant reductions in RNFL thickness (particularly in nasal and inferior RNFL quadrants) in chronically Parkinsonian (MPTP-treated) animals vs. controls as well as significant foveal thinning and decreases in macular volume. Recent developments in OCT have enabled imaging of retinal flavoprotein fluorescence (FPF), a putative marker of oxidative stress and mitochondrial dysfunction in the retina. FPF occurs due to changes in oxidative stress impairing enzymatic complexes of the electron transport chain and reduction in mitochondrial membrane potential, leading to flavoproteins linked to these enzymatic complexes becoming oxidized and, when excited by blue light, emitting green flavoprotein fluorescence. As such FPF imaging, in conjunction with OCT retinal imaging may be used as a non-invasive biomarker for oxidative stress associated with neurodegenerative diseases such as PD. In the present study we have assessed the changes from normal baseline in retinal morphology, together with with FPF imaging, during the development of Parkinsonism in 10 adult male cynomologous MPTP-treated monkeys. Results indicate that there are early changes in both retinal thickness measures and in FPF expression following MPTP exposure and preceding development of overt Parkinsonian symptoms as well as long-lasting increases in FPF signal. These data suggest the potential value of these non-invasive techniques for early detection of a neurodegenerative process, for monitoring disease progression and for evaluating potential neuroprotective therapies in PD.

Title: *In utero* delivery of scAAV9 mediates widespread brain transduction in rats and monkeys : towards new models of Parkinson's disease

Authors: *B. DEHAY[1], M. BOURDENX[1], L. CHANSEL-DEBORDEAUX[1], S. DOVERO[1], V. GROUTHIER[1], J. URANGA[1], N. DUTHEIL[1], S. BRUN[1], A. ESPAGNA[2], L. GROC[2], Q. LI[3], C. JIMENEZ[1], E. BEZARD[1];

Abstract: Transgenic mammals allow to study brain function and diseases. However, technical difficulties associated to classical transgenesis approaches in species such as rats and monkeys have prevented this long awaited technological development for the study of brain function to be further developed in such species. The development of the viral-mediated delivery of genes in the past few years has led to the identification of viruses with unique characteristics. The adeno-associated virus serotype 9 (AAV2/9) crosses the blood brain barrier, is capable of transducing developing cells and neurons after intravenous injection in many species, and mediates a long-term stable transduction. Ability to transduce brain decreases over time, being maximum at P1 and decreasing dramatically by P10 already suggesting a developmental period in which AAV2/9 transduction has maximal efficacy. While P1 is an attractive (and easily accessible) time point, *in utero* gene delivery has clearly demonstrated that a wide transduction of neurons is possible at embryonic stages compatible with the development of the targeted area. To test this hypothesis, we injected intracerebroventricularly (i.c.v.) high-titer bolus of AAV2/9 carrying either mutant human α-synuclein (A53T) or enhanced green fluorescent protein (EGFP) under the synapsin or CMV immediate enhancer/β-actin (CAG) promoter respectively, at embryonic day 16.5 for rat and around 100 days fetal age for monkeys under ultrasound imaging guidance. Animals after birth have then been behaviourally followed-up and were terminated at regular interval to access the brain pathology. We characterized the regional distribution of GFP immunopositivity in brain structures and peripheral organs. We observed transduction of neurons in most regions of the brain – i.e. within hippocampus, thalamus, spinal cord, striatum, globus pallidus, substantia nigra, choroid plexus, cerebellum, and cortex- 25 days after injection in rats. Moreover, the efficacy of transduction seems dependent on the brain structure. Transduction of mutated α-synuclein was then characterized as was defined the specific brain lesions in both rats and monkeys. Overall, these results indicate that an engineered scAAV9 injected *in utero* in rats or rhesus macaques results in efficient, neuronal and widespread transduction of the brain. Altogether, this proof of concept study could facilitate and offer unique opportunities for

modelling brain diseases in rats and rhesus macaques by targeting mutant genes with tissue-specific gene expression, not mentioning future clinical applications for *in vivo* correction of monogenic diseases or abnormalities in humans.

Abstract: Movement problems including bradykinesia, tremor and rigidity have been studied in detail using a variety of animal models of Parkinson's disease (PD), including the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated nonhuman primate model. However, non-motor problems including decreases in motivation, increases in anxiety, changes in social behaviors and increases in daytime sleepiness occur frequently in PD and have profound

negative impacts on the quality of life. This study was performed to determine whether these non-motor problems were apparent in the low dose (0.14-0.16 mg/kg, intracarotid injection), unilateral rhesus monkey MPTP model of PD. Thirty adult female rhesus monkeys (Maccaca mulatta), aged 17-20 years (equivalent to 50-80 human years) received a single unilateral MPTP injection. Motivation to work for a reward was significantly decreased post-MPTP (19% decrease as measured by progressive ratio testing, $p=0.005$), motivation to eat as indicated by a 5% decrease in body weight with ad libitum food available was decreased, $p<0.001$, and latency to take a novel food was increased, $p=0.013$, but no decrease in social motivation was noted (proportion of time spent in close proximity to a penmate, $p=0.48$). Low reactivity, or behavioral inhibition, in response to a threatening stimulus is a common indicator of increased anxiety in children and monkeys. MPTP led to a significant decrease in reactivity, $p=0.001$. Daytime sleep duration, measured by actigraphy, increased from 100.77±9.04 min/day to 248.19±20.37 min/day, $p<0.001$, with confirmation of daytime sleep assessed by videography. No changes in nighttime sleep were found. As these monkeys received a unilateral MPTP injection and none of these non-motor measures were dependent on use of the affected hand, we conclude that the low dose, unilateral MPTP monkey model will be useful for further studies to better understand the etiology of these non-motor impairments and for testing effective therapies to improve these non-motor impairments.

Abstract: Our group recently reported that mice and rats that were inhalationally exposed to a mixture of manganese chloride (MnCl2) and manganese acetate (MnOAc3) developed movement abnormalities, significant loss of Substantia nigra pars compacta (SNc) dopaminergic neurons, dopamine depletion and improved behavior with L-Dopa treatment as Parkinson disease (PD) patients. However, it is not yet evaluated Mn selectivity for SNc dopaminergic neurons. In the present study we directly exposed mice and rats brain slices to the Mn mixture. The brain slices contained the mesencephalon, striatum, Globus Pallidus, hippocampus and Parietal cortex. The slices were incubated for one hour in 0.02M MnOAc3 and 0.04M $MnCl_2$ and the control tissue were exposed to Krebs solution for one hour. Afterwards, we performed immunohistochemistry for NeuN and Tyrosine hydroxylase (for SNc and ventral tegmental area). We found in both, rats and mice, significant cell death mainly in SNc, in comparison with control tissue and the other brain structures evaluated. Our findings strongly suggest that this Mn mixture specifically damage SNc dopaminergic neurons.

Abstract: Introduction Freezing of gait is a debilitating symptom of Parkinson's disease (PD) and constitutes a major unmet therapeutic need. Interleaved deep brain stimulation of the subthalamic nucleus (STN-DBS) and the substantia nigra pars reticulata (SNr) may improve freezing of gait.[1] SNr stimulation alone was described to have a positive effect on axial symptoms.[2] However the mechanism is largely unknown. Here, we characterized cortical activity in PD patients during walking and its modulation with differential neurostimulation therapy. Methods We analyzed eleven PD patients with STN-DBS (7 male, age 62.5 ± 9.7 years). They were instructed to walk at their own comfortable pace fort and back on a straight walkway of nine meters. Patients were measured in three conditions: with stimulation of the STN (STN_On, with stimulation of the SNr (SNr_On) and without stimulation (StimOff). We measured a 48-channel EEG and analyzed cortical activity during straight walking offline. Results Preliminary results show that cortical activity is differently modulated with STN_On and SNr_On. STN_On shows enhanced cortical activity over bilateral supplementary motor area, premotor area and sensorimotor area in the theta frequency band (4-7 Hz) compared to StimOff. Conversely, SNr_On shows attenuated cortical activity over the midline of the frontal, motor and occipital areas in the theta range compared to StimOff. Discussion The effect of SNr stimulation on cortical activity highly differs from STN stimulation showing desynchronization in the theta band during walking over the midline of the frontal, motor and occipital areas. Interestingly, increase of midline cortical activity was identified in transition periods from walking to freezing and during the freezing episode itself.[3] References 1) Weiss D et al., Nigral stimulation for resistant axial motor impairment in Parkinson's disease? Title: Investigation of neuronal circuit responsible for gait

Authors: ***N. FARHANI**[1,2], R. RAJAKUMAR[3], M. S. JOG[4];
[2]Neurosci. Program, [3]Anat. and Cell Biol., [4]Neurol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Background In advanced stages of Parkinson Disease (PD), gait, balance abnormalities, and impaired control of complex movements emerge. These symptoms are not prominent at early stage of PD despite significant dopaminergic neuronal loss. Gait abnormalities are largely not responsive to levodopa. Therefore, the postural and gait abnormalities are believed to not be a consequence of dopaminergic cell loss. One of the candidates for abnormal gait is the dysfunction in the cholinergic neurons of the Pedunculopontine Nucleus (PPN) located in the midbrain. However, no study has comprehensively investigated the connections between the PPN, other brainstem nuclei and the Central Pattern Generators (CPGs) of the spinal cord. Our aim in this study is to delineate these pathways responsible for gait control. Methods Cholera Toxin β subunit (CTB), was microinjected into the lumbar area of the anterior horn of the spinal cord in rats, neurons in the Gigantocellular Nucleus (GiN) were labeled. Then CTB was injected in the GiN of another group of rats and a group of neurons in the Dorsal Raphe Nucleus (DR) were detected. In the next step, we had three groups of rats: in the first group, cannulas were inserted in PPN bilaterally; in the second and third groups, single cannulas were inserted in DR nucleus and GiN respectively. Lidocaine (0.5µl of 4% solution) was injected through the cannulas in PPN and DR and then rats were placed on a catwalk system and their gait was recorded. In the third group of animals, different receptor agonists and antagonists were injected in GiN and their gait was recorded. Results A.DR neurons send projections down to the GiN and GiN sends projections down to the anterior horn of the lumbar spinal cord where CPGs for gait are located. B.Lidocaine injection in DR, caused a significant increase in body speed variation in rats on the catwalk. C.Lidocaine injection in PPN, did not cause any significant change in different aspects of gait on

catwalk. D. Methiothepin maleate (0.5 µL of 2.5 µM solution), a 5HT1,2, and7 antagonist affects many aspects of gait cycle including speed, body movement variability, stand and swing phases significantly. Conclusion Our results suggest a significant role of serotonergic neurons in DR nucleus and their projections to GiN in gait. This study can be a foundation for future pharmacological studies to identify the role of serotonergic neurons in gait and locomotion.

Title: Freezing of gait in Parkinson's disease: a stopping deficit?

Authors: *K. SMULDERS[1], D. S. PETERSON[1,2], M. M. FLEMING[1], N. PAL[1,2], J. G. NUTT[1], F. B. HORAK[1,2], B. W. FLING[1];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Portland VA Med. Ctr., Portland, OR

Abstract: Recent studies suggest that patients with Parkinson's disease (PD) with freezing of gait (FOG) are impaired in response inhibition (e.g. Stroop task, Go-NoGo task). Moreover, neuroimaging studies show that patients with FOG have loss of white matter in nodes that are part of the "stopping" network, comprising the pre-supplementary motor area (preSMA), right inferior frontal gyrus (rIFG) and subthalamic nuclei (STN). This network is particularly important for global stopping of motor actions as assessed in stop signal reaction tasks (SSRT). We evaluated the performance of PD patients with and without FOG on the SSRT and related stopping performance to the structural integrity of the neural stopping network. Methods: 14 patients with FOG (FOG+) and 9 PD patients without (FOG-) completed the SSRT. Probabilistic structural connectivity of the right hemisphere's stopping network was performed to identify quantity and quality of fiber tract connections between 1) preSMA - IFG, 2) preSMA - STN and 3) IFG - STN. Results: There were no significant differences between FOG+ and FOG- patients on the SSRT (p=.467). Also, microstructural integrity of fibers comprising the stopping network

did not differ between FOG+ and FOG- (all p's>.60). Across all participants, we observed a negative association between the SSRT and connectivity quality of the rIFG (r=-.452, p=.030) and preSMA (r=-0.509, p=.013), but not with STN (-.323, p=.133). These significant associations between SSRT and connectivity values were driven by the FOG+ group (r = -0.55, p = 0.04 for both; Fig. 1); there were no significant correlations between SSRT and structural integrity of the stopping network in the FOG- group alone. Conclusion: Our results do not support a global stopping deficit in PD patients with FOG. Similar to previous work in healthy subjects, in patients with FoG+ we report a strong association between inhibitory network structural integrity and SSRT performance. This suggests that integrity of the tracts to/from the rIFG and preSMA is related to the ability to stop a prepared motor action in PD patients with FOG.

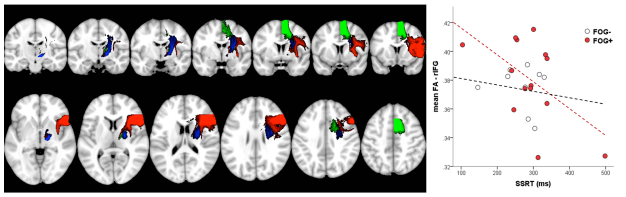

Fig. 1 - Left: Fiber tracts of the stopping network in the right hemisphere. Blue: tracts connecting the STN with IFG and preSMA. Green: tracts connecting the preSMA with STN and IFG. Red: tracts connecting the IFG with STN and preSMA. Right: Correlations between connectivity quality between IFG and performance on SSRT for PD patients with (red filled) and without (white) freezing of gait.

Title: Relationship between circadian rhythm disruption and gait initiation impairment in Parkinson's disease

Authors: G. BACHMAN[1], J. STEWART[1], C. COOPER[1], F. BOMAN[1], L. LIU[2], S. ANCOLI-ISRAEL[2], *L. ALIBIGLOU[3];

Psychiatry, UCSD, La Jolla, CA; [3]Dept. of Physical Therapy and Dept. of Neurosci., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Effective gait initiation is dependent on the appropriate planning and execution of anticipatory postural adjustments (APAs). In patients with Parkinson's disease (PD), APAs may be prolonged, reduced in amplitude, or absent, contributing to impaired gait initiation. In addition to motor symptoms, disturbance of circadian activity rhythm (CAR) is one of the common non-motor symptoms of PD. We investigated whether changes in CAR would influence APAs during gait initiation task. We hypothesized that CAR disruption in PD patients would worsen their ability to appropriately generate APAs during gait initiation in the afternoon compared with the morning. To explore this hypothesis, APAs were compared across two cohorts of subjects (n= 10 for each group): (1) patients with PD, and (2) matched control subjects, at two different time of day (9:00am and 2:30pm). The time between dopaminergic medication intake and gait initiation studies was controlled in PD group. Ground reaction forces (GRFs), center of pressure excursions (CoPs) and tibialis anterior (TA) EMG activity were recorded. Gait initiation tasks included visually cued and self initiated stepping trials. All participants were asked to wear an acti-watch for seven consecutive 24-h periods. Wrist actigraphy was used as a measure of CAR, and two parameters were derived from an extended cosine model: amplitude, which is the distance between the lowest and the highest points of the model, and f-statistic, which is a measure of the goodness-of-fit of the model; higher value of each indicates stronger CARs. Gait initiation studies demonstrated that only in PD group, the amplitude of anterior/posterior and medial/lateral CoP excursions were significantly reduced ($p<0.05$ & $p<0.01$ respectively), the delay in the onset of TA EMG was significantly increased ($p<0.05$), and the duration of the first burst of TA EMG activity was shortened ($p<0.05$), in the afternoon compared with the morning session across all trials. In PD patients, peak loading or unloading GRFs were also reduced markedly in the afternoon but these changes did not reach statistical significance ($p>0.05$). Actigraphy results showed that the CAR f-statistic and amplitude were significantly decreased in the PD group ($p<0.05$), which suggest that the PD group suffered from CAR disruption. Consistent with previous studies, PD subjects demonstrated impaired gait initiation and disrupted CAR. The novel observation of this study was that the PD patients' inability to effectively initiate a gait pattern was significantly worsened in the early afternoon compared with the morning; while the possible effect of medication fluctuation was omitted by study's design.

Title: Impaired postural synergies in patients with Parkinson's disease without clinical signs of postural instability

Authors: A. FALAKI[1], X. HUANG[2], M. M. LEWIS[2], *M. L. LATASH[1];
[1]Dept. of Kinesiology, Pennsylvania State Univ., University Park, PA; [2]Dept. of Neurol., Pennsylvania State Univ. - Hershey Med. Ctr., University Park, PA

Abstract: We used the framework of the uncontrolled manifold (UCM) hypothesis to quantify multi-muscle postural synergies in Parkinson's disease (PD) patients without postural instability signs (Hoehn-Yahr, HY stage-II). PD patients and age-matched controls (n = 11 in each group) performed tasks such as quiet standing, cyclic body sway at 0.5 Hz, quick discrete body sway in the anterior-posterior (AP) direction, and releasing a load from extended arms while standing on a force platform. Surface EMG signals were recorded from 13 muscles on the right side of the body. Integrated indices of muscle activation were subjected to principal component analysis with rotation and factor extraction resulting in four eigenvectors in the muscle activation space (four M-modes). Linear regression analysis was used to link changes in M-modes to shifts in the center of pressure in the AP direction (COPAP). Further, a synergy index was computed reflecting the difference between the inter-trial M-mode variance in two spaces, preserving COPAP (UCM) and leading to its changes (ORT). The PD group tested on-drug showed three main differences from the controls: (1) a lower amount of variance in the muscle activation space accounted for by the four M-modes; (2) significantly lower synergy indices; and (3) significantly reduced anticipatory synergy adjustments (ASAs) in preparation to action. In a follow-up study, 10 PD patients (5 in HY stage-II and 5 in HY stage-III) were tested in the morning prior to taking their medication (off-drug) and one hour after medication ingestion (on-drug). Off-drug, the described differences from healthy subjects became significantly larger. In addition, the amount of M-mode variance within the UCM was significantly lower off-drug. This was consistent across the stage-II and stage-III patients. We conclude that analysis of muscle synergies can detect problems in postural control in PD patients before such problems are recognized based on clinical tests. Further, impairments in postural synergies and their feed-forward adjustments (ASAs) are sensitive to dopamine replacement therapy. The reduced ASAs

may be related causally to later appearing signs such as episodes of freezing. Our results emphasize the importance of the basal ganglia in the neural control of stability of movement and posture.

Abstract: Background: Gait and postural disturbances, predominant clinical features of Parkinson's disease (PD), significantly affect patients' quality of life. The neural pathophysiology that underlies walking impairments in PD is not fully understood. The objective of this study was to begin exploring if and how bi-hemispheric cortical phase synchronization (PS), as reflected by electroencephalography (EEG) during free over ground walking, is associated with gait disturbances in PD in comparison to healthy elderly subjects. Methods: We examined 11 patients with idiopathic PD (68 ± 8 y; 3 women) and 7 elderly subjects (64 ± 9 y; 4 women) while performing 1) two min quiet standing; 2) back and forth straight line corridor walking (turns and freezing episodes, if occurred, were omitted from the analysis); 3) alternating and 4) simultaneous hand tapping. EEG signals were recorded with a 32 electrode array (sampling rate 2048 Hz). The Fourier-mode PS method was used to quantify synchronization in periodic cortical activation between the two brain hemispheres (PS ranges from 0 to 1, representing no to maximal synchronization, respectively). The theta (3.9-7.8Hz), alpha (7.8-15.6 Hz) and beta (15.6-31.2 Hz) bands were studied. Non-parametric statistics were used for the analyses. Results: Bi-hemispheric PS was significantly stronger among PD patients versus

control subjects while standing. Mean PS values (± SEM) (grand averaged across the three bands) were 0.55 ± 0.04 and 0.45 ± 0.01, respectively ($p < 0.001$). This difference in bi-hemispheric PS became even larger during walking, mainly due to increased PS values among the PD group, namely 0.61 ± 0.04 for the PD and 0.43 ± 0.01 for the control group, ($p < 0.001$). The mean ratios of the gait PS to the stance PS were 1.13 ± 0.07 and 0.96 ± 0.02 for the PD and control groups, respectively ($p = 0.056$). Alternating and simultaneous hand tapping also led to increased PS, but differed less between the groups ($p \geq 0.098$). In particular, higher PS values were seen in the simultaneous tapping (0.64 ± 0.04) vs. alternating tapping (0.58 ± 0.03) only for the PD group ($p=0.062$). The mean ratios of PS for simultaneous tapping to alternating tapping - PS ratio were 1.10 ± 0.04 for the PD and 1.03 ± 0.03 for the control group ($p=0.35$). Conclusions: Our findings suggest that excessive bi-hemispheric cortical synchronization may contribute, or alternatively be consequential to stance and gait disturbances in PD.

Title: The effect of motor-cognitive combined rehabilitation on gait performance during dual task in Parkinson's disease

Authors: *E. PELOSIN[1], C. OGLIASTRO[1], G. LAGRAVINESE[1], A. RAVASCHIO[1], A. MIRELMAN[3], J. HAUSDORFF[3], G. ABBRUZZESE[1], L. AVANZINO[2];

Abstract: Multitasking situations exacerbate gait impairments and increase the risk of falling among people with Parkinson disease (PD). These situations include dual-task paradigm. The dual- task (DT) paradigm highlights the cognitive contribution to gait control. When subjects are asked to walk while performing another task, the change in walking performance indicates the extent of the cognitive demand. The aim of the present study was to assess the effects of a motor-

cognitive combined rehabilitative approach on gait performance during normal walking and dual-task in PD. This study involved 14 PD patients (mean age: 73.3 ±5) with a history of 2 or more falls recruited for the V-TIME study[1]. Motor-cognitive combined rehabilitation consisted of a multi-modal treadmill-training program augmented by virtual reality in order to deal with both the motor and cognitive aspects of fall risk and to promote motor learning[1]. Participants were trained for 12 weeks, 3 times a week. Gait evaluations were performed at baseline (V1), after 6 weeks of treatment (V2), at the end of the 12 weeks training program (V3) and 1 month after the end of the treatment (V4). Gait speed (GS) under single-task and dual-task conditions was measured using an electronic walkway. The dual task required participants to perform a verbal fluency task while walking. Gait data collected at V1, V2, V3 and V4 were entered in a RM ANOVA with VISIT and TASK as main factors. Statistical analysis showed first a significant effect of TASK ($p=0.002$). PD patients exhibited a lower gait speed during dual task with respect to normal gait. However we also found a significant effect of VISIT ($p=0.008$) and post hoc analysis showed that mean gait speed across different conditions reduced already after 6 weeks of treatment ($p=0.045$) and remained lower than baseline at the end of the 12 weeks training program ($p=0.014$) and 1 month after the end of the treatment ($p=0.021$). No difference was found between GS recorded at V2 vs V3 vs V4. We did not found any significant interaction VISIT*TASK. In conclusion, our data showed that a motor-cognitive combined rehabilitation induced an improvement in gait speed in PD patients not only during normal walking, but also when patients are requested to execute a cognitive task during walking (dual task). This latter result may suggest that a multimodal training program is likely to have a beneficial effect on those environmental situations that increase the risk of falling in patients with PD. Title: Impact of a proprioceptive training program on reaching movement accuracy and postural stability limits in Parkinson's disease

Authors: ***S. BERGERON**[1,3], P. BLANCHET[2,4], D. MONGEON[1], M. BLANCHET[1], M. JEAN-DÉSILETS[1], J. TREMBLAY[1], F. PRINCE[1], J. MESSIER[1,3];

Hospitalier de l'Université de Montréal (CHUM), Montréal, QC, Canada

Abstract: Evidence suggests that the pathophysiology of movement disturbances in PD includes deficits in proprioceptive processing. Several studies indicated that dopaminergic medication either did not normalize or even worsened sensorimotor performance and/or proprioceptive processing in PD. The aim of this study was to examine the impact of a proprioceptive exercise program on the performance of PD patients in two complex motor tasks that critically depend on proprioceptive processing. We assessed the performance of PD patients and healthy controls (HC) of similar age in a three-dimensional (3D) reaching movements (n=6 PD, n=9 HC) and a postural stability limits tasks (n=6 PD, n=6 HC). In the reaching task, subjects performed 3D reaching movements in two conditions in which the target location and hand positions were defined by either vision or proprioception. The positions of the tip of the index finger and arm segments were recorded using an Optotrak motion analysis system (NDI inc.). In the postural task, subjects stood on a force platform (AMTI, inc.) with bare feet at comfortable stance width and arms crossed on the chest. Subjects were instructed to lean as far as possible in four directions (forward, backward, rightward and leftward) without lifting their feet or flexing their hips and to maintain this maximal leaning position for 10 sec. Subjects were tested in vision and no vision-proprioceptive conditions. Accuracy of reaching movements and center of pressure displacements during the stabilization phase of leaning movements were analyzed. PD patients were tested twice, before (pre-test) and after a 12 week proprioceptive training program (post-test). In the pre-test, PD patients displayed both a greater level of 3D reaching errors in the proprioceptive condition ($p<0.05$) as well as significantly smaller limits of stability relative to healthy volunteers in the visual and proprioceptive conditions ($p<0.05$). The proprioceptive training program increased the average level of spatial accuracy of PD patients in both sensory conditions in the reaching task. Furthermore, the exercise program normalized their reaching accuracy in the proprioceptive condition as well as their stability limits in both the visual and proprioceptive conditions ($p>0.05$). Importantly, the size of the postural stability limits of PD patients was significantly greater in the post-test compared to the pre-test ($p<0.05$). These preliminary findings suggest that a proprioception-based training program improves the proprioceptive control of reaching and postural stability limits in PD.

Title: Detection of symmetry and asymmetry of gait during split-belt treadmill walking in Parkinson's disease

Authors: *K. SOWALSKY, J. A. ROPER, C. J. HASS;
Univ. of Florida, Gainesville, FL

Abstract: Parkinson's disease (PD) is a neurodegenerative movement disorder with symptoms that present asymmetrically initially and progress bilaterally although one side of the body remains more affected throughout the course of the disease. These asymmetries contribute to increased temporal and spatial gait asymmetry in persons with PD. Motor deficits in PD gait are well known, however the contribution of sensory deficits on gait are unclear. The purpose of this study was to determine the ability to detect symmetry and asymmetry in gait during split-belt treadmill walking in PD and to identify potential differences between the more affected and less affected limb. Five patients with idiopathic PD diagnosed by a fellowship trained movement disorders neurologist were evaluated. Participants were male, 66 ± 4 y.o., and tested in the on-medication state. Self-selected and fast self-selected gait speeds were 0.6 ± 0.1 m/s and 1.0 ± 0.2 m/s respectively. Six conditions began with both belts at either a slow speed of 0.5 m/s, a fast speed of 1.0 m/s, or a split speed with one at 0.5 m/s and the other at 1.0 m/s. Slow and fast speeds were manipulated to increase and decrease respectively by 0.03m/s every 3 strides. The number of speed manipulations ranged from 1 (best score to detect asymmetry) to 17 (best score to detect symmetry). Conditions and results (average number of speed manipulations ± standard deviation) were as follows: 1) increased tied belt speed detection (5 ± 3), 2) decreased tied belt speed detection (1 ± 1), 3) split increase in 1 belt from 0.5 m/s to detection of asymmetry (6 ± 3), 4) split decrease in 1 belt from 1.0 m/s to detection of asymmetry (4 ± 2), 5) split start increase in 1 belt to detection of symmetry (12 ± 3), 6) split start decrease in 1 belt to detection of symmetry (11 ± 3). Paired t-tests revealed more sensitivity to detection of decreased tied belt speed compared with increased tied belt speed (p-value < 0.05). Asymmetric belt speed detection was also more sensitive to decreased speed compared with increased speed (p-value < 0.05). Speed change detection in both increasing and decreasing conditions were more sensitive in tied conditions relative to split conditions. In the split start decrease to detection of symmetry condition, manipulation of the more affected limb revealed a significant difference (p-value <

0.05) relative to the less affected limb manipulation. We conclude that persons with PD are more sensitive to decreases in speed as approaching their self-selected pace than increases in speed as approaching their fast self-selected pace. The sensitivity is greater with manipulation of both limbs versus one. Inter-limb detection differences may also be present.

Title: Effects of dual-mode non-invasive brain stimulation on freezing of gait in patients with Parkinson's disease

Authors: *S.-W. KIM, W. CHANG, J.-W. CHO, J.-Y. YOUN, Y. KIM, E. PARK, A. LEE, Y.-H. KIM;
Samgsung Med. Ctr., Seoul, Korea, Republic of

Abstract: Introduction: Freezing of gait (FOG) in Parkinson's disease (PD) would be considered as multiple aspects of motor, cognitive and affective factors. Our previous study demonstrated the favorable effect of repetitive transcranial magnetic stimulation (rTMS) over both the dominant primary motor cortex of lower leg (M1-LL) and the left dorsolateral prefrontal cortex (DLPFC). The aim of this study was to investigate the effects of dual-mode non-invasive brain stimulation (NBS) on FOG using both rTMS and tDCS in patients with PD. Methods: This study was a randomized controlled double-blind study comparing the effect of single vs. dual-mode stimulation. Thirty-two patients (20 males, 12 females) with PD that featured FOG were included and divided into two groups. For the dual-mode stimulation, 10 Hz rTMS over the dominant M1-LL and the anodal tDCS over the left DLPFC were simultaneously applied for 20 mins per session, 5 sessions in a week. For the single stimulation, rTMS were applied at the same manner, however, tDCS were given only during 30 sec. and then fade-off. Behavioral, neurophysiologic and cognitive outcomes were measured before, after, and 1 week after the

intervention by the Timed Up and Go (TUG) test, Standing Start 180° Turn (SS-180° Turn Step/Time) test, Unified Parkinson's Disease Rating Scale (UPDRS) part III, FOG Questionnaire (FOG-Q), motor evoked potential, Korean version of Montreal Cognitive Assessment (K-MOCA), Digit span-Forward/Back and Trail Making-A/B. Results: There were significant improvements in TUG, SS-180° Turn Step, UPDRS part III and FOG-Q in both the dual-mode and the single stimulation group ($p<0.05$). The dual-mode stimulation also resulted in significant improvements in SS-180° Turn Time ($p=0.008$), K-MOCA ($p=0.004$), Digit span-Forward ($p=0.015$) and Trail making-B test ($p=0.010$), whereas single stimulation did not. Furthermore,improvement of Trail making-B test was significantly greater after the dual-mode stimulation than the single stimulation ($p=0.024$). Conclusion: The dual-mode stimulation using the 10 Hz rTMS over the dominant M1-LL and the anodal tDCS over the left DLPFC was more effective than single stimulation for improving FOG in combination with cognitive improvement in patients with PD.

Title: Effects of low (60 Hz) and high (140 Hz) frequency STN DBS on gait and STN beta band power in Parkinson's disease

Authors: *Z. BLUMENFELD[1], T. E. PRIETO[1], M. H. TRAGER[1], E. J. QUINN[1], A. VELISAR[1], C. H. HALPERN[2], J. M. HENDERSON[2], H. BRONTE-STEWART[1]; [1]Neurol., [2]Neurosurg., Stanford Univ., Stanford, CA

Abstract: Objective: High frequency (HF) subthalamic nucleus (STN) deep brain stimulation (DBS) attenuates resting state STN local field potential (LFP) power in the 13 - 30 Hz (beta) band and improves the cardinal motor signs of Parkinson's disease (PD). There is evidence to suggest that low frequency (LF) STN DBS may improve aspects of gait in certain patients. We

report preliminary data on the effect of LF versus HF DBS on STN beta band power as well as on gait during free ambulatory walking using synchronized neural and kinematic recordings outside of the operating room. Methods: Three PD subjects (six STNs), off-medication at least one month after DBS implantation surgery, performed a free ambulatory walking task without DBS (baseline) and during randomized presentations of bilateral LF (60 Hz) and HF (140 Hz) DBS (2.5 - 3V; PW = 60 μsec). STN LFPs were recorded from electrodes 0 - 2 or 1 - 3 of the DBS lead (model 3389, Medtronic, Inc.) and from the investigational Activa® PC+S system via telemetry (FDA-, IDE-, IRB-, and CA Medicare-approved) while DBS was administered through electrode 1 or 2, respectively. One STN was excluded from LFP power analysis due to band-wide artifact. Lower limb kinematics were recorded using wireless Opal® sensors (APDM, Inc.). Gait cycle time (GCT) and shank angular range (SAR) were calculated in LabVIEW (National Instruments, Inc.) and MATLAB (The MathWorks, Inc.). Results: Both GCT and SAR increased during 60 Hz DBS compared to baseline in all three subjects. Preliminary results from LFP power analysis demonstrate that both 60 Hz and HF DBS attenuated both resting state and movement beta band power in all three subjects. Two subjects demonstrated concomitant beta band power attenuation and improvement in both GCT and SAR regardless of DBS frequency. However, one subject's GCT and SAR were worse during HF DBS than during baseline, whereas the subject's GCT and SAR improved during 60 Hz DBS compared to baseline. Conclusions: Sixty Hz DBS improved these gait measures in all three subjects whereas HF DBS was detrimental to gait in one of the subjects, though both frequencies attenuated STN beta band power. This suggests that attenuation of STN beta band power may not be causal to improving the axial symptoms of Parkinson's disease in certain patients.

Title: Synchronized neural and kinematic recordings during freezing episodes in a stepping in place task in Parkinson's disease

Authors: *M. MILLER KOOP[1], M. H. TRAGER[1], E. J. QUINN[1], A. SRIVATSAN[1], Z. BLUMENFELD[1], A. VELISAR[1], M. MALEKMOHAMMADI[1], C. KILBANE[1], J. M. HENDERSON[2], C. H. HALPERN[2], H. M. BRONTE-STEWART[1];
[1]Dept. of Neurol. and Neurolog. Sci., [2]Dept. of Neurosurg., Stanford Univ., Stanford, CA

Abstract: Objective: The neural correlate of freezing of gait (FOG) is unknown although increased high beta band (21-35 Hz) oscillations in the subthalamic nucleus (STN) have been reported in Parkinson disease (PD) Freezers at rest (Toledo et al., 2013). We analyzed synchronized STN neural and kinematic data during standing and a stepping in place (SIP) task in PD Freezers and non-Freezers. Methods: Five PD subjects (3 Freezers and 2 non-Freezers, none with tremor) off meds and OFF DBS, at least 1 month after bilateral DBS surgery, performed a SIP task on adjacent force plates (Neurocom, Inc.). Synchronized force plate data (normalized to body weight) and STN local field potentials (LFP) (model 3389, Medtronic, Inc.) using the investigational Activa® PC+S system via telemetry (FDA-, IDE-, and IRB-approved) were collected. Freezing episodes (FEs) were detected with a custom algorithm (MATLAB, The MathWorks, Inc.) and were confirmed using synchronized videography. Results: Figure 1 demonstrates synchronized neural and kinematic data during SIP for a Freezer (A) and non-Freezer (B). Power spectral density (PSD) plots comparing the FEs to regular stepping show increased synchrony in both leads in the high beta band during FEs compared to regular stepping (Fig. 1A). Total beta band power was lower during regular stepping compared to standing in both the Freezer and non-Freezer. The PSD during SIP that included FEs showed increased high beta band power compared to that during SIP without FEs. Conclusions: Increased beta band power was evident during standing compared to stepping in place in all patients. There was increased power in the high beta band during SIP that included FEs compared to regular stepping. Future investigation will determine whether any trends observed in these cases can be applied to a larger cohort.

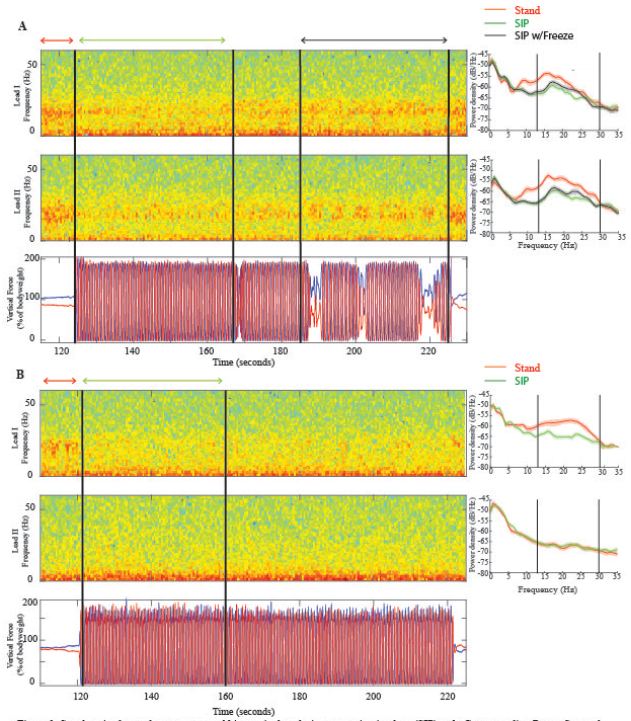

Figure 1. Synchronized neural spectogram and kinematic data during a stepping in place (SIP) task. Corresponding Power Spectral Density (PSD) of the spectograms are shown to the right. (A) Freezer: PSD epochs- stand period is 93-122 s, regular stepping period is 125-166 s and stepping with freezing period is 184-226 s. (B) Non-Freezer: PSD epochs - stand period is 85-117 s, regular stepping period is 120-160 s. Duration of time intervals were selected to maintain consistency in SIP and stand periods between Freezer and nFreezer. Lead II in the nFreezer was not stimulated as the patient does not exhibit PD symptoms on the contralateral body side.

Title: Subthalamic nucleus activity at gait initiation in Parkinson's disease: report of three cases

Authors: *N. G. POZZI[1], G. ARNULFO[1,3], F. STEIGERWALD[1], V. MALTESE[1], C. PALMISANO[1,4], J. BRUMBERG[2], M. M. REICH[1], E. PAVAN[4], J. VOLKMANN[1], I. U. ISAIAS[1];
[1]Dept. of Neurol., [2]Dept. of Nuclear Med., Uni. Hosp. and Julius-Maximilian-University, Wuerzburg, Germany; [3]Dept. of Informatics, Bioenginering, Robotics and Syst. Engin., Univ. of Genoa, Genoa, Italy; [4]Movement Biomechanics and Motor Control, TBM lab, DEIB-Politecnico di Milano, Milan, Italy

Abstract: Background: Gait initiation is defined as the transient state between standing and walking. It is affected in Parkinson's disease (PD) and its impairment is a hallmark of disease progression. Despite Deep Brain Stimulation of the Subthalamic nucleus (STN DBS) has shown to remarkably improve PD symptoms, its effect on gait and posture is still debated. Actually, the physiological role of STN in gait and posture is largely unknown. For the first time we were able to record STN activity (Local Field Potential, LFPs) during locomotion. **Methods:** LFPs were recorded in three patients by means of the Activa PC+S® (Medtronic® Inc., Minneapolis, USA). We also measured striatal dopaminergic innervation by means of [^{123}I]FP-CIT and SPECT. Gait initiation was defined with motion capture system (SIMI Motion System®, Muenchen, DE) and force plates (Kistler, AG) measurements in meds-OFF and -ON state (L-dopa challenge test). Subjects stood upright and started walking, at a natural (preferred) speed when receiving a visual cue. Four phases were identified: (i) *standing* (ST); (ii) *anticipatory postural adjustment (APA):* form ST to instant of heel-off of the leading foot (HO_{ld}); (iii) *gait initiation (GI):* from HO_{ld} to toe-off trailing foot (TO_{tr}); (iv) *walking*. Beta band was defined (±5Hz to patient frequency peak) and data from each subject were normalized to their *standing* condition. **Results:** The main finding was a beta activity reduction during *GI* compared to *APA* (STN_{right}: -93% *GI* vs. *APA*, -1% *GI* vs. *walking*; STN_{left}: -43% *GI* vs. *APA*, -1% *GI* vs. *walking*). No clear difference was observed with regards of the STN ipsi- or contralateral to the leading foot. Interestingly, the right STN, with greater beta activity reduction, happened to be -in all subjects- ipsilateral to the striatum with less dopaminergic innervation loss. Lastly, we confirmed the effect of L-Dopa in suppressing the beta over-activity in all the gait phases. **Conclusion:** Despite being preliminary and in a limited number of subjects, our data suggest a selective involvement of the STN in different gait phases, corroborating the hypothesis of ß-synchrony reduction in movement initiation. In PD subjects, dopamine depletion may lead to an STN inter-neuronal over-activity, which enforces neuronal synchrony in the ß-frequency range. Accordingly, in our study a greater STN modulation was found ipsilateral to the striatum with greater dopaminergic innervation.

Title: Deep brain stimulation: measuring gait parameters objectively using kinematic technologies in Parkinson's disease patients

Authors: *G. GILMORE[1], M. DELROBAEI[2], S. TRAN[2], T. STRATTON[2], M. JOG[3]; [1]Clin. Neurolog. Sci., Western Univ. Hosp., London, ON, Canada; [2]Western Univ., London, ON, Canada; [3]London Hlth. Sci. Ctr., London, ON, Canada

Abstract: Background and Aim: Gait impairments are a hallmark symptom of PD often contributing to patient falls and reducing quality of life. Specifically, it remains unclear whether PD gait improves or worsens with DBS intervention over a long-term. Currently gait changes are monitored using the Unified Parkinsons Disease Rating Scale, which is subjective and qualitative in nature. An objective and quantitative assessment of gait, using kinematic technology, will allow the clinician to more effectively determine whether gait is affected by DBS. Kinematic sensor technologies that are targeted to specifically studying gait are a new avenue being explored to monitor the gait changes with DBS. The goal of the present study is to assess the progression of gait changes, following DBS intervention, over a year long period using kinematically based gait measures. **Methods:** 24 PD participants undergoing bilateral STN-DBS alongside 24 healthy age-matched controls will be used in the study. The participants will be recruited from the Movement Disorder Clinic at the University Hospital in London, Ontario. STN-DBS participants are assessed one week pre-operatively and then up to one year post-operatively. The participants gait is captured using the Zeno walkway and the PKMAS software. The carpet provides spatio-temporal gait parameters, including: stride length, stride width, gait cycle, center of mass/pressure and single/double support time. The study has been approved by the university ethics committee and each participant has signed informed consent. **Results:** 10 of the total patients have completed the 6 month session. Preliminary data has shown an improvement in important areas of gait performance up to 6 months post-operatively. Stride length (Pre-op: *M*=99.87 cm, 6 months: *M*=112.22 cm, z = 2.427, p = .015) and step length (Pre-op: *M*=47.53 cm, 6 months: *M*=59.89 cm, z = 2.501, p = .012.) both increased from pre-operative baseline. Double support time decreased from PD pre-operative baseline (Pre-op: *M*=.30 sec, 6 months: .26 sec, z = -2.259, p = .024). There was no change in stride width (Pre-op: *M*=7.86 cm, 6 months: *M*=8.56 cm, z = .224, p = .823) and cadence (Pre-op: *M*=110.82, 6 months: *M*=112.70,

z = .709, p = .478). **Conclusions:** Preliminary data analysis suggests STN-DBS intervention may improve gait over a 6 month period post-operatively. Further analysis, up to 1 year post-operation, will better elucidate the long-term efficacy of DBS intervention on gait. Our method provides the first objective and quantitative measure of long-term gait variances in PD patients undergoing DBS treatment.

Title: DBS improves gait speed in Parkinson's disease: a meta-analysis

Authors: *J. ROPER[1], J. H. CAURAUGH[1], N. KANG[2], J. BEN[1], M. OKUN[1], C. J. HASS[1]; [1]Univ. of Florida, Gainesville, FL; [2]Univ. of Florida, University of Florida, FL

Abstract: Gait speed is often considered a clinical vital sign. In Parkinson's disease (PD), slow gait speed is significantly related to clinical ratings of disease severity, impaired performance of daily activities, as well as increased overall disability. We conducted a systematic review and meta-analysis that analyzed the effects of deep brain stimulation (DBS) surgery on gait speed in patients with PD to gain fundamental insight into the nature of therapeutic effectiveness. A random effects model meta-analysis on 28 studies revealed a significant overall standardized mean difference medium effect size equal to 0.61 (SE = 0.06; p < 0.0001; Z = 10.80; I2 = 0.00%). Analysis of the 12 studies that tested the effects of DBS on gait speed in participants on medication showed an overall effect of 0.56 (SE = 0.09; p < 0.0001; Z = 6.32; I2 = 0.00%). Analysis of the 16 off medication studies revealed a significant medium effect size (ES = 0.64; SE = 0.09; p < 0.0001; Z = 8.77; I2 = 0.00%). Seven studies reported the effects of unilateral stimulation, and the analysis indicated a significant ES = 0.57 (SE = 0.09; p < 0.0001; Z = 6.14; I2 = 0.00%). Further, analysis of the 21 bilateral DBS studies revealed a significant standardized effect = 0.63 (SE = 0.07; p < 0.0001; Z = 8.89; I2 = 0.00%). Thus, DBS provided simultaneously to both hemispheres shows a slightly higher ES. The effects of DBS on gait speed were similar in the data collection sessions after surgery (n=22) (DBS on vs. off) than data collection before surgery (n =6). Both subgroup analyses indicated significant standardized mean effects: (a) pre-surgery: ES = 0.62; SE = 0.19; p = 0.001; Z = 3.33; I2 = 43.51% and (b) post-surgery data

collection only: ES = 0.62; SE = 0.06; p < 0.0001; Z = 9.95; I2 = 0.00%). Based on our synthesis of the 28 studies, we determined the following: 1) DBS improves gait speed in persons with PD; 2) DBS improved gait speed regardless of whether the patients were tested off medication or on medication; 3) Bilateral DBS led to a slightly higher improvement in gait speed compared to unilateral DBS; and 4) The effects of DBS on gait speed were greater in the data collection sessions after surgery (DBS on vs. off) than comparisons made to gait speed before surgery (before surgery vs. DBS after surgery). In sum, the current analysis provides robust evidence that DBS provides a therapeutic benefit to gait speed in persons with PD.

Title: Temporal, but not spatial, gait variability is affected in persons with Essential Tremor

Authors: *S. AMANO[1], R. ROEMMICH[3], J. W. SKINNER[4], S. HONG[2], C. J. HASS[4]; [2]Biomed. Sci., [1]Ohio Univ., Athens, OH; [3]Kennedy Krieger Inst., Baltimore, MD; [4]Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: This experiment compared gait patterns of individuals with Essential Tremor (ET, n = 11; 66.0±7.7 years, 175.4±13.1cm, 92.2±23.6kg) and healthy older adults (HOA, n = 12; 63.6±7.8 years, 170.9±7.2cm, 75.7±13.3kg). Kinematic data were collected at 120 Hz using a 10-camera motion capture system while participants walked for 5 minutes on a split-belt treadmill at their preferred speed. Step length was calculated as the distance between ankle markers along the anteroposterior axis at heel-strike, and step time was calculated as the time between contralateral heel-strikes. Entropy of step length and step time were computed on the dominant (D) and non-dominant side (ND) individually to measure the unpredictability of step patterns of each side. Joint Entropy of step length and step time was then computed to measure the combined uncertainty across both limbs, allowing us to compute mutual information. Mutual information was normalized by joint entropy. Independent samples t-tests were performed on the dependent variables with significance set at p=0.05. Persons with ET exhibited significantly

higher step time entropy (D: 3.47±.59, ND:3.53±.58) than HOA (D: 2.64±.27, ND:2.56±.34; both p's<.01) on both limbs. However, step length entropy in the ET group (D: 4.25±.0.25, ND: 4.20±.27) did not differ from the HOA group (D: 4.16±.30, ND: 4.30±.17; both p's>.05). Similarly, persons with ET exhibited significantly higher joint entropy (6.20±.80) and mutual information (0.13±.08) associated with step time than the HOA group (4.86±.45; p<.01, and 0.07±.04; p=.05, respectively), while joint entropy (7.05±.40) and mutual information (0.20±.09) in step length for the ET group did not differ from those for the HOA group (7.21±.25, and 0.17±.03 respectively; both p's>.05). An important finding is that ET seems to affect temporal (step time), but not spatial (step length) variability in gait patterns. These results indicate that stepping patterns are more uncertain in persons with ET if examined at the level of the individual limb. However, higher mutual information values indicate that the entropy in gait patterns is actually shared across both limbs. Thus, while each limb behaves more unpredictably, their collective uncertainty is more restricted than in HOA, perhaps reflecting dedifferentiation of temporal motor patterns. These results are consistent cerebellar deficits (impaired temporal control of movement) in gait in ET.

Title: Effects of potential therapeutics on the behavior of mice treated with chronic MPTP

Authors: *S. A. FERGUSON, D. LAW, S. SARKAR;
Natl. Ctr. Toxicological Res., Jefferson, AR

Abstract: The chronic MPTP+probenecid (MPTPp) treatment paradigm has been used to successfully model the neurochemical, neuropathological, and behavioral effects associated with Parkinson's Disease. Here, the effects of 6 different potential therapeutic compounds to attenuate MPTPp-related behavioral alterations were assessed. Adult male C57Bl/6 mice (n=6/group) were injected ip with 25 mg/kg MPTP and 250 mg/kg probenecid (MPTPp) or probenecid only twice weekly for a total of 10 injections. Prior to the MPTPp treatment, mice were exposed to one of 6

potential therapeutic agents which continued until the last MPTPp injection: morin (10 mg/kg/day, oral), tetramethylpyrazine (TMP) (20 mg/kg/day, ip), tauroursodeoxycholic acid (TUDCA) (500 mg/kg/day, ip), pomalidomide (15 mg/kg/day, ip), dimethylaminoethylamino-17-demethoxygeldanamycin (DMAG) (2 mg/kg, 3x/week, ip), trehalose (2% in water bottle daily). Thus, there were 8 treatment groups: 1) MPTPp, 2) probenecid only, 3) morin+MPTPp, 4) TMP+MPTPp, 5) TUDCA+MPTPp, 6) pomalidomide+MPTPp, 7) DMAG+MPTPp, and 8) trehalose+MPTPp. Motor coordination and locomotor activity were assessed before (i.e., baseline) and after therapeutic and MPTPp treatment. Body weight was unaffected by any treatment. Motor coordination performance of the DMAG+MPTPp group was superior to the MPTPp group. Locomotor activity was significantly increased in the second post-treatment session in the TUDCA+MPTPp and trehalose+MPTPp groups relative to the MPTPp group. No other potential therapeutic compound produced significant effects. Effects of DMAG on motor coordination are difficult to interpret as baseline performance was also increased. Increased locomotor activity during the second post-treatment session by the TUDCA+MPTPp and trehalose+MPTPp groups might indicate poor habituation. These results suggest that at these doses, there are few effects of these 6 agents on the behavior of MPTPp-treated male mice. (Supported by NCTR/FDA Protocol E7512)

Title: Squamosamide derivative FLZ attenuates α-synuclein-induced neurotoxicity by activating heat shock protein 70 function in transgenic mouse model of Parkinson's disease

Authors: *D. ZHANG, X. BAO;
Inst. of Materia Medica, Beijing, China

Abstract: Parkinson’s disease (PD) is the second most prevalent neurodegenerative disease. The pathologies of PD are progressive degeneration of dopaminergic neurons in the substantia nigra pars compacta and the presence of distinct intracellular inclusion with the major component of α-synuclein, known as Lewy bodies. Subtantial evidences linked aggregated α-synuclein to familial and sporadic forms of PD. Heat shock proteins (HSPs) are highly conserved molecular chaperones, which are crucial to control protein aggregation in neurodegenerative diseases. In

particular, the 70-kDa heat shock protein (HSP70) was shown to interact with α-synuclein, prevent α- synuclein aggregation and protect neurons against toxicity induced by α- synuclein, thus shows neuroprotective effects in PD models. FLZ (formulated as: N-(2-(4-hydroxy-phenyl)-ethyl)-2-(2, 5-dimethoxy-phenyl)-3-(3-methoxy-4-hydroxy-phenyl)-acrylamide, the code name: FLZ), a natural squamosamide derivative from a Chinese herb, has been shown to protect several *in vivo* and *in vitro* PD models in previous studies, and FLZ was reported as HSPs inducer to protect against MPP^+-induced neurotoxicity, but the mechanism remains unclear. In this study, we investigated the possible beneficial effects of HSP70 induced by FLZ treatment in α-synuclein (A53T) transgenic mice and cells. The results showed that FLZ treatment alleviated motor dysfunction, improved dopaminergic neuronal function of α-synuclein transgenic mice. Treatment of FLZ elicited a pronounced reduction of α-synuclein aggregation and toxicity both *in vivo* and *in vitro*. Moreover, FLZ treatment produced a remarkable production of HSP70 protein expression, together with a significant increase in HSP70 transcriptional activity. Notably, inhibition of HSP70 expression by quercetin or HSP70 siRNA markedly attenuated the neuroprotective effects of FLZ. *In vitro* mechanistic study revealed that the inducible effect of FLZ on HSP70 was mediated by its interaction with the co-chaperone of HSP70. FLZ treatment increased the expression of Hip, one co-chaperone of HSP70, and directly bound to Hip, thus up-regulated HSP70 system function. In conclusion, the present study supported that FLZ exerts neuroprotection against α-synuclein -induced neurotoxicity, which is mediated by binding to Hip and up-regulating HSP70 function. Furthermore, this study defined a critical role of HSP70 and its co-chaperones in neurodegeneration, and suggested that particular approach targeting HSP70 may be a potential treatment for α-synuclein related diseases such as PD.

Title: Pharmacological blockade of dopamine D3 receptor attenuates l-dopa-induced dyskinesia by targeting d1 receptor-mediated striatal signaling

Authors: *O. SOLÍS CASTREJÓN[1,2], J. R. GARCIA-MONTES[1,2], M. XU[3], R. MORATALLA[1,2];
[1]Cajal Inst., Madrid, Spain; [2]CIBERNED, Inst. de Salud Carlos III, Madrid, Spain; [3]Dept. of Anesthesia and Critical Care, The Univ. of Chicago, Chicago, IL

Abstract: The dopamine D3 receptor (D3R) belongs to the dopamine D2-like receptor family and is principally located in the ventral part of the striatum. However, previous studies have reported an overexpression of D3R in the dorsal striatum following L-DOPA treatment in dopamine-denervated striatum. This has drawn attention to the importance of D3R in L-DOPA-induced dyskinesia (LID). To study the role of D3R in LID, we assessed the effects of PG01037 (D3R-preferring antagonist) on LID in the 6-OHDA mouse model of Parkinson's disease (PD). Mice were treated with L-DOPA (10 mg/kg) followed by PG01037 (10 mg/kg) after 15 min (to evaluate the effect in the expression and development of LID). Axial, limb and orolingual dyskinetic symptoms were evaluated as abnormal involuntary movements and the rotarod test used as a measure of the antiparkinsonian effect of L-DOPA. Alterations in FosB and histone3 (pAcH3) activation were examined by immunohistochemistry 1 h after the last L-DOPA injection. PG01037 treatment to hemiparkinsonian mice decreased dyskinesia development upon chronic exposure to L-DOPA, attenuating dyskinesia once established, without affecting the antiparkinsonian effect of L-DOPA. The expression of FosB and pAcH3 was associated with the development and expression of dyskinesia. Moreover, PG01037 significantly reduced FosB and pAcH3 when co-administered with L-DOPA. We demonstrate that targeting D3R can modify both the behavioral and molecular consequences of L-DOPA treatment. Together, our results demonstrate that D3R modulates the development of dyskinesia by targeting D1R-mediated intracellular signaling and suggest that decreasing D3R activity may help to ameliorate LID.

Title: Orally-active highly effective fast-onset long-acting dopamine D3/D2 agonists in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated macaque model of Parkinson's disease

Authors: *G. PORRAS[1], H. STARK[2], T. KOTTKE[2], E. Y. PIOLI[3], A. CROSSMAN[3], E. BEZARD[3];
[1]Motac, Manchester, United Kingdom; [2]Inst. fuer Pharmazeutische Chemie, Johann Wolfgang Goethe-Universitate, Fankfurt, Germany; [3]MOTAC, Manchester, United Kingdom

Abstract: Introduction. Dopamine replacement therapy with L-DOPA or D2/D3 dopamine receptor agonists remains the gold standard treatment for Parkinson's disease. However, both strategies take several minutes to act and are therefore inefficient to alleviate sudden OFF events in fluctuating patients. While the D2/D3 agonists are less dyskinesiogenic than L-DOPA, they also convey lower antiparkinsonian activity. The ideal profile of a dopamine receptor agonist should thus feature (i) an oral administration to ease administration, (ii) a long-acting profile to reduce daily intake, (iii) a fast onset of action to potentially improve OFF events and (iv) an antiparkinsonian activity comparable if not better than L-DOPA. We here present a new dopamine D2/D3 agonist, ST-836, which fulfils these criteria and shows a promising toxicology profile. Methods. Parkinsonian symptoms were produced in 6 fascicularis macaques by daily administration of MPTP (0.2 mg/kg, i.v.). Regular treatment with L-DOPA resulted in the development of dyskinesia. PD motor disability, dyskinesia and on-time were assessed following oral administration of ST-836 (0.1, 1 and 10 mg/kg) in comparison to L-DOPA, ropinirole and pramipexole at therapeutically relevant doses. Results. ST-836 dose-dependently rapidly improved parkinsonian symptoms despite oral administration, decreased disability score comparably to L-DOPA over time, dramatically increased on-time while also increasing the good on time (i.e. with less dyskinesia) compared to L-DOPA but also compared to ropinirole and pramipexole. Conclusions. ST-836, therefore, bears the potential for becoming the first dopamine receptor agonists therapeutically superior to both L-DOPA and existing agonists, requiring in addition a single daily administration.

Title: Nicotine reduces levodopa-induced dyskinesia but not striatal dopamine release in the intrastriatal 6-hydroxydopamine mouse model of Parkinson's disease

Authors: *S. LEINO, L. AALTONEN, S.-T. PELTOLA, O. SALMINEN;
Univ. of Helsinki, Helsinki, Finland

Abstract: Parkinson's disease is a neurodegenerative motor disorder, where the death of dopaminergic neurons of the nigrostriatal pathway results in loss of dopamine in the dorsal striatum. Treatment with levodopa is effective but often complicated by levodopa-induced dyskinesias (LIDs). The mechanisms of LIDs remain unclear and treatment options are sparse. Among promising drug targets for treating LIDs are nicotinic acetylcholine receptors (nAChRs). Preclinical studies have shown that both nicotinic agonists and antagonists can reduce LIDs, and nAChR subtypes expressed on striatal dopaminergic terminals are implicated in these effects (Quik et al. 2013, Biochem Pharmacol 86). In rats the antidyskinetic effect of nicotine is associated with a decrease in nAChR-mediated release of [3H]dopamine (DA) from striatal synaptosomes (Bordia et al. 2013, J Neurochem 125). Antidyskinetic effects of nicotine have therefore been suggested to result from desensitization of striatal nAChRs. We studied the effects of chronic nicotine treatment on LIDs and striatal nAChR-mediated dopamine release in mice with unilateral dopaminergic denervation. Mice were lesioned with intrastriatal injections of 6-hydroxydopamine (6-OHDA), as the antidyskinetic effect of nicotine after intrastriatal lesioning has not been studied previously. After recovery, mice were given daily injections of levodopa (30 mg/kg) and benserazide (12 mg/kg). Nicotine treatment in drinking water (up to 300 μg/ml) was started simultaneously with the levodopa treatment. LIDs were rated weekly using a validated scale for mice (Cenci & Lundblad 2007, Curr Protoc Neurosci 41). nAChR-mediated dopamine release was investigated by measuring nicotine-induced [3H]DA release from synaptosomes prepared separately from dorsal and ventral striata. Chronic nicotine treatment resulted in lower LID severity in the lesioned mice. 5 weeks after lesioning [3H]DA release from the lesioned hemisphere was markedly reduced. After 7-8 weeks of levodopa and nicotine treatment there were no differences in [3H]DA release compared to mice treated with levodopa only. Interestingly, after the chronic drug treatments the release of [3H]DA from the lesioned hemisphere had partially recovered, with the recovery being less prominent in mice treated with both levodopa and nicotine. In conclusion, while chronic nicotine treatment reduced LIDs in mice lesioned with intrastriatal 6-OHDA injections, striatal dopamine release assays showed no decline in nAChR function. These results suggest that the antidyskinetic effect of nicotine in mice may be mediated at least in part through other mechanisms than nAChR desensitization.

Title: Early functional changes induced by overexpression of α-synuclein in mouse dopamine and serotonin neurons: new therapeutic opportunities for antisense oligonucleotide treatment of Parkinson's disease

Authors: D. ALARCÓN-ARÍS[1], M. GALOFRÉ[2], E. RUIZ-BRONCHAL[2], A. FERRÉS-COY[2], A. MONTEFELTRO[3], F. ARTIGAS[2], I. FARIÑAS[4], M. VILA[5], *A. Abstract: Pathological changes in end-state of Parkinson's disease (PD) are well characterized from postmortem studies. However, there is an urgent need to identify early functional changes to develop new therapeutic strategies stopping the development of the illness. α-Synuclein is a protein that accumulates in the brain of patients with sporadic PD. Likewise, whole locus multiplications and point mutations in the α-synuclein gene cause a familial form of PD. To better understand the sequence of events occurring in PD, we generated a mouse model overexpressing the human wild-type α-synuclein in dopamine (DA) neurons from the substantia nigra (SN) or serotonin (5-HT) neurons from the raphe nuclei (RN). We used an adeno-associated virus type-5 (AAV5)-α-synuclein vector (kindly donated by MJF foundation), unilaterally injected in SN or RN, respectively. AAV5-α-synuclein mice showed increased human α-synuclein mRNA levels in the ipsilateral SN and RN over time which reached to a

maximal of 278 and 290% of sham mice (8 weeks post-infection), whereas the expression of endogenous α-synuclein remained unaltered. Immunohistochemistry analysis confirmed these results showing the presence of increased human α-synuclein and phospho-α-synuclein levels; but, the mice did not display any loss of tyrosine hydroxylase-(TH)-positive DA neurons or tryptophan hydroxylase-(TPH2)-positive 5-HT neurons 16 weeks post-injection. However, impairments in DA or 5-HT release paralleled development of α-synuclein-positive axonal swelling in the striatum, hippocampus and cerebral cortex at 4 weeks post-injection. Hence, local perfusion by reverse dialysis of the depolarizing agent veratridine (50μM) decreased DA and 5-HT release in the striatum of AAV5-α-synuclein mice injected in SN or RN. In addition, the effects of DA and 5-HT reuptake inhibitors nomifensine (1-10-50μM) and citalopram (1-10-50μM), respectively, on striatal DA or 5-HT levels were profoundly reduced in AAV5-α-synuclein versus sham mice. Moreover, these mice showed motor impairments at 8 weeks post-infection into SN and depressive-like behaviors (tail suspension and forced swim tests) at 4 weeks post-infection into RN. Recent data showed that intranasal treatment (30 days) with a conjugated antisense oligonucleotide targeting α-synuclein in DA and 5-HT neurons (ASO1233) reduced α-synuclein expression in these midbrain nuclei. Synaptic DA and 5-HT dysfunctions and axonopathy would thus be the hallmark of early-stage of PD and suggest that ASO targeted α-synuclein in monoamine neurons may lead to new therapies for PD.

Title: Dietary interventions with strong preventive and therapeutic effects on both motor and non-motor symptoms in a mouse model of Parkinson’s disease

Authors: *L. M. BROERSEN[1,2], P. PEREZ PARDO[2], H. DOUNA[2], E. M. DE JONG[2], N. VAN WIJK[1], A. ATTALI[1], J. GARSSEN[1,2], B. OLIVIER[2], A. D. KRANEVELD[2];

[1]Nutricia Res. Ctr., Utrecht, Netherlands; [2]Utrecht Inst. for Pharmaceut. Sci., Utrecht, Netherlands

Abstract: Introduction. Administration of dietary precursors and cofactors for membrane synthesis may enhance synapse formation relevant for neurodegenerative disorders. This approach may be relevant for PD, as preventive treatment with the precursors UMP and DHA reduced rotational behavior in unilateral 6-OHDA model (Cansev2008). The aim of the present study was to test the efficacy of dietary interventions in the rotenone model of PD, inducing both motor and non-motor symptoms, including gastrointestinal dysfunction. In addition, we tested the effects of an extended nutritional formula based on the same precursors. Method. Rotenone exposure in rodents is a frequently used model of PD since it reproduces brain and gut-related pathology and induces both motor and non-motor symptoms. Male C57Bl/6J mice received rotenone (5.4 ug) unilaterally in the striatum. Dietary interventions started either 1 week before (preventive) or 3 weeks after surgery (therapeutic). Readout parameters included behavioral tasks (rotarod, novel object discrimination, grip strength, and inverted screen test) and histological examination of brain and gut. Results. Rotenone induced clear deficits in all parameters, whereas dietary interventions clearly alleviated symptoms. Preventive treatment with precursors improved rotarod performance and intestinal transit time. Therapeutic treatment additionally alleviated rotenone-induced deficits in novel object discrimination, grip strength, and inverted screen test. Furthermore, our extended nutritional intervention was more effective than the diet providing membrane precursors only. Conclusion. This is the first study demonstrating a therapeutic effect of specific dietary interventions in a mouse model of PD. The improved efficacy of the extended nutritional intervention suggests synergies within our specific multi-nutrient approach. Brain and gut histology are currently being investigated.

Title: The therapeutic effects of environmental and physical enrichment on motor behavior in a 6-ohda rat model of Parkinson's disease

Authors: *R. A. WORTMAN[1], A. STAVNEZER[2];
[1]Neurosci., Col. of Wooster, Connellsville, PA; [2]Neurosci., Col. of Wooster, Wooster, OH

Abstract: Previous studies have indicated that an enriched environment and exercise are neuroprotective and promote the survival of dopaminergic neurons in the 6-OHDA rat model of Parkinson's Disease (PD). In this study, we demonstrate that exposure to a combination of environmental and physical enrichment improves performance on several behavioral measures. Environmental enrichment was characterized by group housing, in a multi-tiered environment with a variety of toys. Physical enrichment was characterized by forced treadmill exercise at 11 m/min for 20 minutes each day. For the Prevention+Treatment condition, the intervention of environmental and physical enrichment was started 21 days before a right hemisphere substantia nigra 6-OHDA lesion, and was then continued for 21 more days following a one-week recovery period. For the Treatment only condition, the intervention of environmental and physical enrichment was 7 days after a right hemisphere substantia nigra 6-OHDA lesion and continued for 21 days. Both groups demonstrated some improvement on balance beam, rotarod and cylinder task, but the Prevention+Treatment group performed better and was near the No lesion control performance on several tasks. This suggests that the Prevention + Treatment protocol strategy has a greater impact on building cognitive brain reserve, fostering cellular plasticity, and improving motor behavior in the 6-OHDA rat model of PD.

Title: Repeated pharmacological inhibition of the sGC-cGMP signaling pathway is equally effective as L-dopa in ameliorating motor deficits in experimental Parkinsonism

Authors: *V. R. JAYASINGHE[1], B. PHAM[2], V. VERMA[3], R. YOGENDRAN[3], A. R. WEST[3], K. Y. TSENG[2];
[2]Cell. and Mol. Pharmacol., [3]Neurosci., [1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: L-DOPA is by far the most effective pharmacological option currently available for treating motor symptoms in Parkinson's disease (PD). However, chronic treatment with L-DOPA often results in the development of side effects termed L-DOPA-induced dyskinesias. Here we compared the therapeutic action of L-DOPA to the potential utility of a non-dopaminergic target in ameliorating motor deficits using the well-known 6-OHDA rat model of parkinsonism and stepping behavior. One such target is the striatal sGC-cGMP signaling pathway, which becomes abnormally upregulated following chronic dopamine depletion. We found that systemic administration of the sGC-cGMP inhibitor ODQ improved stepping performance in 6-OHDA-treated rats over the course of the 7-day treatment period in a dose-dependent manner (5-20 mg/kg/day, i.p.). Notably, the stepping improvement was sustained for up to 72 h following the last treatment, particularly in the 20 mg/kg dose group. Systemic administration of L-DOPA also resulted in comparable dose-dependent improvements in stepping performance over the course of 7 days (2.5 and 5 mg/kg/day, i.p.) to those observed with ODQ. However, approximately 50% of rats that received the 5 mg/kg dose of L-DOPA developed dyskinesias by the end of the 7-day treatment period. Collectively, these results demonstrate that repeated inhibition of the sGC-cGMP signaling is as effective as L-DOPA in improving motor behavior in dopamine-depleted rats with the advantage that it does not induce dyskinesias. Thus, pharmacological downregulation of striatal sGC-cGMP-PKG signaling may be a superior non-dopaminergic therapy for treating motor dysfunction observed in patients with PD.

Title: Evaluation of the effects an implant TiO2DA inserted in the caudate in rat model hemiParkinsonism on motor behavior and its relationship to the levels of catecholamines

Authors: ***A. S. ROJAS**[1], G. VALVERDE AGUILAR[3], M. PALOMERO RIVAS[4], M. VELAZQUEZ PANIAGUA[2], I. SANCHEZ CERVANTES[2], I. LOPEZ MARTINEZ[2], R. MAYEN DIAZ[2], D. VAZQUEZ MATIAS[2], R. GONZALEZ TREJO[2], K. PINEDA ROMERO[2], P. VERGARA ARAGON[2];
[2]Physiol., [1]Fac. of Medicine, Natl. Autonomous Universit, Mexico City, Mexico; [3]CICATA Legaria, IPN., Mexico City, Mexico; [4]Cell. Physiol. Institute, UNAM., Mexico City, Mexico

Abstract: Introduction. Parkinson's disease(PD) is characterized by motor symptoms (rigidity, tremor, postural instability and bradykinesia) and non-motor symptoms: anxiety, depression, chronic fatigue and sleep disorders. Anxiety and depression affect 40% of PD patients mainly associated with three neurotransmitters; dopamine, norepinephrine and serotonin. It has been established that the decrease in dopamine transporters in the mesolimbic pathway structures contribute to anxiety disorder. Currently they are looking for alternative treatments to counteract the symptoms in PD. Objective. Determine the effects that an implant TiO2DA inserted in the caudate in a rat model hemiparkinsonism on motor behavior and its correlation with the levels of dopamine, adrenaline and serotonin. Material and/or methods. Male wistar rats(250-300gr) were used, which were randomly divided into 4 groups: a)control b)injury (Lx); c)Lx+implant; d)implant. Post-injury for 21 days anxiety behavior and locomotor activity of the rats of each group through the open field test was evaluated. The test was conducted in an acrylic box (with transparent walls and floor), whose floor is divided with painted black lines formings squares and iluminated with floodlights. The test was recorded for five minutes, the following measurement parameters were assessed: total distance traveled and the number of crossed lines marked on the floor. The tests were recorded. In each group, determinations adrenaline levels, 5HT and striatal dopamine were performed, by HPLC. Results. In the open field test it was found that the group of rats Lx group had lower locomotor activity relative to the control group rats. The Lx+implant group showed significant changes in locomotor activity compared to the group with Lx group being similar in the control group and the implant group showed an increase in locomotor activity producing a state of hyperactivity. HPLC Lx group showned a decreased DA, A and 5-HT in striatum. Conclusions. Implant placement (TiO2DA) in rats hemiparkinsonian improved locomotor activity due to increased levels of DA in striatum and increased in the concentrations of 5HT in striatum, that correlating with an improvement in the condition of adaptability, characterized by decreased anxiety state.

Title: The effects of clinically used anti-Parkinsonian drugs on whole-body kinematics in the MPTP-treated macaque model of Parkinson's disease: therapeutic validation of a translational platform for movement disorder research

Authors: *D. W. KO[1], I. VOLLENWEIDER[2], L. BAUD[2], Q. LI[1], G. COURTINE[2], E. BEZARD[3];
[1]Motac Neurosci. Ltd, Greater Manchester, United Kingdom; [2]Ctr. for Neuroprosthetics and Brain Mind Inst., Swiss Federal Inst. of Technol., Lausanne, Switzerland; [3]Inst. of Neurodegenerative Dis., Univ. of Bordeaux, Bordeaux, France

Abstract: Anti-parkinsonian treatment therapies are often developed in preclinical studies that utilise animal models of Parkinson's disease but translation into clinical benefit remains uncommon. A major contributing factor to this predicament is an inconsistency in methodological approaches between preclinical and clinical research. There is a lack of consensus on the most appropriate measures for rating motor performance and defining useful experimental endpoints. In this study, we employ the translational experimental platform of whole-body kinematic analyses in MPTP-treated macaques, the gold-standard model for parkinsonian motor symptoms, for evaluating clinically proven anti-parkinsonian agents. Animals were first trained to perform unconstrained locomotor tasks, following which the effects of pharmacological treatments were tested in the same conditions. The functional impact of drug treatment on gait, posture and limb dysfunction were determined using quantitative biomechanical analyses and objective statistical procedures. These unbiased quantitative analyses of motor function during unrestricted movement execution allowed mechanistic identification of clinically effective treatments against parkinsonian motor disabilities (i.e. L-DOPA, pramipexole, ropinirole, amantadine and istradefylline). The high resolution of these analyses dissociates specific clusters of motor control parameters that are improved from those that remain affected. For example, L-DOPA enhanced movement velocity and stride length

during walking, but had no effect on stance duration or foot elevation. These recording methodologies and analytical tools for assessment of motor control capacities are readily transferable to a clinical setting, offering an efficient and reliable avenue for predicting and evaluating therapeutic benefit of novel treatment strategies. This experimental platform and methodological approach, which has been validated in human patients, bridges the gap between preclinical and clinical research. Together, these tools support (i) greater translational efficacy of novel therapeutic interventions and (ii) objective fine-tuning of existing drug treatments used in patients with parkinsonian or other neuro-motor disorders.

Title: Cannabis resin extract in Parkinson’s disease: behavioral, neurochemical, and histological evaluation

Authors: *S. A. EL SHEBINEY;
Narcotics, Natl. Res. Ctr., Cairo, Egypt

Abstract: Levodopa is the first therapeutic strategy for the treatment of Parkinson’s disease (PD) but motor drawbacks associated with long-term use limit its usefulness, emphasizing the search for other agents. The current study aimed at evaluating the modulatory role of cannabis resin extract in a rotenone model of PD based on a clinical report providing evidence for the amelioration of motor deficits in some PD patients by cannabis. Male Swiss mice received rotenone (1.5 mg/kg/48h, s.c., 6 injections). Cannabis resin extract (5, 10, and 20 mg/kg expressed as Δ9-tetrahydrocannabinol, i.p.) or levodopa (25 mg/kg, p.o.) was given daily alone or concomitantly with rotenone for 15 days. Rotenone induced marked PD features, characterized by depressed motor behavior, assessed by wire hanging test. This was

accompanied by decrease in striatal dopamine, norepinephrine, glutathione, adenosine triphosphate (ATP), γ-aminobutyric acid (GABA), paraoxonase 1 (PON1) activity, and tyrosine-hydroxylase immunoreactivity (TH-ir). On the other hand, elevation in glutamate, serotonin, lipid peroxides, nitric oxide, and lactate dehydrogenase (LDH) contents were noticed. Rotenone evoked a memory deficit as recognized by water maze test. Though cannabis resin extract did not affect memory impairment nor histopathological changes induced by rotenone, it improved the motor deficit induced by rotenone exposure at the highest dose level. These effects were associated by restored striatal catecholamines content, as well as decreased oxidative and nitroactive stress markers that were reflected by restored brain LDH, ATP, and PON1 levels. However, cannabis resin extract neither affected TH-ir nor the concentrations of glutamate, serotonin, and GABA. The present work displays that cannabis resin extract ameliorates motor deficits elicited by rotenone, via enhancement of dopamine in the striatum, its antioxidant and antinitrosative properties but without improvement in memory or degenerative changes.

Title: D-512, a novel dopamine D2 / D3 receptor agonist, demonstrates superior anti-Parkinsonian efficacy over ropinirole in Parkinsonian rats

Authors: *D. LINDENBACH[1], S. MEADOWS[1], Y. AVNOR[1], E. NUSS[1], M. MELKHOV-SOSIN[1], L. GROSS[1], N. VILCEUS[1], N. SCHUMAN[1], B. DAS[2], A. K. DUTTA[2], C. BISHOP[1]; [1]Psychology, Binghamton Univ., Binghamton, NY; [2]Pharmaceut. Sci., Wayne State Univ., Detroit, MI

Abstract: Parkinson’s disease (PD) is a movement disorder commonly treated with dopamine receptor agonists, such as ropinirole, which target D2 and D3 receptors. Although symptomatically effective, D2/D3 agonists typically have moderate half-lives and provide little

to no disease-modifying effects. Recently, a novel D2/D3 agonist, D-512, was shown to provide protracted motor activation and neuroprotection in rodent models of PD (Santra et al., 2013, Shah et. al., 2014). Extending upon this work, in the present experiment, D-512 and the clinically-employed agonist ropinirole were directly compared for: degree and length of anti-Parkinsonian effects, propensity to evoke dyskinesia (a drug side effect), and ability to restore dopamine cell viability. To examine these effects, we used the 6-hydroxydopamine lesion rat model of PD. Three weeks after lesion, rats were given daily injections of ropinirole (0.7 - 5.1 μmol/kg), D-512 (1.0 - 8.6 μmol/kg) or vehicle for 22 d and monitored for PD status, spontaneous movement and dyskinetic behavior. The next day, animals were transcardially perfused with formaldehyde for examination of the number of remaining DA cells in the substantia nigra pars compacta. Results show that, compared to ropinirole, D-512 provided a longer duration of motor activation and anti-Parkinsonian benefit. Both drugs elicited similarly mild levels of dyskinesia. Investigations into potential neurorestorative effects of D-512 are ongoing. Our data provide pre-clinical evidence that D-512 is superior to an available dopamine receptor agonist, suggesting further investigations are warranted.

Title: Effects of a titanium dioxide dopamine loaded microimplant on Susbtantia Nigra neuron density and rotational behavior in a hemiParkinsonian rat model

Authors: *R. MAYEN DÍAZ[1,2], I. LOPEZ MARTINEZ[3], I. SÁNCHEZ CERVANTES[2], D. VÁZQUEZ MATÍAS[2], E. FRAGOSO ALCALÁ[3], R. GONZALEZ TREJO[2], K. PINEDA ROMERO[2], A. SOLANA ROJAS[2], M. VELAZQUEZ PANIAGUA[2], M. PALOMERO RIVAS[4], M. VALVERDE AGUILAR[5], P. VERGARA ARAGÓN[2];
[1]Univ. Nacional Autónoma De México, Ciudad DE Mexico, Mexico; [2]Dept. of Phisiology Fac. of Med., [3]Cell and Tissue Biol. Dept. Fac. of Med., [4]Cell. Physilogy Inst., UNAM, Mexico City, Mexico; [5]CICATA Legaria, IPN, Mexico City, Mexico

Abstract: The purpose for this study was to evaluate the effects produced by microimplant TiO2DA, placed in striatum on a model of hemiparkinsonian rats, over the motor alterations, neuronal density in Substantia Nigra and determine whether exists an association between neuron density and induced spin behavior . Materials and Methods: For this study were used 40 male Wistar rats divided in 4 groups: A) 10 control rats: (Control), B) 10 injured rats by administration of the dopaminergic specific neurotoxin (6-OHDA 8µg/4µl) by stereoscopic surgery in left or right median forebrain bundle: (Lx), C) 10 rats with the same lesion and the colocation of an titanium dioxide implant: (Lx+TiO2DA) , and D) 10 rats only with the colocation of implant: (TiO2DA). 21 days after the injury all the groups underwent to apomorphine induced rotation test (0.05 mg/kg, sc) during 50 minutes to determine damage in dopaminergic system, this test was performed again 360 days after the colocation of the implant. Once finalized the test, the animals were slaughtered to obtain the brains and the neuron density was analyzed by optical microscopy. p values <0.0001 were considered significant. Results: In induced rotation test there were 5 significant results, Lx group showed more spins realized, than implanted and control groups: control vs Lx (4.4±2.6 vs 301.3±19.0), control vs Lx+TiO2DA (4.4±2.6 vs 31.8±14.9), Lx vs Lx+TiO2DA (301.3±19.0 vs 31.8±14.9), Lx vs TiO2DA (301.3±19.0 vs 9.5±7.1), and Lx+TiO2DA vs TiO2DA (31.8±14.9 vs 9.5±7.1). In the assessment of neuron density on the left side there were 5 significant results where the implanted and control groups, which displayed higher density than injured groups: Control vs Lx (8.3±1.5 vs 0.5±0.5), control vs Lx+TiO2DA (8.3±1.5 vs 5.7±1.0), Lx vs Lx+TiO2DA (0.5±0.5 vs 5.7±1.0), Lx vs TiO2DA (0.5±0.5 vs 9.5±1.5), Lx+TiO2DA vs TiO2DA (5.7±1.0 vs 9.5±1.5). On the right side there were 3 significant results where the implanted and control groups had higher neuron density than injured groups: control vs Lx (8.8±1.2 vs 4.8±0.8), Lx vs Lx+TiO2DA (4.8±0.8 vs 7.8±1.5), and Lx vs TiO2DA (4.8±0.8 vs 9.6±3.0). The Pearson correlation between neurons on the left and right side and spins on the induced rotation test showed a negative association: r= -0.9458; r= -0.9641. Conclusion: The microimplant achieves to revese the hemipakinsonims, as observed in our Lx+TiO2DA rats who diminish their number of spins. Likewise, Lx+TiO2DA rats displayed a higher neuron density than injured rats. The correlation analysis reported an inverse relation between neuron density and the number of spins.

Title: Drp1 inhibition amelioratesα-synuclein-mediated neurodegeneration in rats

Authors: *S. BIDO[1], L. ARCURI[1], M. HELLEY[2], R. FAN[2], K. TIEU[2], E. BEZARD[1]; [1]CNRS UMR 5293, Inst. des Maladies Neurodégénératives, Bordeaux, France; [2]Plymouth Univ., Plymouth, United Kingdom

Abstract: In Parkinson's disease the α-synuclein (α-syn) accumulation in the dopaminergic neurons can overburden the clearance mechanisms, increase production of reactive oxygen species, and induce imbalanced mitochondrial dynamics, thus eliciting the necrosis/apoptosis pathways that finally culminate in cellular death. Fusion and fission play an important role in the regulation of mitochondria dynamics. The disruption of this equilibrium can lead to the induction of apoptosis/necrosis pathway. It has been reported that inhibition of the mitochondrial fission dynamin-related protein 1 (Drp1) has protective effects in different *in vitro* and in-vivo models with mitochondrial dysfunction. In order to investigate whether inhibition of Drp1 could be effective in reducing the neurotoxicity caused by the overexpression of α-syn, we used rats overexpressing the mutated form of α-syn (A53T) specifically in the substantia nigra pars compacta (SNc) and treated them chronically with the Drp1 inhibitor mdivi-1. After eight weeks of daily injection of mdivi-1 (twice a day) or vehicle, we sacrificed the animals and processed the brain for the immunohistochemistry assays. Rats that received mdivi-1 displayed a significant reduction of the phenotype and neurotoxicity induced by A53T compared with the vehicle treated animals. The mechanisms of this neuroprotection are being investigated. Using ecdyson-inducible dopaminergic neuronal cells, mdivi-1 improved mitochondrial function 48h after α-syn expression. Furthermore, because mdivi-1 blocks Drp1, which induces apoptosis, we try to understand which necrotic/apoptotic pathway is mostly regulated by the mitochondrial fission/fusion process. With this study we provide new insights on the relationships occurring between mitochondria physiology and α-syn accumulation, thereby providing an already-exploitable pharmacological tool to counteract the neurodegenerative process.

Title: Therapeutic potential and antidyskinetic activity of the combined antagonism of adenosine A2A receptors and stimulation of 5HT1A/1B receptors in models of Parkinson's disease : acute and chronic studies

Authors: *A. PINNA[1,2], G. COSTA[2], N. SIMOLA[2], E. TRONCI[2], M. CARTA[2], M. MORELLI[2];

Abstract: Recent report demonstrated that mixed serotonin 5-HT1A/1B receptor agonist, eltoprazine, produces a near to full suppression of dyskinetic-like behaviors in animal models of Parkinson’s disease (PD). However, eltoprazine resulted in a partial reduction of motility induced by L-dopa, both in rodents and in non-human primates. Moreover, in a recent clinical trial, the partial 5-HT1A agonist sarizotan has been found to be only partially effective. Preclinical and clinical studies showed that adenosine A2A receptor antagonists as preladenat, significantly increase L-dopa efficacy in PD, without exacerbating dyskinetic-like behaviors. On this basis, we hypothesize that combination of eltoprazine with preladenant may produce prevention or suppression of L-dopa-induced dyskinesia, without impairing the efficacy of L-dopa in relieving motor symptoms. Unilateral 6-hydroxydopamine-lesioned rats, L-dopa-naïve or rendered dyskinetic by repeated-L-dopa-treatment, were administered with eltoprazine (0.3 or 0.6 mg/kg) and preladenant (0.3 or 1 mg/kg), alone or in combination with L-dopa (4 or 6 mg/kg), and rotational behavior, as index of motility, and abnormal involuntary movements (AIMs) as index of dyskinesia, were evaluated. Results show that combined administration of L-dopa (4 mg/kg) plus eltoprazine (0.6 mg/kg) plus preladenant (0.3 mg/kg) significantly prevented or reduced dyskinetic-like behaviors, as revealed by AIMs test without impairing the motor activity, as revealed by similar number of contralateral and ipsilateral rotations. Moreover, acutely, the combined treatment appears to prevent worsening of the motor performance induced in L-dopa-naïve animals by eltoprazine plus L-dopa in the adjusting step test and the initiation time of stepping, two tests with high predictive validity of PD associated motor disability. Analogous results were obtained with the vibrissae-evoked forelimb placing test, which is used to specifically evaluate sensory-motor impairment. Overall these data suggest that combination

of L-dopa (4mg/kg) with eltoprazine (0.6mg/kg) and preladenant (0.3mg/kg) could be a new therapeutic strategy for treating motor symptoms and dyskinesia in PD.

Title: Extremely low frecuency magnetic fields exposition decreases L-DOPA induced-dyskinesias in a rat model of Parkinson's disease

Authors: ***M. RAMIREZ LOPEZ**[1], D. MILLÁN ALDACO[2], M. PALOMERO RIVERO[2], M. GUERRA CRESPO[2], R. DRUCKER COLÍN[2];

Abstract: Parkinson's disease (PD) is a frequent and incapacitating neurological disorder. Dopamine (DA) precursor molecule, 3,4-dihydroxyphenyl-L-alanine (L-DOPA) is currently the most effective pharmacotherapy for PD. However, the prolonged use of L-DOPA along with the progressive degeneration of nigrostriatal pathway, induces the development of incapacitating movement complications known as L-DOPA-induced dyskinesia (LID). Mechanisms underlying LIDs in PD are not fully understood and its medical treatment is generally unsatisfactory. Recently, extremely low frequency magnetic fields (ELF-MF) exposure has been proposed as a non-invasive therapy for PD due to the effects it has on motor system. Several studies suggest that motor effects of ELF-MF exposure might be due to a dopamine system modulation. To the best of our knowledge, this technique has not been explored as a possible therapy for LID. Thus, the aim of the present study was to investigate whether ELF-MF exposure decreases LIDs in a

Parkinson's rat model. In addition, we studied the ELF-MF effects on the expression of FosB in the dorsal striatum as a histological marker for LIDs. Our results showed that global LIDs score significantly decreased after ELF-MF exposure compare to sham-exposure in 6-OHDA lesionaded rats. In order to evaluate changes before ELF-MF, exposure was put off one week. When ELF-MF exposure ceased for a week, LIDs manifestation increased again to a similar value of control group. Afterwards, rats were treated with ELF-MF for a second time, consequently LIDs score significantly decreased compare to sham-exposure. In contrast, no modification of LIDs scores with sham-exposure after the first evaluation was display. LIDs manifestation's decrease was accompanied by a low expression of FosB in the dorsal striatum. Therefore, exposure to these magnetic fields may be an alternative as a non-invasive therapy for LIDs. Nevertheless, further research is needed to elucidate its mechanisms of action.

Title: Comparison between chromosphere and chromaffin grafts in a 6-OHDA rat model of Parkinson's disease

Authors: ***A. BORONAT-GARCÍA**, M. PALOMERO-RIVERO, D. MILLÁN-ALDACO, M. GUERRA-CRESPO, M. N. ZARIÑANA-CAMACHO, R. DRUCKER-COLÍN;
Inst. de Fisiologia Celular, Mexico, Mexico

Abstract: Chromaffin cells, the catecholamine-releasing neuroendocrine cells from the adrenal medulla, and sympathetic neurons, derive from a common fate-restricted sympathoadrenal progenitor. Due to their neuron-like properties and their capacity to synthetize and release

dopamine, chromaffin cells have been employed in Parkinson´s disease cell replacement therapy studies, in which their grafting produced a gradual improvement of functional motor deficits in parkinsonian animal models. However, these cells have not yielded the expected motor results as a consequence of poor graft survival. Recently, Enhart-Bornstein and coworkers developed an isolation and cell-culture protocol, which permits the expansion of chromaffin progenitor-like cells from adult bovine and human adrenal medulla. Under low-attachment conditions, these cells aggregate and grow as spheres, named chromospheres. Chromosphere-cells have the ability of self-renewal and express several sympathoadrenal and neuronal progenitor cell markers. We found that in chromosphere cell cultures there is an increase in cells with dopaminergic phenotype, together with an increase in dopamine release relative to chromaffin cells. Here, we explored the possibility of chromospheres being a better cell source for decreasing motor alterations (evaluated with amphetamine-induced turning behavior), and also having a better survival than chromaffin cells in a 6-OHDA rat model of Parkinson´s disease. Animals with chromaffin grafts showed a 38% decrement in turn-number during the first evaluation, similar to chromosphere-grafted animals. However, the decrement in turn number over the rest of the analyzed time points did not show a significant reduction compared with lesioned animals without graft, whereas chromosphere grafted animals showed a significant reduction of 52% over the 3 months post-grafting that were evaluated. In addition, chromosphere grafts showed a significant 7-fold higher survival than chromaffin cell grafts, with an average number of TH+ cells of 6,441 in chromosphere grafts and 868 in chromaffin grafts. These data suggest that when compared with chromaffin cells, chromosphere grafts have a higher survival and give rise to a better motor improvement.

Title: Investigation of the therapeutic effects of J-147 in two animal models of Parkinson's disease

Authors: *M. KOPYNETS[1,2];
[1]The Salk Inst. For Biol. Studies, LA Jolla, CA; [2]Univ. of California San Diego, San Diego, CA

Abstract: Human idiopathic Parkinson's disease (PD) is a progressive motor system disorder caused by the extensive depletion of dopaminergic neurons in the nigrostriatal pathway. PD affects approximately one million people in the United States. Here, we tested the therapeutic potential of the neuroprotective compound J147 in two well-established rodent models of PD. J147 was developed on the basis of preventing nerve cell death in a wide range of brain toxicities associated with old age, and it is about to start clinical trials for the treatment of Alzheimer's disease. The hypothesis is that J147 should have therapeutic efficacy in other disorders where nerve cells die. One Parkinson's model was generated by the unilateral injection of 6-hydroxidopamine (6-OHDA) into the striatal pathway, and the other by the intraperitoneal injection of 1-methyl-4-phenyl-1,2,3,6 tetrahydropyridine (MPTP). Levels of the neurotransmitter dopamine were assayed by HPLC. Tyrosine hydroxalase (TH) and inflammation markers were determined by Western blotting. Followed by the studies of behavioral changes between the J147-treated and drug-untreated groups. The obtained data showed that J147 treatment reduces the loss of TH-positive neurons, decreases inflammation, and ameliorates the dopamine depletion following the 6-OHDA and the MPTP treatments. In addition, J147 improved some of the behavioral motor deficits assessed by the rotometer and tremor tests. These results plus the outstanding pharmacological properties of J147 suggest that J147 has the potential for the clinical treatment of Parkinson's disease.

Title: Remote control of transplanted human dopamine neurons in Parkinson's disease mice

Authors: *Y. CHEN, M. XIONG, Y. DONG, S.-C. ZHANG;
Waisman Center, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Cell therapy using human stem cell-derived neurons represents one of the most promising options for treating neurological diseases. Yet, regulation of grafted human cell function in a neural circuitry and hence therapeutic outcomes by non-invasive means has not been achieved. By engineering human pluripotent stem cells to express active or inhibitory form of GPCRs, we found that the function of differentiated midbrain dopamine (DA) neurons was precisely regulated *in vitro* by the pharmacologically inert compound clozapine-N-oxide (CNO). By transplanting the DA neurons into the striatum of Parkinson's disease mice, we found that the mouse behavioral recovery was reversed in animals that received the inhibitory form of GPCR-expressing DA neurons or enhanced in those that received active form of GPCR-expressing DA neurons, upon CNO treatment. By brain slice recording, we found that activation of the grafted DA neurons increased sEPSCs in host striatal neurons, which was abolished by a D1 receptor antagonist, suggesting modulation of glutamatergic synaptic transmission onto striatal GABA neurons in the host striatum. Our findings raise the prospect of human stem cell therapy for neurological diseases by rebuilding and/or modulating neural circuitry.

Title: Thiol-repletion therapy for Parkinson's disease guided by *ex vivo* assessment of neuronal anti-oxidant capacity and human CSF analyses

Authors: *S. WON[1], G. CITTOLIN-SANTOS[1], R. C. REYES[1], M. KATZ[1], A. M. BRENNAN-MINNELLA[1], D. P. JONES[2], R. A. SWANSON[1];

Abstract: Parkinson's disease is a common neurodegenerative disorder with both genetic and environmental causes. The disorder most prominently affects dopaminergic neurons involved in motor control. Both human and animal studies indicate that this dopaminergic neuronal population is particularly vulnerable to oxidative stress. Glutathione is the most abundant thiol antioxidant in neurons, and in Parkinson's disease glutathione depletion precedes death of these neurons. Pharmacological repletion of glutathione is, therefore, a potential approach for slowing disease progression. We developed a method for evaluating approaches for restoring glutathione content in neurons. The method involves use of the EAAC1$^{-/-}$ transgenic mouse, which has reduced glutathione content selectively in neurons due to a defect in neuronal cysteine transport and a resultant age-dependent loss of dopaminergic neurons. Neuronal glutathione content was evaluated by immunohistochemical quantification of neuronal GSH in brain sections. In parallel, the capacity of the neurons to scavenge reactive oxygen species (ROS) was assessed in ex-vivo brain sections by monitoring the formation of nitrotyrosine during incubation with SIN-1. Neurons in the EAAC1$^{-/-}$ mice showed substantially reduced glutathione content and reduced ROS scavenging capacity relative to wild-type mice. EAAC1$^{-/-}$ mice treated orally with a membrane-permeable analogue of cysteine, N-acetyl cysteine (NAC), showed near-normalization of both neuronal glutathione content and reactive oxygen species scavenging capacity, and a much-attenuated loss of dopaminergic neurons. The cerebrospinal fluid NAC concentration associated with this biological effect was less than 150 nM, thus establishing a dosing target for use in humans. In a parallel study, human subjects with Parkinson's disease were given NAC at doses ranging from 7- 70 mg/kg twice daily. Doses above 35 mg/kg achieved CSF concentrations well above 150 nM. A clinical trial of NAC in Parkinson's disease has been funded on the basis of this pre-clinical work.

Title: Intranasal hGDNF DNA nanoparticles induce transfection and protein expression by perivascular cells throughout rat brain

Authors: *A. E.-E. ALY[1], B. T. HARMON[1], L. PADEGIMAS[2], O. SESENOGLU-LAIRD[2], M. J. COOPER[2], B. L. WASZCZAK[1];

Abstract: The therapeutic potential of glial cell line-derived neurotrophic factor (GDNF) has been limited thus far by its inability to cross the blood-brain barrier. We are investigating the intranasal route of administration of PEGylated lysine 30-mer (PEG-CK30) DNA nanoparticles (NPs) encoding GDNF. These NPs, developed by Copernicus Therapeutics, Inc., compact a single molecule of expression plasmid, have a minimum diameter of 10 nm, and provide a non-immunogenic, non-viral vector for CNS gene therapy. We have previously demonstrated that DNA NPs expressing either enhanced green fluorescent protein (eGFP) alone, or eGFP linked with hGDNF (pUGG), transfect cells *in vitro* and brain cells *in vivo.* We further showed that intranasal administration of Copernicus' pGDNF NPs provides neuroprotection of substantia nigra (SN) dopamine neurons in the rat 6-hydroxydopamine model of Parkinson's disease (PD). The goals of the current study were to determine the regional transfection pattern and assess which cell type(s) were transfected 7 days after intranasal administration of these hGDNF DNA NPs. eGFP immunohistochemistry (IHC) was performed on brain sections from rats that received intranasal pUGG NPs, naked pUGG, or saline. The number of fluorescent cells was significantly higher across brain regions in rats given intranasal pUGG NPs compared to saline controls, with the highest number of eGFP+ cells in the midbrain. Double-label IHC was also carried out for eGFP and a cell specific marker, i.e. either rat endothelial cell antigen (RECA-1), glial fibrillary acidic protein (GFAP), the neuronal marker NeuN, or the dopamine neuronal marker tyrosine hydroxylase (TH). Most of the eGFP+ cells found in brain 7 days after intranasal delivery of pUGG NPs were abluminal and immediately adjacent to capillary endothelial cells staining for RECA-1. eGFP+ cells were often found contiguous to GFAP+ astrocytic endfeet enwrapping capillaries, recapitulating their perivascular localization. When eGFP+ cells were observed adjacent to TH+ neurons in the SN, or to NeuN+ cells in any brain region, these neurons were also located within 15 μm of a capillary. Collectively, these results indicate that transgene expression occurred primarily in cells lining the vasculature, most likely pericytes. This is consistent with distribution of intranasally administered agents by perivascular transport. Ongoing studies will examine the dose-response relationship and the time-course of protein expression after intranasal delivery of Copernicus' hGDNF DNA NPs. These studies will determine an optimal dosing regimen for future development of this intranasal pGDNF gene therapy for PD.

Title: Role of Growth Differentiation Factor-15 in the 6-hydroxydopamine mouse model of Parkinson's disease

Authors: *K. UNSICKER[1,3,4], V. MACHADO[2], B. SPITTAU[2], K. KRIEGLSTEIN[2], S. J. P. HAAS[3], A. WREE[3];
[2]Dept. of Anat. and Cell Biol., [1]Univ. of Freiburg, Freiburg, Germany; [3]Dept. of Anat., Univ. of Rostock, Rostock, Germany; [4]Spemann Grad. Sch. of Biol. and Medicine, Univ. of Freiburg, Freiburg, Germany

Abstract: Growth Differentiation Factor-15 (GDF-15) is a novel member of the transforming growth factor-beta cytokine superfamily. It is one of the most divergent members of this family and is widely expressed in liver, lungs, heart, kidney and exocrine glands. At lower levels, GDF-15 mRNA and protein are ubiquitously found in the CNS, its site of highest expression being the choroid plexus, which secretes the protein into the cerebrospinal fluid. GDF-15 has been shown to be significantly upregulated in lesioned neurons and in activated microglia, suggesting that it may have roles in the lesioned CNS. These results indicate that the molecule may either function in the execution of survival or cell death promoting mechanisms or might be involved in the regulation of microglia activation. Microglia, the resident immune cells of the brain, are known to infiltrate sites of neuronal damage and inflammation. It has been observed that microglia also produce GDF-15, and hence, it is crucial to study the relation and interactions of this molecule. In our study, we used the unilateral 6-hydroxydopamine (6-OHDA) Parkinson mouse model and compared Gdf-15 +/+ and Gdf-15 -/- mice. Using quantitative real-time PCR, we revealed that GDF-15 mRNA levels increase at 2d post-lesion. mRNA levels of inflammatory markers such as TNF-a, iNOS and IL-6 were significantly higher upregulated in Gdf-15 -/- mice. Finally, Gdf-15 -/- mice exhibited decreased midbrain dopaminergic neuron survival and lesser microglia numbers post-lesion. In addition to the *in vivo* studies, we addressed the molecular cues underlying neuron death and the involvement of microglia in the 6-OHDA model by using Gdf-15 +/+ and Gdf-15 -/- mixed neuron-glia and neuron cultures from the ventral midbrain, as well as primary microglia cultures. Exogenous GDF-15 application enhanced survival of midbrain dopaminergic neurons in neuron cultures, but not in mixed neuron-glia cultures, indicating a

direct neurotrophic supportive role for GDF-15 in a 6-OHDA lesion paradigm. Dopaminergic neurons in the mixed neuron-glia cultures had better survival rates as compared to the neuron cultures, as well as elevated IL-6 levels, pointing to a glia-mediated protective effect in this culture model. Taken together, our results indicate that GDF-15 is essential for the survival of midbrain dopaminergic neurons and that its loss impairs the inflammatory response of Gdf-15 -/- mice, following 6-OHDA administration. Title: AntiParkinsonian drug actions in the striatal microcircuit

Authors: *E. LARA-GONZALEZ, S. CRUZ, M. DUHNE, J. BARGAS;
Univ. Nacional Autónoma de México, México, D.F, Mexico

Abstract: There have been many biochemical, physiological and behavioral studies on pathophysio-logical models of Parkinson's disease. However, L-DOPA is still the drug of choice to treat the disease and the development of drugs such as “dopamine agonists” have not been

tested and compared with L-DOPA in preparations that preserve the workings of the striatal circuit. We used dynamic calcium imaging techniques to record the activity of dozens of neurons simultaneously with single cell resolution. As previously described, the striatal circuitry exhibits time windows with spontaneous co-activation of neurons (network states) that show recurrence, alternation among states and reverberant behavior (Carrillo-Reid et al. 2008). This circuit behavior changed in the Parkinsonian circuit-depleted of dopamine (Jaidar et al. 2010; Plata et al. 2013) revealing an obstruction of reverberant behavior, hy-peractivity, and excessive recurrence of the same state which becomes dominant. The application of L-DOPA eliminated hyperactivity returning the circuit to normal activity. Apormorphine returned the circuit to normal reverberant activity but does not completely eliminate hyperactivity. Pramipexole and ropinirole which mainly act on D2-class receptors had similar actions as L-DOPA. These results show that calcium imaging on striatal slices work as a valid bioassay to test the action of antiparkinsonian drugs.

Title: Boosting of tyrosine hydroxylase activity as a treatment for Parkinson’s disease

Authors: L. P. VAN DER HEIDE, *J. A. VAN HOOFT, M. P. SMIDT;
Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Parkinson’s disease is the second most common neurodegenerative disorder after Alzheimer’s disease. The main features of Parkinson’s disease (PD) are bradykinesia, progressive rigidity, tremor, and loss of postural stability. The clinical manifestations are mainly caused by a loss of dopaminergic neurons in the substantia nigra pars compacta (SNpc) of the midbrain, resulting in a loss of input to the striatum. It is estimated that at the onset of clinical symptoms more than half of the dopaminergic neurons in the SNpc has been lost. Currently, there is no cure for PD. Most therapeutic approaches aim to replenish dopamine levels by supplementation or attenuating dopamine turnover. The dopamine precursor L-Dopa is most frequently used to relief PD motor symptoms. However, L-Dopa treatment is far from ideal as it creates non-physiological situations both within and outside of the dopaminergic circuitry. In the present study, a symptomatic treatment paradigm for PD is proposed that opposes the striatal

dopamine depletion in a more physiological and specific way, namely by acting on tyrosine hydroxylase (TH), the rate-limiting step in dopamine biosynthesis. The activity of the enzyme TH is strictly controlled to maintain dopamine levels, with the post-translational phosphorylation of TH being the principal short-term regulatory mechanism. TH phosphorylation on Ser40 increases its catalytic activity and thereby the rate of dopamine synthesis, whereas Ser31 is suggested to be required for TH stability and subsequent Ser40 phosphorylation. TH Ser40 phosphorylation levels are low under nonstimulated conditions, whereas they are high for Ser31 as detected in MN9D dopaminergic cells. We find that stimulation of MN9D cells with forskolin (an activator of PKA) leads to an increase in Ser40 phopshorylation, but surprisingly leads to a reduction in Ser31 phosphorylation. Inhibition of ERK1/2 signaling under non-stimulated conditions also reduced phopshorylation of Ser31, but not Ser40. Further investigation into the crosstalk between the Ser40 kinase and Ser31 kinase suggest that forskolin-activated PKA leads to an inhibition of ERK1/2 signaling via phosphorylation of Raf on Ser259, leading to Raf inhibition and failure to acivate ERK1/2. Crosstalk between PKA and ERK1/2 pathways is sugested to tightly control the extent of TH phosphorylation and activity and be a manipulatable target to boost TH activity.

Title: Anodal transcranial direct current stimulation enhances survival and integration of dopaminergic cell transplants in a rat Parkinson’s disease model

Authors: *B. FRITSCH, J. REIS, N. HOFFMANN, C. MÜNKEL, A.-K. GELLNER, H. HULSHOF, M. DÖBRÖSSY, L. FURLANETTI, J. GARCIA, C. WINKLER;
Univ. of Freiburg/ Neurocenter, Freiburg, Germany

Abstract: Background: Restorative therapy concepts such as fetal ventral mesencephalic cell transplantation aim to restitute impaired neurotransmission in neurodegenerative diseases. However, new strategies to enhance grafted cell survival and accelerate graft-derived reinnervation are still needed to enable fast and complete functional recovery. Anodal direct current stimulation promotes BDNF-dependent synaptic plasticity *in vitro*. Here, we assessed whether transcranial direct current stimulation (tDCS) can provide trophic and/or electrotactic

support to grafted stem cells in an *in vivo* rat Parkinson disease model. Methods: Transcranial direct current stimulation (as anodal, cathodal or sham tDCS) was applied daily for 14 days following striatal fetal ventral mesencephalic cells transplantation. Results: Anodal tDCS significantly enhanced graft survival and dopaminergic reinnervation of the surrounding striatal tissue relative to sham treatment control rats. Cathodal stimulation only minimally improved graft survival and had no effect on reinnervation. Both types of stimulation accelerated early motor recovery measured two weeks after transplantation, and behavioral effects correlated with the degree of striatal reinnervation. Discussion: Our results suggest anodal tDCS could be effective to advance restorative therapy in Parkinson disease patients.

Title: The enhancement of protein degradation systems via autophagy in cellular models of neurodegenerative diseases

Authors: *H. ADACHI[1], Z. HUANG[1], K. OKADA[1], K. OHNARI[1], T. HASHIMOTO[1], T. TOYOTA[1], Y. IWANAKA[1], G. SOBUE[2];

Abstract: A common characteristic of neurodegenerative diseases is the accumulation of abnormal proteins. In chronic neurodegenerative disorders such as polyglutamine (polyQ), commonly observed phenotypes include the abnormal accumulation of disease-causing proteins and the formation of nuclear and cytoplasmic inclusions. Under pathologic conditions, the accumulated level of such misfolded and toxic proteins may exceed the protective ability of the proteolytic machinery; the inability to either maintain misfolded proteins in a soluble form or degrade them results in their accumulation and the formation of inclusions. Macroautophagy is a set of bulk degradation processes in which cells form double-membrane vesicles, called

autophagosomes, around a portion of the cytoplasm. These autophagosomes ultimately fuse with lysosomes, resulting in the degradation of their substrates. The transcription factor EB (TFEB) has been reported to regulate autophagy by upregulating genes that belong to the coordinated lysosomal expression and regulation (CLEAR) network, thereby controlling lysosomal biogenesis. We examined the effects of the overexpression of TFEB in cultured cell models of neurodegenerative diseases. NSC34 cells were transfected using Lipofectamine 2000 with plasmids encoding mutant androgen receptor, huntingtin, ataxin-1, ataxin-3 and TFEB. The overexpression of TFEB decreased the expression of each causative protein in the neuronal cell models. The expression of the autophagic marker LC-3 II was significantly elevated in the cells expressing TFEB. These findings demonstrated that the high expression of TFEB induced autophagosome formation and enhanced the degradation of the disease-causative proteins.

Title: Loss of adult myosin heavy chain isoforms in spinal and bulbar muscular atrophy muscle

Authors: ***K. HALIEVSKI**[1], Y. XU[1], M. KATSUNO[2], H. ADACHI[3], G. SOBUE[2], S. M. BREEDLOVE[1], C. L. JORDAN[1];
[1]Neurosci., Michigan State Univ., East Lansing, MI; [2]Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [3]Univ. of Occup. and Envrn. Hlth., Kitakyushu, Japan

Abstract: Muscle weakness is a core symptom of spinal and bulbar muscular atrophy (SBMA), an androgen-dependent neuromuscular disease linked to a CAG expansion mutation in the androgen receptor (AR) gene. Recent studies of muscle function have revealed a loss of intrinsic muscle strength that is independent of muscle mass in SBMA mice (Oki et al., Muscle Nerve, (2013)47:823; Oki et al., J Appl Physiol, (2015)118:941). Searching for candidate mechanisms to explain this loss, we now report that diseased muscle is relatively insensitive to the pharmacological inhibitor of skeletal muscle myosin II, N-benzyl-p-toluene sulphonamide (BTS), suggesting defects in myosin heavy chain (MHC), an important mediator of muscle

strength. We used qPCR to investigate the expression of MHC mRNA in muscle of diseased males of two transgenic (tg) mouse models that recapitulate SBMA in a male-biased and androgen-dependent manner, the “myogenic” and “97Q” models. We examined four MHC genes in the prototypical fast (extensor digitorum longus) and slow (soleus) muscles: Myh4 (fast, IIb), Myh7 (slow, β), Myh3 (embryonic), and Myh8 (perinatal). In both SBMA models, we find a dramatic loss of mRNA expression of the adult MHC isoforms in both fast and slow twitch muscles (>45 fold down-regulated) while mRNA encoding the embryonic and perinatal isoforms are up-regulated in both muscle types (2.1-394 fold). We also examined MHC expression in muscle of acutely diseased tg females and find comparable changes in the expression of the adult MHC isoform: mRNA expression of the adult slow isoform (Myh7) is robustly down-regulated (24 fold) in the soleus muscle of acutely diseased myogenic females after only five days of androgen exposure. However, levels of the early forms of MHC (i.e., Myh3 and Myh8) were decreased (1.5-4.4 fold) rather than increased as found in males. These results suggest that expression of adult isoforms of myosin are robustly down-regulated in both fast and slow muscle in the face of disease, potentially contributing to the loss of muscle strength. Up-regulation of early MHC forms in muscles of chronically diseased males, but not in muscles of acutely diseased females, may reflect some compensatory process, which is still not enough to rescue force production, probably due to weak ATPase activity of these early isoforms. That disease impairs the expression of critical contractile proteins in muscle suggests that such proteins may be good therapeutic targets for rescuing muscle function in SBMA patients.

Title: MBNL1 deubiquitination results in nuclear translocation and impairs neurite outgrowth in myotonic dystrophy

Authors: *G.-S. WANG, T.-Y. KUO, P.-Y. WANG, Y.-M. LIN, M.-H. TAO;
Academia Sinica, Taipei, Taiwan

Abstract: Myotonic dystrophy (DM) is the most common cause of adult onset muscular dystrophy. Cognitive deficits are found in a high percentage of individuals with DM, type 1 (DM1). The cognitive and behavioral abnormalities include mental retardation, attention deficit and hyperactivity disorder, excessive daytime sleepiness and psychiatric disorders. The genetic basis of DM1 is caused by an expansion of CTG repeats in the 3' untranslated region (UTR) of the Dystrophia Myotonica Protein Kinase (DMPK) gene. DMPK mRNA containing expanded CUG repeats accumulates in nuclear foci and affect nuclear and cytoplasmic functions of RNA binding proteins such as muscleblind like 1 (MBNL1) and CELF1 (CUGBP and ETR3 Like Factor). Structural change in the brain is a DM1 feature; however, the causal mechanism remains unknown. Here we find that dysfunction of cytoplasmic MBNL1 due to deubiquitination may contribute to DM1 histopathological abnormality. Cytoplasmic MBNL1 was functioning in promotion of neurite outgrowth and its cytoplasmic localization was regulated by K63-linked ubiquitination in a brain-specific manner. In DM1 mouse and human brains, the extent of K63 ubiquitination was reduced and reduction of cytoplasmic MBNL1 was accompanied with dendrite fragmentation. Importantly, expanded CUG RNA induced MBNL1 deubiquitintation resulting in nuclear translocation and morphological defects that can be rescued by preventing degradation of K63-linked polyubiquitin chains. In summary, we show that deubiquitination of cytoplasmic MBNL1 has a critical role in DM1 neural pathogenesis through affecting the subcellular localization of MBNL1 and the integrity of neuronal morphology.

Title: Analysis of nuclear export of polyglutamine-expanded androgen receptor in a cell model of spinal and bulbar muscular atrophy

Authors: *F. ARNOLD[1], D. MERRY[2];
[2]Biochem., [1]Thomas Jefferson Univ., Philadelphia, PA

Abstract: Spinal and bulbar muscular atrophy (SBMA) is an X-linked neurodegenerative disease caused by a polyglutamine (polyQ) expansion in the androgen receptor (AR). The AR is a steroid hormone receptor that, upon ligand binding of testosterone or dihydrotestosterone (DHT), undergoes a conformational change that induces nuclear localization and subsequently, the transcriptional regulation of AR-target genes. In SBMA, both the presence of hormone and the nuclear localization of the AR are necessary for toxicity, with the formation of intranuclear inclusions of aggregated AR a hallmark of the disease state. Given the importance of nuclear localization in disease-mediated toxicity, we sought to examine whether there are alterations in the nuclear export of polyQ-expanded AR, compared with wild-type AR and, if so, whether enhancing the nuclear export of polyQ-expanded AR is protective in cell models of SBMA. A heterokaryon analysis of PC12 cells expressing human AR under the control of a tetracycline-inducible promoter revealed that polyQ-expanded AR is, in fact, deficient in nuclear export relative to wildtype AR. This difference will be further evaluated using cells expressing human AR fused to photoswitchable DENDRA2 tags, which will allow us to quantify the rate of nuclear export of polyQ-expanded and wildtype AR *in vitro*. Concurrently, we have created nuclear export sequence (NES)-tagged AR constructs to evaluate the effect of enhanced nuclear export on numerous aspects of disease pathogenesis, including: toxicity, intranuclear inclusion formation, and protein degradation. All together, these experiments will provide us with a new understanding of the role of nuclear export in SBMA pathogenesis and new insights into the effect of the polyQ-expansion on nuclear export.

Title: Protein interaction networks in the pathogenicity of Spinal and Bulbar Muscular Atrophy

Authors: ***A. PLUCIENNIK**[1], T. BERGER[1], S. FINKBEINER[2], D. MERRY[1];
[1]Thomas Jefferson Univ., Philadelphia, PA; [2]Gladstone Inst. of Neurolog. Dis., San Francisco, CA

Abstract: Spinal and bulbar muscular atrophy is caused by a loss of brainstem and spinal cord motor neurons (and of the associated innervated muscles). Genetic basis of this disease is an expansion of a polyglutamine-encoding CAG repeat within androgen receptor (AR) gene. Several hypotheses have been put forward to explain the cytotoxic consequences of polyQ expansion at the molecular level, including aberrant protein-protein interactions, altered post-translational modifications, and perturbations to global protein folding homeostasis. Here, we have employed a quantitative proteomics approach involving stable isotope labeling of amino acids in cell culture (SILAC) to identify alterations in the AR interactome due to polyQ expansion. Rat neuronal PC12 cells expressing polyQ expanded AR were labeled with heavy isotopic (13C and 15N) forms of the essential amino acids lysine and arginine, whereas corresponding PC12 cells expressing wild type AR were not labeled. Using the expanded polyQ- and conformation specific antibody 3B5H10, polyQ expanded AR and its protein interaction partners were immunoprecipitated. Our approach has identified several promising protein candidates whose interactions with AR are altered by the polyQ expansion. The potential roles of these AR interacting proteins in pathogenesis are currently being evaluated.

Title: Mass spectrometry analysis of normal and polyglutamine expanded ataxin-3 interaction partners

Authors: *L. V. KRISTENSEN[1,2], R. HARTMANN-PETERSEN[2], K. THIRSTRUP[1];
[1]H. Lundbeck A/S, Valby, Denmark; [2]Dept. of Biol., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: The group of polyglutamine (polyQ) diseases comprises nine different neurodegenerative disorders, characterized by an expanded polyglutamine tract within the respective protein. The disorders include Huntingtons disease (HD) and different spinocerebellar ataxias (SCA-1-3, SCA-6-7, and SCA-17). SCA3 also known as Machado-Joseph disease is the most common dominantly inherited ataxia worldwide and is caused by a polyQ expansion within

the ataxin-3 gene. The polyQ expansion confers toxicity to the protein ataxin-3, leading to neuronal dysfunction and loss in various brain areas. How the polyQ expansion confers toxicity to ataxin-3 is currently not very well understood and existing treatment strategies of SCA3 patients are insufficient. Therefore investigations of how the polyQ expansion alters functional properties of ataxin-3 are essential to further increase the understanding of the SCA3 disease pathology. It is conceivable that the polyQ expansion of ataxin-3 alters the repertoire of interacting proteins, which may represent a part of the explanation for its key role in SCA3 pathophysiology. Hence we sought to investigate differences in interaction partners of normal (14Q) and polyQ expanded ataxin-3 (82Q) by mass spectrometry. Flag-ataxin-3 variants were expressed in HEK293 cells and purified by Flag-immunoprecipitation. Samples were then analyzed by mass spectrometry to assess differences between normal and polyQ expanded ataxin-3. In the present study we report the data obtained from this mass spectrometry analysis and discuss how these results can further increase our understanding of the pathological role of polyQ expanded ataxin-3.

Title: Impaired neuronal activity in hippocampal and neocortical slices from a mouse model of Juvenile Batten disease

Authors: N. KARPUK[1], M. BURKOVETSKAYA[1], *T. KIELIAN[2];
[2]Dept. of Pathology and Microbiology, [1]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Juvenile Neuronal Ceroid Lipofuscinosis (JNCL or Juvenile Batten Disease) is a debilitating lysosomal storage disorder caused by an autosomal recessive mutation in CLN3. JNCL symptoms typically present between 5-10 years of age, beginning with blindness and progressing to seizures, motor incoordination, cognitive deficits, and early death (late teen-early 20s). JNCL is typified by progressive neurodegeneration in thalamocortical structures, which has

been suggested to occur from excessive excitatory and impaired inhibitory synaptic function. However, these conclusions were made by *ex vivo* analysis of neurotransmitter levels and treatment of JNCL mouse models with glutamate receptor antagonists and direct analysis of synaptic communication using electrophysiology methods has not yet been performed. Here we evaluated evoked field potentials (FP) in acute hippocampal and neocortical slices from a mouse model of JNCL (i.e. CLN3Δex7/8) and wild type (WT) animals. FP measurements were compared between CLN3Δex7/8 and WT slices at 3, 7, and 12 months of age to identify the onset of synaptic defects and alterations with advancing disease. Our findings demonstrated that FP paired-pulse facilitation (PPF) was significantly attenuated in CLN3Δex7/8 hippocampus (CA1 to CA3) that was already evident at 3 months of age. This finding is intriguing since neuronal loss is not evident in CLN3Δex7/8 mice until 12 months and suggests that synaptic changes are an early disease manifestation. Changes in FP were more complex in the neocortex, namely PPF and FP amplitude were significantly increased in the upper layers of the visual neocortex (i.e. layers I-III) of CLN3Δex7/8 mice, whereas these values were slightly reduced in deeper neocortical layers (i.e. layers IV-V). These FP changes in the CLN3Δex7/8 brain may be one mechanism to explain impaired hippocampal memory and neuronal afferent/sensory signaling in the neocortex that are hallmarks of JNCL in affected children.

Abstract: Batten disease or Neuronal ceroid lipofuscinosis (NCL) is the most frequent autosomal-recessive neurodegenerative disease of childhood [1]. There are 14 forms of NCL caused by mutations in different genes affecting lysosomal function. All of them lead to the same features of clinical progression including, the accumulation of autofluorescent storage material in the lysosome (the main hallmark of these conditions), early synaptic loss and premature death [2, 3]. The most prevalent forms of this devastating condition are the CLN1 disease variant or infantile NCL (INCL) and the slightly later onset CLN3 disease or Juvenile NCL (JNCL) variant [4, 5]. Here we have used a proteomic based approach in murine models of NCL disease to demonstrate that although the gross appearance of CLN3 KO muscle fibres remains unchanged at early disease stages, there are significant molecular perturbations detectable at early time points. These include but are not limited to pathways involved in small molecule biochemistry and mitochondrial dysfunction. Thalamic synapses are an early pathological target in NCL [6, 7, 8]. We hypothesise that a tractable biomarker will be something which is constitutively expressed, but which changes in response to a mutation of interest in a tissue specific manner. We therefore compared the changes observed in muscle and thalamic synaptic proteomes. Constitutively expressed proteins were examined for higher order functional clustering and candidates were temporally tracked using label free proteomic profiling of CLN1 KO muscle throughout the time course of CLN1 disease progression. Here we identify multiple potential peripherally accessible biomarkers of disease progression which are mitochondrial in origin and whose expression is conserved in both CLN1 and CLN3 forms of NCL disease. Title: An animal disease model for episodic ataxia 6

Authors: *P. KOVERMANN, V. UNTIET, C. FAHLKE;
Inst. for complex systems 4, Forschungszentrum Jülich Gmbh, Juelich, Germany

Abstract: Mutations in the SLC1A3 encoding the glial excitatory amino acid transporters 1 (EAAT1) are associated involved in several neurological diseases such as Tourette syndrome (Adamczyck et al. 2011, Psychiatr. Genet. 21, 90-97.1) or episodic ataxia type 6 (Jen et al. 2007, Brain 130, 2484-2493). Recently, a point mutation in SLC1A3 was found in a patient with a severe form of episodic ataxia type 6, who suffered from long lasting attacks of ataxia and seizures (Jen et al. Neurology 65, 529-534). This mutation predicts the exchange of a highly conserved proline to arginine at position 290 (P290R) in EAAT1. Functional analysis of mutant transporters in heterologous expression systems revealed gain-of-function of the EAAT1-associated ion channel (Winter et al. 2012, Brain, 135, 3416-3425) as well as reduced glutamate transport via dramatic deceleration of a conformational change associated with sodium binding to the glutamate-free mutant transporters (Hotzy et al. 2013, J. Biol. Chem. 288, 36492-36501) in P290R EAAT1. However, the cellular mechanisms by which changes in glutamate transport or EAAT- associated anion channel activity might result in ataxia and seizures are still insufficiently understood. We here study the consequences of this mutation on cerebellar morphology and motor function in a knock-in animal disease model carrying the P290R mutation. P290R knock-in mice exhibit impaired balance and prominent ataxia as well as spontaneous generalized seizures and premature death. The changes in motor coordination are accompanied by dramatic changes in the morphology of the cerebellar cortex. Confocal microscopy of slices from cerebellar hemispheres of P290R knock-in mice show a reduced number of Bergmann glia cells in the Purkinje cell layer and a substantial number of Purkinje neurons with ectopic localization. Moreover, we observed highly increased density of neurons in the molecular layer. We conclude that changes in EAAT1/GLAST function impair the developmental migration of cerebellar granule cells and enhance the incidence of other types of neuronal cells in the molecular layer.

Title: Regulation of neuronal hemoglobin expression and potential roles in mitochondrial respiration

Authors: S. LI, N. SINGHAL, R. GEGORY, J. MCDONOUGH, *E. J. FREEMAN;
Kent State Univ., Kent, OH

Abstract: It has been demonstrated in multiple sclerosis (MS) cortex that mitochondrial function is compromised and is associated with increased markers of oxidative damage. A previous analysis of the mitochondrial proteome in diseased and control postmortem cortex revealed an increase in the presence of the β subunit of hemoglobin (Hb) in MS cortex. In addition, in the CNS, Hb mRNA and protein have been localized to neurons and a potential role for Hb in mitochondrial respiration has been proposed. Indeed, Hb may function to ensure adequate delivery of oxygen, but may also serve to protect against oxidative damage, since Hb has been shown to express high affinity binding for other gas molecules, including nitric oxide (NO), as well as, act as a scavenger of peroxynitrite. Therefore, we examined the extent and distribution of Hb expression in brain and its regulation in response to various challenges, as well as, investigated its role in mitochondrial respiration. Using immunofluorescent staining, western blotting and flow cytometry we identified the presence of Hb throughout many brain regions in rat and confirmed its expression in primary neuronal cultures. Expression of Hb was regulated by oxygen concentration, inhibition of electron transport, and oxidative stress. Neurons cultured under hypoxic conditions (2-10% O_2) demonstrated increased Hb expression (80-100%) compared to those cultured under atmospheric conditions. In addition, treatment of neurons with low levels of rotenone or peroxide resulted in modest increases in Hb expression (25-30%), while increased concentrations reduced expression by 70-80% of controls. In respirometry experiments, we noted that rotenone, peroxide, as well as exposure to the NO-donor sodium nitroprusside (SNP) significantly attenuated mitochondrial respiration. Conversely, overexpression of Hb induced by erythropoietin (EPO) or transfection increased neuronal respiration through interactions with mitochondria and up-regulation of mitochondrial gene expression. We observed that NO-induced reductions in mitochondrial respiration could be reversed in transfected cells or those pretreated with EPO. Further, in cells transfected with Hb we identified increases in histone H3K4 trimethylation that was associated with increased expression of complex V of the electron transport chain. MS cortical tissue has been linked with mitochondrial dysfunction and oxidative stress, thus based on our observations, we suggest that the increase in Hb expression identified in MS cortex may occur in response to these influences to promote increased mitochondrial function and protect from oxidative damage.

Title: Involvement of specific nur77 family genes during neurite outgrowth induced by forskolin and a histone deacetylase inhibitor in PC12 cells

Authors: *K. SHIMOKE[1], R. YAMAZOE[2], T. TOMIOKA[2], K. TSUMURA[2], Y. NISHIHATA[2], H. MARUOKA[3];
[1]Kanasai Univ., Suita, Osaka, Japan; [2]Kansai Univ., Osaka, Japan; [3]Technol. Res. Lab., KURABO, Osaka, Japan

Abstract: Neurite outgrowth is involved in neuronal differentiation. In this process, specific genes are expressed during neurite formation. Identification and functional analyses of these genes are important in developing a new strategy for regenerative therapy. We have demonstrated that forskolin (FSK), an intracellular cAMP producer, or valproic acid (VAL), a histone deacetylase inhibitor, both induce the nur77 gene, which belongs to the Nur nuclear receptor family, along with two other genes, within 4 hours in PC12 cells. We have previously revealed that nur77 protein induces neurites in PC12 cells. In the present study, we investigated which genes belonging to the Nur family are important in elongation of the neurites in the presence of FSK or VAL. Knock-down experiments showed that siRNA against nur77 or nurr1 mRNA suppressed neurite elongation in response to treatment with both FSK and VAL, while siRNA only suppressed the elongation induced by the treatment with FSK, suggesting that nur77 and nurr1 are essential for neurite outgrowth in the presence of FSK or VAL. We also found that epigenetic regulation via histone H3 modification (i.e., acetylation of lysine) was important for the FSK- or VAL-induced neurite outgrowth. These results show that up-regulation of nur77 and

nurr1 genes are involved in neurite outgrowth induced by FSA or VAL through acetylation of histone H3 at the lysine residue, and suggest that different mechanisms are also involved among the nur77 family genes in inducing neurite outgrowth.

Title: Chorein /HDAC6 interaction confers resistance to nutrient deprivation in chorein-overexpressing HEK293 cells

Authors: *M. NAKAMURA, N. SASAKI, A. KODAMA, N. SHIOKAWA, A. SANO; Kagoshima Univ, Dept of Psychiatry, Kagoshima, Japan

Abstract: Loss of chorein function causes an autosomal recessive neurodegenerative disorder chorea-acanthocytosis, which is characterized by striatal neurodegeneration and erythrocyte acanthocytosis. Detailed physiological role of chorein at the molecular level remains unclear. Recently autophagy pathway had been implicated in several neurodegenerative diseases. In the present study, chorein-overexpressing human embryonic kidney (HEK) 293 cells demonstrated increased cell viability following nutrient starvation. Co-immunoprecipitation assays using chorein stably overexpressing HEK 293 cells revealed that chorein interacts with HDAC6, which is known as a central component of basal autophagy. Selective HDAC6 inhibitor tubacin decreased cell viability of chorein stably overexpressing HEK293 cells under nutrient starvation condition. These results suggest that chorein/HDAC6 interaction may have an important role in autophagic pathway and the collapse of this mechanism may be one of the molecular pathogenesis of chorea-acanthocytosis.

Title: Uridine protects against hypoxic-ischemic brain injury by reducing histone deacetylase activity in neonatal rats

Authors: *T. ALKAN[1], T. KOYUNCUOGLU[1], M. TURKYILMAZ[2], B. GOREN[1], M. CANSEV[2];
[1]Physiol., [2]Pharmacol., Uludag Univ. Med. Sch., Bursa, Turkey

Abstract: A significant cause of neurological disability in newborns is hypoxic-ischemic encephalopathy (HIE), a disorder which involves an enhancement in histone deacetylase (HDAC) activity among underlying pathological mechanisms. We showed recently that exogenous administration of uridine to newborn rats with HIE reduced brain injury in a dose-dependent manner. The present study was performed to investigate whether uridine modulates histone acetylation/deacetylation balance in a neonatal rat model of HIE. Newborn rats that were subjected to hypoxic-ischemic (HI) insult on postnatal day 7 (P7) were injected intraperitoneally with either saline or uridine (500 mg/kg) for three consecutive days. One day after completion of treatment, brains of pups were collected for evaluation of brain infarct volume, apoptosis, HDAC activity and acetylated-Histone H3 (Ac-H3) and H4 (Ac-H4) protein levels. Results revealed that uridine administration reduced infarct volume, active Caspase-3 levels and HDAC activity while increasing the expressions of Ac-H3 and Ac-H4 proteins. We conclude that one mechanism by which uridine provides neuroprotection in neonatal rat HIE model involves reduction in HDAC activity. Experimental protocol was approved by the Ethical Committee on Experimental Animals in Uludag University, Bursa, Turkey (2013-14/03), and the experiments conformed to the National Institutes of Health Guide for the Care and Use of Laboratory Animals (NIH Publications No. 80-23) revised 1996 and EC Directive 86/609/EEC.

Title: Long-term white matter instabilities after neonatal hypoxic-ischemic brain injury

Authors: *H. JEONG[1], R. KHAWAJA[1], J. D. ROTHSTEIN[2], S. H. KANG[1,3];
[1]Shriners Hosp. Pediatric Res. Ctr., Philadelphia, PA; [2]Dept. of Neurol. and Neurosci., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Dept. of Anat. and Cell Biology,, Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Periventricular leukomalacia (PVL) is the predominant form of white matter brain injury associated with premature birth, and such injury often leads to long-term neurological disabilities, such as cerebral palsy. Oligodendrocytes (OLs), the CNS myelinating glia, are known to be particularly vulnerable to various injury-causing insults in the developing brain. Accordingly, this form of brain injury has been attributed to early death of OLs and/or maturation failure of developing OLs. However, given the abundance of highly regenerative OL progenitors (OLPs) in the developing brain, the mechanisms underlying post-injury, long-term white matter deficits remain elusive. In the present study, we followed the fate of NG2-expressing OLPs, and examined the growth of the OL population until adulthood in a mouse model of perinatal hypoxic-ischemic (HI) injury, utilizing various OL lineage-specific transgenic mice. Following a surgical procedure that induced unilateral HI into the brain at P7, the injured hemisphere exhibited marked gliosis and ventricle enlargement, which persisted to adult ages. Despite an instant loss of subsets of OLs, there followed a robust proliferation of OLPs, with enhanced differentiation into OLs in the injured areas. Unexpectedly, the number of mature OLs in the injured side was even larger than in the control side at P15, and it remained elevated for at least one month after HI, indicating an active OL development, as well as an intact regenerative response of OLPs. However, the activated OLP responses gradually subsided to a normal level afterwards, and the number of OLs was significantly decreased in the injured white matter by two months after HI. In parallel, the degree of myelination in the injured areas also followed this multi-phasic OL growth pattern. Furthermore, many surviving OLs in the injured white matter failed to express monocarboxylate transporter-1 (MCT1), a lactate transporter that may mediate metabolic support for axons, as assessed by a reporter expression in MCT1-tdTomato mice. Maturation of nodes of Ranvier was also impaired in the adult brain. Taken together, these results suggest that the long-lasting white matter deficits observed after perinatal HI, are not

primarily caused by early OL loss and/or developmental maturation arrest, but rather are attributable to shorter survival of mature OLs, and structural and functional impairments of OLs in the adult brain. Insufficiency of OL-mediated metabolic support for axons, as well as delayed demyelination, may play a role in the long-lasting neuronal dysfunctions associated with perinatal white matter injury.

Title: Nicotinamide Mononucleotide Adenylyltransferase 3 protects the mouse neonatal hippocampus from the effects of neonatal hypoxia-ischemia

Authors: *R. GALINDO[1], M. B. GREENBERG[2], T. ARAKI[3], D. M. HOLTZMAN[2]; [1]Neurol., Washington Univ. In St. Louis, Saint Louis, MO; [2]Neurol., Washington Univ., St. Louis, MO; [3]Dept. of PNS Res., Natl. Inst. of Neurocience, Kodaira Tokyo, Japan

Abstract: Neonatal cerebral hypoxia-ischemia (H-I) is a major cause of death and disability in the pediatric population. There are only limited treatments available for this condition and the mechanisms that lead to acute and chronic cerebral dysfunction are poorly understood. The family of NAD-synthetizing enzymes, nicotinamide mononucleotide adenylyltransferases (NMNATs), consist of three isoforms and they all have been implicated in the protection of axons and neurons after different forms of neuronal injury. However, it is not known whether NMNAT3 protects immature neurons or axons following neonatal cerebral injury. In this study, we find that endogenous NMNAT3, although present at low levels in immature healthy neurons, is strongly induced following neonatal cerebral hypoxia and ischemia. Utilizing NMNAT3 overexpressing transgenic mice, we find that NMNAT3 overexpression decreases overall neonatal mortality following H-I and also decreases cerebral tissue injury in the neonatal hippocampus and cortex. We then sought to determine the mechanism via which NMNAT3 was exerting its neuroprotective effects. Utilizing biochemical assays, we show that NMNAT3 overexpression decreases the activation of caspase-3. NMNAT3 overexpression was also associated with decreases in calpain- and caspase-mediated cleavage of brain alpha-spectrin

following cerebral ischemia. We then investigated whether the above effect was downstream of the activation of key signaling pathways involved in the regulation of cell death of injured neurons. The calpain-inhibitor protease, calpastatin, has been recently implicated in the neuroprotective mechanism of NMNAT1 after peripheral axonal injury. Furthermore, calpastatin has also been implicated in the modulation of caspase activation in ischemic neurons. Therefore, we asked whether NMNAT3 overexpression results in decreases in injury-dependent proteolytic degradation of calpastatin. NMNAT3 overexpression prevented the degradation of calpastatin after neonatal H-I. Taken together, the present data indicates that NMNAT3 protects ischemic immature neurons by inhibiting apoptotic and necrotic associated cellular damage possibly via a calpastatin-mediated mechanism. Abstract: Perinatal asphyxia is a main cause of long-term neurological damage, requesting novel therapeutic ideas to prevent its deleterious consequences. HIF-1α is a key molecule in the signalling elicited by hypoxia, triggering neuroprotective or deleterious cascades depending upon the intensity of the insult. Here, we show that severe PA increases HIF-1α translocation, leading to astrocyte reactivity and neuronal impairments in rat hippocampus, prevented by systemic treatment with the HIF-1α inhibitor, YC-1. Asphyxia was induced by immersing G22 foetuses into a water bath at 37°C for 21 min. Surviving and control pups were treated with YC-1 (2 mg/kg, i.p.) or saline (1 mL/kg, i.p.), 10 min after delivery. For preparing primary cultures of neurons or astrocytes, hippocampi from control and asphyxia-exposed rats were dissected 6 h or 1 day after delivery. Sibling animals were given to surrogate dams pending further analysis. It was found that perinatal asphyxia: (i) increased HIF-1α protein levels, translocated to the nuclei of neurons and astrocytes immediately after delivery; (ii) increased astrocyte reactivity, assessed by Bystin, Aldh1L1 and GFAP markers, 1, 8 and 24 h after-asphyxia; (iii) reduced the number of neurons, neurite length, and pre- and post-synaptic dots assessed by MAP-2, Synaptophysin and PSD95, respectively, in cultures at DIV 7-18; (iv) impaired synaptic structure, reducing the number of synapses in CA3 at P 7-22; (v) decreased long term potentiation at P24, and (vi) impaired learning and non-spatial memory at P90. YC-1 treatment precluded several of the morphological and functional impairments elicited by perinatal asphyxia. The present results provide evidence that HIF-1α is a pivotal molecule responding to asphyxia, leading to astrocyte reactivity, and long-term synaptic, neuronal and functional deficits affecting the plasticity of hippocampus, prevented by systemic YC-1 treatment. Thus, HIF-1α is a prominent target for therapeutic strategies aiming the deleterious effects of perinatal asphyxia.

Title: Effects of normobaric oxygen treatment on brain injury after hypoxia- ischemia in newborn mice

Authors: *T. KELESTEMUR[1], A. B. CAGLAYAN[2], M. C. BEKER[2], U. KILIC[3], S. ALTUNAY[2], B. CAGLAYAN[2], E. YALCIN[2], R. Z. GUNDUGDU[2], E. KILIC[2];

Abstract: Hypoxic-ischemia (HI) is a widely used animal model to mimic the preterm or perinatal sublethal hypoxia. It causes diffuse neurodegeneration in the brain and results in mental retardation, hyperactivity, cerebral palsy and epilepsy. Normobaric oxygen (NBO) enhances post-ischemic tissue re-oxygenation and promotes neuronal survival. However, its therapeutic effect is compromised by reactive oxygen species which are formed in response to oxygen. In this contex, we investigated effects of NBO combined with free radical scavenger melatonin after newborn hypoxic-ischemia. For this aim we anesthesized 7 days old mice with 1% isoflurane (30% O_2; reminder N_2O) and exposed to 8% Oxygen for 1 hour after right carotid artery ligation which controlled by laser speckle imaging and evaluated effects of normobaric oxygen (70% or 100% over 120 min), administered either alone or in combination with melatonin (4 mg/kg, i.p.), on apoptotic cell death, neuronal survival, infarct volume, brain swelling and cell signalling. Combination of oxygen and melatonin treatment decreased infarct volume, neuronal injury, brain swelling more strongly than oxygen or melatonin alone. As compared with Oxygen and melatonin treatment, phosphorylation of SAPK/JNK-1/2 was reduced and ERK-1/2, CREB phosphorylation were increased in NBO/melatonin combined animals. Here, we provided evidence that NBO treatment is beneficial after newborn HI, which was associate with improved neuronal survival and ERK-1/2 and CREB activities. This data encourages proof-of- concept studies in human hypoxic-ischemia treatment.

Title: Intrauterine growth restriction results in lower cortical glutamine concentrations in the adult rat brain

Authors: *M. ALEXANDER[1], I. TKAC[2], G. OZ[2], R. RAO[1], A. MALISZEWSKI-HALL[1]; [1]Pediatrics, Univ. Minnesota, Minneapolis, MN; [2]Ctr. for Magnetic Resoance Spectroscopy, Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Children who are born with intrauterine growth restriction (IUGR) are at increased risk for long-term neurodevelopmental deficits including motor, cognitive and attention impairments. The nature of these deficits suggests that the cerebral cortex and hippocampus are particularly vulnerable to injury, however the mechanisms of injury are unknown. Using *in vivo*, high-field (9.4T) 1H MRS, we recently showed lower concentrations of several metabolites responsible for energy metabolism and glutamatergic neurotransmission in the cerebral cortex of postnatal (P) day 7 IUGR rats versus normally grown (NG) controls. Whether these early metabolite changes persist long-term is unknown. Objective: To evaluate the neurochemical profile of the cortex and hippocampus in adult IUGR and NG rats using *in vivo* 1H MRS at 9.4T. Methods: IUGR was induced using bilateral uterine artery ligation at gestational day 19 (term=22.5d) in pregnant Sprague Dawley dams. MR spectra were obtained from the cortex and hippocampus at P60 (adulthood) in IUGR (N=8) and NG (N=7) pups. All spectra were acquired as previously described (Maliszewski-Hall et al., 2015). Differences in neurochemical concentrations in each region were compared between IUGR and NG groups using a two-way ANOVA and follow-up students T-test. Results: In the P60 cortex, IUGR resulted in lower concentrations of Gln compared to NG. There was no effect of IUGR on neurometabolite concentrations in the hippocampus. Conclusion: IUGR differentially effects the neurochemical profile in a regional dependent manner in the adult rat brain. Specifically Gln concentrations were lower in the IUGR cortex but unchanged in the hippocampus compared to NG. Using1H MRS Gln concentrations are considered a good measure of the turnover of glutamate involved in neurotransmission. Lower Gln concentrations in the IUGR cortex suggest disruptions in glutamate-glutamine neurotransmission. We speculate a lower concentration of Gln may be one underlying mechanism leading to cortex-based long-term cognitive impairments in human IUGR infants.

Title: Effects of metformin and enriched rehabilitation on recovery following neonatal hypoxia-ischemia

Authors: *S. ANTONESCU[1,2], M. JEFFERS[2], J. LIVINGSTON-THOMAS[2], C. MORSHEAD[3], D. CORBETT[2,4];
[1]Neurosci., [2]Univ. of Ottawa, Ottawa, ON, Canada; [3]Univ. of Toronto, Toronto, ON, Canada; [4]Canadian Partnership for Stroke Recovery, Ottawa, ON, Canada

Abstract: Neonatal hypoxia-ischemia (HI) is one of the most common causes of mortality and morbidity in children, often leaving survivors with profound physical and cognitive disabilities. Effective treatments capable of supporting long-term recovery and reducing the severity of disabilities are needed. Previous research using adult animal models of stroke has shown that metformin, an antidiabetic drug, promotes neurogenesis, oligogenesis and angiogenesis to enhance motor and cognitive function following injury. This study aims to determine whether metformin, enriched rehabilitation (ER) or a combination of the two could provide a clinically relevant therapeutic option for enhancing motor function following neonatal HI. At post-natal day (PND) 7, Sprague-Dawley rats were assigned to two groups: sham or hypoxia-ischemia. The Rice-Vannucci model was used to induce unilateral injury, in which HI animals had their left carotid artery permanently ligated prior to being placed in a hypoxia chamber (8% O2) for 90 minutes. At weaning (PND 21), animals assigned to ER were housed in an enriched environment and received reach training for 4 weeks. All other animals were standard housed. Once weaned, pups received subcutaneous metformin (200mg/kg/day) or saline injections for 4 weeks. Motor function was assessed pre- and post-combined therapy using the following tests: adhesive-strip removal, ladder-walking and Montoya staircase. Following four weeks of treatment, rats receiving ER made fewer errors with their impaired forelimbs and hindlimbs on the ladder-walking test and displayed a decreased latency to contact the adhesive strip on their impaired forelimb. In addition, animals receiving either metformin or enriched rehabilitation showed an improved learning curve on the Montoya staircase. In conclusion, enriched rehabilitation promoted motor recovery following HI, while the effects of metformin on recovery are further being investigated. Future experiments will be examining the effects of metformin and enriched rehabilitation on cognitive function following HI.

Title: Magnetic resonance imaging and O-15 gas positron emission tomography in immature rats with hypoxic-ischemic brain injury

Authors: *M. TSUJI[1,2], J. ENMI[3], T. MORIGUCHI[3], K. KOSHINO[3], M. OHSHIMA[2], H. IIDA[3];

Abstract: Background & Objectives: Hypoxic-ischemic (HI) brain injury results from birth asphyxia in perinatal period and from cardiopulmonary arrest with heart diseases or near-drowning in childhood. Magnetic resonance imaging (MRI) and positron emission tomography (PET) are used to evaluate the brain damage and to predict the outcome in those neonates and children. However, precise temporal changes in MR/PET imaging are not known, and their predictive values are not high. Recently we have developed a non-invasive MR/O-15 gas PET imaging system for small animals that does not require tracheal intubation/tracheostomy and arterial blood sampling. Objectives of this study are; 1) to clarify temporal profiles of brain injury and hemodynamics in immature rats with HIE by using the MR/PET imaging; 2) to analyze correlations between early parameters in the imaging and the later morphological damage to see if there is a highly predictive parameter. Methods: Postnatal day 21 rats were subjected to unilateral common carotid artery ligation followed by 80 min hypoxic insult. Each of nine rats was sequentially evaluated with 7-tesla MR/O-15 gas PET imaging system at 2-3h, 24h, 48h, 7, and 41 days after the HI insult. We measured three parameters in the MRI, i.e. T2-weighted signal (T2WS), apparent diffusion coefficient (ADC), and fractional anisotropy (FA), and three parameters in the PET, i.e. cerebral blood flow (CBF), cerebral metabolic rate of oxygen (CMRO2), and cerebral blood volume (CBV). We set regions of interest in the cortices, and calculated the ipsilateral/contralateral ratios of each parameter. The brains were removed at 42 days after the HI and evaluated morphological damage by calculating the ipsilateral/contralateral ratios of hemispheric volume. Results: At 2-3h after the HI, the mean ratio of CBF was the only parameter distinctively altered, i.e. decreased. At 24h after the HI, the mean ratio of T2WS increased, and that of ADC decreased, while the ratio of CBF returned to

normal. At 48h after the HI, the ratios of FA and CMRO2 decreased. T2WS at 24h and ADC at 24h and 48h after the HI significantly correlated with the later brain damage. CMRO2 at 24h and 48h after the HI exhibited trend in correlation with the later brain damage. Other than those parameters at the specific time points, no parameters correlated with the later brain damage. Conclusions: Our MR/PET imaging revealed temporal changes in brain injury and hemodynamics in immature rats with HI. T2WS, ADC, and CMRO2 at subacute phase were predictive of the later brain damage. This study showed that predictive value of the MR/PET imaging is parameter- and timing-dependent.

Title: Crosstalk of estrogen receptor alpha with TrkB receptors in sexed hippocampal neurons after *in vitro* ischemia

Authors: V. CHANANA[1], W. SUN[1], D. KINTNER[1], E. UDHO[1], P. FERRAZZANO[1], R. A. SHAPIRO[2], J. E. LEVINE[2], *P. CENGIZ[3];
[1]Pediatrics and Waisman Ctr., Univ. of Wisconsin, Madison, WI; [2]Neurosci., Univ. of WIsconsin, Madison, WI; [3]Dept. Pediatrics and Waisman Center, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Objective: Hypoxia-ischemia (HI) related brain injury after perinatal asphyxia is a major cause of death and life-long disability. We recently showed in-vivo that the hippocampal ERα expression increases significantly in the female hippocampi compared to males post-HI. In addition, the sexually differentiated TrkB phosphorylation gets ablated in ERα knockout (KO) mice, indicating a role of ERα in conferring responsiveness to the HI and the potent/selective TrkB agonist [7,8 dihydroxyflavone (7,8-DHF)]. Cytoplasmic Src Family kinase, src, got

phosphorylated significantly in the female hippocampus but not in males post-HI and after 7,8-DHF therapy, a response which also got ablated in ERα KO mice in-vivo. We hypothesize that ERα is required for src phosphorylation which in turn results in TrkB phosphorylation in primary sexed hippocampal neurons after *in vitro* ischemia. We intend to define the pathway through which this mechanism works in sexed primary hippocampal neuronal cultures *in vitro* using ER WT and ERα KO mice. Methods: Sexed hippocampal primary neuronal cultures were prepared from 1-day old C57BL/6J ERα WT and ERα KO mouse pups as described previously. Neurons were grown on coverslips after being treated with Ara-C to kill astrocytes and then exposed to either normoxia or OGD (1% O2, 5% CO2, balance N2, 37ºC) for four hours at DIV 7. After 24 hours of REOX, cells were stained by either Hoechst, calcein and propidium iodide (PI) for cell survival studies or with ERα, p-src or p-TrkB. Fluorescent signals from culture dish were obtained by confocal microscope and by imaging 6-9 random fields (20x). The results from each coverslip were averaged. For multiple comparisons ANOVA was used. Results: There were increased ERα and p-TrkB expressions in female primary hippocampal neurons compared to males after OGD-REOX. In addition, TrkB agonist therapy (7,8-DHF) increased the p-TrkB expression further and decreased the cell death only in female hippocampal neurons following OGD-REOX. The p-TrkB expression was ablated in both male and female hippocampal neurons obtained from ERαKO mice. Conclusion: There is sexually differential response of the hippocampal neurons to TrkB signaling mediated by the ERα, favoring females after *in vitro* ischemia. We will be testing the role of the src in mediating the cross-talk between the ERα and TrkB by using an SFK inhibitor and genetically knocking down the src. Identifying the role of ERα-SFK-TrkB interaction in neuronal survival will provide a new target for preventive and therapeutic interventions post-HI.

Title: Combination of resveratrol and docosahexanoic acid shows a synergic effect raising their neuroprotective effects in perinatal hypoxia-ischemia in rats

Authors: *A. ALVAREZ[1], O. ARTEAGA[2], E. HILARIO[2], L. URIGÜEN[1], M. REVUELTA[2]; [2]Cell Biol., [1]Univ. of Basque Country, Leioa, Spain

Abstract: Neonatal hypoxia-ischemia (HI) brain injury remains one of the major causes of life-long neurological morbidity. Docosahexanoic acid (DHA) and resveratrol (RVT) are antioxidants whose interest has grown due to their neuroprotective possibilities. DHA is a long-chain omega-3 fatty acid, commonly found in fish such as salmon and tuna, while RVT is a natural polyphenol found in different plant species, including grapevines, peanuts and pomegranates. The aim of the present work was to evaluated the protective effects of the combination of resveratrol and docosahexanoic acid when administered before HI brain injury in neonatal rats using the Rice-Vannucci model. Seven-day-old (P7) rats were randomly assigned to: one Control group (n=8), hypoxia-ischemia (HI) group (n=8) and a group of HI animals that received a single dose of a combination of DHA (1 mg/kg) and RVT (20 mg/kg) 10 minutes before hypoxia (RVT+ DHA, n=8). Injury was induced by permanent ligature of the left common carotid artery and then by asphyxia for 2 hours and 15 minutes with 8% O2. On P14 brains were evaluated neuronal and oligondendroglial injury and on P90 we evaluated the long-lasting memory impairments by T-maze and novel object recognition tests. One-way analysis of variance followed by Bonferroni-Dunn correction was performed and $P<0.0001$ was considered to indicate a statistically significant difference. Microscopic photographs and a semi-quantitative neuropathological scoring system demonstrated a damage located at the level of hippocampus and parietal cortex of ipsilateral hemisphere in HI group, but this damage was reduced by RVT+DHA. HI animals also showed a significant decrease in Myelin Basic Protein-immunostaining pattern in comparison with the Control group that was restored with the pretreatment. On PN90, animals pretreated with RVT+DHA performed better at the T-maze and novel object recognition tests than HI animals, reaching similar values to those of control rats. Our results suggest that a pretreatment with a combination of resveratrol and docosahexanoic acid led to a neuroprotective effect by reducing the neuronal damage and preserving myelin in short-term and improving cognitive impairments in long-term.

Title: Tinnitus profoundly modifies the dynamics of neuronal rhythms of the thalamo-cortical circuitry of a rodent experimental model of this brain disorder

Authors: *P. VIANNEY[1,2], B. AUERBACH[2], S. MANOHAR[2], G.-D. CHEN[2], S. HAYES[2], A. SHEPPARD[2], R. SALVI[2];

Abstract: Tinnitus is a brain disorder characterized by the perception of a phantom ringing sensation. Approximately 1% of adults seek medical treatment for severe debilitating tinnitus. However, there are no FDA approved drugs to treat tinnitus and the lack of safe and effective treatment is due to our poor understanding of the cellular mechanisms underlying tinnitus. The "thalamocortical dysrhythmia model" to explain tinnitus proposes that tinnitus arises from a persistent miscommunication between the thalamus and cortex. However, there is little or no data in animals attempting to explore whether tinnitus changes the thalamo-cortical rhythmic patterns. Here, we performed 32 multi-site simultaneous acute electrophysiological recordings from the Medial Geniculate Body (MGB) and the Primary Auditory Cortex (A1) of anesthetized rodents (n=11) injected with 250 mg/kg of sodium salicylate (SS), a drug that reliably induces tinnitus in rodents and humans. SS induced a threshold shift in the MGB and A1 as well as a neuronal enhancement of suprathreshold response in both structures. Importantly, SS profoundly changed the rhythmic dynamics in the MGB and A1. Spectrogram and power spectrum density analysis in MGB show that SS induced a reduction of oscillatory activity in the theta (4-8 Hz), alpha (8-12 Hz) and beta (15-25 Hz) frequency bands whereas it substantially increased the power of gamma frequency bands (30-80 Hz). Although SS increased the oscillatory activity of theta and alpha as well as a relative increase in theta as compared to alpha frequency bands in some recording sites of the cortex, the most robust finding is that SS decreased the oscillatory activity of theta and alpha frequencies whereas it increased gamma frequency bands. Moreover, spectral analysis of the LFPs in MGB and A1 also revealed a decrease in coherence of low frequency bands (theta, alpha and beta) with a simultaneously increase in coherence at gamma frequency bands in these structures. In conclusion, our results indicate that tinnitus profoundly changes the rhythmic dynamics of large neuronal ensembles in the thalamus and cortex and suggest that high frequency oscillations might be involved in the perception of tinnitus.

Title: Effect of modulation of the frontostriatal gating system using transcranial direct current stimulation on tinnitus perception

Authors: *A. J. MAUDOUX[1], P. E. TURKELTAUB[2,3], J. P. RUSCHECKER[1];
[1]Lab. of Integrative Neurosci. and Cognition, Dep. of Neurosci., Georgetown Univ. Med. Ctr., Washington, DC; [2]Cognitive Recovery Laboratory, Dep. of Neurology, Georgetown Univ., Washington, DC; [3]Res. Division, MedStar Natl. Rehabil. Hosp., Washington, DC

Abstract: Background: Tinnitus is defined as a perception of sound in the absence of any external auditory stimuli. Despite the prevalence of this disorder, tinnitus pathophysiology remains poorly understood. We have proposed previously [1] that tinnitus perception arises only if two conditions are met: (1) a tinnitus signal is being generated within the auditory system, and (2) this uninformative signal fails to be suppressed by a cortico-striatal limbic network encompassing ventromedial prefrontal cortex (vmPFC) and nucleus accumbens (NAc) ("gating theory"). Methods: In our current study, we have chosen to test this model using a combination of transcranial direct current stimulation (tDCS) and functional magnetic resonance imaging (fMRI). In a randomized, doubleblind, shamcontrolled cross-over design, chronic tinnitus subjects are submitted to 15 minutes of 2-mA tDCS anodal stimulation of the vmPFC and cathodal stimulation of the right dorsolateral prefrontal cortex (dlPFC). Participants are scanned before and after each of the tDCS sessions. The locations of anode and cathode are based on a recent study showing that this noninvasive direct stimulation of prefrontal cortex can induce neural activity in the distally connected midbrain, with a direct behavioral effect on an attractiveness rating task [2]. Using this stimulation protocol we aim to target major regions of the gating system, such as the prefrontal region and the NAc. Our primary outcome measure is a change in tinnitus intensity and/or distress assessed with a Visual Analog Scale. We are also looking at how tDCS stimulation modifies the pleasantness rating of a series of affective auditory stimuli [3]. During the fMRI session, subjects are listening to tinnitus-like and non-tinnitus sounds and are making pleasantness ratings of these sounds. Results: We will present our

preliminary results regarding the behavioral effects of the tDCS stimulation on the perception of tinnitus and on the pleasantness rating of affective auditory stimuli. The imaging analysis will examine tDCS-induced changes in neural function associated with the behavioral changes. 1.Rauschecker, J.P., A.M. Leaver, and M. Title: Physiological characteristics of multiple auditory fields in the tinnitus animal model

Authors: *E. BUELL[1], M. S. BORLAND[2], M. P. KILGARD[2];
[1]Univ. of Texas At Dallas, Richardson, TX; [2]UT Dallas, Richardson, TX

Abstract: Specific Aim: To test the hypothesis that hyperactivity in cortical regions outside of A1 is associated with the rat model of tinnitus. Tinnitus is associated with abnormal activity throughout the central auditory system and in many non-auditory structures. The proposed experiments will test the hypothesis that tinnitus is an emergent property of pathological neural activity in multiple brain regions. Recordings were made in inferior colliculus and two non-primary auditory fields. Materials and Methods *Subjects* Fifteen female adult Sprague-Dawley rats were used in this study. Seven were noise-exposed as part of the experimental group and eight remained naïve for the control group. *Auditory Brainstem Recordings* Auditory brainstem recordings (ABRs) were recorded using custom headcap electrodes, BRAINWARE v8.12, and a speaker. Recording and reference screws were placed over cerebellum and cerebral cortex. *Tinnitus Testing* The behavioral correlate of tinnitus was determined using the Turner Gap Detection Method. A 50 ms silent gap inserted into the narrowband noise 100 ms before a 100 dB noise burst. Animals pass the task when they are able to detect the silent gap. Animals are placed in “Tinnitus” group when they fail the task for 2+ consecutive weeks. *Anesthetized Recordings* Four parylene coated tungsten microelectrodes record neuron responses from layer

4/5 of the right primary auditory cortex in barbiturate anesthetized rats. The stimuli used to generate neural responses consist of 1,296 tones at 81 frequencies (1 to 32 kHz) and 16 intensities (0 to 75 dB) Current Results We obtained 839 sites in experimental group and 939 sites in naïve group. Our current data suggests that there are significant increases in spontaneous activity for tinnitus in all fields except the anterior field in tinnitus animal models. Excitability (driven spikes) does not currently show significance as in previous experiments, which indicates more data is needed before forming conclusions. Both the posterior field and inferior colliculus show significant shifts in tonotopicity. Conclusions Results from A1 are consistent with research citing cortical changes in response to noise-exposure and tinnitus. Auditory Brainstem Reponses indicate profound losses at high frequencies (32 kHz), moderate losses at mid-frequencies (10-16 kHz), and no loss at low frequencies (4kHz). Hearing loss at tinnitus frequency is consistent with what is often seen clinically. The anterior shows significant changes in latency and bandwidth only. The posterior field shows changes in tonotopicity, which is consistent with previous work demonstrating this field's susceptibility to shifts.

Title: Tinnitus detection in three mouse models with salicylate injections, noise exposure or optogenetic stimulation as tinnitus inducers

Authors: *K. T. NAKAMOTO, H. ZUO, D. LEI, J. BAO;
Anat. and Neurobio., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Subjective tinnitus, the perception of a phantom sound, is a common phenomenon in humans. Both operant and reflex based tests have been developed to detect tinnitus-like behavior in mice mainly because of its wide ranges of genetically modified strains for mechanistic studies. Recently, the most widely used behavioral paradigm has been the gap prepulse inhibition of the acoustic startle reflex (GPIAS). In GPIAS the startle reflex is elicited by an abrupt onset of a noise burst. This noise burst is presented on a background of continuous noise and a brief silent interval (gap) is inserted into the background noise. Perception of the gap reduces the startle

response in normal animals, but the reduction is thought to be less in animals with tinnitus. The underlying assumption is that the tinnitus will partially fill in the silent gap, reducing the gap inhibition of the start reflex. However, this assumption has recently come into question (Campolo et al., 2013; Eggermont, 2013; Fournier and Hebert, 2013; Radziwon et al., 2015). This has highlighted the need to validate GPIAS with well-established behavioral methods. In the present study, we assessed the validity of GPIAS to detect tinnitus-like behavior in mice, by comparing it to a well-established operant conditioning (OC) method. We used three known manipulations that can create a "phantom" sound (tinnitus): salicylate injections, noise exposure, or optogenetic stimulation of auditory cortex. By comparing the same animal in both OC and GPIAS methods after salicylate injections we demonstrated that OC method was consistent across salicylate injections, while GPIAS was highly variable. More importantly, we did not find any agreement between OC and GPIAS indication of tinnitus. We then used OC and GPIAS over a four month period to measure behavioral indications of tinnitus after unilateral noise exposure. OC indications of tinnitus were consistent across time, however GPIAS indications of tinnitus were not. Again, we did not find agreement between the OC indication of tinnitus and the GPIAS indication of tinnitus. Finally we optogenetically stimulated the auditory cortex of the mice, inducing a "phantom" sound. Again, we did not find agreement between OC and GPIAS. We believe that this evidence demonstrates that the GPIAS is not a reliable indicator of tinnitus in mice, though it may be still useful to monitor functional changes in the auditory system during tinnitus pathogenesis. In short, this study clearly demonstrated the limitation of GPIAS in future tinnitus studies.

Title: Manipulating endocannabinoid signalling in a guinea pig model of tinnitus

Authors: *B. COOMBER[1], J. I. BERGER[1], S. P. H. ALEXANDER[2], A. R. PALMER[1], M. N. WALLACE[1];
[1]MRC Inst. of Hearing Res., Nottingham, United Kingdom; [2]Sch. of Life Sci., Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Animal models of tinnitus have revealed long-term hyperexcitability and altered neural synchrony, thought to arise from a pathological imbalance between excitatory and inhibitory neurotransmitter systems. The release of neurotransmitters is regulated by neuromodulators, such as endogenous cannabinoids (endocannabinoids). Endocannabinoids are produced on-demand in response to depolarisation and act to regulate presynaptic neurotransmitter release. Cannabinoid drugs are potent anti-nociceptive agents in models of chronic neuropathic pain, a condition that has substantial parallels with tinnitus, i.e. a phantom sensory percept in the absence of sensory input, initiated peripherally through deafferentation and subsequently involving central mechanisms. In the present study, guinea pigs were subjected to either (1) unilateral acoustic over-exposure (AOE), to induce chronic tinnitus, or (2) sodium salicylate administration, to induce acute tinnitus. In animals subjected to AOE, tinnitus was objectively identified with the gap prepulse inhibition of acoustic startle (GPIAS) behavioural test, eight weeks after AOE. Hearing status was assessed using auditory brainstem responses. Animals were then retested on five occasions after being administered either the cannabinoid CB1 receptor agonist arachidonyl-2'-chloroethylamide (ACEA; 1 mg kg-1, i.p.) or drug vehicle. Treatment with ACEA produced variable effects in animals with AOE-induced tinnitus, but did not produce either a consistent augmentation or an attenuation in tinnitus behaviour across all animals. In the second group of animals, GPs were first implanted with electrocorticography (ECoG) multi-electrode arrays, before being administered with sodium salicylate (350 mg kg-1; i.p.) to induce tinnitus, and either ACEA (1 mg kg-1, i.p.) or drug vehicle. Resting-state and auditory-evoked neural activity recorded in awake, freely-moving animals was compared between groups. In salicylate-treated animals resting-state brain activity was altered and auditory-evoked neural responses were enhanced. Preliminary data collected from animals co-administered ACEA and salicylate indicated a reduction in auditory hypersensitivity (induced by salicylate). These data indicate that manipulating endocannabinoid signalling can affect tinnitus-related neural activity, but these changes may be too subtle to detect using the GPIAS behavioural approach.

Title: Salicylate-induced changes in brain activity in awake guinea pigs

Authors: *J. BERGER, B. COOMBER, M. N. WALLACE, A. R. PALMER;
MRC Inst. of Hearing Res., Nottingham, United Kingdom

Abstract: Tinnitus - the perception of phantom sounds - chronically affects an estimated 8-15% of people. Tinnitus is difficult to characterise and frequently intractable, and presents a significant burden to healthcare resources. Studies conducted in human subjects with tinnitus have shown altered patterns of resting-state oscillatory brain activity. However, to date this has not been extensively explored using animal models, which allow more invasive examination of changes in neural activity and their correlation with objective behavioural measures of tinnitus. Here, we describe the development of an awake preparation for examining tinnitus-related changes in resting-state and auditory-evoked brain activity. Guinea pigs were implanted with electrocorticography (ECoG) electrode arrays, with electrodes positioned on the surface of the dura over left and right auditory cortex and over the cerebellum, to monitor auditory brainstem responses. ECoG responses were subsequently compared before and two hours after tinnitus induction with sodium salicylate (350 mg kg^{-1}; i.p.), a drug which reliably induces tinnitus in both humans and animals. Subtle salicylate-induced changes in oscillatory activity were observed in all animals recorded from electrodes over auditory cortex, predominantly at low frequencies, i.e. delta, beta, and alpha bands. Click-evoked cortical field potentials were dramatically enhanced (~100% increase) following salicylate treatment, compared with vehicle treatment, potentially indicating increased sensitivity to sound (hyperacusis). These salicylate-induced changes in spontaneous and auditory-evoked cortical potentials may be due to direct effects on neuronal excitability. Furthermore, small increases in neural gap detection thresholds were observed, suggestive of a slight worsening in temporal processing. Tinnitus induction with salicylate is widely used as an acute tinnitus model. The next stage will involve a chronic tinnitus model (induced by acoustic over-exposure), that will allow us to track neural changes throughout tinnitus development in an awake-behaving model.

Title: Circadian influence on the salicylate-induced changes in the acoustic startle responses of rats

Authors: *M. J. FERRAGAMO[1], T. C. SIGAFOOS[2], B. K. TITUS[2], J. M. WOTTON[2]; [1]Biol. and Psychologcal Sci., [2]Gustavus Adolphus Col., Saint Peter, MN

Abstract: Relatively high doses of sodium salicylate (aspirin) are used to induce temporary tinnitus in rodents. A common test of the effectiveness of this treatment is to compare the responses of the gap detection and pre-pulse inhibition (PPI) tasks in the acoustic startle paradigm. The assumption is that the induced tinnitus will partially fill in the gap and thus the signal will be less effective in inhibiting the response to the subsequent pulse. Typically this is reported as percentage suppression which is calculated by comparing the response to the gap-preceded pulse with that of the pulse alone. Circadian activity is known to influence the acoustic startle response and we examined whether time of day would differentially impact these responses to salicylate-induced tinnitus. Ten male Long-Evan rats were tested on gap and PPI (both in a single session) in a repeated measures experiment at four different times (8:00, 12:00, 16:00, 20:00) on different days established by a pseudo-random schedule. The rats were given IP injections of either saline or sodium salicylate (350 mg/kg) two hours prior to testing. Animals were maintained in 12 hours light (8:00 - 16:00) and 12 hours dark condition. As predicted, the salicylate condition caused less suppression of the response when compared to the saline control in the gap detection task but not in the PPI task. However, the change in suppression for the gap task was at least in part mediated by the change in the response to the pulse alone and to the time of day. In the gap detection task there was a decreased response to the pulse in the salicylate condition compared to control and this difference was greatest in the light phase. The gap trials also showed lower responses with salicylate but this varied with time of day with the light onset and offset times having the biggest difference. In the PPI task the response to pulse alone was greater in the dark than the light phase and with salicylate the pulse response increased especially in the dark. This change to pulse alone in the PPI task may indicate salicylate induced hyperacusis which is sensitive to time of day.

Abstract: More clinical cases showed that the diabetic hearing loss is one of the common complaints of type II diabetic patients. It was known that glucose is a fundamental source of energy for mammalian cells; however, whether glucose is taken up through the lateral walls of cochlear outer hair cells (OHCs) is unknown. The OHC lateral wall is complex, composed of a plasma membrane, cortical lattice, and subsurface cisternae. This study assessed the uptake of glucose by OHCs using live cell microscopy and examined the distributions of glucose transporter isoforms by immunohistochemistry. We found that glucose transporter-4 was mostly expressed on the inner membrane of the OHC's lateral walls of guinea pig. Glucose crossed the lateral walls of OHCs via glucose transporters-4 mainly, and this process could be modulated. These results suggest that the lateral walls are involved in modulating energy transport into OHCs and may be useful to understand the mechanism of diabetic hearing loss.

Title: Progressive hearing loss in mice carrying a mutation in the inactive deubiquitinating enzyme usp53

Authors: *M. SCHWANDER[1], M. KAZMIERCZAK[1], S. HARRIS[1], P. KAZMIERCZAK[2], P. SHAH[1], V. STAROVOYTOV[1], K. OHLEMILLER[3];

Abstract: Disordered protein ubiquitination has been linked to neurodegenerative disease, yet its role in inner ear homeostasis and hearing loss is largely unknown. Here we show that progressive hearing loss in the ethylnitrosourea (ENU)-generated mambo mouse line is caused by a mutation in Usp53, a member of the deubiquitinating enzyme family. USP53 contains a catalytically inactive ubiquitin-specific protease (USP) domain and is expressed in cochlear hair cells and a subset of supporting cells. While hair cell differentiation is unaffected in mambo mice, outer hair cells rapidly degenerate after the first postnatal week. USP53 colocalizes and interacts with the tight junction scaffolding proteins TJP1 and TJP2 in polarized epithelial cells, suggesting that USP53 is part of the tight junction complex. The barrier properties of tight junctions of the stria vascularis appeared intact in a biotin tracer assay, but the endocochlear potential is reduced in adult mambo mice. Hair cell degeneration in mambo mice precedes endocochlear potential decline and is rescued in cochlear organotypic cultures in low potassium milieu, indicating that hair cell loss is triggered by extracellular factors. Remarkably, heterozygous mambo mice show increased susceptibility to noise injury at high frequencies. We conclude that USP53 is a novel tight junction-associated protein that is essential for the survival of auditory hair cells and normal hearing in mice, possibly by modulating the barrier properties and mechanical stability of tight junctions.

Title: A comparison of projections to primary (A1) and non-primary (PAF) fields of the cat auditory cortex following hearing loss

Authors: *B. BUTLER[1], N. CHABOT[1], S. LOMBER[2];
[1]Physiol. & Pharmacol., [2]Physiol. & Pharmacol. / Psychology, Univ. of Western Ontario, London, ON, Canada

Abstract: When a sensory modality is lost, compensatory advantages are often observed in remaining modalities. For example, both humans and animal models show behavioural advantages in peripheral acuity and motion perception following hearing loss. These advantages are thought to result from recruitment of cortical areas that typically process stimuli from the missing modality. While there remains some controversy regarding crossmodal reorganization of primary sensory cortices, there is growing evidence for age-dependent changes in higher-level cortical structures across modalities and species. Indeed, visually-evoked activity has been observed in the posterior auditory field (PAF) in the cat cortex using functional MRI. This current study examines how patterns of thalamo-cortical and cortico-cortical projections to PAF are altered following deafness in an effort to determine the anatomical basis of these functional changes. A retrograde neuronal tracer (biotinylated dextran amine; BDA) was deposited in the PAF of hearing and ototoxically-deafened cats. Coronal sections were taken and neurons showing a positive retrograde labeling were counted and assigned to cortical and thalamic areas according to published criteria. The proportion of labelled neurons in each area was determined in relation to the total number of labeled neurons in the entire brain. Group level analyses of the proportion of labels arising from auditory and non-auditory fields will be discussed to illustrate the intra- and inter-modal effects of hearing loss. Additionally, the results of cats deafened at the onset of hearing will be compared to those deafened following normal auditory development to examine those effects that are related to the age at the onset of deafness. Finally, these changes in high-level auditory cortex will be compared to changes in a primary field (A1) to illustrate differences in the capacity for reorganization between primary and non-primary areas.

Title: Blast-induced hearing loss and differential gene expression in the inner ear and brainstem of rat

Authors: *Y. WANG, Y. WEI, S. OGUNTAYO, Y. SU, D. WILDER, I. GIST, P. ARUN, J. B. LONG;
Walter Reed Army Inst. of Res., Silver Spring, MD

Abstract: Blast exposure may cause long term neurological and neurosensory deficits. Hearing loss, tinnitus and dizziness are disabilities commonly experienced by victims exposed to improvised explosive devices. However, the mechanisms underlying these injuries are largely undefined. In previous studies, we have demonstrated that closely coupled blast exposures caused motor coordination defects and axonal degeneration in rodents. The present research aimed to investigate the changes in auditory function and gene expression in the inner ear and brainstem structures involved in auditory signal processing. An air-driven shock tube was used to simulate primary blast on anesthetized SD rats (male, ~350 g). We have evaluated time-course effects of blast exposure on auditory function by assessing auditory brainstem response (ABR). The differentially expressed genes were screened using RT^2 Profiler PCR Array system (QIAGEN). Audiometry data revealed that blast exposure caused: (1) significant elevation of ABR threshold; (2) increased latency on ABR waves I, II and V; and (3) reduction in ABR amplitude immediately following insult which persisted over 7 days. These changes were over the entire acoustic frequency spectrum. Compared to lower frequency (2 KHz), ABR response to high frequency (32 KHz) tone stimulus displayed a stronger impairment after injury. Among the genes involved in inflammation, DNA repair and neural growth, we found IL-1β, IL-6, TNF, CCL2, CCL12 and Prok2 were significantly up-regulated, while Trpv3, Ngf and Ntf4 were down-regulated in the inner ear and brainstem at 6 h post injury. The results indicate that both of peripheral and central auditory systems are vulnerable to blast injuries. Neuroinflammation, which occurred during the early phase post injury, could be a major factor leading to secondary neuronal damage.

Title: Cortical crossmodal plasticity following adult-onset noise-induced hearing loss in multisensory and auditory areas

Authors: *A. L. SCHORMANS, M. TYPLT, B. L. ALLMAN;
Anat. and Cell Biol., Western Univ., London, ON, Canada

Abstract: Complete or partial hearing loss results in crossmodal plasticity, which is characterized by an increased responsiveness of neurons to other sensory modalities (e.g., auditory neurons become more responsive to visual and/or tactile stimuli). At present it is relatively unknown how adult-onset partial hearing loss affects areas of the cortex that are already capable of integrating multisensory information. Thus, we investigated the effect of noise-induced hearing loss on neurons in the dorsal auditory area (AuD) of the rat, as well as the neighboring lateral extrastriate visual cortex (V2L), an area known to integrate audiovisual stimuli. Adult male rats underwent an auditory brainstem response (ABR) test to determine their baseline hearing levels, followed by a bilateral noise exposure (0.8-20 kHz at 120dB for 2 hours). Two weeks later, hearing levels were reassessed, and an acute electrophysiological recording experiment was performed under ketamine/xylazine anesthesia. Using a 32-channel electrode, recordings were completed with either a dorsal/medial-to-ventral/lateral approach to record single neuron activity, or a laminar approach to simultaneously record local field potentials (LFPs) across the cortical layers. For each electrode penetration, computer generated auditory (noise burst), visual (light flash) and combined audiovisual stimuli were delivered, and the associated spiking activity and LFPs were recorded. In age-matched controls, the same ABR and acute electrophysiology experiments were performed. Noise exposure increased ABR threshold by 14.3 ± 4 dB and decreased wave 1 amplitude by 50%. In comparing noise exposed rats to controls, the proportion of visual neurons in V2L, increased 38%, and the proportion of multisensory neurons moderately decreased 17%. This reduction in multisensory neurons in V2L was inconsistent with the crossmodal plasticity observed in AuD, where the proportion of multisensory neurons nearly doubled. Current source density (CSD) analysis revealed altered laminar processing in AuD following noise exposure, in which there was a near doubling of sink amplitudes to auditory and audiovisual stimuli in most of the cortical layers. In contrast, no changes in sink amplitude were observed in V2L. Overall, noise-induced hearing loss resulted in an increase in the proportion of visually-responsive neurons; however, the degree and nature of crossmodal plasticity differed across cortical areas such that only the dorsal auditory area, AuD, showed altered laminar processing and an increased proportion of neurons capable of processing multisensory information following the adult-onset partial hearing loss.

Title: Differentiation of spiral ganglion-derived neural stem cells into functional synaptogenetic neurons

Authors: *X. LI, A. ALEARDI, J. WANG, Y. ZHOU, R. ANDRADE, Z. HU;
Wayne State Univ., Detroit, MI

Abstract: Spiral ganglion neurons (SGNs) transmit sound signals from the inner ear to the brainstem, but they are usually damaged in sensorineural hearing loss. SGN-derived neural stem cells (NSCs) have been identified and proposed to differentiate into neurons to replace damaged SGNs. However, it remains unclear whether SGN-NSC-derived neurons are electrophysiologically functional and possess the capability to form neural connections. In this study, postnatal mouse spiral ganglia were harvested and cultured in suspension, followed by adherent cultures to study neuronal differentiation and function. It was found that SGN-derived cells demonstrated NSC characteristics, as they were able to proliferate to form neurospheres and express NSC markers Sox2 and nestin. These SGN-NSCs differentiated into bipolar SGN-like glutamatergic neurons expressing neuronal proteins (TUJ1, neurofilament, NeuN, and NeuroD) and the glutamatergic protein VGLUT1. Brain derived neurotrophic factor (BDNF) significantly increased neuronal differentiation and the neurite length of SGN-NSC derived neurons (ScNs). Patch clamp recording revealed that newly-generated ScNs possessed SGN-like NaV and HCN channels, suggesting that ScNs were electrophysiologically functional. Immunofluorescence showed positive synaptic protein staining in ScNs cultures, indicating that ScNs possess the capabilities to form neural connections. Moreover, astrocyte condition medium was found to be able to stimulate ScNs to express synaptic proteins. These data suggested that BDNF is able to stimulate postnatal mammalian SGN-NSCs to differentiate into glutamatergic, functional ScNs with the capability to form synaptic connections *in vitro*. This study opens avenues to develop stem cell-based replacement to substitute the function of damaged neurons in the peripheral sensory system.

Title: Two amusic stroke patients: Behavior and imaging results

Authors: ***S. ROSEMANN**, P. ERHARD, M. FAHLE;
Univ. of Bremen, Bremen, Germany

Abstract: Music processing involves perception and cognitive analysis of melodic and temporal information and is accomplished by a distributed neuronal network including auditory cortices, frontal areas and basal ganglia. A stroke affecting one of these regions may impair music perception. The deficit termed amusia can affect both the melodic and rhythmic stream of music perception. The aim of this study was to find anatomical and functional correlates of amusia by means of functional MRI. Two amusic stroke patients and 16 healthy control subjects of the same age participated. Patient 1 had a right basal ganglia infarction and deficits in rhythm perception. Patient 2 had a left fronto-parietal lesion and severe deficits in melodic and moderate deficits in rhythmic perception. The functional MRI paradigm consisted of stimulation alternating with a rest condition in a 3 tesla scanner (Siemens). Stimulation sequences consisted of a section of a German musical and contained visual and/or auditory material without any task for the subjects. Our main aim was to identify brain regions associated with processing these stimuli in healthy subjects and to compare them with those of both of our patients. The rest condition was contrasted with activation associated with a) unimodal auditory, b) unimodal visual and c) bimodal visual and auditory perception. Group analysis of the healthy control subjects was based on a random effect analysis with separate subject predictors ($p<0.001$, uncorrected, cluster size > 25 voxels). Bainvoyager QX software served to analyze the data. The superior temporal cortex, occipital and occipito-temporal cortex, intraparietal sulcus, superior parietal lobule, parts of pre- and primary motor cortex, Wernicke and Broca areas were all activated in healthy subjects. Amusia-patients showed similar activation patterns for visual and auditory cortices. Parietal activation was missing completely in patient 2 for all contrasts. Patient 1 showed a disturbed activation pattern in parietal and frontal regions (ten patches of interest in somatosensory cortices) for auditory stimulation and no parietal activation for bimodal

stimulation. The lesions of both patients correspond to the network involved in healthy musical processing and suggest that basal ganglia (rhythmic) and frontal (melodic) regions are involved in the cognitive analysis of music. Both patients presented a disturbed activation pattern in the parietal cortex for both unimodal and bimodal auditory stimuli. This suggests that parietal regions play a major role in music perception.

Title: Three-dimensional ultrastructure of retinocollicular synapse mitochondria in early glaucoma

Authors: *B. R. SCHOFIELD[1], M. A. SMITH[2], C. Z. XIA[2], K. M. FENING[2], C. M. DENGLER-CRISH[2], D. M. INMAN[2], S. D. CRISH[2];

Abstract: We have previously reported persistence of retinal ganglion cell terminals (RGC) in the superior colliculus after axon transport deficits are seen in the DBA/2J mouse model of high-pressure glaucoma. The vast majority of these synapses exhibited normal synaptic structures, including large mitochondria with sparse cristae, round, clear synaptic vesicles, and dense active zones. Paralleling morphometric changes in other RGC compartments in this model, RGC synapses and their mitochondria increase in volume early in the progression of pathology with later reductions in both measures. However, it is unclear how functional these hypertrophic mitochondria are at these stages, or their relationship to other aspects of synaptic changes. Using serial blockface scanning electron microscopy, we examined the ultrastructure of retinocollicular synapses in glaucomatous DBA/2J mice and age-matched controls. We found that, even though there were significant reductions in mitochondrial health score compared to controls, the overwhelming majority of mitochondria in our glaucoma models appeared healthy, a measure determined primarily by cristae appearance and density. Collicular areas exhibiting anterograde

axonal transport deficits had a greater number of unhealthy mitochondria and fewer active zones, suggesting reduced oxidative capacity and signaling capability. These findings suggest an early defect in synaptic metabolism and function in this model and may present useful therapeutic targets for glaucoma.

Title: Relationship of retinal ganglion cell number and function in the glaucomatous murine eye

Authors: *L. L. COUGHLIN[1,2], D. M. INMAN[1];
[1]Dept. of Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH; [2]Sch. of Biomed. Sci., Kent State Univ., Kent, OH

Abstract: Glaucoma is an optic neuropathy that results in progressive and irreversible blindness due to retinal ganglion cell (RGC) axon degeneration. The exact mechanism that leads to RGC degeneration is not yet known. Neuroprotection has become a focus of therapeutic development in glaucoma, the rationale being that preserving RGCs will preserve vision. Inherent in this view is the notion that more RGCs translates to better vision. We decided to examine this assumption in the DBA/2J (D2) mouse, an inbred strain that develops glaucoma secondary to iris pigment dispersion disease-related increases in intraocular pressure (IOP). Visual acuities in young (5 month) and old (12 month) D2 mice were measured using a forced choice swim task. Mice were trained to associate a submerged platform with a vertical sinusoidal grating. By changing the cycles/degree of the sinusoidal grating, we could detect visual perceptual threshold based on the success of the mice to find the submerged platform. After visual acuities were established, RGCs were retrogradely labeled using FluoroGold (FG). We also injected Cholera Toxin B (CTB) into the vitreous chamber to anterogradely trace RGC axons. After quantifying FG-positive RGCs, we determined that overall visual acuity did not correlate well with RGC number in neither the young nor old age groups. Interestingly, 58 percent of the old D2 mice had a significant discrepancy in RGC number between the left and right eyes, suggesting that mice could compensate for extreme RGC loss by relying on remaining function in the more intact eye. The wide range of RGC number within an established visual acuity indicates that cell counts do not

capture function; therefore, functional testing should be an essential component of neuroprotective therapeutic development.

Title: Electrophysiology alterations in primary visual cortex neurons in the s334ter-line3 transgenic rat

Authors: *K. CHEN[1], Y. WANG[2], L. CHAN[2];
[1]Univ. of Electronic Sci. and Technol. of, Chengdu Sichuan, China; [2]City Univ. of HongKong, HongKong, China

Abstract: The role of the dynamic nature of the brain is critical in the success of treatments aimed at restoring visions at the retinal level, such as bioelectronic implants and stem-cell therapy. The success of these treatments highly relies on the functionality of the surviving neurons along the entire visual pathway. Hence, not only the retina but the visual cortex also plays an important role to allow patients suffering from retinal disease to perceive the fine details of a visual scene. The S334ter-line-3 rat is a transgenic model of retinal degeneration (RD) developed to express a rhodopsin mutation similar to that found in human retinitis pigmentosa (RP) patients. The electrophysiological properties on retina level during the progress of degeneration have been well investigated, however, little is known about the changes of electrophysiological properties in primary visual cortex (V1) during the course of retinal degeneration. By conducting the extracellular recording, we examined the electrophysiological properties of primary visual cortex in rat RD S334ter line-3 model. We have measured the orientation tuning, spatial and temporal frequency tuning and receptive field size from 18 S334ter line-3 rats and 16 long-Evans rat . Comparing to the control group (long-Evans rat), the V1 neurons in S334ter line-3 rats showed weaker orientation selectivity, lower values in optimal spatial and temporal frequency, but larger receptive field size. In addition, we found the V1 neurons in RD model have much stronger spontaneous neural firing than the control group.

These results suggest the visual cognitive ability significantly changed during the retinal degeneration.

Title: Crizotinib disrupt visual processing in the mouse retina

Authors: T. ISHII[1], S. IWASAWA[2], R. KURIMOTO[2], A. MAEDA[1,3], Y. TAKIGUCHI[2], *M. KANEDA[1];

Abstract: Molecular target therapy for cancer is characterized by unique adverse effects that are not usually observed with cytotoxic chemotherapy. For example, the anaplastic lymphoma kinase (ALK)-tyrosine kinase inhibitor crizotinib causes characteristic visual disturbances, whereas such effects are rare when another ALK-tyrosine kinase inhibitor, alectinib, is used. To elucidate the mechanism responsible for these visual disturbances, the responses to light exhibited by retinal ganglion cells treated with these ALK-tyrosine kinase inhibitors were evaluated using a multi-electrode array system in the mouse retina. Both crizotinib and alectinib changed the firing rate of ON and OFF type retinal ganglion cells. Both an increase in firing rate and a decrease in firing rate were observed. However, the ratio of alectinib-affected cells (15.7%) was significantly lower than that of crizotinib-affected cells (38.6%). Furthermore, these drugs changed the response properties to light stimuli of retinal ganglion cells in some of the affected cells, i.e., OFF cells responded to both ON and OFF stimuli, etc. Finally, the expressions of ALK (a target receptor of both crizotinib and alectinib) and of MET and ROS1 (additional

target receptors of crizotinib) were observed at the mRNA level in the retina. Our findings suggest that these drugs might target retinal ganglion cells and that the potency of the drug actions on the light responses of retinal ganglion cells might be responsible for the difference in the frequencies of visual disturbances observed between patients treated with crizotinib and those treated with alectinib.

Title: Rapid and objective quantification of high-level visual impairment with fast periodic oddball stimulation in acquired prosopagnosia

Authors: ***J. LIU-SHUANG**[1], K. TORFS[1], A. NORCIA[2], B. ROSSION[1];
[1]IPSY, Louvain-la-Neuve, Belgium; [2]Stanford Univ., Stanford, CA

Abstract: Perceptual deficits are common in many neurological conditions, but their assessment can be hindered by many unrelated factors (e.g. attention, comprehension, motor impairments…). Hence, a method allowing for an objective, sensitive, and efficient quantification of perception without requiring explicit behavioural output would be highly valuable. In the recently developed fast periodic oddball paradigm, base stimuli appear at a fixed rate (F Hz) with oddball stimuli, differing on a dimension of interest, inserted at regular intervals (every nth stimulus, or F/n Hz; Liu-Shuang et al., 2014, Neuropsychologia, 52, 57-72). Periodic EEG responses at the F/n Hz oddball frequency and harmonics (2F/n Hz, 3F/n Hz…) reflect the perceptual discrimination between base and oddball stimuli. We tested this approach with PS, well-

described patient who is specifically impaired at face individualisation following brain damage (acquired prosopagnosia). PS was first presented with sequences of base "object" stimuli at 6 Hz with periodically interleaved oddball "face" stimuli at 1.2 Hz (every 5th stimulus). In line with her preserved ability to detect faces, PS showed periodic oddball responses within the normal range. However, when face identity discrimination was tested with "different" oddball face identities (B, C, D···) inserted into sequences containing a repeated "same" base face identity (A; sequence structure: AAAABAAAACAA···, Liu-Shuang et al., 2014), significant oddball responses were found in all control (young and age-matched) participants but were absent for patient PS. These observations were obtained within 8 and 12 min of recording, respectively. Overall, our findings underline the value of the fast periodic oddball paradigm as a diagnostic tool for the rapid and objective characterisation of visual discrimination in neuropsychology.

Title: Prevention of retinal ganglion neuron degeneration by a selective calpain-2 inhibitor in a mouse model of acute glaucoma

Authors: *Y. WANG, D. LOPEZ, K. NGUYEN, P. DAVEY, Y. LIU, E. MARQUEZ, X. BI, M. BAUDRY;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Primary angle-closure glaucoma (PACG) is a major cause of blindness in the world and is expected to become more prevalent as longevity increases. Angle-closure glaucoma produces a rapid rise in intraocular pressure (IOP), which results in retinal ischemia and retinal ganglion cell (RGC) death. However, the mechanisms by which increased IOP leads to RGC death are not currently understood. Previous studies have shown that NMDA receptor blockade as well as several pan-calpain inhibitors reduced RGC loss after retinal ischemia. However, none of the studies have specifically addressed the roles of the two major calpain isoforms in the

retina, calpain-1 and calpain-2. In this study, we first determined the time-course of calpain-1 and calpain-2 activation following increased IOP by analyzing changes in immunoreactivity for the spectrin breakdown product (SBDP) generated by either calpain-1 or calpain-2 and for PTEN, a calpain-2 selective substrate in the inner plexiform layer (IPL) containing dendrites of RGC. We also compared the time-courses in wild-type (wt) and calpain-1 knock-out (ko) mice. While calpain-1 was rapidly activated in the IPL at 2 h following increased IOP, calpain-2 activation was delayed and was only observed in the retina at 4 h after increased IOP. Increased IOP for 1 h resulted in about 42% decrease in the number of RGC in wt mice after 3 days. Calpain-1 ko mice exhibited more degenerating RGCs (about 63% decrease) than wt mice, supporting the notion that calpain-1 activation is neuroprotective. Systemic or intravitreal injection of a selective calpain-2 inhibitor (C2I) 2 h after increased IOP prevented calpain-2 but not calpain-1 activation, and promoted RGC survival (about 21% decrease after systemic injection and 19% decrease after intravitreal injection). Our data indicate that calpain-2 activation plays a critical role in acute glaucoma-induced RGN degeneration and support the idea that a selective calpain-2 inhibitor has the potential to prevent acute glaucoma-induced blindness.

Title: Brain-derived neurotrophic factor protects large retinal ganglion cells following acute optic nerve crush injury

Authors: *L. FENG[1], Z. PUYANG[4], H. CHEN[1], P. LIANG[4], J. B. TROY[2], X. LIU[1,3]; [1]Ophthalmology, [2]Biomed. Engin., [3]Neurobio., Northwestern Univ., Evanston, IL; [4]Sch. of Biomed. Engin., Shanghai Jiao Tong Univ., Shanghai, China

Abstract: Brain derived neurotrophic factor (BDNF) is known to regulate neuronal differentiation and survival in the central nervous system. For a number of neurodegenerative and psychiatric disorders, BDNF has been shown to play an important role in both their pathogenesis and treatment. Here we investigated whether BDNF preserves retinal ganglion cells (RGCs) against the acute optic nerve crush injury. We performed the partial optic nerve crush (pONC) following published procedures. Using a tamoxifen-induced Cre system, BDNF was over-expressed in the mouse retina following the pONC. We monitored the survival of RGCs expressing Thy-1-YFP transgene with the Micron III *in vivo* imaging system and RGC somas were counted using a customized Matlab program. Mice were sacrificed at different time points post pONC, confocal images were taken, and the numbers of axons were counted. First, we demonstrated that retinal BDNF was up-regulated in the BDNF overexpression (BDNF_OE) mice. *In vivo* retinal images were taken, and large RGC somas were identified, which was confirmed by double-immunostaining with RGC markers. A significant RGC and axon loss was found in control group following the pONC, consistent with previous findings. The numbers of RGC somas were 48 ± 8% and 16 ± 5% at 1- and 2- weeks post pONC, respectively. The number of axons was 25 ± 7% at 2-weeks post pONC. By contrast, more RGCs survived in BDNF_OE mice. The numbers of somas were 70 ± 8% and 36 ± 6% at 1- and 2- weeks post pONC, respectively. The number of axons was 61 ± 9% in BDNF_OE mice at 2-weeks post pONC. Our results demonstrated that the over-expression of BDNF delayed the RGC and axon loss following the partial optic nerve crush injury. Our studies provide new insights on how BDNF protects RGCs and vision against the optic nerve injury.

Title: A potent, long-lasting photoswitch for restoring visual function to the blind retina

Authors: *I. TOCHITSKY[1], M. KIENZLER[2], V. MESEGUER[2], N. GALLERANI[2], J. TRAUTMAN[3], R. KRAMER[2];
[1]Harvard Med. Sch., Brookline, MA; [2]Univ. of California, Berkeley, Berkeley, CA; [3]Photoswitch Biosciences, Inc., Menlo Park, CA

Abstract: Retinitis pigmentosa (RP) and age-related macular degeneration (AMD) are blinding diseases caused by the degeneration of rod and cone photoreceptors, leaving the remainder of the visual system unable to respond to light. We have recently developed a novel pharmacological therapy that can potentially restore visual function in RP and AMD patients. Our strategy involves the use of photoswitches - light sensitive ion channel blockers - to generate visual responses in blind retinas. Here, we describe our most promising photoswitch compound, BENAQ, and evaluate its therapeutic potential. BENAQ restores retinal responses to white light with an intensity equivalent to ordinary daylight in animal models of RP. A single intraocular injection of BENAQ photosensitizes blind mouse retinas for weeks, with no apparent toxicity. BENAQ is the most potent photoswitch described to date, allowing for a larger potential therapeutic window. BENAQ restores visual function in retinas suffering from photoreceptor degeneration, while leaving healthy retinas unaffected. BENAQ's selective action on the blind retina suggests it may photosensitize regions of the retina undergoing degeneration, for example, in early stage RP patients or AMD patients with geographic atrophy, and not interfere with their remaining vision. BENAQ's potency, long lifetime, acceptable light sensitivity and selective targeting to diseased tissue make it a prime drug candidate for vision restoration in patients with RP and AMD.

Title: Cell-type-specific mechanism employed by photoswitch compounds to re-animate the blind retina

Authors: *R. H. KRAMER, I. TOCHITSKY, V. MESEGUER, Z. HELFT, N. GALLERANI; Univ. California Berkeley, Berkeley, CA

Abstract: Azobenzene photoswitches, such as AAQ, DENAQ, BENAQ, and QAQ, can confer light sensitivity onto retinal ganglion cells (RGCs) in blind mice. The high-sensitivity, fast kinetics, and low toxicity of these compounds make them interesting candidates as vision-restoring drugs in humans with degenerative blinding diseases, such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD). Remarkably, photosensitization is manifest only in photoreceptor-degenerated strains of mice, but absent from wild-type mice with intact rods and cones. Here we show that P2X receptors (ionotopic receptors for ATP) mediate the entry of photoswitches into RGCs where they associate with voltage-gated ion channels, enabling light to control action potential firing. While photoswitch compounds differ in which ion channels they affect, all of the compounds require membrane permeation through P2X receptors, whose gene expression is up-regulated in degenerated retina. Ordinarily membrane-impermeant fluorescent dyes also penetrate through P2X receptors to label a subset of RGCs in degenerated retina. Dendritic mapping and patch-clamp recording of dye-filled cells suggests that only the OFF-RGCs are labeled and re-animated; On-RGCs are unaffected. Hence P2X receptors are a natural

conduit for cell-type specific delivery of photoswitches to restore visual function in degenerative blinding disease, reinforcing their potential as drugs for treating advanced stages of RP and AMD.

Title: MEG reveals early activation of the occipital cortex by tactile stimulation in congenitally blind subjects

Authors: ***R. C. KUPERS**[1], F. MÜLLER[1], A. IOANNIDES[2], S. BAILLET[3], M. PTITO[1,4]; [1]Inst. of Neurosci. & Pharmacol. (INF), Copenhagen, Denmark; [2]Lab. for Human Brain Dynamics, AAI Scientific Cultural Services Ltd, Nicosia, Cyprus; [3]4McConnell Brain Imaging Ctr., McGill Univ., Montreal, QC, Canada; [4]Sch. of Optometry, Univ. of Montreal, Montreal, QC, Canada

Abstract: Following loss of vision from birth or later in life, the occipital cortex undergoes cross-modal neuroplastic changes and becomes involved in the processing of a variety of non-visual sensory inputs, and also in cognitive information processing (1). However, it remains unclear through which pathways non-visual information reaches the visual cortex in visually deprived individuals. Several studies suggested a strengthening of existing cortico-cortical pathways (2-5). Using magnetoencephalography (MEG), we recently provided evidence that in congenital blindness, tactile input is routed from somatosensory to occipital cortex via the posterior parietal cortex (6). However, the possibility that non-visual information is rerouted to the occipital cortex via an additional subcortical pathway cannot be ruled out and finds empirical support in some animal studies (7). In order to further elucidate this question, we used MEG to investigate tactile information flow in 8 congenitally blind, 3 late blind and 10 age and sex-matched sighted control subjects. We studied the spatio-temporal characteristics of occipital

cortex activations to electro-tactile stimulation of the index fingers. Our preliminary results show first cross-modal occipital cortex activations in the congenitally blind already at 37 and 55 ms. No such early occipital cortex activations were found in the sighted or late blind subjects. Source analysis revealed that these early occipital activations were located in BA17. In addition, we measured later occipital activations (> 85 ms) in both blind and sighted subjects. The timing of the early occipital responses in the congenital blind subjects suggests a direct rerouting of non-visual information from the thalamus to striate cortex. The later occipital activations may be mediated via a cortico- cortical pathway. Together, our data suggests that tactile information reaches the occipital cortex not only through a cortico-cortical pathway, but likely also through a direct route likely involving a thalamo-cortical pathway. Title: White matter microstructural differences in bipolar disorder detected using ENIGMA-DTI protocols for data harmonization

Authors: ***S. M. KELLY**[1], N. JAHANSHAD[1], J. FASKOWITZ[1], C. CHING[1], D. P. HIBAR[1], G. ZUNTA-SOARES[2], B. MWANGI[2], J. C. SOARES[2], P. M. THOMPSON[1];
[1]Neuroimaging and Informatics, USC, Marina Del Rey, CA; [2]Dept. of Psychiatry and Behavioral Sci., Univ. of Texas, Houston, TX

Abstract: Introduction: Abnormal brain white matter (WM) structure has been reported in bipolar disorder (BP), but not consistently. Collaborative efforts in neuroimaging from the

ENIGMA Consortium have affirmed the importance of large-scale collaborations to increase statistical power and result in more robust estimates of effect size. To identify the most robust disease effects, we applied the ENIGMA-DTI data harmonization protocol to process DTI data from bipolar patients and controls scanned at multiple sites. Methods: We analyzed DTI data from 69 BP-1 patients and 53 healthy controls (HCs) with an age range of 18-64 years and an average age of 34 years. 45% of HCs were male while 42% of patients were male. Of the total sample, 92 participants were scanned using a 3T Siemens Allegra scanner and 30 participants were scanned using a 3T Philips Intera. Preprocessing of the DWI images, including motion/distortion correction and tensor calculation, was carried out using FSL. The ENIGMA-DTI protocols were run on the FA maps, as detailed online: http://enigma.ini.usc.edu/protocols/dti-protocols/. 24 bilateral WM regions of interest (ROIs) were extracted from the skeletonized images and the average FA within each ROI was determined. Cohen's d was calculated for the group difference between patients and controls for all ROIs after controlling for age and sex. Results: Compared to HCs, BP-1 patients showed lower FA in the anterior corona radiata (ACR) and corpus callosum (CC), including the body and genu, and the cingulum (CGC) ($p < 0.0022$, corrected for multiple comparisons). Conclusions: Using the ENIGMA-DTI protocol, we found significant FA differences between BP-1 patients and HCs. This illustrates the sensitivity of the ENIGMA-DTI protocol to detecting WM differences in BP-1 disorder. Using these harmonized protocols, future research will incorporate multi-site data in a large-scale collaboration for meta-analysis. With increased statistical power, subtle differences in WM FA between BP subtypes, and the factors that modulate them, may also be detected.

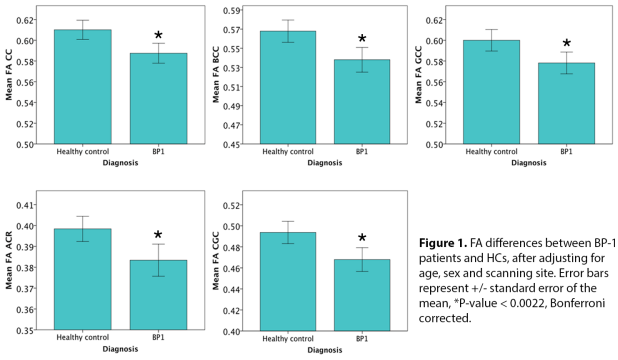

Figure 1. FA differences between BP-1 patients and HCs, after adjusting for age, sex and scanning site. Error bars represent +/- standard error of the mean, *P-value < 0.0022, Bonferroni corrected.

Title: Cortico-striatal and amygdala-striatal structural connectivity uniquely relates to risk for bipolar disorder

Authors: *K. DAMME[1], C. YOUNG[2], R. NUSSLOCK[2];
[2]Psychology, [1]Northwestern Univ., Evanston, IL

Abstract: Risk for developing bipolar disorder is associated with particular traits; elevated reward sensitivity, increased goal-directed activity, etc. Elevated striatal activity in hypo/mania may result from differences in cortico-striatal reward connectivity, a synthesis of connections from both the subcortical and cortical-striatal input. The present study used DTI to examine the relationship between structural connectivity within the cortical-striatal and subcortical networks to the Hypomanic Personality Scale, and considers the specificity of these goal-oriented, mania relevant paths to paths generally related to depression, i.e. the uncinate fasciculus (UF). Methods- 49 healthy volunteers were recruited from the Chicago area to complete MRI scanning and the Hypomanic Personality Scale. Hypomanic Personality Scale is related to increased risk of developing bipolar disorder and is robust in subclinical populations. Individually defined masks, specifically the bilateral nucleus accumbens (NAcc), amygdala, and medial orbitofrontal cortex (mOFC), were seed regions for the diffusion weighted probabilistic tractography. Fractional anisotropy (FA) was extracted from the probabilistic tracts. A combined model compared mean FA for cortical and subcortical paths in predicting hypomanic personality traits. Results- Elevated structural connectivity between the Amygdala and NAcc was associated with elevated traits of hypomania ($F(1,47)=9.88$, $p=0.002$). Increased structural connectivity between the mOFC and NAcc were associated with higher symptoms of mania ($F(1,48)=6.945$, $p=0.011$). In a combined model, the structural integrity between Amygdala and NAcc (t-value= 2.55, $p=0.01$) demonstrates a unique contribution and the path between mOFC to NAcc (t-value= 1.92, $p=0.06$) is at a trending level, while the overall model is significant ($F(3, 46)=7.08$, $p=0.002$). This finding is unique to hypomania as the UF, which relates to negative emotionality, is not significantly related to hypomanic traits $F(1, 47)= 0.38$, $p= 0.5408$). Conclusion- These findings suggest that both cortical and subcortical paths account for variance in an overall model of risk for hypomania. Risk for hypomania is associated with increased integrity in white matter connectivity between NAcc and Amygdala, as well as the NAcc and mOFC, each conferring unique contributions in a combined model; this relationship does not hold equally well with all tracts related to emotion. As predicted the UF provides evidence of specificity of these pathways, demonstrating that not all emotion relevant tracts are equally effective at explaining variance in hypomanic risk.

Title: The dopaminergic response to acute stress in health and psychopathology: a systematic review

Authors: *T. VAESSEN, D. HERNAUS, I. MYIN-GERMEYS, T. VAN AMELSVOORT; Maastricht Univ., Maastricht, Netherlands

Abstract: Previous work in animals has shown that dopamine (DA) in cortex and striatum plays an essential role in stress processing. For the first time, we systematically reviewed the *in vivo* evidence for DAergic stress processing in health and psychopathology in humans. All studies included (n studies=25, n observations=324) utilized positron emission tomography and measured DAergic activity during an acute stress challenge. The evidence in healthy volunteers (HV) suggests that physiological, but not psychological, stress consistently increases striatal DA release. Instead, increased medial prefrontal cortex (mPFC) DAergic activity in HV was observed during psychological stress. Across brain regions, stress-related DAergic activity was correlated with the physiological and psychological intensity of the stressor. The magnitude of stress-induced DA release was dependent on rearing conditions, personality traits and genetic variations in several SNPs. In psychopathology, preliminary evidence was found for stress-related dorsal striatal DAergic hyperactivity in psychosis spectrum and a blunted response in chronic cannabis use and pain-related disorders, but results were inconsistent. Physiological stress-induced DAergic activity in striatum in HV may reflect somatosensory properties of the stressor and readiness for active *fight-or-flight* behavior. DAergic activity in HV in the ventral striatum and mPFC may be more related to expectations about the stressor and threat evaluation, respectively. Future studies with increased sample size in HV and psychopathology assessing the function of stress-induced DAergic activity, the association between cortical and subcortical DAergic activity and the direct comparison of different stressors are necessary to conclusively elucidate the role of DAergic activity during stress.

Title: Resting state oscillatory activation associated with schizophrenia and high and low cognitive control

Authors: *R. V. HART[1], A. M. BOBILEV[2], W. T. OLIVER[2], M. E. HUDGENS-HANEY[2], L. K. HAYRYNEN[2], D. A. PARKER[2], P. BUCKLEY[3], J. E. MCDOWELL[2], B. A. CLEMENTZ[2]; [1]psychology, [2]Univ. of Georgia, Athens, GA; [3]Georgia Regents Univ., Augusta, GA

Abstract: Poor performance on tasks requiring cognitive control (CC) is a hallmark of schizophrenia (SZ). A substantial portion of the healthy population, however, exhibit similar performance deficits, while manifesting neither signs nor symptoms of SZ. Contrasting these healthy individuals with low CC, individuals with SZ, and also healthy individuals with particularly high CC allows for differentiation of aberrations specific to the pathology of SZ from those merely associated with poor CC. We examine the differences amongst the three groups by utilizing a resting state paradigm, which is a visual stimulus that allows us to see differences in oscillatory power at baseline level activation. This study examines the difference in resting state neural activity between person's with SZ and healthy subjects with high and low CC. Cognitive control was assessed via working memory capacity, measures of which have high reliability and high correlation with performance on CC tasks. In the current study, working memory capacity was determined by a conglomerate score based on performance on computerized operation, symmetry, and reading span tasks. Participants completed a five-minute eyes-open resting state paradigm while whole-head magnetoencephalography (MEG) data were collected. Time-frequency analysis of resting state activity demonstrated differences in oscillatory power between all groups (SZ, High CC, and Low CC) across frequency bands. The Low CC group exhibited commonalities with both the High CC and SZ groups, though these commonalities were found at distinct frequencies. Schizophrenia-specific oscillatory patterns were found in lower frequency bands such as delta and theta. Conversely, the higher frequency bands, including low and high-gamma, show cognitive control-specific activation that differentiates individuals with high CC from those with low CC regardless of DSM diagnosis. Power in alpha band activity is dissociable between all three groups. Results from this study suggest that frequency-specific intrinsic activity may markedly contribute to differences in

cognitive control in both healthy persons and persons with schizophrenia. Further, resting state oscillatory activity in different frequency bands may differentially characterize variation in cognitive control in the healthy population as well as deficits which are exclusive to clinical populations. In this way, resting state neural activity could be a candidate endophenotype for elucidating cognitive control deficits in schizophrenia

Title: Cognitive impairments and brain morphological alterations in schizophrenia

Authors: N. MATSUKAWA, *J. MIYATA, H. SASAKI, J. FUJINO, H. TAKAHASHI, T. ASO, S. URAYAMA, H. FUKUYAMA, T. MURAI;
Kyoto Univ., Kyoto, Japan

Abstract: Introduction: It is well known that cognitive deficits affect quality of life and social functions in individuals with schizophrenia. To elucidate the neural basis of cognitive impairments in schizophrenia, we explored associations of cognitive functions with gray matter volume as well as white matter integrity. Methods: Fifty-four individuals with schizophrenia and 45 healthy controls underwent structural magnetic resonance imaging. Cognitive functions were assessed using the brief assessment of cognition in schizophrenia Japanese version (BACS-J), comprising six subscales measuring various dimensions of cognition: verbal memory, working memory, motor speed, verbal fluency, attention and processing speed of information, and executive function. Voxel-based morphometry and tract-based spatial statistics were applied to investigate the correlation of BACS-J scores and regional gray matter volume as well as white matter fractional anisotropy (FA). Results: The schizophrenia group exhibited significant gray matter volume reductions and FA reductions in several regions relative to controls. In the schizophrenia group, the composite score of BACS-J was positively correlated with gray matter volume in inferior and middle frontal gyrus, parahippocampal gyrus as well as anterior cingulate gyrus. The score was also positively correlated with FA in the body of corpus callosum. In some brain regions, morphological change was correlated with multiple subscores of BACS-J, while in others, it was correlated with a specific subscore. Conclusion: Our findings demonstrate that different aspects of cognitive impairments have common as well as specific neural bases in schizophrenia. Comprehensive cognitive assessments are suggested to be important to uncover complex cognition-anatomy correlations in schizophrenia.

Title: Variability of structurally constrained and unconstrained functional connectivity in schizophrenia

Authors: *Y. YAO[1], L. PALANIYAPPAN[2], P. LIDDLE[2], J. ZHANG[3], S. FRANCIS[4], J. FENG[1];
[1]Warwick Univ., Coventry, United Kingdom; [2]Ctr. for Translational Neuroimaging in Mental Health, Inst. of Mental Hlth., Nottingham, United Kingdom; [3]Fudan Univ., Shanghai, China; [4]Sir Peter Mansfield Magnetic Resonance Centre, Sch. of Physics and Astronomy, Univ. of Nottingham, Nottingham, United Kingdom

Abstract: Spatial variation in connectivity is an integral aspect of the brain's architecture. Without this variability, the brain may act as a single homogenous entity without regional specialization. In this study, we investigate the variability in functional links categorized on the basis of the presence of direct structural paths (primary) or indirect paths mediated by one (secondary) or more (tertiary) brain regions ascertained by diffusion tensor imaging. We quantified the variability in functional connectivity using an unbiased estimate of unpredictability (functional connectivity entropy) in a neuropsychiatric disorder where structure-function relationship is considered to be abnormal. 34 patients and 32 healthy controls underwent DTI and resting state functional MRI scans. Less than one-third (27.4% in patients, 27.85% in controls) of functional links between brain regions were regarded as direct primary links on the basis of DTI tractography, while the rest were secondary or tertiary. The most significant changes in the distribution of functional connectivity in schizophrenia occur in indirect tertiary paths with no direct axonal linkage in both early ($p=0.0002$, $d=1.46$) and late ($p=1x10-17$, $d=4.66$) stages of schizophrenia, and are not altered by the severity of symptoms, suggesting that this is an invariant feature of this illness. Unlike those with early stage illness, patients with chronic illness show some additional reduction in the distribution of connectivity among functional links that have direct structural paths ($p=0.08$, $d=0.44$). Our findings address a critical gap in the literature linking structure and function in schizophrenia, and demonstrate for the first time that the abnormal state of functional connectivity preferentially affects structurally unconstrained links in schizophrenia. It also raises the question of a continuum of dysconnectivity ranging from less direct (structurally unconstrained) to more direct (structurally constrained) brain pathways underlying the clinical severity and persistence of schizophrenia.

Sch. of Med., Ube/Yamaguchi, Japan; [4]Psychiatry and Neurosciences, Hiroshima Univ., Hiroshima, Japan; [5]Mental Disorder Res., Natl. Inst. of Neuroscience, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [6]Psychiatry, Hokkaido Univ., Sapporo, Japan; [7]Psychiatry, Tokyo Med. Sch., Tokyo, Japan

Abstract: Diagnostic differentiation of depressed patients with bipolar (BD) and major depressive disorder (MDD) is clinically a crucial issue because the two disorders show similar depressive symptoms and have different strategy for pharmacological treatment. The misdiagnosis of them leads to make the outcomes solemn. However biological markers of the differentiation has been unknown. The aim of this study was to determine whether depressed patients with BD and MDD show different morphometric abnormalities involved in the pathophysiology of these disorders using voxel-based morphometry (VBM) in multi-centers. This study was a part of the Strategic Research Program for Brain Science. Subjects consisted of 140 patients with BD and 569 those with MDD and 717 healthy subjects in 8 scanners of 6 sites. All patients were depressed. Distribution of sex and age were statistically matched between the three groups. Image preprocessing was performed using VBM8 in SPM8 software. We analyzed the gray matter (GM) image implemented a General Linear Model. The analysis was applied to a full-factorial model with two factors with diagnosis with 2 levels (patients and healthy subjects) and scanners with 8 levels and with age, sex and intracranial volume as covariates in SPM8. The whole brain analysis showed significant main effect of diagnosis in GM volume of hippocampus/amygdala complex, insular and medial and orbitofrontal cortex, significant main effect of scanners in GM volume of extra-nuclear and significant interaction of diagnosis with scanner in GM volume of striatal and temporal areas. The GM volume of anterior cingulate, insula and middle frontal gyrus statistically survived by the analysis of the main effect of diagnosis masked exclusively the main effect of scanner. The significant voxels obtained from the analyses were compared among patients with BD and MDD and healthy subjects by analysis of covariance. The GM volumes of the 3 regions showed significantly small in patients with BD, MDD and healthy subjects in the order. The results suggest that depressed patients with the two disorder are distinctive morphometric abnormalities in the brain regions relevant to emotion processing, which abnormalities are observed more pronounced in BD.

London, London, United Kingdom; [5]Dept. of Neuroinformatics,, ARAYA Brain Imaging, Tokyo, Japan; [6]Sackler Ctr. for Consciousness Science, Univ. of Sussex, Sussex, United Kingdom

Abstract: Introduction: Recent studies reported that schizophrenic patients showed focal brain volume reduction in temporal lobe, and frontal lobe (e.g. Borgwardt et al., 2008). In this confirmatory study, we asked if we could obtain similar results reported in previous studies in middle-aged (over 40) chronic schizophrenia patients in Japan. Method: We collected brain structure data with 35 schizophrenia patients (aged 40 - 79) met to DSM-IV criteria from Hizen psychiatric hospital and the ratio of age- and gender-matched 35 normal control from Sefuri town, a rural town in Saga prefecture in Japan. 1.5T MRI machine (Philips Achieva) was used to acquire T1 weighted high-resolution images with 1mm × 1mm × 1mm resolution, with 160 slices covering the whole brain (slice repetition time, 9.30ms; echo time, 4.60ms; flip angle, 10°). We analyzed the structural images with DARTEL tools (Ashburner et al., 2007) in Statistical Parametric Mapping software (SPM12). Results: We asked which area showed gray matter reduction in schizophrenia patients comparing to healthy controls and found significant gray-matter reduction in the frontal lobe and anterior insula cortex and orbitofrontal cortex ($p < 0.05$, FWE corrected). The central functional roles of the insula cortex is to mediate self-consciousness and process pain sensation, and orbitofrontal cortex is known as a part of the pathway of emotion. The current results support the previous studies that patients with schizophrenia show volume reduction in specific brain regions involved in impaired functions in schizophrenia (Hirao et al. 2008; Segall et al., 2009) Conclusion: This study showed that schizophrenia patients had volume reduction in the insula, and orbitofrontal cortex. These results corroborate the previous VBM findings that frontal lobe volume reduction is a characteristic feature of schizophrenia and focal brain structure could potentially be a biomarker to assess the condition of schizophrenic patients.

Title: The relationship between glutamate, gaba, and mismatch negativity in schizophrenia

Authors: *S. A. KORENIC, A. SUMMERFELT, S. A. WIJTENBURG, X. DU, J. CHIAPPELLI, F. MUELLERKLEIN, P. KOCHUNOV, L. E. HONG, L. M. ROWLAND; Univ. of Maryland Sch. of Med. (MPRC), Baltimore, MD

Abstract: Auditory mismatch negativity (MMN) is a replicated biomarker for schizophrenia and is thought to reflect glutamate NMDA receptor function and excitatory-inhibitory neurotransmission balance. However, the glutamate-MMN association has not been directly examined. A GABAergic link to MMN is even less clear. This study investigated the relationship between glutamate, GABA, and MMN in schizophrenia. Fifty-three controls and 45 persons with schizophrenia completed this study. Participants completed an EEG session for MMN and a magnetic resonance spectroscopy (MRS) session for glutamate and GABA. The ERP paradigm was a duration-deviant oddball task. Subjects were presented with 1000 auditory stimuli, of which 800 (80%) were standard tones presented at 75 dB, 60-ms, 1000 Hz; 200 (20%) were duration-deviant tones at 75 dB, 150-ms, 1000 Hz. FZ was used for MMN measurement. The center of the MRS voxel was positioned below the electrode FZ and covered the anterior cingulate. For detection of glutamate, spectra were acquired with a phase rotation STEAM: TR/TM/TE = 2000/10/6.5-ms, VOI ~ 24-cm3, NEX=128, 2.5-kHz spectral width, 2048 complex

points. For detection of GABA, spectra were acquired using a macromolecule-suppressed MEGA-PRESS sequence: TR=2000, TE=68 ms, 20.36 ms length and 44 Hz bandwidth full width at half maximum (FWHM) editing pulses applied at 1.9 (ON) and 1.5 (OFF) ppm, and 256 averages. Metabolites were referenced to water and corrected for proportion of CSF, white and gray matter tissue concentrations. The schizophrenia group showed significantly reduced MMN amplitude ($p = 0.039$) but not latency ($p = 0.28$) compared with controls. Glutamate levels were significantly lower in the schizophrenia group compared to the control group ($p = 0.002$) but GABA levels and glutamine/glutamate ratio were not significantly different between groups (p's > 0.05). The relationship between glutamate and MMN amplitude was significant in schizophrenia, such that higher glutamate levels were associated with greater (more negative) MMN amplitude ($r = -0.29$, $p = 0.05$). The smaller the glutamine/glutamate ratio, which could be interpreted as more glutamine to glutamate conversion, was related to greater (more negative) MMN amplitude in schizophrenia ($r= 0.45$, $p =003$). Higher GABA levels were also associated with greater MMN amplitude ($r= -0.39$, $p =008$). There were no significant correlations observed in the control group. This is the first study to show a strong association between *in vivo* glutamate, GABA, and MMN in schizophrenia. These data provide strong support for the involvement of glutamatergic and GABAergic systems in the generation of MMN in schizophrenia.

Title: Characterization of white matter integrity deficits in cocaine-dependent individuals with substance-induced psychosis compared to non-psychotic cocaine users

Authors: *T. WILLI[1], A. M. BARR[2], W. J. PANENKA[2], D. J. LANG[2], W. G. MACEWAN[2], W. SU[2], A. E. THORNTON[3], F. VILA-RODRIGUEZ[2], O. LEONOVA[2], V. STREHLAU[2], K.

Abstract: With sufficient drug exposure, some individuals develop transient psychotic symptoms referred to as "substance induced psychosis" (SIP), which closely resemble the symptoms observed in schizophrenia spectrum disorders. The comparability in psychotic presentation between SIP and the schizophrenias suggests that similar underlying neural deficits may contribute to the emergence of psychosis across these disorders. Only a small number of studies have investigated structural alterations in SIP, and all have been limited to volumetric imaging methods, with none controlling for the effects of chronic drug exposure. To investigate white matter abnormalities associated with SIP, diffusion tensor imaging was employed in a group of individuals with cocaine-associated psychosis (CAP; n=24) and a cocaine dependent nonpsychotic group (CDN; n=43). Tract based spatial statistics (TBSS) was used to investigate group-differences in white matter diffusion parameters. The cocaine-associated psychosis group showed significantly lower fractional anisotropy values than cocaine dependent nonpsychotic group ($p<0.05$) in voxels within white matter tracts of fronto-temporal, fronto-thalamic, and interhemispheric pathways. The greatest magnitudes of difference in white matter integrity were present in the corpus callosum, corona radiata, bilateral superior longitudinal fasciculi, and bilateral inferior longitudinal fasciculi. Additionally, the cocaine-associated psychosis group had voxels of significantly higher radial diffusivity in a subset of the above mentioned pathways. These results are the first description of white matter integrity abnormalities in a SIP sample, and indicate that differences in these pathways may be a shared factor in the expression of different forms of psychosis.

Title: Nicotine reduces hippocampal hyperactivity in schizophrenia

Authors: *J. SMUCNY[1,2], A. OLINCY[1,2], D. C. ROJAS[3], J. R. TREGELLAS[1,2];
[1]Dept. of Psychiatry, Univ. of Colorado, Aurora, CO; [2]Res. Service, VA Med. Ctr., Denver, CO;
[3]Dept. of Psychology, Colorado State Univ., Fort Collins, CO

Abstract: Although intrinsic hippocampal hyperactivity and deficits in nicotinic signaling are increasingly recognized as core features of schizophrenia, no studies have yet examined the effects of nicotinic agonists on hippocampal activity in the illness. To that end, in this study we examined the effects of an acute dose (7 mg patch) of nicotine vs. placebo on hippocampal activity during the resting state as well as during a selective attention task in nonsmoking patients with schizophrenia and healthy subjects using functional magnetic resonance imaging. We found that nicotine, relative to placebo, reduced hyperactivity in patients during both the resting state and the attention task. Nicotine also reduced hyperactivity of the ventral parietal cortex in schizophrenia. These results suggest that hippocampal hyperactivity is reduced by nicotine in schizophrenia, and that hippocampal response may be targeted by nicotinic agonists and other investigational compounds in the illness.

Title: Gamma band auditory response with fMRI BOLD in schizophrenia

Authors: *H. KUGA[1,2], T. UENO[1], N. ORIBE[1], H. OKAMOTO[2], I. NAKAMURA[2], Y. HIRANO[2], H. MIZUHARA[3], T. ONITSUKA[2];

Abstract: INTRODUCTION Schizophrenia has been conceptualized by dysfunctional cognition and behavior related to abnormalities in neural circuitry. The functioning of the neural circuitry can be assessed using the auditory steady state response (ASSR). Moreover, in recent years, research on high (> 60-Hz) gamma band oscillations has become of increasing interest. The current study used 1.5 Tesla Magnetic Resonance Imaging(MRI) and investigated low and high gamma band oscillations with the ASSR. METHODS 24 patients with schizophrenia and 26 normal controls participated in this study. ASSR to 20, 30, 40 and 80-Hz binaural click trains were measured with 1.5 T MRI (Achieva, Philips). The duration of one click was 1 msec, and the duration of click trains was 500 msec(5 scans). The intensity of the click trains was 80 dB sound pressure level. The interval between each click trains was 500 msec. The experiments were designed as "block design". Each block task (15 sec, 5 scans) contained 15 click trains and intervals, which was followed by resting state without any stimuli (15 sec, 5 scans). In total, we performed 240 sec (80 scans) on each subject. SPM8 was used in order to analyze BOLD fMRI data within each subject, as well as a group. The mean ASSR BOLD intensity were analyzed using repeated measures analysis of variance (rmANOVA) with group (SZ or NC) as a between-subjects factor; and frequency (20, 30, 40 or 80-Hz) and hemisphere (left or right) as within-subjects factors. RESULTS Schizophrenia showed bilaterally increased ASSR BOLD to 80-Hz frequency, compared to healthy subjects. CONCLUSIONS The current study indicated that patients with schizophrenia showed increased ASSR BOLD to the 80-Hz frequency. The BOLD-ASSR activation found in broadman 41 and 42 area might reflect GABAergic system dysfunction in schizophrenia, as ASSR is linked to GABAergic inhibitory interneuron activity. This study highlighted the abnormal 80-Hz ASSR and provided clear evidence that schizophrenia is characterized by abnormalities in neural circuitry.

Title: Psychosis chronicity and fMRI responses during basic visuo-motor function

Authors: *K. RAMASESHAN[1], F. BADOUI[1], S. TOLIA[1], M. BELLANI[2], G. RAMBALDELLI[2], V. A. DIWADKAR[1], P. BRAMBILLA[3];
[1]Wayne State Univ., Detroit, MI; [2]Univ. of Verona, Verona, Italy; [3]Univ. of Milan, Milan, Italy

Abstract: Background: The chronicity of psychosis may exert accumulative effects on the integrity of brain function. For example, patients with a diagnosis of psychosis may transition to chronic schizophrenia, yet differences in brain function are relatively understudied across populations. Inter-hemispheric transfer (IT) which relies on the integrity of the macroscopic brain networks, is a useful domain in which to examine this question. We assessed fMRI activations during IT in three age- and gender matched group of participants: Typical controls, first-episode psychosis patients (FEP) and chronic schizophrenia patients (SCZ). IT was assessed using the Poffenberger paradigm (Poffenberger, 1912): A probe is briefly presented to one visual hemi-field and subjects detect it signally with the hand that is contra- or ipsilateral to the hemi-field thus generating inter- or intra-hemispheric visuo-motor transfer. **Methods:** Data from eighteen HC subjects were age and gender matched to FEP and SCZ patient groups (14 male, 4 female, mean age = 33 years). Whole brain fMRI scans were acquired (3T, Siemens Trio) and data were modeled in SPM8 using typical methods. IT was assessed for right-handed responses by contrasting inter- with intra-hemispheric transfer at the first level. A one-way (Group as single facto) random-effects analysis of variance was used to assess comparative changes in activation as a function of illness chronicity. A contrast was used to assess changes in activation across groups (representing effects of psychosis chronicity). **Results:** Three regions in the core and extended motor circuit showed increases in activation associated with chronicity: Left M1 (i.e., responding M1), the supplementary motor area (SMA), and the basal ganglia. Increased chronicity was associated with decreased brain activation in the right (i.e., stimulated) visual cortex (lingual gyrus). **Conclusion:** In this cross-sectional analysis, illness chronicity appeared to exert complementary effects in the visual and motor regions. Chronicity was associated with decreased responses in the primary visual cortex, but increase responses in responding motor regions. These effects may constitute complex effects of psychosis at the level of regional brain function, detectable using even basic tasks.

Title: The contribution of cognitive-affective interactions to motivational deficits in schizophrenia: an fMRI study

Authors: *N. RAMAKRISHNAN[1], R. CHO[1], T. A. LESH[2], C. S. CARTER[2], S. URSU[1]; [1]Psychiatry, Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [2]Univ. of California, Davis, Sacramento, CA

Abstract: Background: Recent research suggests that individuals with schizophrenia (SZ) show unimpaired in-the-moment emotional reactivity, and that symptoms traditionally attributed to impaired affective processing may be in fact closely related to deficits in higher order cognitive control consistently associated with this disorder. Similarly, it has been proposed that the motivational deficits characterizing schizophrenia may also reflect impaired cortical-striatal interactions rather than a primary alteration of affective states (Barch & Dowd, 2010). The goal of the work presented was to examine the neural substrates of motivational and control processes in schizophrenia and to analyze the engagement of networks of brain activity to incentives and cognitive control load in both schizophrenia patients and healthy controls. A secondary aim was to examine the influence of treatment with antipsychotic medications when processing cues that represent reward or punishment. Methods: Twenty-three patients and twenty-one demographically matched controls were scanned using Functional Magnetic Resonance Imaging (fMRI) while performing a computerized task that orthogonally manipulates monetary incentives (potential monetary reward, avoiding monetary loss, and no monetary consequence) and cognitive control demands (task of responding consistent or against a pre-potent response bias (Ursu and Carter, 2005). A 3-way repeated measures ANOVA (Group x Incentive x Control Load) of response accuracy showed main effects of task demands, incentives, and group ($P < 0.05$), but no 3-way interaction, $F(1.7, 72.2) = 0.79$, n.s. The Group x Task interaction was significant, $F(1,42)=4.25$, $p = 0.04$, and reflected a greater change in accuracy between the low and high cognitive control load in the patient group than in controls. In contrast, the effect of incentives on accuracy was similar across the two groups, (Group X Incentives, $F(2,84) =1.58$, n.s). In analyses of fMRI data, the patients showed a deficit in prefrontal and striatal activation in response to task demands, but similar activity in response to the prospect of monetary gain. Furthermore, performing responses resulting in monetary gains was associated with robust activation of reward-related brain structures in both groups. Conclusions: These results provide additional novel evidence that primary affective experience is relatively spared in schizophrenia, and emphasize the role of impaired cognition in dysfunctions of motivated behavior in this disorder.

Title: Resting state functional connectivity of the hippocampus in psychosis

Authors: ***I. NWABUDIKE**, S. KEEDY;
Univ. of Chicago, Chicago, IL

Abstract: CONTEXT: Psychotic disorders like schizophrenia are associated with temporal lobe abnormalities. These may be from neurodevelopmental problems that result in altered synaptic plasticity mechanisms and impact network function. These mechanisms are key for the hippocampus given its role in memory formation, and hippocampal abnormality could account for psychosis symptoms such as auditory hallucinations. We tested hippocampal integrity via resting state functional connectivity in 13 psychosis patients with auditory hallucination (AH) histories and 18 matched healthy individuals. METHODS: Resting state fMRI was acquired with a Philips 3.0T scanner (8 channel headcoil, TR=2.5s, TE=25ms, 3.5x3.5x3.3mm voxel size, 43 oblique axial slices, flip angle=90deg, 144 volumes). A high-resolution T1-weighted image was also acquired to aid spatial standardization. Data was preprocessed using AFNI, including regressing motion estimates, white matter and CSF –related signal, and drift parameters. Separate right and left hippocampus masks served as seed regions for correlation with other voxels for each participant to characterize connectivity. These connectivity maps were submitted to group comparison t tests, and abnormal connectivity was correlated with symptom severity measures including detailed AH assessment. RESULTS: Psychotic subjects had relatively decreased connectivity between the left hippocampus and bilateral ventrolateral prefrontal cortex as well as left lentiform nuclei, but increased connectivity between left hippocampus and left thalamus. For the right hippocampus, patients had decreased connectivity to left insula. There was a strong negative correlation between connectivity of left hippocampus to ventral prefrontal cortex and severity of past AH, and not general psychosis symptom severity or current AH severity. CONCLUSIONS: The right and left hippocampus may have differentially altered connectivity, with overall greater extent of abnormality for left hippocampus. Of the alterations, reduced left hippocampal connectivity with prefrontal cortex

was associated with past AH severity. This is consistent with the notion that AH is dominantly verbal in nature and thus may be more associated with alterations in the left hemisphere where language functions are mediated. The findings also support a research strategy of parsing psychosis symptoms and seeking specific associations to neural system abnormalities to address disease heterogeneity.

Abstract: Distributed aberrant neural connectivity is thought to be involved in the pathophysiology of schizophrenia. Disturbances in functional connectivity within different regions of the cerebral cortex as well as between cortex and other major nodes of neural processing (such as the thalamus) have been shown in schizophrenic patients. These findings highlight that perturbations in connectivity occur at a whole-brain level and that distributed neural networks are likely implicated in schizophrenia. The cerebellum shares dense reciprocal connections with the thalamus and cerebral cortex and contains approximately 60% of all neurons in the central nervous system. This makes the cerebellum a critical target for pathogenic brain-wide dysconnectivity. Furthermore, a growing body of literature implicates the role of the cerebellum in higher-order cognitive functions that are notably affected in schizophrenia. Yet, brain-wide disturbances in cerebellar connectivity in schizophrenia remain unknown. Here, we characterized whole-brain cerebellar connectivity using resting-state functional magnetic resonance imaging in a population of patient diagnosed with schizophrenia and matched controls. Data were collected using the acquisition methods harmonized with the Human Connectome Project (Glasser et al., 2013). Using an a priori functionally-defined parcellations of the human cerebellum (Buckner et al. 2011), we generated a map of functionally correlated

regions for each of 7 major cerebellar functional subdivisions. Analyses revealed hyper-connectivity between cerebellum and bilateral sensory-motor cortices in patients relative to controls, specifically prominent for executive cerebellar subdivisions. Additionally, patients showed hypo-connectivity between cerebellum and regions of prefrontal and parietal association cortex as well as striatum, also prominent for executive cerebellar subdivisions. Previous findings have shown a highly similar pattern of whole-brain dysconnectivity in schizophrenic patients for associative thalamic nuclei. This disturbance may reflect weakened top-down gating of sensory information in schizophrenia, and adds to our basic understanding of cerebellar dysconnectivity in psychiatric disease.

Title: Cortical hierarchy underlies preferential connectivity disturbances in schizophrenia

Authors: *G. J. YANG[1], J. D. MURRAY[2], G. REPOVS[3], M. W. COLE[4], X.-J. WANG[2], D. C. GLAHN[1], G. D. PEARLSON[1], J. H. KRYSTAL[1], A. ANTICEVIC[1];
[1]Yale Univ., New Haven, CT; [2]New York Univ., New York City, NY; [3]Univ. of Ljubljana, Ljubljana, Slovenia; [4]Rutgers Univ., Newark, NJ

Abstract: Schizophrenia (SCZ) is a neuropsychiatric illness associated with abnormal neural connectivity. In particular, patients show prefrontal cortex (PFC) hypo-connectivity, assessed by computing blood-oxygen level-dependent (BOLD) signal correlations. However, recent studies reveal elevated BOLD signal variance in SCZ, which may impact correlations, computed as covariance normalized by variance. We hypothesized that functional connectivity (using covariance) may be elevated in SCZ, but that this may occur in the context of elevated signal variance. Further, we hypothesized that preferential PFC effects may intrinsically arise from the information-processing hierarchy and corresponding physiological consequences, which we tested via biophysically grounded computational modeling. We conducted resting-state fMRI in 161 SCZ and 164 matched healthy subjects, assessing group differences in connectivity and BOLD variance. Both voxel-wise and network-level analyses were performed. To mechanistically inform fMRI findings, we used a large scale neural network model to simulate a well-known synaptic hypothesis of SCZ pathology—namely excitation/inhibition (E/I) imbalance, and analyzed resulting *in silico* 'BOLD' signals. Empirically, we observed hyper-connectivity in PFC and other associative regions in SCZ, with concurrent increases in BOLD variance. These effects were absent in a comparison group of bipolar patients (N=73). In initial simulations of E/I imbalance, we observed global elevations in covariance and variance of model-generated BOLD signals. To investigate our empirical associative effects, we extended our model to reflect known differences in associative vs. sensory neuronal dynamics. This extended model reproduced preferential associative effects, and predicted that covariance and variance elevations would be positively correlated, which we confirmed empirically. Collectively, we show that elevations in BOLD covariance and variance in chronic SCZ co-occur and are strongly related phenomena. Thus, some connectivity elevations may not be fully captured by correlation measures that normalize connectivity by variance. Hypo-connectivity seen in previous studies may be reconciled with our findings by considering the effect of elevated variance in reducing correlation-based measures. We also computationally demonstrate how a common cellular-level mechanism can produce elevations in covariance and variance of BOLD signals. Further, we show how this global perturbation can produce preferential effects in associative regions due to neural differences arising from the intrinsic functional cortical hierarchy.

Title: Brain activity associated with intrinsic motivation in patients with schizophrenia

Authors: *K. TAKEDA[1], M. MATSUMOTO[2], Y. OGATA[3], K. MAIDA[4], H. MURAKAMI[3], K. MURAYAMA[5], K. SHIMOJI[6], T. HANAKAWA[3], K. MATSUMOTO[7], K. NAKAGOME[8]; [1]Dept. of Psychiatry, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Tokyo, Japan; [2]Dept. of Psychiatry, Univ. of Tokyo, Tokyo, Japan; [3]Integrative Brain Imaging Center, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [4]Dept. of Psychiatry, Natl. Ctr. Hospital, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [5]Fac. of Life Sciences, Univ. of Reading, Reading, United Kingdom; [6]Dept. of Radiology, Tokyo Metropolitan Geriatric Hosp. and Inst. of Gerontology, Tokyo, Japan; [7]Brain Sci. Institute, Tamagawa Univ., Tokyo, Japan; [8]Natl. Ctr. Hospital, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan

Abstract: In search for the biological marker of intrinsic motivation in patients with schizophrenia (SCZ), we adopted a stopwatch (SW) task developed by Murayama et al. (2010). In the task, participants were presented with a SW that starts automatically, and the goal was to press a button with the right thumb within 50 ms around the 5-s time point. The control task was a watch-stop (WS) task, in which participants passively viewed a SW and were asked to simply press a button when it automatically stopped. Both tasks were pseudorandomly intermixed and preceded by a cue that indicated which task to perform. Because the accumulated number of successful trials in SW task was continuously presented at the top right corner of the screen and was updated only after every success in SW task, the SW task was considered more interesting than the WS task. In an fMRI study, Murayama et al. (2010) demonstrated that in response to the task cue the lateral prefrontal cortex (PFC) showed a larger activation in the SW task as compared to the WS task, suggesting that the healthy subjects were more engaged in mental preparation for tasks with higher value. Therefore we hypothesized the difference activation induced by the task cue between the SW and WS tasks in PFC may act as a biological marker for intrinsic motivation in SCZ. Sixteen patients and 17 healthy control subjects (HC), age and sex matched, participated in the study. The study was approved by the ethical committee in National Center of Neurology and Psychiatry. The subjects all gave informed consent before participating in the study. In addition to fMRI data acquisition, we evaluated intrinsic motivation inventory (IMI) (Choi, et al. 2010). First, difference scores of IMI obtained by subtracting the scores for the SW task from the WS task were considered to represent the intrinsic motivation to this task in general. The difference scores of IMI showed a significant between-group difference suggesting that intrinsic motivation to the task in SCZ was lower than that in HC. Correspondingly, the difference striatal activation in response to the task cue between SW and

WS tasks was significantly lower in SCZ than in HC. Interestingly, difference PFC activation in response to the task cue between the SW and WS tasks was positively and significantly correlated with difference scores of IMI in HC, whereas this was not true for SCZ. Although highly speculative as it is, the lack of significant correlation between the PFC activation and IMI in SCZ may reflect the anomalous neural activity in the PFC which may have been necessary to adequately integrate intrinsic motivation in the cognitive process supporting the correct performance based on intrinsic motivation.

Title: Resting state connectivity in prodromal schizophrenia

Authors: *A. S. POTTER[1], I. SOULOS[2], G. SCHAUBHUT[3], S. DUBE`[3];
[1]Dept. of Psychiatry, Burlington, VT; [2]Mount Holyoke Col., South Hadley, MA; [3]Psychiatry, Univ. of Vermont, Burlington, VT

Abstract: Introduction: Schizophrenia is a debilitating mental illness affecting between 0.5-1% of the world population. The prodromal stage of the illness is characterized by subtle perceptual, social, and behavioral dysfunctions. rsfMRI describes the temporal correlation of activity between spatially separate brain regions at rest. Hypothesis: Prodromal schizophrenics (PRO) will display hyperconnectivity between the amygdala and sensory cortices compared to controls (CTRL). Methods: 11 PRO and 11 CTRL subjects completed phenotypic characterization using the Structured Interview for Prodromal Syndromes (SIPS) and rsfMRI data collection (6 minutes). Data analysis used a seed-based approach using an anatomically defined amygdala mask. Results: PRO subjects showed increased functional connectivity between the amygdala and the right postcentral gyrus, the left precentral gyrus, the orbitofrontal cortex, and the left

superior temporal gyrus. Conclusion: This study found hyperconnectivity in PRO subjects between the amygdala and brain regions associated with processing and interpreting emotional information.

Abstract: Major depression (MDD) and bipolar disorder (BD) are serious affective disorders with overlapping symptomatology. Many studies have shown both conditions to be associated with reduced gray matter volume, suggesting that structural brain alterations may be involved in these disorders. However it is unclear whether the two conditions show common or distinct

patterns of structural changes. We conducted a meta-analysis of voxel-based morphometry (VBM) studies in MDD and BD to identify patterns of gray matter changes that are common and distinct in these conditions. Literature was searched up to January 2015 for studies comparing whole brain gray matter volume in patients with MDD and BD vs. healthy individuals. We conducted voxel-based meta-analysis on the data using Anisotropic Effect Size Signed Differential Mapping. Original statistical maps were used when available to improve the sensitivity of the analysis, but peak coordinates, as reported in articles, were used if these were not available. We used meta-analytic comparisons of effect sizes and conjunction analyses to identify regions showing shared and distinct gray matter changes in the two conditions.41 studies comparing MDD vs. healthy individuals and 32 studies comparing BD vs. healthy controls were included, with statistical maps included for 14 of these. Medial prefrontal volumetric reduction, specifically in the bilateral medial superior frontal gyri, ventromedial prefrontal cortex, and anterior cingulate cortex, was common to both conditions, as was reduction in the bilateral insula. When groups were contrasted, volume reduction was greater in MDD in the left hippocampus, right inferior temporal gyrus, right middle frontal gyrus and left inferior parietal gyrus. BD showed greater reductions in the left orbitofrontal cortex.These results indicate that both disorders are associated with gray matter volume decreases in the medial prefrontal cortex and insula, regions involved in affective processing. Findings suggest that common morphometric alterations in key neurobiological circuits may underlie the aberrant mood states that characterize both conditions. Robust differences between MDD and BD were identified in a number of regions. The left hippocampus and small areas in the frontal, temporal and parietal lobes showed more substantial reductions in MDD than BD, we found greater reductions in BD in the left orbitofrontal cortex. This might reflect differences in the affective and cognitive profiles of the two disorders, although it is possibly that confounding effects of mood state or medication use in the included studies may influence our results.

Title: Auditory hallucination severity and abnormal auditory cortex connectivity in psychotic disorders

Authors: V. RAMIREZ[1], *S. KEEDY[2];
[2]Psychiatry and Behavioral Neurosci., [1]Univ. of Chicago, Chicago, IL

Abstract: Background: Psychotic disordered individuals show numerous neural system abnormalities, such as in the default mode network when at rest, but these findings have been poorly linked to symptoms. A hallmark symptom of psychotic disorders is auditory hallucinations (AH), which involve the auditory cortex (AUD) when occurring. However, it is not determined whether auditory networks have general functional alterations and whether any alterations may be associated with AH severity. Methods: Patients with psychosis (Pts) with AH histories and healthy controls (HC) were instructed to lie still with eyes open during a 6-minute fMRI resting-state task. Data was preprocessed using AFNI, including regressing out motion estimates, white matter and CSF-related signal and drift parameters. Each participant's bilateral AUD was identified via response to sounds in a separate fMRI run and used as a seed region to correlate with the rest of the brain to characterize AUD connectivity. Pts and HC connectivity maps were compared with t tests, cluster corrected at $p < .05$ (familywise). Average connectivity values were then extracted from each patient for each significant cluster and were correlated with hallucination symptom measurements. Results: Pts had significantly lower auditory cortex connectivity in the left fusiform, right and left insula, left lenticular formation, and cerebellum. Pts with greater insula-AUD connectivity reported worse past AH symptom severity overall, and with specific Emotional and Cognitive dimensions of past AH severity. Conclusion: The analysis of fMRI resting-state data revealed lower auditory cortex connectivity with the insula cortex for Pts with AH histories relative to Ctls, as well as with basal ganglia and cerebellar regions. Together, these findings are consistent with hypotheses of cortical-subcortical-cerebellar loop dysfunction in psychosis. Further, past AH symptom severity was uniquely related to

connectivity of AUD to insula, an area believed to be responsible for emotional regulation and general salience, used for monitoring the environment. This study provides insight that connectivity between AUD and insula could be a neural system mechanism of vulnerability to hallucinations. It also highlights the utility of symptom-based hypothesis testing and detailed symptom assessment, allowing for clearer links between neural system abnormalities and clinical presentation.

Title: Multivariate classification algorithm effectively identifies individuals with MDD using whole brain white matter microstructure calculated from diffusion tensor MRI

Authors: *D. M. SCHNYER[1], P. C. CLASEN[2], C. GONZALEZ[3], C. G. BEEVERS[4]; [1]Univ. of Texas, Austin, Austin, TX; [2]Dept. of Psychology, Stanford Univ., Palo Alto, CA; [3]Natl. Inst. of Hlth., Baltimore, MD; [4]Psychology, Inst. for Mental Hlth. Res., Univ. of Texas, Austin, TX

Abstract: Considerable research has examined the relationship between white matter microstructure and major depressive disorder (MDD) using diffusion tensor MRI (DTI). A recent meta-analysis (Liao Y, Huang X, Wu Q, et al., 2013) examined 11 studies that utilized whole brain univariate approaches for revealing important voxel-based DTI differences between MDD and non-MDD controls - revealing 4 consistent locations of decreased fractional anisotropy (FA) in patients with MDD - the right frontal lobe, right fusiform gyrus, left frontal lobe and right occipital lobe. While univariate approaches are useful in identifying localized differences between patients and controls, they don't tell us how well these differences perform in identifying who has MDD and who doesn't. Here we examine the potential value of applying multivariate classification algorithms in order to identify individuals with MDD based on the totality of their brain white matter. DTI data from forty individuals, 20 each MDD and non-MDD matched on gender and age were examined. Whole brain DTI was acquired for 25 directions using a dual shot echo planar imaging and a twice-refocused spin echo pulse sequence,

optimized to minimize eddy current-induced distortions (GE 3T, TR/TE = 12000/71.1, B = 1000, 128 × 128 matrix, 3-mm (0 mm gap) slice thickness, 0.94 × 0.94 mm in plane resolution, 1 T2 + 25 DWI). Forty-one slices were acquired and diffusion tensors and multiple scalar measures, including FA values were calculated on a voxel-by-voxel basis using conventional reconstruction methods. A support vector machine-learning algorithm, C-classification with a linear kernel and 5-fold cross validation was applied for multivariate classification. Average classifier training accuracy using FA across each of the sets with 1/5th of the participants randomly removed was 73.4% - corresponding to a Kappa 0.40. After removing regions that showed univariate between group differences, the classification accuracy remained statistically unchanged. Moreover, of the multiple scalar measures examined - mean, radial and axial diffusivity, FA resulted in the most accurate classification. Finally, a searchlight procedure will be applied to understand the possible predictors of response to an attention training treatment regime in the patients with MDD. These results support the contention that distributed microstructural differences across the entire white matter network are important for understanding the brain basis of MDD.

Title: Decreased social connectedness in women with Premenstrual Dysphoric Disorder

Authors: *L. LIANG[1], N. PETERSEN[2], D. GHAHREMANI[2], R. GERARDS[2], A. CHOUDHARY[2], L. GOLDMAN[2], A. RAPKIN[2], E. LONDON[2];
[1]Semel Inst., [2]UCLA, Los Angeles, CA

Abstract: Premenstrual Dysphoric Disorder (PMDD) is a disorder that afflicts approximately 5% of women in their reproductive years. Women with PMDD experience psychological, physical, and behavioral symptoms in the days that precede the onset of menses, and symptoms abate as the menstrual cycle begins. PMDD can cause extreme mood disturbances that decrease quality of life and daily functioning. Based on evidence that social ties are significantly related to mental health outcomes, we hypothesized that women with PMDD may experience deficits in

social connectedness. To test this hypothesis, 16 women with PMDD and 22 healthy controls were recruited. Social connectedness was assessed using the Social Connectedness Scale, Revised (SCSR), a well-validated 20-item questionnaire evaluating the degree to which participants feel connected to others and their environments, and neural correlates of social connectedness were evaluated using resting state functional magnetic resonance imaging in an exploratory analysis. Participants completed the resting-state scan and SCSR once during the follicular phase and once during the luteal phase. Consistent with our hypothesis, women with PMDD had significantly lower social connectedness scores than healthy controls ($p=0.0179$). Menstrual phase did not significantly influence social connectedness scores in PMDD participants or healthy controls. Our findings suggest that women with PMDD experience significant deficits in social connectedness regardless of cycle phase, suggesting that therapies to increase social connectedness may represent an effective clinical target for therapeutic investigations.

Title: Alterations of cortical activity at local and network levels during visual working memory updating in major depressive disorder

Authors: ***T. M. LE**[1], J. KANG[2], D. TYSZ[2], D. KLEIN[2], H.-C. LEUNG[2];
[2]Psychology, [1]Stony Brook Univ., Stony Brook, NY

Abstract: Major depressive disorder (MDD) is associated with deficits in cognitive control including the ability to efficiently update working memory in the face of irrelevant or obsolete information. While prefrontal dysfunction is strongly implicated in cognitive control deficits in MDD, the few studies examined visual areas (e.g., V4) have also found reduced activity and abnormal functional connectivity during visual perception and attention. To determine whether working memory updating impairment in MDD involves alterations in regional and network activity, we examined visual association regions involved in selective maintenance and

processing as well as their functional connectivity with the prefrontal cortex (PFC). We acquired functional magnetic resonance imaging data from 17 unmedicated participants with MDD and 21 healthy controls (CTL) while they performed a visual delayed recognition task with an updating cue inserted in the delay period. Three cues, Remember Face (Ignore Scene), Remember Scene (Ignore Face) and Remember Both, were used to indicate which one or both of the two memorized stimuli (a neutral face and a neutral scene) would remain relevant for the recognition test. Regions of interest (ROIs) were functionally defined by face versus scene contrasts using data from a localizer task. Compared to the CTL group, the MDD group showed lower accuracy on the Remember Scene condition and reduced category selectivity in the scene-selective areas during postcue delay. Intriguingly, activity in the fusiform face area during Remember Scene positively correlated with rumination across the MDD subjects. At the network level, beta series analysis revealed a significant increase in coupling between the left lateral PFC and scene-selective areas in the parahippocampal gyrus and posterior parietal cortex during Remember Scene compared to Remember Both in the CTL group. No such enhancement in functional connectivity was observed in the MDD group even at very lenient threshold ($p<0.01$, uncorrected). In sum, our findings suggest impairments in working memory updating performance and rumination are associated with alterations in category-specific activity in visual association areas in MDD. Such local changes may be a result of changes at the network level affecting modulatory top-down control from the PFC, producing dysfunctions in working memory updating. Such results provide new evidence of the role of visual association areas in working memory updating deficits in depression while supporting the role of prefrontal dysfunction in the disorder.

Abstract: Behavioral activation is known to be an effective treatment for subthreshold depression to prevent development from major depressive disorder. Behavioral activation is equally effective to cognitive behavioral therapy for the treatment of depression and has been a growing interest for its feasibility. To date, a few studies have examined the neural effects of psychotherapy on depression, mainly cognitive behavioral therapy. However, neural correlates of behavioral activation has not been clearly understood. Here, we investigated neural response using functional magnetic resonance imaging during reward processing to study neural mechanisms of behavioral activation in subthreshold depression. 16 subthreshold depression (age 18-20) with high BDI score and 16 age-matched controls with low BDI score participated in two identical functional magnetic resonance imaging scans with monetary incentive delay task, frequently used for MDD to detect changes in neural activity in response to the processing of reward and punishment. Between scans, subthreshold depression group received a 5 week behavioral activation therapy without medication. We demonstrated that behavioral activation significantly reduced depressive symptoms. Relative to changes in brain function in controls, behavioral activation resulted in functional changes in structures that mediate cognitive emotion regulation, including left ventrolateral prefrontal cortex and angular gyrus during loss anticipation in subthreshold depression. In conclusion, the present study revealed neural effects of brief behavioral activation treatment to subthreshold depression , that is, improved functioning of fronto-parietal region during loss anticipation. These results provide further evidence for understanding mechanisms underlying specific psychotherapy.

Title: Increased excitability of lateral habenula neurons via down regulation of m-type potassium channel in rats withdrawn from repeated ethanol exposure

Authors: *S. KANG, J.-H. YE;
Dept. of Anesthesiology, New Jersey Med. Sch., Rutgers, The State of Univ. of New Jersey, Newark, NJ

Abstract: Accumulating evidence suggests the lateral habenula (LHb), an epithalamic structure, plays a pivotal role in neuropsychiatric diseases, including drug addiction; neuronal changes in the LHb after chronic drug exposure may therefore represent a critical mechanism leading to addiction. However, the effects of ethanol exposure on LHb neurons have not been well investigated. In this study, we investigated how LHb neuronal activity is changed by repeated ethanol exposure. Since many studies have shown that potassium channels, including the m-channel (KCNQ/Kv7 family), are importantly involved in alcohol abuse, and histological evidence indicates the abundance of m-channel expression in the LHb, we investigated whether m-channel is involved in the ethanol-induced changes of LHb neurons. Using patch-clamp techniques and the Western blot approaches, we found that in rats at 24 h withdrawal from repeated ethanol exposure (2 g/kg, i.p., twice/d for 7 d), the excitability of the LHb neurons was increased. In addition, the m-channel current as well as the protein expression of m-channel subunit, KCNQ2, were decreased in the LHb of ethanol-treated rats, compared to the ethanol-naïve counterparts. These observations suggest that m-channel has an important role in ethanol-induced neuronal adaptation on LHb and imply that m-channel could serve as a target for treatment of ethanol dependence.

Title: Role of afferents and efferents of the lateral habenula in ethanol-directed behaviors

Authors: *C. SHETH[1], T. M. FURLONG[1], K. A. KEEFE[1], S. A. TAHA[2];
[1]Dept. of Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT; [2]The Kavli Fndn., Santa Barbara, CA

Abstract: Alcohol has both rewarding and aversive properties, each of which play a critical role in drug intake. The aversive properties of alcohol (e.g. nausea, sedation) are important in limiting alcohol intake and implicated in determining vulnerability to developing an alcohol use disorder. The lateral habenula (LHb) is an epithalamic brain region that plays an important role in processing aversive stimuli and aversion learning. In previous work, we demonstrated that LHb lesions increase voluntary ethanol consumption, increase operant ethanol self-administration; block yohimbine-induced reinstatement of ethanol-seeking and attenuate conditioned-taste aversion (CTA) to ethanol. However, the anatomical circuit through which the LHb mediates ethanol-directed behaviors is unknown. Given that the LHb inhibits the midbrain dopaminergic system through a disynaptic pathway involving the rostromedial tegmental nucleus (RMTg) and that the RMTg itself has been implicated in mediating aversion-driven behavior, we hypothesized a role for RMTg in mediating ethanol-directed behaviors. To test this hypothesis, male Long-Evans rats received bilateral excitotoxic RMTg or control lesions. After recovery from surgery, rats were subjected to intermittent alcohol access (IAA) for 8 weeks to induce voluntary ethanol consumption. Rats were then trained to lever press for ethanol, extinguished and tested for yohimbine-induced reinstatement. Finally, ethanol-induced conditioned taste aversion (CTA) was measured in a group of rats with RMTg or control lesions. We found that RMTg- lesioned rats consumed significantly more ethanol in the IAA paradigm than the controls. There were no differences between lesioned and control rats in ethanol-seeking and yohimbine-induced reinstatement of ethanol-seeking. Finally RMTg-lesioned rats showed robust CTA comparable to control levels in our paradigm, but extinguished this conditioned aversion significantly faster than control animals. Thus the RMTg, like the LHb, plays a role in regulating voluntary alcohol consumption potentially by mediating aversion to alcohol. Along similar lines, we investigated whether afferent input to LHb from reward-relevant structures including ventral pallidum (VP) and lateral hypothalamus (LH) is critical for regulating ethanol-directed behaviors. We found that LH to LHb input regulates voluntary ethanol consumption but is not critical in other ethanol-directed behaviors. We conclude that LH and RMTg are potential afferent and efferent targets in mediating LHb effects on voluntary ethanol consumption.

Title: Excitatory activity in lateral habenula neurons during expression of ethanol-induced conditioned taste aversion

Authors: *S. TANDON[1], K. A. KEEFE[1], S. TAHA[2];
[1]Univ. of Utah, Salt Lake City, UT; [2]The Kavli Fndn., Santa Barbara, CA

Abstract: Ethanol, similar to other drugs of abuse, has potent rewarding and aversive properties. Clinical and preclinical data suggest that sensitivity to ethanol's aversive effects negatively modulates voluntary alcohol intake and thus may play a role in vulnerability to develop alcohol use disorders. We previously showed that bilateral lesions of the lateral habenula (LHb) in rats attenuate ethanol-induced conditioned taste aversion (CTA) (Haack et al., 2014). To understand the role of neural encoding in the LHb in contributing to learned aversion induced by ethanol injection, we recorded neuronal activity in the LHb of freely behaving, water-deprived rats (n=6) during an operant task to obtain a saccharin solution (0.125%) both before ("Pre-CTA" session after control saline injection) and after an ethanol-induced CTA ("CTA" session after injection of 1.5 g/kg 20% ethanol). Ethanol-induced CTA caused robust behavioral effects: relative to pre-CTA sessions, rats responded less frequently and at longer latencies in the operant task to obtain saccharin. Four major differences in LHb neural firing properties were apparent in comparing pre-CTA vs. CTA sessions. First, baseline firing rates in CTA sessions were significantly higher. Second, firing evoked by cues predicting saccharin availability shifted from a pattern of primarily inhibition during pre-CTA sessions to primarily excitation during CTA sessions. Third, lever press-evoked firing rates were higher in CTA sessions. Finally, LHb neurons were significantly more excited during consumption of the devalued saccharin solution in CTA sessions. Together, these results suggest that a shift from inhibition to excitation of LHb neurons contributes to expression of ethanol-induced CTA. To directly evaluate the role of LHb activity in ethanol-induced aversion, we next compared behavior in sham vs. LHb-lesioned rats in an identical operant CTA paradigm. LHb lesion attenuated CTA effects: LHb-lesioned rats initiated more trials and completed trials faster as compared to controls. Our data thus show that LHb excitatory activity is important in regulating expression of alcohol-induced aversion and point towards the LHb as a major node in modulating alcohol-seeking behaviors.

Title: The role of the rostromedial tegmental nucleus in ethanol-induced conditioned taste aversion in male and female rats

Authors: *E. J. BURNETT[1], T. C. JHOU[2], L. J. CHANDLER[2];
[1]Dept. of Neurosciences, [2]Dept. of Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: The past several decades have witnessed a closing of the gender gap in the prevalence of alcohol use disorders (AUDs). In addition, recent work suggests the presence of a telescoping phenomenon, with women developing dependence over a shorter drinking duration and fewer total drinks compared to men. Current theories suggest that a competitive balance between a drug's rewarding and aversive properties changes as drug use progresses from recreational use to addiction. While the involvement of alcohol's rewarding properties in the path to dependence continues to be extensively investigated, the role of alcohol's aversive characteristics has been less well studied, particularly as it relates to differences between the sexes. The rostromedial tegmental nucleus (RMTg) exerts inhibitory control over midbrain dopamine neurons and is involved in encoding aversive stimuli and the behavioral responses to those stimuli. Recent work has also implicated activity within the RMTg in mediating the aversive effects of stimulants. To begin to investigate the role of the RMTg in signaling the aversive properties of alcohol, we measured cFos induction in this brain region following conditioned taste aversion (CTA). Adult male and female Long-Evans rats were exposed to three pairings of a novel 0.1% saccharin solution followed by an i.p. injection of 20 ml/kg 0.15 M lithium chloride (LiCl), 1.5 g/kg 20% ethanol (EtOH) or saline. Ninety minutes after a fourth exposure to saccharin only, the rats were sacrificed and brains processed for cFos immunohistochemistry. Both LiCl and EtOH produced significant CTA of equal magnitude between males and females compared to saline ($p<0.01$). LiCl-induced CTA was significantly stronger than EtOH-induced CTA in both sexes ($p<0.01$). Both LiCl- and EtOH-induced CTA significantly enhanced cFos expression in the RMTg compared to saline ($p<0.05$). cFos expression was similarly significantly enhanced in the lateral

habenula (LHb; $p<0.05$) - a source of prominent glutamatergic input to the RMTg. No significant sex differences in cFos expression were observed. Of note, cFos expression in both the RMTg and LHb were significantly positively correlated with CTA magnitude ($p<0.05$). In addition, RMTg cFos expression was significantly positively correlated with LHb cFos expression ($p<0.01$). Together, these data suggest that activity within the RMTg, possibly driven by activity within the LHb, plays a role in the aversive properties of drugs, including alcohol, in both male and female rats.

Title: The medial habenula and interpeduncular nucleus differentially modulate nicotine sensitization

Authors: B. L. EGGAN, *S. E. MCCALLUM;
Ctr. for Neuropharm. and Neurosci., Albany Med. Col., Albany, NY

Abstract: The habenulo-interpeduncular pathway has previously been shown to modulate both rewarding and aversive effects of nicotine. The medial habenula (MHb) and interpeduncular nucleus (IPN) communicate directly via the fasciculus retroflexus. Further downstream these nuclei influence the mesolimbic reward pathway which extends from the ventral tegmental area (VTA) to the nucleus accumbens (NAc). Previously, we have shown that blocking α3β4 nicotinic acetylcholine receptors (nAChR) in the MHb decreases nicotine self-administration and blocks nicotine induced dopamine release in the NAc. In this study we sought to fully investigate both cholinergic and peptidergic signaling in the habenulo-interpeduncular pathway and elucidate the role of these two transmitter systems in nicotine sensitization, a phenomenon believed to be mediated by the VTA. Rats were sensitized to nicotine via 5 days of nicotine administration (0.4 mg/kg, s.c.) and underwent either locomotor activity testing (to quantitate behavioral sensitization) or *in vivo* microdialysis (to quantitate neurochemical sensitization in the NAc). Treatment drugs were administered directly to the MHb or IPN via indwelling cannulae. Intra-MHb administration of the α3β4 nAChR antagonists α-conotoxin AuIB and 18-methoxycoronaridine significantly reduced behavioral and neurochemical sensitization to nicotine. Sensitization was not blocked in the MHb by the α4β2 nAChR antagonist dihydro-β-

erythroidine, the partial α4β2 nAChR agonist varenicline, or the neurokinin-1 receptor antagonist, ezlopitant. Somewhat surprisingly, intra-IPN drug administration did not parallel that of the intra-MHb injections. While intra-IPN administration of α3β4 nAChR antagonists had no effect, behavioral sensitization was blocked by ezlopitant administered in the IPN. Further analysis of the IPN's role in neurochemical and behavioral sensitization is currently underway. Our results suggest that α3β4 nicotinic receptors in the MHb are important for the expression of behavioral and neurochemical sensitization to nicotine, which is in agreement with recent findings implicating habenular α3, β4 and α5 subunits in nicotine reward and dependence. In contrast, in the IPN, substance P signaling appears to modulate nicotine sensitization, while nicotinic receptors in the IPN do not contribute to this phenomenon.

Title: Lateral habenula in nicotine addiction: an electrophysiological *in vivo* study in rats

Authors: G. DEIDDA[1], M. PIERUCCI[2], R. COLANGELI[2], *G. DI GIOVANNI[2];
[1]Physiol. and Biochem., Univ. of Malta, Msida, France; [2]Physiol. and Biochem., Univ. of Malta, Msida, Malta

Abstract: Tobacco smoking represents a well-known risk factor for health. So far, existing smoking cessation therapies have not been proven very successful at stopping this habit completely. Consequently, there remains a need for a better understanding of the neurobiology of tobacco dependence. Nicotine, the neuro-active compound in tobacco, is responsible for its rewarding and reinforcing properties through its action on the midbrain dopaminergic (DA) system. The lateral habenula (LHb), an epithalamic structure involved in pain, stress, depression and in encoding aversive stimuli, is known to inhibit the DA system through activation of the rostromedial tegmental nucleus (RMTg), a GABA-ergic area located caudally to the ventral

tegmental area (VTA). The RMTg receives a strong glutamatergic input from the LHb and is activated by systemic injection of nicotine in rats. Thus, the LHb might represent a possible target for the action of nicotine. Our data show that systemic administration of nicotine increases LHb neuronal activity *in vivo* in rats. Following chronic nicotine treatment this response is drastically decreased, while after 1 day of withdrawal only low doses of nicotine are able to significantly affect the firing rate of the LHb neurons compared to controls. To further elucidate the role of the LHb in central nicotine effects, we recorded the activity of VTA putative-DA neurons following electrolytic LHb lesion after acute and chronic nicotine administration. Acute systemic administration of nicotine induced a significant increase of VTA DA neuronal activity. Moreover, splitting the neurons on the basis of their localization within the VTA, revealed a significant effect of nicotine only on paranigral nucleus (PN) neurons compared to those of parabrachial pigmented nucleus (PBP). The electrolytic LHb lesion did not modify the nicotine acute effect on overall DA neurons. Strikingly, LHb lesion completely abolished the effect of nicotine on PN neurons and produced a significant excitation of PBP neurons. Following chronic nicotine treatment, an acute challenge with nicotine in LHb-lesioned rats failed to increase VTA DA cells neuronal activity compared to sham-lesioned and control rats. Our evidences strongly suggest that the LHb may play an important role in mediating the effects of nicotine on the midbrain DA system, thus participating to the mechanism of addiction to this drug.

Title: Cellular and synaptic mechanisms of nicotine aversion

Authors: ***S. L. WOLFMAN**[1], F. BOGDANIC[2], D. F. GILL[1], R. AL-HASANI[3], J. G. MCCALL[3], M. R. BRUCHAS[3], D. S. MCGEHEE[2];

Abstract: Nicotine addiction remains a major health problem in the US and throughout the world. Nicotine has rewarding effects at relatively low doses and intensely aversive effects at higher doses. The projection from the medial habenula (MHb) to the interpeduncular nucleus (IPN) contributes to these aversive effects. This “aversive” pathway may influence the development and maintenance of nicotine dependence and also contributes to withdrawal effects. Thus, improved understanding of the mechanisms that underlie the aversive effects of nicotine may be important in developing more effective therapies for smoking cessation. Excitation of the MHb-IPN projections enhances aversion to nicotine, while inhibition of this pathway increases appetitive responding for high doses of nicotine that were previously aversive. Although these results implicate the MHb-IPN circuitry, the downstream post-synaptic targets of the IPN that mediate these effects remain largely uncharacterized. Our hypothesis is that the aversive effects of nicotine occur through an indirect suppression of the excitability of VTA dopamine (DA) neurons. Burst activity in DA neurons is important for reward-associated behaviors, and aversive experiences can suppress DA neuron activity. While the IPN projects to several brain areas, it strongly innervates the lateral dorsal tegmental nucleus (LDTg), a brainstem cholinergic center that controls burst firing of VTA DA neurons. To test the nature of synaptic transmission between IPN projections and LDTg, we expressed Channelrhodopsin (ChR2) in IPN neurons and stimulated the terminals with light while recording specifically from LDTg neurons that project to the VTA. We found that light-evoked synaptic inputs were blocked by the GABAA receptor antagonist bicuculline. Additionally, optogenetic stimulation of either the IPN directly, or the IPN terminals in the LDTg specifically, results in aversion. We are testing the modulation of these inhibitory inputs by high and low concentrations of nicotine, and preliminary evidence suggests that high concentrations of nicotine selectively enhance light-evoked GABAergic currents from the IPN onto LDTg neurons that project to the VTA. We also have evidence that optogenetic inhibition of IPN terminals in the LDTg not only reduces aversion to a high dose of nicotine, but actually shifts the aversion to reward. These findings highlight the importance of the IPN-LDTg connection in mediating the aversive effects of nicotine and reveal interactions between reward and aversive circuitries that influence overall affective state.

Title: Septohabenular regulation of nicotine consumption

Authors: *G. VOREN[1], P. J. KENNY[2];
[2]Pharmacol. and Systems Therapeut., [1]Mount Sinai Sch. of Med., New York, NY

Abstract: The medial habenula (MHb) projects almost exclusively to the interpeduncular nucleus (IPN) via the fasciculus retroflexus. This major descending projection serves to connect the limbic forebrain and midbrain monoaminergic centers. Recently, our laboratory has shown that the MHb-IPN system, which densely expresses nicotinic acetylcholine receptors (nAChRs), plays an important role in regulating aversive properties of nicotine that limit consumption of the drug. Genetic evidence suggests that deficits in the sensitivity of this system to nicotine increases vulnerability to tobacco dependence. The MHb receives prominent excitatory input almost exclusively from the triangular nucleus of the septum (TNS) and inhibitory input from medial septum (MS) and diagonal band nucleus (NDB). The role of septohabenular pathways in regulating nicotine intake had not yet been explored. Here, we report that TNS neurons are highly sensitive to nicotine in a dose-dependent manner, as measured using *in vivo* single-unit recordings in freely behaving rats. DREADD-mediated excitation of TNS neurons decreased intravenous nicotine self-administration in rats. Conversely, pharmacological blockade of nicotinic signaling in TNS increased nicotine intake. We hypothesized that nicotine stimulates TNS projections to MHb, and that the TNS-MHb pathway inhibits nicotine intake. Surprisingly, DREADD-controlled activation or inhibition of TNS projections to the MHb did not alter nicotine intake. Similarly, modulation of direct TNS projections to the IPN that bypass the MHb did not alter nicotine intake. These data suggest the TNS functions to regulate nicotine consumption independent of its projections to the MHb or IPN. These data reveal the TNS region of the posterior septum as an important neuroanatomical substrate that regulates nicotine intake, but the circuit-level mechanisms through which TNS acts are unknown.

Title: Effect of DREADD-mediated transient activation of Gq-coupled signaling in lateral habenula neurons on cocaine and food self-administration in rats

Authors: *S. G. NAIR[1], D. SMIRNOV[2], J. F. NEUMAIER[2];
[1]Psychiatry and Behavioral Sci., [2]Univ. of Washington, Seattle, WA

Abstract: The lateral habenula (LHb), an epithalamic nucleus located in the dorsal diencephalon is an important regulator of midbrain dopaminergic systems that are known to be involved in the reinforcing properties of cocaine. We previously examined the effect of DREADD (hM4Di) - induced transient activation of Gi/o-coupled signaling in LHb neurons and found that it significantly increased operant cocaine self-administration. Here, we firstly examined the effect of DREADD (hM3Dq)-induced transient activation of Gq coupled signaling on cocaine reinforced operant responding. Male Long-Evans rats were injected with hM3Dq into the LHb and implanted with jugular venous catheters. Approximately 10-12 days after viral infusions, rats were trained to self-administer cocaine (0.75 mg/kg/infusion) on a fixed ratio 1 (FR1) reinforcement schedule. Initial results indicate that activation of hM3Dq by the pharmacologically inert synthetic ligand clozapine-N-oxide CNO (1 and 3 mg/kg, i.p) decreases cocaine reinforced operant responding. Secondly, a distinct cohort of rats was infused with viral vectors as described above and trained to self-administer cocaine (0.75 mg/kg/infusion) on a progressive ratio reinforcement schedule. CNO-induced activation of hM3Dq significantly decreased operant responding on a progressive ratio reinforcement schedule. Thirdly, rats infused with hM3Dq into the LHb were trained to self-administer 45 mg food pellets on either a FR 1 or a progressive ratio reinforcement schedule. Interestingly, our initial results indicate that this manipulation decreases food reinforced operant responding on both FR1 and progressive ratio reinforcement schedules. To determine if the observed effects are due to locomotor depression, we measured locomotor activity in rats previously infused with hM3Dq into the LHb. Following CNO (1 and 3 mg/kg) injections we found a decrease in locomotor activity at baseline levels as well as upon challenge with an acute injection of cocaine (10 mg/kg). Taken together, our results suggest that DREADD-mediated transient activation of Gq-coupled signaling in the LHb decreases operant cocaine and food self-administration and that these effects may, in part, be due to deficits in locomotor activity.

Title: Cocaine and cue encoding in the rodent entopeduncular nucleus

Authors: *H. LI, J. L. THOMPSON, T. C. JHOU;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Previous studies have shown that lateral habenula (LHb) neurons are activated by aversive stimuli and their predictors. We recently showed also that LHb neurons show a biphasic response to cocaine, with an initial inhibition followed by a delayed excitation that parallels the rewarding and aversive effects of cocaine. We sought to test whether these patterns of responses are also present in the entopeduncular nucleus (EPN), which provides a major afferent to the LHb. We found using retrograde labeling and cFos that rostral parvalbumine negative EPN neurons projecting to the LHb were activated by 30x footshocks and by 0.75 mg/kg intravenous cocaine infusion. Furthermore, the animals were conditioned with three different auditory cues: an appetitive cue paired with food pellet delivery, an aversive cue paired with a footshock, and a neutral cue paired with neither food nor footshock. Electrophysiological recordings from awake behaving animals further showed that most of neurons in the rostral EPN showed excitations to the footshock, and that cue-responsive EPN neurons exhibited relatively higher firing after aversive and neutral cues than after appetitive cues. Further experiments are underway to determine whether these neurons encode motivational properties of cocaine.

Title: The projection from the entopeduncular nucleus to the lateral habenula encodes aspects of cocaine withdrawal

Authors: *F. MEYE[1], T. SMIT[2], M. MAMELI[1];
[1]Inst. Du Fer A Moulin, UMR-S 839 INSERM/UPMC, Paris, France; [2]Master Neurosci. and Cognition, Utrecht Univ., Utrecht, Netherlands

Abstract: The lateral habenula (LHb) plays a pivotal role in the processing of negative emotional states, including those that occur after the intake of addictive drugs. The negative withdrawal state is an important contributor to relapse behavior and the maintenance of drug addiction. Therefore it is critical to understand the neural underpinnings of aversive drug withdrawal. Previously, we found that cocaine induces synaptic and intrinsic plasticity in the LHb, which results in hyperexcitability of this region, and which promotes the development of a negative emotional state. However, it is currently unknown how specific afferent regions that project to the LHb play a role in this. In the current study we investigate the role of the projection from the entopeduncular (EP) nucleus, the output structure of the basal ganglia, to the LHb in cocaine withdrawal. To this end we make use of a combination of *in vitro* electrophysiology and optogenetics. After stereotactic injection of viral vectors encoding for channelrhodopsin-2 into the EP, we treated mice with chronic saline or cocaine. After 1.5 days or 2 weeks of withdrawal, whole-cell voltage clamp recordings in LHb were made and EP-LHb connectivity was assessed. We show that abstinence after cocaine exposure induces persistent GABAergic synaptic plasticity in the EP-LHb projection. We also demonstrate the functional relevance of these modifications in controlling LHb neuronal output, as GABAergic masking of the excitatory transmission from EP to LHb neurons was reduced after cocaine exposure. To determine the neural circuits affected by these cocaine-evoked modifications, we use rabies viral strategies to determine which downstream neuronal subpopulation in the midbrain is mostly affected by EP-LHb signaling. Overall, our findings show that the connection between the basal ganglia and lateral habenula can be relevant in encoding aspects of drug withdrawal.

Title: A role for the lateral habenula and downstream efferent pathways in repeated probabilistic reversal learning

Authors: *K. S. KIDDER[1], P. M. BAKER[2], S. J. Y. MIZUMORI[2];
[2]Psychology, [1]Univ. of Washington, Seattle, WA

Abstract: A number of neuropsychiatric disorders including depression, autism spectrum disorder, and Parkinson's disease are characterized by deficits in the ability to rapidly switch behaviors under changing reward contingencies. This ability to change responses when outcomes change is an executive function commonly termed cognitive flexibility. A common task used to test cognitive flexibility across species is known as reversal learning. Previous studies have shown that manipulations of serotonin (5-HT) and dopamine (DA) affect cognitive flexibility in tasks such as reversal learning. Importantly, these two neurotransmitters are known to play a role in a variety of neuropsychiatric conditions, including the ones mentioned, raising the possibility that a common mechanism may play a role across diseases. The lateral habenula (LHb) may be a key structure in mediating reversal learning as it is known to affect transmission of 5-HT and DA. Behaviorally, the LHb is thought to provide an error signal during decision making tasks making it likely that it is critically involved in tasks requiring learning from errors such as reversal learning. To test this hypothesis, a maze based probabilistic reversal learning task (PRL) with male Long-Evans rats was used to examine the role of the LHb via neurotransmitter inactivation with the gamma-aminobutyric acid (GABA) agonists baclofen and muscimol (50ng/0.2 μL).Prior to behavioral testing rats were implanted with guide cannula aimed at the LHb for subsequent injections. The PRL task took place on a t-shaped maze with return arms. The correct arm resulted in reward on 80% of choices while the incorrect arm was never reinforced. Rats ran 200 trials per daily session. If an animal chose the correct arm over 10 consecutive trials, the reward contingences were reversed. Once animals were able to complete at least 3 reversals per session over consecutive days, injections began. Results revealed that inactivation of the LHb led to fewer overall reversals than rats injected with a saline control. Error analysis revealed a slight increase in perseverative errors and a large increase in regressive errors. Additionally deceases in stay/win behavior and increases in shift/loose behavior indicated a generalized reward sensitivity impairment after LHb inactivation. Current work is utilizing designer receptors engineered and activated by designer drugs (DREADDs) to target LHb projections to dopamine systems to further understand it's involvement in cognitive flexibility. Overall, these findings suggest that the LHb is important for learning and/or implementing switches in behavior when reward contingencies change.

Title: Microarray analysis of transcripts with elevated expressions in the rat medial or lateral habenula indicate GABAergic excitation in the medial habenula and habenular involvement in the regulation of circadian rhythm and energy balance

Authors: F. WAGNER[1], L. FRENCH[2], C. DERST[3], R. BERNARD[3], *R. W. VEH[3];
[1]Clin. for Neurol., Univ. of Jena, Jena, Germany; [2]Rotman Res. Inst. at Baycrest, Toronto, ON, Canada; [3]Universitaetsklinikum Charite, Berlin, Germany

Abstract: In vertebrates the "anti-reward-system" mainly is represented by the habenula and its medial (MHb) and especially lateral (LHb) complexes. So far, considerable knowledge has accumulated especially concerning subnuclear structures and the connectivities of MHb and LHb subnuclei. The present investigation aimed to obtain novel information, whether MHb or LHb or their subnuclei display characteristic gene products, which may shed more light on biological functions of these areas. Using microarray analysis of mRNAs expressed in microdissected habenular and thalamic control areas yielded expression values of 17,745 RNAs representing protein-coding genes, to which annotated gene names could be assigned. High relative values of genes with known expression in MHb, LHb or thalamus in the corresponding areas indicated a high precision of the microdissection procedure. The present investigation focused on gene transcripts related to major transmitter systems, catecholamines and neuropeptides. Quite surprisingly, our data indicate potentially inhibitory effects of acetylcholine and glutamate in the habenula and support a largely excitatory role of GABAergic transmission especially in the MHb. The high expression of the prokineticin 2 receptor is in line with a suspected role of the LHb during the circadian rhythm. Furthermore, several G-protein related receptors (Grp83, Grp139, Grp149, Grp151, Grp158) and many neuropeptides related to feeding are differentially expressed in the habenular region, indicating that the involvement of MHb and LHb in the regulation of food consumption and energy expenditure may have been underestimated so far.

Title: Functional adaptations of mesolimbic dopamine neurons underlying individual alcohol drinking behaviors

Authors: *B. JUAREZ[1], A. K. FRIEDMAN[1], E. S. CALIPARI[2], J. T. YORGASON[3], M. CRUMILLER[4], S. M. KU[1], H. ZHANG[1], C. MOREL[1], D. CHAUDHURY[5], M.-H. Univ., Portland, OR; [4]Rockefeller Univ., New York, NY; [5]New York University- Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: Most individuals are known to consume alcohol in a controlled manner throughout their lifetimes, while others succumb to pathological, compulsive drinking behaviors. In order to understand the emergence of individual alcohol drinking behaviors, there is a need to explore the neural substrates involved in mediating the different phases of alcohol-use. The initial rewarding phase of alcohol-use is known to recruit brain regions involved in dopamine release and signaling, particularly the ventral tegmental area (VTA) sending dopaminergic projections to the nucleus accumbens (NAc). To determine if there are any neuroadaptations in this circuit (VTA-NAc) that result in individual alcohol drinking behaviors, we used a continuous access, two-bottle choice alcohol drinking paradigm in C57BL/6J mice to establish individual alcohol drinking behaviors based on alcohol preference and consumption. We discovered that low alcohol drinking mice display increased *in vivo* VTA dopaminergic firing activity and bursting parameters, while high alcohol drinking mice surprisingly maintained control-like *in vivo* firing properties. Utilizing a circuit-dissecting approach to label VTA-NAc dopamine neurons with retrograding viral eYFP tags, we performed *in vitro* electrophysiological recordings and discovered that the VTA-NAc dopamine cells of low alcohol drinking mice consistently show increased firing activity, while high alcohol drinking mice continue to display control-like levels of firing. We then used fast-scan cyclic voltammetry to determine if there were any differences in dopamine release in the NAc. We have discovered distinct differences in dopamine release and uptake in the NAc core and shell between the alcohol drinking groups. These results implicate an adapted response to alcohol's rewarding effects on the VTA-NAc pathway.

Title: Optogenetic-induced corticostriatal synaptic plasticity in the dorsomedial striatum of adult rodents

Authors: ***T. MA**, C.-Y. HUANG, X. WANG, J. WANG, J. WANG;
Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: The dorsomedial striatum (DMS) receives glutamatergic cortical input, which form a critical circuit controlling the learning of goal-directed instrumental actions. Long-term potentiation (LTP) in the DMS is thought to be the cellular substrate underlying the strengthening of instrumental actions in this circuit. However, large is unknown about this synaptic plasticity, due to the unreliable induction of LTP in striatum. Here, we used optogenetics to induce LTP in adult DMS slice. We found that tetanic electrical stimulation pairing with optogenetic-mediated postsynaptic depolarization, which efficiently removes Mg2+ blockade of postsynaptic NMDA receptors, induces robust LTP in DMS slices from adult rats. Importantly, activation of NMDA receptors, but not of dopamine D1 receptors (D1Rs), is required for the LTP induction. The LTP was observed in both D1R- and D2R-expressing DMS neurons of mice. In addition, using dual-channel optogenetics, we found that corticostriatal LTP was reliably induced by pairing optogenetic stimulation of prefrontal inputs with optogenetic-mediated postsynaptic depolarization of DMS neurons. Lastly, we discovered that the NMDA receptor in the distal dendrites of DMS neurons is effectively unblocked by optogenetic-induced postsynaptic depolarization. Together, these results suggest that postsynaptic optogenetic depolarization facilitates the induction of NMDAR-dependent corticostriatal LTP in the adult DMS, which help the investigation of corticostriatal LTP in instrumental learning and memory.

Title: D1r-msns of the dorsomedial striatum positively control excessive alcohol intake via the nmda receptor

Authors: *Y. CHENG, T. MA, C.-Y. HUANG, X. WANG, J. WANG;
Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Dopamine D1 receptor (D1R)- and D2 receptor (D2R)-expressing medium spiny neurons (MSNs) in the striatum give rise to the direct and indirect pathways that contribute to "Go" and "NoGo" actions in rewarding behaviors, respectively. It was recently found that excessive alcohol intake enhances synaptic strength in D1R-MSNs of the dorsomedial striatum (DMS), which may contribute to the maintenance of excessive alcohol intake. Here, we examined whether and how D1R-MSNs in the DMS control alcohol consumption. We infused into the DMS of Drd1a-Cre mice with a viral vector containing Cre-dependent hM4Di. Mice were then trained to consume high levels of alcohol using the intermittent access 2-bottle choice drinking procedure. We found that chemicogenetic downregulation of D1R-MSNs activity in the DMS of mice significantly reduced excessive alcohol intake accompanying by a decrease in alcohol preference. However, neither locomotion activity nor saccharin intake was altered following chemicogenetic manipulation. In addition, we observed that excessive alcohol consumption caused an increase in NMDA receptor activity in D1R-MSNs of the DMS. Together, our results suggest that D1R-MSNs play a positive role in alcohol consumption, which is specific mediated by glutamatergic receptors.

Title: Input-specific aberrant synaptic plasticity in the dorsomedial striatum of alcohol-drinking rats

Authors: *J. WANG, T. MA, E. HELLARD, C.-Y. HUANG, X. WANG;
Dept. of Neurosci. & Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Accumulated evidence suggests that the dorsomedial striatum (DMS) of the basal ganglia plays an essential role in pathological excessive alcohol consumption. The DMS receives multiple glutamatergic inputs. However, whether and how alcohol consumption distinctly affects these excitatory afferents in the DMS remains unknown. Here we used optogenetics to selectively activate the prefrontal cortex (PFC) and basolateral amygdala (BLA) inputs in the DMS slices from alcohol-drinking rats and measured glutamatergic transmission in corticostriatal and amygdalostriatal circuits. We found that excessive alcohol consumption leads to increases in activities of NMDA and AMPA receptors at the corticostriatal input in the DMS. Furthermore, we found that the NR2B/NMDA ratio was increased in the corticostriatal input and the NMDA/AMPA ratio remained unchanged in both inputs. We are currently examining whether *in vivo* optogenetic reversal of alcohol-evoked plasticity at the corticostriatal input abolishes alcohol seeking. Taken together, we describe how the glutamatergic input changes in the DMS of alcohol-drinking adult rats and these results suggest that excessive alcohol intake enhances corticostriatal input plasticity, which may in turn contribute to pathological alcohol consumption.

Title: Inhibition of D1R-MSNs in the dorsomedial striatum decreases operant alcohol consumption

Authors: *E. R. HELLARD, C. HUANG, Y. CHENG, J. WANG;
Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: The striatum of the basal ganglia contains two types of principle medium spiny neurons (MSNs), dopamine D1 receptor (D1R)- and D2 receptor (D2R)-expressing MSNs, both of which have been reported as dysfunctional in neuropsychiatric diseases, including alcohol use disorder. Currently, identification and manipulation of these neuronal populations are largely dependent on the use of transgenic mice. Unfortunately, many alcohol addictive behaviors are measured better in rats and rat genetics is not nearly as advanced as mouse genetics. To target specific cell populations in the rat brain, we have developed a method called "Dual Virus Infusion" in which two viruses, a retrograde containing a Cre-recombinase and an anterograde Cre-dependent, are infused at different locations along the neural pathway of interest. Using this method, we targeted the striatonigral pathway in order to suppress D1R-MSN activity with an inhibitory light-activated channel, halorhodopsin. Our results show that using this technology we are able to label and manipulate striatonigral neurons, originating in the dorsomedial striatum (DMS) and synapsing in the substantia nigra pars reticulate. Light stimulation from optic fibers implanted into the DMS inhibited D1R-MSN firing and significantly decreased operant self-administration of alcohol. Importantly, inhibition of D1R-MSN firing did not decrease locomotion activity in an open-field test. In addition, D1R-MSN inhibition decreased cue-induced reinstatement of operant alcohol intake. These data illustrate a potential role of DMS D1R-MSNs in alcohol consumption and relapse.

Title: Ethanol decreases the spontaneous firing rate of a specific subset of Globus Pallidus neurons: role of the Large-Conductance Ca^{2+}-activated potassium channel

Authors: *D. M. LOVINGER[1], K. P. ABRAHAO[2];
[1]Chief, Lab. Integrative Neurosci, [2]Lab. Integrative Neurosci, Natl. Inst. Alcohol Abuse & Alcohol, Rockville, MD

Abstract: The Globus Pallidus external segment (GPe) is a large nucleus located in the core of the basal ganglia, caudomedial to the striatum. The GPe receives strong GABAergic innervation from the striatal indirect pathway. GPe neurons generate autonomous pacemaker activity which helps to control basal ganglia output, placing GPe as a central pacemaker of the basal ganglia. Little is known about ethanol effects on neuronal pacemaker activity, and especially on GPe neurons. We performed whole-cell patch-clamp recordings from GPe neurons in brain slices from wildtype C57BL/6J mice and mice expressing GFP under control of the promoter for the Lhx6 gene (Lhx6-GFP mice) to examine acute ethanol actions. Recent work has shown that the GPe is comprised of different GABAergic neuronal subtypes and a small percentage of cholinergic neurons. Each neuronal subpopulation shows specific electrophysiological properties. We have developed a cluster analysis-based classification model to identify GPe neuron subpopulations, to facilitate the study of drug effects in different neuronal subtypes. Bath application of 40mM ethanol decreased the firing rate of low-frequency-firing GPe neurons by ~25% but it did not alter the firing rate of high frequency-firing neurons. The effect was not blocked by GABAergic or glutamatergic antagonists, indicating that ethanol may affect specific channels involved in the intrinsic control of the pacemaker activity. The application of a specific BK channel antagonist, Penitrem-A (500nM), blocked the ethanol-induced decrease in firing rate, suggesting that BK channel activity is affected by ethanol in the low-frequency-firing GPe neurons. The Lhx6-GFP mouse has been used to label a subpopulation of GPe neurons with low-frequency firing rate. In Lhx6-GFP positive neurons, ethanol also decreased firing rate and this effect was blocked by the BK channel antagonist. Ongoing studies are examining the effect of *in vivo* chronic ethanol exposure on the firing rate of Lhx6-GFP GPe neurons. This knowledge may provide better understanding of the mechanisms contributing to ethanol effects on the Basal Ganglia and associated behaviors.

Title: A role for Kv7 channels in alcohol drinking: Genetics, pharmacology, and neuroadaptations

Authors: *N. M. STRAIGHT MCGUIER[1], W. C. GRIFFIN, III[1], J. T. GASS[1], A. E. PADULA[1], E. J. CHESLER[2], P. J. MULHOLLAND[1];
[1]Med. Univ. of South Carolina, Charleston, SC; [2]The Jackson Lab., Bar Harbor, ME

Abstract: Emerging evidence suggests that anticonvulsants are a promising class of drugs for treating individuals with AUDs. Retigabine (RTG), a unique anticonvulsant in that it opens Kv7 (Kcnq) channels was recently approved for the treatment of partial onset seizures. Using an integrated functional genomics approach (GeneWeaver), we examined the genetic relationship between Kcnq genes and alcohol-related behaviors in rodents including alcohol consumption, preference, and acceptance. This suggested that Kv7 channels regulate drinking. We next used the 2-bottle choice intermittent access (IAA) drinking model to investigate the ability of RTG to modulate drinking both when systemically administered (0 - 7.5 mg/kg) and when microinjected (0 - 10 ng) to key nodes of the addiction neurocircuitry of high drinking (HD) and low drinking (LD) Wistar rats. 7.5 mg/kg IP RTG reduced alcohol consumption and preference in HD and LD rats, however 5.0 mg/kg IP RTG increased consumption in LD rats, suggesting a genetic component to the ability of RTG to alter drinking. We then microinjected RTG directly to the nucleus accumbens (NAc) core and the ventral tegmental area (VTA). 10 ng of RTG in the NAc reduced alcohol drinking in HD rats, but had no effect on LD rats. Similarly, 5 and 10 ng of RTG in the VTA reduced consumption in HD rats, but increased alcohol preference in LD rats, suggesting that Kv7 channels in both the NAc and VTA regulate drinking behaviors, but individual differences in drinking are mediated through the VTA. Finally, a history of alcohol consumption increased sensitivity to Kv7 antagonist-induced seizure activity, indicating a drinking-induced alteration in Kv7 channel expression and/or functionality. Given the large number of alcohol-induced neuroadaptations in the NAc, we used western blots to investigate changes in Kv7.2 expression in the NAc after IAA and 3 d withdrawal. Kv7.2 expression was increased in triton X-100 insoluble membranes (i.e. postsynaptic density, axon initial segment) and decreased in triton X-100 soluble membranes. Furthermore, the expression of SUMOylated Kv7.2 was decreased in insoluble membranes, suggesting that Kv7 channels are de-SUMOylated and recruited to scaffolded signaling domains during withdrawal. To our knowledge, these data are the first to show evidence for post-translational modification by SUMOylation in a model of

alcohol or drug exposure. Altogether this work indicates that retigabine may be a promising treatment for AUDs, and that Kv7 channels are a target of alcohol-induced neuroadaptations.

Title: Gene regulation as a basis for investigating pharmacological therapies that target Kv7 channels to reduce drinking

Authors: J. A. RINKER, D. B. FULMER, *P. J. MULHOLLAND;
Neurosciences, MUSC, Charleston, SC

Abstract: Alcohol (ethanol) dependence is a chronic relapsing brain disorder largely influenced by genetics and characterized by an inability to regulate harmful levels of drinking. Emerging evidence suggests that Kcnq2/3 genes that encode Kv7 channels are included in the support interval for replicated QTLs for alcohol consumption and alcohol-related behaviors in rodents. Recent data from our lab has shown that Kv7 channel positive modulators are more effective at reducing consumption in high-drinking Wistar rats. This led us to further explore the relationship between Kcnq genes and escalation of drinking in a mouse chronic intermittent ethanol (CIE) exposure model of dependence. Using the GeneNetwork.org database, we found that the CIE-induced change in transcript levels for Kcnq1 (Kv7.1 subunit) in the prefrontal cortex and both Kcnq1 and Kcnq5 (Kv7.5 subunit) in the nucleus accumbens significantly correlated ($p < 0.05$) with the change in ethanol consumption after CIE-induced dependence in BXD mice. To determine if retigabine, an FDA-approved anticonvulsant and Kv7 channel opener, reduces consumption in a high drinking strain, we utilized an intermittent access to alcohol (IAA) model where C57BL/6J mice were given 24-hour access to 20% ethanol and tap water every other day. After establishing a stable baseline of intake (approximately 8 weeks), mice were injected with retigabine (5, 10 or 15 mg/kg, IP) or vehicle (0.9% saline) 15 min prior to ethanol access, and

consumption was assessed at 4 and 24 hour. Retigabine dose dependently reduced ethanol consumption at the 4-hour time point ($F_{3,15} = 3.904$, $p = 0.03$), but the effect of retigabine on drinking was no longer evident at the 24-hour time point. Taken together, these data suggest that dependence-induced regulation of Kcnq1/5 genes correlated with post-dependence ethanol consumption. Additionally, these data in mice showing that retigabine reduces drinking provide additional evidence that Kv7 channel openers, such as retigabine, could be useful pharmacotherapeutics for regulating heavy alcohol drinking in individuals with an alcohol use disorder.

Title: KCa2 channels modulate forced swim test behavior and voluntary alcohol consumption in nondependent C57BL/6J mice

Authors: *A. E. PADULA[1], M. F. LOPEZ[2], W. C. GRIFFIN[3], H. C. BECKER[4], P. J. MULHOLLAND[3];
[1]Neurosci., [2]Psychiatry & Behavioral Sci., [3]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [4]Psychiatry & Behavioral Sci., Ralph H. Johnson Dept. of VA Med. CenterMedical Univ. of South Carolina, Charleston, SC

Abstract: A large body of evidence indicates that alcohol dependence produces altered responses to stress, which may enhance relapse vulnerability as well as further exacerbate excessive levels of drinking. In an animal model of alcohol dependence and relapse drinking, repeated cycles of chronic intermittent ethanol (CIE) vapor exposure produce escalated voluntary alcohol drinking. CIE exposure was also shown to produce aberrant coping behavior to a stress challenge - the forced swim test (FST). That is, CIE-exposed mice compared to controls persisted in struggling in the face of an inescapable stress situation (Lopez and Becker,

unpublished observations). Previous studies also have shown that pharmacological manipulation or genetic depletion of small-conductance Ca2+-activated K+ (KCa2) channels can influence FST behavior. KCa2 channels regulate neuronal excitability and synaptic plasticity and have recently been implicated in alcohol and drug addiction. KCa2 channels in the nucleus accumbens (NAc) regulate heavy alcohol drinking, and we have shown that ethanol dependence reduced expression and function of KCa2 channels in hippocampus and NAc. The purpose of this study was to determine if CIE-induced modulation of KCa2 channels influences behavior on the FST. Treatment of ethanol-naïve C57BL/6J mice with systemic injections of the KCa2 channel allosteric inhibitor apamin (0.1 and 0.2 mg/kg) significantly decreased immobility during the FST (n=8/group), producing the same behavioral phenotype of mice exposed to CIE exposure. A separate cohort of mice was exposed to CIE treatment and received the KCa2 channel positive modulator 1-EBIO (5, 10 and 20 mg/kg, IP, n=10/group) 30 min prior to the FST. In contrast to our expectations, 1-EBIO did not prevent the CIE-induced change in coping behavior on the FST. In another study using a two-bottle (15% ethanol (v/v) vs. water), long intermittent (22hr) access design, our preliminary results in non-dependent mice show that systemic administration of 1-EBIO (2.5, 5 and 10mg/kg) dose-dependently reduced alcohol consumption in C57BL/6J mice two hours into their drinking cycle. In summary, while blockade of KCa2 channels in naïve mice produced a similar behavioral phenotype as dependent mice, positive modulation of KCa2 channels did not reverse the CIE-induced deficit on coping behavior in the FST. However, 1-EBIO markedly reduced drinking in naïve mice, suggesting that KCa2 channels may be a target to prevent escalation of drinking in dependent mice exposed to chronic FST.

Title: Ethanol-associated social avoidance in male sprague-dawley rats and the involvement of the endogenous dynorphin/kappa opioid receptor system

Authors: ***T. L. DOREMUS-FITZWATER**, E. I. VARLINSKAYA;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Adolescence is an ontogenetic period characterized by a unique responsivity to ethanol, with younger animals demonstrating attenuated sensitivity to a number of ethanol effects relative to adults. More specifically, adolescents are less sensitive to social avoidance induced by acute ethanol, thus requiring higher doses of ethanol in order to observe comparable ethanol-induced reductions in social preference (and enhancement of social avoidance) that are exhibited by adult animals at lower doses. Given the aversive effects (e.g., anxiogenesis, dysphoria) evident following activation of the dynorphin/kappa opioid receptor (DYN/KOR) system, the present study was designed to assess whether attenuated sensitivity of adolescents to ethanol-induced social avoidance was associated with ontogenetically decreased responsiveness of the DYN/KOR system to acute ethanol. Adolescent and adult male Sprague-Dawley rats were first pretreated systemically with a selective long-lasting KOR antagonist, nor-binaltorphimine (nor-BNI; 0, 2.5, or 5.0 mg/kg), 24 hr prior to an acute ethanol challenge (0, 0.5, 1.0, 1.5, or 2.0 g/kg). Whereas acute ethanol alone induced social avoidance with as low as 1.0 g/kg in adults, adolescents demonstrated ethanol-related social avoidance only after a dose of 1.5 g/kg ethanol or higher. Furthermore, nor-BNI was more effective in adults at preventing the occurrence of ethanol-induced social avoidance following the 1.0, 1.5, or 2.0 g/kg doses: although the 2.5 mg/kg dose of nor-BNI significantly reversed ethanol-induced social avoidance in adults, nor-BNI had similar effects in adolescents only following the 5.0 mg/kg dose. By far the most striking age-related difference in sensitivity to social inhibitory effects of acute ethanol_and its reversal by nor-BNI_was observed at the 1.0 g/kg dose of ethanol. Thus, to further examine the possible involvement of the DYN/KOR system to these ethanol effects, a separate group of adolescent and adult male rats were given an acute 1.0 g/kg ethanol challenge and mRNA expression of several genes associated with the opioid system were assessed 30 min later in the amygdala and anterior cingulate cortex (ACC). Results showed that acute ethanol did not significantly impact expression of opioid-related genes in the amygdala. In contrast, acute ethanol was associated with modest increases in expression of prodynorphin and KOR mRNA in adults but not adolescents in the ACC. Taken together, these results suggest that age-related differences in social consequences of ethanol may be related, at least in part, to an adolescent-typical decrease in sensitivity of the DYN/KOR system to acute ethanol challenge.

Title: NMDA receptor channel blockers and alcohol-escalated aggression in mice

Authors: *E. L. NEWMAN[1], T. WANG[1], M. TERUNUMA[2], J. F. DEBOLD[1], K. A. MICZEK[1];
[1]Psychology, Tufts Univ., Medford, MA; [2]Dept. of Cell Physiol. and Pharmacol., Univ. of Leicester, Leicester, United Kingdom

Abstract: NMDA receptor antagonists including memantine and ketamine may possess therapeutic potential for the treatment of major depressive disorder and alcohol use disorder. However, in mice that self-administer a moderate dose of alcohol, memantine can promote aggression. The present investigation aimed to determine whether individual differences in aggressive phenotype could predict the effects of ketamine and memantine on alcohol-heightened aggression. First, breeding resident males were conditioned to rapidly self-administer 1.0 g/kg of ethanol (EtOH, 6% w/v) or water. Stable aggressive behavior was then evaluated via five-minute, resident-intruder confrontations. To identify mice as alcohol-heightened (AHA) or alcohol non-heightened aggressors (ANA), agonistic behavior was assessed every other day ten minutes after EtOH or water self-administration. Subsequently, mice were administered doses of memantine (i.p., 0.0-30.0 mg/kg) or ketamine (i.p. 0.0-30.0 mg/kg) after consuming either 1.0 g/kg of 6% EtOH (w/v) or water. Following water intake and treatment with a moderate dose of memantine (3.0 mg/kg), AHAs showed a significant increase in attack bite frequency. ANAs expressed an equally pronounced increase in aggression following EtOH intake and administration of memantine (3.0 mg/kg). After water self-administration, treatment with a moderate dose of ketamine (5.6 mg/kg) increased aggression in AHA mice; however, unlike memantine, ketamine had no effect on aggression in ANAs. These findings suggest that moderate doses of alcohol, ketamine and memantine can escalate aggression in AHAs, possibly due to similar mechanisms of action on NMDA receptors. Interestingly, memantine interacted with alcohol to increase aggression in alcohol non-heightened aggressors. Studies suggest that memantine may have some preference for receptors with weaker Mg2+ blocks while alcohol may selectively phosphorylate NR2B-containing NMDA receptors. Therefore, we speculate that Western blot analysis may reveal differential expression of NR2D and phosphorylated NR2B in AHA versus ANA mice within the prefrontal cortex and hypothalamus.

Title: Decreased hippocampal cell proliferation following chronic ethanol exposure: reversal by cholinergic mechanisms

Authors: *S. RAHMAN, M. RONI;
Pharmaceut. Sci., South Dakota State Univ., Brookings, SD

Abstract: We have shown that brain nicotinic cholinergic signaling plays a critical role in ethanol exposure-induced depression-like behavior. Cholinergic mechanisms might be associated with changes in hippocampal cell proliferation that are characteristic of major depression following chronic ethanol exposure. Adult C57BL/6J male mice were allowed to drink 10% ethanol or water for 28 days using a two-bottle choice procedure. Twenty-four hour after removal of ethanol, mice received once daily injection of saline or 1 mg/kg of lobeline (a nicotinic acetylcholine receptor ligand) during a 14 day abstinence period. Mice were tested after the last injection using the forced swim test (FST), a measure to test depression-like behavior, and brain samples were collected for immunohistochemistry. Chronic ethanol exposure significantly increased immobility time in the FST. Repeated lobeline treatment decreased immobility time in ethanol-exposed mice (control: 163±12 sec, lobeline: 84±10 sec, $p<0.05$). Chronic ethanol exposure also significantly ($p<0.05$) reduced the number of BrdU-positive cells in the dentate gyrus of hippocampus, indicating decreased hippocampal cell proliferation. Similarly, chronic ethanol exposure significantly ($p<0.05$) reduced brain-derived neurotrophic factor (BDNF)-positive cells in the dentate gyrus of hippocampus. In contrast, repeated lobeline treatment significantly ($p<0.05$) increased both BrdU and BDNF-positive cells in the dentate gyrus, indicating the antidepressant-like effects of lobeline associated with changes in hippocampal cell proliferation. These results suggest that nicotinic cholinergic signaling mechanisms play important role in hippocampal cell proliferation following chronic ethanol exposure. Title: Exposure to ethanol during adolescence alters CB_1-dependent synaptic plasticity in hippocampal dentate gyrus of adult mice

Authors: *P. GRANDES[1,2], S. PEÑASCO[1,2], N. PUENTE[1,2], A. RAMOS[1,2], N. ROYO[1,2], A. GUTIÉRREZ[1,2], I. BONILLA[1,2], L. REGUERO[1,2], M.-J. CANDUELA[1,2], J. MENDIZABAL-ZUBIAGA[1,2], F. RODRÍGUEZ DE FONSECA[3], J. SUÁREZ[3], I. ELEZGARAI[1,2];
[1]Univ. of the Basque Country, Leioa, Spain; [2]Achucarro Basque Ctr. for Neurosci., Zamudio, Spain; [3]Hosp. Regional Universitario de Málaga, Málaga, Spain

Abstract: Alcohol dependence affects millions of people worldwide, and alcohol consumption in adolescence has reached alarming rates. Ethanol interacts with the endocannabinoid system (ECS) and that the function of this system may be altered in ethanol dependence. Here we investigated the effect of ethanol consumption on excitatory synaptic transmission and plasticity mediated by the cannabinoid CB_1 receptor in hippocampal dentate gyrus (DG). Male C57BL6 mice were exposed to intermittent ethanol intake (20% (v/v) in tap water) using a 4 days drinking-in-the-dark (DID) procedure during adolescence (PD 30 ± 2 to 54 ± 2). Animals were given access to ethanol (or water) for 2-h sessions during three days, and for an additional 4-h session on the 4th day. At 18 - 21 days withdrawal from DID procedure, ethanol and control adult mice were sacrificed. Electrophysiological, immunohistochemical, and molecular techniques were applied. Excitatory postsynaptic potentials (fEPSPs) were evoked after stimulation of the medial perforant path and recordings were made in the supragranular zone of the dentate molecular layer (ML) in the presence of the $GABA_A$ antagonist picrotoxin. CB_1 receptor activation by CP55,940 (10 μM) inhibited fEPSPs in controls (26.43 ± 2.77% of baseline, ** $P < 0.01$, Mann Whitney test), as was previously described. However, this effect was not observed in ethanol-exposed mice (4.9 ± 7.47% of baseline, ns). Furthermore, ML

synaptic stimulation (10 min, 10 Hz) triggered a long term depression (LTD) of the excitatory synaptic transmission (about 20% of inhibition) that was absent in adult mice after ethanol consumption during adolescence (2.7 ± 3.12% of inhibition, ** $P < 0.0001$, Mann Whitney test). This excitatory plasticity was CB_1 dependent as the CB_1 receptor antagonist AM251 (4 μM) abolished LTD (8 ± 6.6% of inhibition, *** $P < 0.0001$, Mann Whitney test). CB_1 immunoreactivity decreased in the dentate ML of ethanol-exposed (87.47 ± 0.58%) versus control (100 ± 0.77%) mice (*** $P < 0.0001$, Mann Whitney test). Also, the relative mRNA and CB_1 protein significantly decreased, while a significant increase in MAGL (mRNA and protein) was detected after ethanol exposure. Altogether, repetitive exposure to ethanol during adolescence leads to a deficit of endocannabinoid-dependent LTD in adult DG excitatory synapses, probably due to a down-regulation of CB_1 receptors and a reduction of the endocannabinoid tone by an increase of MAGL. Title: Effects of alcohol preference, exposure, and withdrawal on c-Myc protein levels in the brain

Authors: T. AKINYEKE[1], *J. RABER[2];
[1]Behavioral Neurosci., [2]Behavioral Neurosci. L-470, OHSU, Portland, OR

Abstract: Alcoholism is a use disorder categorized by significant impairments that are directly related to persistent and extreme intake of alcohol. Alcoholism can affect multiple organs. With regard to the brain, many brain regions and a range of cellular and molecular processes in those

regions are involved in alcoholism. The CNS impairments involve physiological, psychological, and/or social dysfunction. c-Myc is a multifunctional, nuclear phosphoprotein that plays a role in regulation of cell cycle progression, apoptosis, and cellular transformation. Previous studies in rats exposed to ethanol for less than 24 h have suggested that increased c-myc levels may be instrumental in skeletal muscle, possibly via activating transcriptional pathways. The effects of alcohol exposure and withdrawal on c-Myc protein expression in the brain are not clear. In a 2008 study, in which a proteomics analysis was used to determine protein levels in frontal cortices of chronic alcoholics and controls, chronic and excessive alcohol consumption lead to increases in c-Myc protein levels. To study the effects of alcohol preference, exposure, and withdrawal on c-Myc protein levels in the brain, we started to analyze by Western blot c-Myc protein levels in the hypothalamus and amygdala in mouse lines selected for alcohol preference or dislike (SOT/NOT) and mouse lines selectively bred for severe or mild ethanol withdrawal handling-induced convulsions (HICs) after cessation of three days of ethanol vapor inhalation (WSR/WSP). In addition, we started to analyze the effects of acute alcohol exposure on c-Myc protein levels in the brain. In addition to c-Myc levels, Western blot analysis is used to determine protein levels of β-catenin (upstream target) and p21 (downstream target). The results of these studies will be presented at the meeting. This work was supported by the NIAAA Training Grant 5T32AA007468-28 and the development account of Dr Raber.

Title: Low concentrations of ethanol potentiates non-synaptic glycine receptors in D1 medium spiny neurons

Authors: *B. MUÑOZ[1], D. M. LOVINGER[2], L. G. AGUAYO[1];
[1]Dept. of Physiol., Univ. of Concepcion, Concepcion, Chile; [2]Natl. Inst. on Alcohol Abuse and Alcoholism, NIH, Rockville, MD

Abstract: Introduction Alcohol, like other drugs of abuse, activates the mesolimbic dopaminergic system increasing dopamine in the nucleus accumbens (nAc) and producing reinforcement and abuse. Glycine receptors (GlyRs) in the nAc were reported to regulate the release of dopamine in the presence of ethanol. Here, we examined the effects of ethanol on dissociated medium spiny neurons (MSN) and nAc slices from D1-GFP+ mice. Results MSNs presented phasic and tonic GlyR activated currents. We found different GlyR properties between D1-GFP+ and D1-GFP- neurons. For example, the EC50 for D1-GFP+ neurons was 37±5 μM, whereas the EC50 for D1-GFP- neurons was 61±22 μM. Interestingly, D1-GFP+ neurons were strongly potentiated by 1-100 mM ethanol. On the other hand, D1-GFP- were only sensitive to high ethanol concentrations (100 mM). In addition, ethanol increased the tonic current in D1 MSN, which was sensitive to Org24598, and this effect was inhibited by strychnine (STN). However, phasic synaptic currents (mIPSC and eIPSC) were insensitive to ethanol modulation, but sensitive to STN. Finally, we evaluated the role of GlyR in neuronal excitability finding that STN increased the action potential (AP) firing. Ethanol slightly decreased the frequency of AP firing and when co-applied with STN, this effect was blocked. Conclusion This study shows that the GlyR-mediated tonic current is potentiated by ethanol. Finally, these data show that ethanol sensitive GlyRs are expressed in the mesolimbic dopamine system, specifically in D1 MSNs, which possibly regulate the addictive properties of alcohol. Title: Excessive alcohol drinking in rodents induces increased mTORC1-dependent Prosapip1 translation in the nucleus accumbens

Authors: *S. LAGUESSE, F. LIU, N. MORISOT, D. RON;
neurology, Univ. of California San Francisco, san francisco, CA

Abstract: We previously found that excessive alcohol consumption activates a PI3K/AKT signaling pathway that ultimately lead to the activation of the mechanistic target of rapamycin

complex 1 (mTORC1) in the nucleus accumbens (Nac) of rodents (1, 2). mTORC1 is localized in dendrites, promotes the translation of synaptic proteins and plays an important role in synaptic plasticity (3). Together, these findings suggest that mTORC1-dependent mRNA to protein translation could play a major role in neuroadaptations induced by alcohol drinking that underlie the development and/or maintenance of excessive consumption. To identify novel gene products whose translation is induced in the Nac in response to the alcohol-dependent mTORC1 activation, we utilized the high throughput RNA sequencing (RNA seq) approach. Specifically, mice underwent an intermittent access to 20% alcohol or water only using 2-bottle choice paradigm for 8 weeks, and were then treated with rapamycin or vehicle. The NAc was dissected, polysomes (e.g. RNA undergoing translation) were isolated, and RNA seq was performed. Among the 12 identified candidates whose translation was dependent of mTORC1 was ProSAP-interacting protein 1 (Prosapip1), a synaptic protein that interacts with the scaffolding protein ProSAP2/Shank3 and the Rap GAP SPAR (4). Using quantitative Real-Time PCR (qRT-PCR), we first confirmed the RNAseq data and showed that the translation of Prosapip1 was induced in response to excessive alcohol drinking in an mTORC1-dependent manner. We further obtained data suggesting that the increase in mRNA of Prosapip1 was due solely to a translation and not a transcription event, as Prosapip1mRNA expression was only increased in the polysomal mRNA fraction and not in the total mRNA fraction. By western blot analysis, we found that Prosapip1 protein expression is significantly increased in the Nac of mice after a 4 hours binge drinking session and was maintained even after 24 hours of withdrawal. Prosapip1 levels were not altered in other brain regions where mTORC1 is not activated by alcohol. Finally, similar findings were obtained in rats undergoing an intermittent 20% alcohol 2-bottle choice paradigm. Together our data suggest that Propapip1 is a novel mTORC1-dependent gene product whose levels are induced by voluntary alcohol intake in the Nac. Functional consequences of the molecular findings will also be described. 1.Neasta,J., Proc Natl Acad Sci U S A (2010). 2.Neasta,J., Biological psychiatry (2011). 3.Lipton, J.O. and Sahin, M., Neuron (2014). 4.Wendholt, D., The Journal of biological chemistry (2006).

Title: GABAA signaling mediates the locomotor stimulant response to ethanol in *Drosophila* melanogaster

Authors: C. W. DAACK, *C. L. KLIETHERMES;
Dept. of Psychology, Drake Univ., Des Moines, IA

Abstract: The fruit fly *Drosophila melanogaster* shows a repertoire of behavioral responses to ethanol that is remarkably similar to that of rodents. These homologous behaviors are believed to result from ethanol's effects on conserved neurotransmitter systems, but few studies have directly tested this assumption. In the current experiments, we used genetic and pharmacological approaches to determine whether a conserved behavioral response to ethanol, low dose locomotor stimulation, might be mediated by GABAergic signaling in *D melanogaster.* We first used pan-neuronal expression of RNAis to downregulate expression of the three known $GABA_A$ subunits in *D melanogaster,* GRD, RDL, and LCCH3. Decreased expression of GRD or RDL resulted in a non-selective decrease in basal and ethanol-stimulated locomotion, while LCCH3 downregulation resulted in a relatively selective attenuation of the stimulant response. Feeding flies the $GABA_A$ antagonist picrotoxin prior to ethanol exposure resulted in a biphasic effect on the locomotor stimulant response, with low doses increasing and high doses attenuating the response to ethanol. These results suggest that $GABA_A$ receptors are involved in the locomotor stimulant response to ethanol in flies, a finding that further validates their usefulness in studying ethanol's conserved neurobiological effects. We are currently examining the effects of adult-specific receptor downregulation on the stimulant response, and have also begun studies aimed at localizing the GABAergic neurons that mediate this effect.

Title: Decreased lysine demethylase 1 (Lsd1) and increased H3K9 dimethylation in the adult amygdala after adolescent alcohol exposure

Authors: *E. J. KYZAR[1,2], H. ZHANG[2], A. SAKHARKAR[2], S. C. PANDEY[2,3];
[1]Univ. of Illinois At Chicago, Psychiatric Ins, Chicago, IL; [2]Dept. of Psychiatry, Univ. of Illinois at Chicago, Ctr. for Alcohol Res. in Epigenetics, Chicago, IL; [3]Jesse Brown VA Med. Ctr., Chicago, IL

Abstract: Alcohol exposure in adolescence predisposes to the development of alcoholism and psychiatric disturbances in adulthood. Epigenetic processes in the amygdala have been implicated in the persistence of alcohol-related behavioral and physiological changes to adulthood. Rats were exposed to 2g/kg ethanol (2 days on/2 days off) on post-natal days (PND) 28-41, corresponding to adolescence. Animals were sacrificed 1 hr and 24 hr after last ethanol exposure for measurement of enzymes involved in histone methylation mechanisms in the amygdala immediately following adolescent alcohol exposure. A cohort of animals was allowed to mature to PND 92 to measure the lasting effects of adolescent ethanol exposure on histone methylation mechanisms. Adolescent intermittent ethanol (AIE) exposure increased Lsd1 mRNA expression in the amygdala 1 hr after last alcohol exposure. When measured at adulthood, AIE rats displayed increased anxiety-like behaviors in the elevated plus maze (EPM) and a decrease in mRNA levels of Lsd1 and Lsd1+8a, a neuron-specific splice variant, in the amygdala. Decreased LSD1 immunostaining was observed only in the central nucleus of amygdala (CeA) but not the medial nucleus of amygdala (MeA) or basolateral amygdala (BLA), while Lsd1+8a mRNA was decreased in both the CeA and MeA as measured by *in situ* PCR. Interestingly, AIE increased H3K9 dimethylation (H3K9me2) in the CeA and MeA, but not the BLA, in adult rats, while no change was found in H3K4me2 protein levels. We also observed a decrease in mRNA levels of the H3K9 demethylase Kdm4c. Our results indicate that AIE specifically modulates epigenetic enzymes involved in histone methylation at particular residues in the amygdaloid structures, and that some of these effects persist into adulthood and are possibly involved in AIE-induced anxiety-like behaviors as observed here and reported earlier by our laboratory. These results also highlight the importance of developmental plasticity by splice variants of Lsd1 in the amygdala during adolescent alcohol exposure.

Title: Repeated cycles of chronic intermittent ethanol exposure alters BDNF signaling in the prefrontal cortex of C57BL/6J mice

Authors: *H. HAUN[1], W. GRIFFIN[2], L. LUDERMAN[2], K. KOCH[3], H. BECKER[2]; [1]Med. Univ. of South Carolina, Charleston, SC; [2]Charleston Alcohol Res. Ctr., Med. Univ. of South Carolina & VAMC, Charleston, SC; [3]Col. of Charleston, Charleston, SC

Abstract: Repeated cycles of chronic intermittent ethanol (CIE) exposure significantly decreases expression of brain-derived neurotropic factor (BDNF) in the medial prefrontal cortex (mPFC), which is associated with escalation of voluntary ethanol drinking in C57BL/6J mice. Additionally, we found BDNF microinfusion into the mPFC decreased CIE-induced elevated drinking to control (nondependent) levels of intake. The present study examined expression and phosphorylation of the BDNF receptor, TrkB, and downstream intracellular ERK1/2 expression and phosphorylation in the prelimbic (PRL) subregion of the mPFC in ethanol dependent and nondependent mice. Adult male C57BL/6J mice were first trained to drink ethanol in a limited access (2 hr/day) 2-bottle choice (15% ethanol vs. water) situation. Once stable baseline intake was established (2.3±0.2 g/kg), mice were separated into two groups and exposed to 4 weekly cycles of CIE vapor (EtOH group) or control air (CTL group) exposure (16 hr/day x 4 days/week), which alternated with weekly limited access 2-bottle choice drinking sessions (2 hr/day x 5 days/week). As expected, following four cycles of CIE exposure, voluntary ethanol intake escalated in the EtOH group (3.7±0.2 g/kg) while remaining relatively stable in the CTL group (2.7±0.2 g/kg) ($p< 0.05$). Tissue was collected from the PRL prior to the last scheduled drinking test session after the 4th cycle of CIE exposure. Western blot analysis revealed no change in TrkB expression, but a significant decrease (40%) in TrkB phosphorylation (Tyr-706) in EtOH mice compared to CTL mice ($p< 0.05$). Similarly, there was no change in total ERK1/2 expression in the PRL, but a significant decrease (32%) in ERK1/2 phosphorylation in EtOH mice compared to CTL mice ($p< 0.05$). Ongoing studies are exploring TrkB and ERK1/2 expression and phosphorylation within the infralimbic subregion of the mPFC under the same conditions as above. Together, these data support our earlier findings and suggest long lasting adaptations in BDNF signaling within discrete subregions of the mPFC after chronic ethanol exposure that may play a role in mediating CIE-related escalated drinking. Title: Ethanol activates midkine and anaplastic lymphoma kinase signaling in neuroblastoma cells and in the brain

Authors: D. HE[1], H. CHEN[1], H. MURAMATSU[2], *A. W. LASEK[1];
[1]Psychiatry, Univ. of Illinois At Chicago, Chicago, IL; [2]Psychological and Physical Sci., Aichi Gakuin Univ., Aichi, Japan

Abstract: Alcohol engages signaling pathways in the brain. Midkine (MDK) is a neurotrophic factor that is overexpressed in the prefrontal cortex of alcoholics. MDK and one of its receptors, anaplastic lymphoma kinase (ALK), also regulate behavioral responses to ethanol in mice. The goal of this study was to determine whether MDK and ALK expression and signaling are activated by ethanol. We found that ethanol treatment of neuroblastoma cells increased MDK and ALK expression. We also assessed activation of ALK by ethanol in cells and found that ALK and ALK-dependent extracellular signal-regulated kinase (ERK) and signal transducer and activator of transcription 3 (STAT3) phosphorylation increased rapidly with ethanol exposure. Similarly, treatment of cells with recombinant MDK protein increased ALK, ERK and STAT3 phosphorylation, suggesting that ethanol may utilize MDK to activate ALK signaling. In support of this, transfection of cells with MDK siRNAs attenuated ALK signaling in response to ethanol. Ethanol also activates ERK signaling in the brain. We found that inhibition of ALK or knockout of MDK attenuated ethanol-induced ERK phosphorylation in mouse amygdala. These results demonstrate that ethanol engages MDK and ALK signaling, which has important consequences for alcohol-induced neurotoxicity and the regulation of behaviors related to alcohol abuse.

Title: Time-dependent Wnt/β-catenin signaling in response to 25mM ethanol exposure

Authors: *A. BURGOS[1], R. APONTE[2], S. N. TREISTMAN[2], C. VELAZQUEZ-MARRERO[1]; [1]Inst. of Neurobio. Univ. of Puerto Ric, San Juan, PR; [2]Inst. of Neurobio. Univ. of Puerto Ric, San Juan, Puerto Rico

Abstract: Molecular alcohol tolerance includes and important persistent component characterized by the redistribution of the high conductance voltage- and calcium-dependent potassium channel (BK) plasma membrane surface expression. This form of alcohol tolerance has been shown to be protein synthesis-dependent after 6 hr ethanol exposure (Velázquez-Marrero et al., 2014 - In Progress). Redistribution of the BK channel only occurs after 6hr exposure and not 1 or 3 hrs and further persists after 24 hr withdrawal. Protein synthesis is required for certain forms of learning and memory. It has been characterized in the development of long-term memory and eventually maintenance of long-term plasticity (Sutton and Schuman, 2006). As has been shown, neuronal plasticity, specifically related to neurotransmission, is critical to the development and maintenance of an addiction and directly correlated to the reward-related learning process (Mulholland et al., 2009). We have characterized global changes in *de novo* protein synthesis in response to 6hr ethanol treatment with 25mM EtOH in HEK 293 cells using Click-iT technology coupled to Tandem Mass Spectrometry and Western Blot analysis. HEK293 cells show one hundred and forty five proteins with significant increase in spectral counts after ethanol incubation when exposed to 25mM EtOH for 6hrs. The highest increase was observed for β-catenin which more than doubles. This suggests a possible role in the protein synthesis-dependent regulation of BK channel redistribution at the plasma membrane. Furthermore, prior to 6hr EtOH exposure, the increase of β-catenin during 1 and 3hr treatment is not IWP-2 dependent. This suggests that the activation of the Wnt receptor during ethanol exposure only occurs after 6hr exposure. The current study allows an overview of how synthesis of specific proteins, particularly β-catenin, is correlated to EtOH exposure and presents a possible regulatory mechanism mediating protein synthesis-dependent BK channel alcohol tolerance.

Title: Increase in apoptosis following a single binge ethanol exposure is followed by subsequent compensatory events in hippocampal CA1 in rats

Authors: *Z. GURSKY[1], K. J. CRISS[1], R. M. A. NAPPER[2], A. Y. KLINTSOVA[1];
[1]Dept. of Psychological & Brain Sci., Univ. of Delaware, Newark, DE; [2]Otago Sch. of Med. Sci. and Brain Hlth. Res. Ctr., Univ. of Otago, Dunedin, New Zealand

Abstract: Ethanol (EtOH) exposure in early development can lead to deleterious effects on the central nervous system. Significant increases in apoptosis are observed in many brain structures, an effect that is dependent on time and pattern of exposure (Bonthius & West, 1900; Ikonomidou et. al., 2000; Smith et al., 2015). The CA1 region of hippocampus is particularly vulnerable to EtOH exposure during the early postnatal period in rat pups (Tran & Kelly, 2003). We utilized a one-day binge model to characterize the effects of a single-day EtOH exposure on hippocampal CA1. Apoptosis in the CA1 was evaluated at three time-points following EtOH exposure on PD4. In examining rates of apoptosis following PD4 EtOH exposure, we hypothesized an increase in apoptosis of pyramidal cells in CA1 24 hours after exposure, which would gradually return to baseline over the week following the insult. On PD4, rats were assigned to one of three treatments: moderate binge exposure of EtOH via intragastric intubation (AE; 4.5 g/kg/day, two doses 2 hours apart, in milk substitute), intubated without EtOH administration (sham intubated, SI), or left undisturbed (suckle control, SC). On PD5, 8 or 11 the pups were perfused. Horizontal 40 um sections of the entire hippocampus were mounted on slides and stained with cresyl violet; using unbiased stereology, apoptotic bodies in hippocampal CA1 were quantified. A dramatic increase (by 300%) in apoptosis was found on PD5 in AE compared to SI pups. On PD8 the number of apoptotic cells in AE was significantly less than in AE on PD5 but also, AE apoptosis was significantly lower than in SC. There were no significant effects at PD11. This shows a single-day binge-like EtOH exposure on PD4 can significantly increase apoptosis which may be

compensated for by a decline in normal apoptosis on subsequent days. In addition, we observed numerous proliferating cells (labeled with BrdU) in CA1 layer at PD8 and PD11; the phenotyping of these cells is underway. Based on other models of CNS damage (e.g., asphyxiation, ischemia) (Bendel et. al., 2005; Morales et. al. 2008), a certain percentage of newly proliferated cells in CA1 appearing beyond the time of normal development could be neuronal. We conclude that a single-day binge EtOH exposure first produces an increase of apoptosis in hippocampus 24 hours after the insult; however, the brain partially compensates for initial EtOH effect by decreases in apoptosis.

Title: Regulation of α-synuclein splice variants in human alcoholic brain by miRNAs

Authors: *P. JANECZEK, J. M. LEWOHL;
Griffith Univ., Menzies Hlth. Inst. Queensland, Griffith Univ., Gold Coast, Australia

Abstract: Chronic alcohol abuse results in alterations in gene expression in brain regions susceptible to the neurotoxic effects of alcohol. α-Synuclein exists in a number of different splice variants and its expression is influenced by genetic factors and microRNAs. Here we investigate the influence of ethanol on the expression of the SNCA-140, SNCA-112 and SNCA-115 variants following exposure of HEK293T cells to 75 mM ethanol. Real-time PCR was used to measure α-synuclein splice variant mRNA levels. Comparisons were made between chronic and chronic-intermittent treatment with and without a withdrawal period to determine if the variants are differentially expressed in response to ethanol. Two transfection methods were used to investigate the miRNA-mediated regulation of miR-7, -153, -144 and -203 on α-synuclein. Results show that the expression of SNCA-140 and SNCA-112 was down-regulated following chronic ethanol exposure with ($P < 0.001$, $n = 16$) and without withdrawal ($P < 0.001$, $n = 8$), whereas the expression of SNCA-115 was up-regulated ($P < 0.001$, $n = 16$ and $P < 0.001$, $n = 8$).

HEK293T cells transfected with miR-203 mimic showed no change in SNCA-140 expression ($P = 0.988$, $n = 8$), a significant decrease in expression of the SNCA-115 ($P < 0.001$, $n = 8$) and a marginal decrease for the SNCA-112 variant ($P = 0.084$, $n = 8$). The same was seen in cells transfected with miR-144 mimic ($P = 1.000$, $n = 8$; $P = 0.002$, $n = 8$ and $P = 0.098$, $n = 8$ respectively). Preliminary studies where HEK293T cells were transfected with SNCA 3′UTR and miRNA precursor clones showed a small decrease in luciferase activity in those cells transfected with the miR-203 precursor however this was not significant ($P = 0.317$, $n = 5$). These findings suggest that ethanol may alter the expression of the α-synuclein variants differently. MiRNAs may regulate the expression of these variants and could be responsible for many of the gene expression changes that occur in the brain of chronic alcoholics.

Title: A sphingolipid pathway into co-morbidity of depression and alcoholism

Authors: *C. P. MUELLER[1], T. STÖCKL[1], E. SPRENGER[1], J. TIESEL[1], S. E. HUBER[1], D. AMATO[1], M. WITT[2], J. FUCHSER[2], J. BECKMANN[2], E. GULBINS[3], M. REICHEL[4], J. KORNHUBER[4];
[1]Section of Addiction Med., Dept. of Psychiatry and Psychotherapy, Erlangen, Germany; [2]Bruker Daltonik GmbH, Bremen, Germany; [3]Dept. of Mol. Biol., Univ. of Duisburg-Essen, Essen, Germany; [4]Dept. of Psychiatry and Psychotherapy, Univ. of Erlangen-Nuremberg, Erlangen, Germany

Abstract: Alcohol addiction is a very common psychiatric disorder with severe health consequences for the individual and for society. A common aetiology is the depression/anxiety-induced alcohol addiction. Stress, or a particular susceptibility lead to a primary depression and anxiety. In an attempt to reduce this aversive state, controlled alcohol consumption can develop into alcohol addiction. The acid sphingomyelinase (ASM)-ceramide pathway has been shown to

control the balance between neurogenesis and apoptosis in the brain. ASM hydrolyses the lipids sphingomyelin to ceramide. Levels of both lipids are crucial for the formation of lipid rafts in synaptic membranes. Genetically induced overexpression of ASM (tgASM) results in a depressive/anxious phenotype in mice. We used tgASM and heterozygous ASM knock out (hetKO ASM) mice and tested alcohol preference and escalation of consumption after repeated withdrawls. We found a significantly enhanced alcohol preference in tgASM mice, which is persistent over time for 16 vol.% alcohol solution. After repeated withdrawals, tgASM mice showed massively enhanced alcohol consumption compared to baseline and wild type. HetKO ASM mice in turn showed a reduced alcohol preference at medium alcohol concentrations and attenuated consumption after repeated withdrawals. This was in line with a significantly enhanced and reduced alcohol-induced conditioned place preference and locomotor sensitization in tgASM and hetKO ASM mice. Mass spectrometric analysis of brain slices performed by FTMS SolariX XR 12 T revealed that alcohol reduces content of sphingomyelin species in the ncl. accumbens (Nac) and hippocampus in WT animals. ASM overexpression reduced sphingomyelin species in the Nac, but not hippocampus, and reversed the alcohol effect in the Nac. These findings suggest the ASM-sphingomyelin/ceramide pathway as a potential mediator of depression-induced alcohol preference, and possibly, addiction, by controlling lipid levels in the reward system.

Title: Effect of voluntary binge drinking on microglial activation in the medial prefrontal cortex of male and female rats

Authors: *A. SILVA-GOTAY[1], W. VARGAS[1], M. K. HOLDER[2], H. N. RICHARDSON[1]; [1]Univ. of Massachusetts Amherst, Amherst, MA; [2]Georgia State Univ., Atlanta, GA

Abstract: Adolescence is a period of development when teenagers are engaging in risky behaviors including binge drinking. Heavy alcohol use may be particularly hazardous at this time because prefrontal circuits are undergoing maturational processes that are important for increased cognitive function and behavioral control in adulthood. Alcohol is been shown to induce inflammation in the brain. Microglia, the brain immune cells, not only mediate inflammation but also play a role in neural development. The goal of the present study was to examine if voluntary alcohol activates microglia in the medial prefrontal cortex (mPFC) early in adolescence, as this could alter the trajectory of neural development. Adolescent male and female rats (PD 28-42) were exposed to two weeks of operant binge alcohol self-administration and brains were collected one day after the last drinking session. Activated microglia were labeled using an ionized calcium-binding adapter molecule 1 (Iba1) antibody. Preliminary results using threshold analysis suggest alcohol may differentially affect microglia in males and females, with a dampening effect on microglia activation in females. Future directions include detailed morphological analysis of microglia as well as examination of specific neuroinflammatory mediators to better understand that nature of this sex difference.

Title: Synaptic dynamics and microglial phenotype in adolescent mice with deficient activity-dependent plasticity after early postnatal high binge ethanol exposure

Authors: *E. L.-Y. WONG[1], G. O. SIPE[2], C. E. LAMANTIA[2], A. K. MAJEWSKA[2];
[1]Dept. of Envrn. Med., [2]Neurobio. and Anat., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Fetal alcohol spectrum disorder (FASD) is the leading cause of life-long, non-heritable mental disability, but the mechanisms by which developmental ethanol (EtOH) exposure causes long-term changes in brain function are still poorly understood. Microglia are the brain's resident immune cells and the first responders to environmental insult, infection, or injury. Outside of pathology in the healthy brain, microglial processes contact neurons at synapses, influencing synaptic architecture during plastic events. We hypothesize that developmental EtOH exposure perturbs both these pathological and physiological functions of microglia, thus contributing to long-lasting changes in synaptic connectivity and experience-dependent synaptic plasticity. We modeled EtOH exposure during the human third trimester, a period of intense synaptogenesis and initial formation of neural networks, termed the 'brain growth spurt.' Daily from P4-P9, the peak of the 'brain growth spurt' in mice, C57/BL6 pups were subcutaneously injected with two doses of 1.8g/kg EtOH, delivered two hours apart in 20% v/v EtOH in saline. Two control groups of: 1) littermates handled at dosing times but not injected and 2) saline-injected littermates, were included for all experiments. We found that mice developmentally exposed to EtOH exhibited reduced ocular dominance plasticity, which is normally induced in the primary visual cortex (V1) by monocular deprivation during the visual critical period (peak at ~P28 in mouse). Because this plasticity relies on the dynamic remodeling of dendritic spines, the postsynaptic sites of most excitatory synapses, we used *in vivo* two-photon microscopy to chronically image dendritic spines through a thinned skull. We found no change in basal turnover rate of dendritic spines, suggesting that brain growth spurt EtOH exposure does not affect dendritic spine stability in adolescence. We also found that early EtOH exposure did not induce changes in microglial morphology, density, or distribution in V1, either early in development (P10) or in adolescence (P28). While these results indicate that a robust and persistent inflammatory response to developmental EtOH exposure is unlikely, we are currently examining whether basal microglial process dynamics, microglial interactions with dendritic spines, or the response of microglia to laser ablation injury are altered. Even subtle effects of developmental EtOH exposure on these microglial behaviors could have important implications for normal cognitive functions, including experience-dependent plasticity, and the brain's ability to resolve pathological insult.

Title: Impact of alcohol on human neural stem cells

Authors: *L. DE FILIPPIS, A. HALIKERE, Z. PANG;
Child Hlth. Inst. of New Jersey, New Brunswick, NJ

Abstract: Alcohol abuse causes an enormous impact on health, society, and the economy. Currently, there are very limited effective therapies available, largely due to the poor understanding of mechanisms underlying alcohol use disorders (AUDs). Neurogenesis from Neural Stem Cells (NSCs) is important in brain development and neuronal functions such as behavior, learning, and memory. Both neurons and NSCs are known to be sensitive to alcohol exposure, but most of the reported studies exploring effect of alcohol on NSCs are incomplete and often controversial. To better understand the effects of ethanol on NSC basal properties such as self-renewal and multipotency, we generated NSCs from induced pluripotent stem (iPS) cells (iPS-NSC) through epigenetic induction to the neural lineage and studied the neurotoxic effects of both acute or chronic exposure on both iPS cells and NSCs. We showed that transient exposure to a sub-lethal dose of ethanol (70mM, resembling alcohol blood concentration in heavy drinkers) does exert a similar effect on iPS cells and NSCs. In particular, ethanol exposure for 24 hours or 7 days does not affect the proliferation or the multipotency of iPS cells and neural progenitors but primes an innate immune-like response by activating the inflammasome-mediated pathway. We observed a partial impairment of the mitochondrial and lysosomal patterns with a decrease of the number of iPS cell-derived neurons following ethanol exposure. However, the electrophysiological activity of alcohol challenged NSC-derived neurons is preserved, since they are able to fire action potentials similar to untreated cells. Our hypothesis is that ethanol exposure increases the vulnerability of NSCs to further damage (with specific reference to oxidative damage) that could originate either from genetic background (gene risk variants) or the external environment. Hence, unraveling the mechanisms underlying the neurogenic dysfunction induced by alcohol abuse will allow us to better predict how AUD patients will develop age related disorders. This will also elucidate how increased vulnerability of neural progenitors may contribute to the development of multifactorial disorders such as Alzheimer's Disease, Parkinson's Disease and lysosomal storage diseases.

Abstract: Pentameric ligand-gated ion channels are heavily implicated in neurological effects of alcohol, yet high-resolution structural data in this family of receptors are limited. The prokaryotic ligand-gated ion channel GLIC is a potentially valuable model system whose structure has been determined in multiple conformations and bound to various ligands. In particular, modification of the 14' position in GLIC rendered it potently sensitive to alcohol modulation, and enabled co-crystallization with ethanol as well as other anesthetics. In order to elucidate the physicochemical determinants of alcohol modulation via the 14'-proximal site in further detail, we substituted a wide range of amino acids of varying volume, polarity, and charge at GLIC position 14', expressed the mutated channels in frog oocytes, and measured their gating and modulation properties by two-electrode voltage-clamp electrophysiology. We correlated the resulting changes in agonist and modulator sensitivity with standard amino acid properties and molecular modeling of the predicted binding site. Our results clarify the relative contributions of volume and hydrophobicity in alcohol binding in the intersubunit transmembrane region of GLIC, with implications for the system's relevance as a model for human alcohol targets.

Title: Differential diagnosis of seizures for a patient with Alcohol abuse

Authors: *Z. KONE[1,2];
[1]Cheikh Anta Diop Univ., Dakar, Senegal; [2]Neurol. Clinic, Point G Teaching Hosp., Univ. of Bamako, Dakar, Mali

Abstract: Introduction: Alcohol abuse is associated with 40% of seizure that may be the primary cause or trigger. Aim: This observation is to attract the attention of doctors on differential diagnoses of an epileptic seizure in the chronic alcoholic abuse. Observation: Man, 47 years, alcohol abuse and smoking since 20 years, presented abruptly a generalized tonico-clonic seizure and repeatedly. The EEG was normal. The MRI found a large mass iso-intense T1 and T2 with strong enhancement after injection. It has a wide base of implantation of the clivus lateralized to the right coming into contact with the mammillary body and insinuating on the right temporal fossa coming into contact with the hippocampus (46x30mm). Discussion: The occurrence of seizures in alcohol abuse is so frequents that their etiology is systematically relatead. The discovery in our patient with a newly formed processes character strongly epileptogenic, shows the problem of exclusivity etiopathogenic seizures in the alcohol abuse. The issue has been studied in the literature in a paper entitled " Alcohol and epilepsy: A case report between alcohol withdrawal seizures and neuroborreliosis", etiology was infectious. Conclusion: Every epileptic seizure in an alcohol abuser is not necessarily related to alcohol and/or is not solely because of alcoholism.

Title: Chronic intermittent nicotine delivery with lung alveolar region-targeted aerosol technology to rats produces circadian blood pharmacokinetics resembling human smokers

Authors: *X. M. SHAO[1], S. LIU[2], H. PEI[2], J. LIANG[2], R. MUDGWAY[1], J. ZHANG[3], J. L. FELDMAN[1], S. LOUIE[2], X. S. XIE[3];
[1]Neurobio., David Geffen Sch. Med. at UCLA, Los Angeles, CA; [2]Sch. of Pharm. Univ. of Southern California, Los Angeles, CA; [3]AfaSci Res. Labs., AfaSci Inc., Redwood City, CA

Abstract: Cigarette smoke is an aerosol containing concentrated tiny particles that carry nicotine (Nic) into lung alveolar regions to be rapidly absorbed into the circulation. Episodic inhalation of Nic aerosol during smoking activates nicotinic receptors followed by a cycle of desensitization/resensitization. Smokers' exposure to Nic is a chronic intermittent process, with intake during wakefulness and abstinence during sleep (withdrawal) resulting in circadian fluctuation of blood Nic levels. Withdrawal plays an important role in Nic addiction which has been difficult to study properly due to lack of clinically relevant animal model that mimics episodic inhalation of Nic and produces circadian blood concentration pattern resembling that of human smokers. We previously developed a non-invasive method with alveolar region-targeted aerosol technology for delivering Nic to rodents that produced blood pharmacokinetics resembling smoking a cigarette in humans. We have now developed an integrated platform with computer control where freely moving rodents in a chamber are exposed to episodic Nic aerosol on scheduled intervals and number of times. We have optimized the parameters of aerosol generation and exposure. Nic aerosol was generated with a Collison nebulizer that contained a solution of 0.12% Nic in saline. Rats were exposed to Nic aerosol for 1 min every half hour, for a total of 24 times in each 12-hour (h) dark phase of 12/12 h dark/light circadian cycles for multiple days. Rats were returned to their home cage during the light phase when there was no aerosol delivery. We collected rat blood samples every 2 h at the end of the half hour intervals between aerosol deliveries during the 12-h dark phases and every 4 h during the light phases. Plasma concentrations of Nic and its metabolite cotinine were determined with a LC-MS/MS method. Nic concentrations gradually increased during the dark phase and reached a plateau of 30 to 40 ng/ml in 8 to 10 h from the start of the daily Nic aerosol deliveries. Nic levels gradually decreased to 5 to 10 ng/ml during the light phase when no aerosol was delivered. The circadian fluctuation patterns of blood Nic and cotinine levels match the circadian blood pharmacokinetics of human smokers (Benowitz et al., 1982). In summary, we have developed methods and devices that produce chronic intermittent Nic exposure animal models with the route of administration and circadian blood pharmacokinetics equivalent to those of human smokers. This methodology is a powerful tool for studies of behavior, pharmacology and toxicology of chronic Nic exposure, nicotine addiction, tobacco-related diseases, teratogenicity, and for discovery of therapeutics.

Title: Mechanisms of nicotinic modulation of glutamatergic neuroplasticity in humans

Authors: *M. A. NITSCHE[1,2], G. BATSIKADZE[2], M.-F. KUO[2], W. PAULUS[2], S. FRESNOZA[2], J. GRUNDEY[2], M. LUGON[3], E. NAKAMURA-PALACIOS[3];

Abstract: Nicotine (NIC) alters cognitive functions by modulating neuroplasticity and cortical excitability in animals and humans. It was recently shown that NIC can not only stabilize, but also disrupt formation of glutamatergic plasticity in the human cerebral cortex. The impact of NIC on plasticity is thought to be primarily determined via calcium channel properties of nicotinic receptor subtypes, and glutamatergic plasticity is likewise calcium-dependent. Therefore glutamatergic plasticity is likely modulated by the impact of nicotinic receptor-dependent neuronal calcium influx. We tested this hypothesis for transcranial direct current stimulation (tDCS) -induced long-term potentiation-like plasticity, which is abolished by nicotine in healthy non-smokers, possibly due to calcium overflow. To reduce calcium influx under NIC, we blocked NMDA receptors, which have calcium channel properties. We hypothesized that NMDA receptor block alone will prevent tDCS-induced plasticity, but should re-establish it under nicotine due to reduction of calcium influx. We applied anodal tDCS in 13 healthy non-smokers combined with 15 mg nicotine patches and the NMDA receptor antagonist dextromethorphan (DMO) in three different doses (50, 100 and 150 mg) or placebo medication. Corticospinal excitability was monitored by single-pulse transcranial magnetic stimulation (TMS)-induced motor evoked potential (MEP) amplitudes for up to 36 h after plasticity induction. NIC abolished the anodal tDCS-induced motor cortex excitability enhancement, which was however restituted under the medium dosage of DMO. In contrast, low-dosage DMO did not affect the impact of nicotine on tDCS-induced plasticity and high-dosage DMO abolished plasticity. For DMO alone, the low dosage had no effect, but medium and high dosages abolished tDCS-induced plasticity. These results enhance our knowledge about the proposed calcium-dependent impact of nicotine on plasticity and might be relevant for the development of novel nicotinic treatments for cognitive dysfunction.

Title: Alpha6-containing nicotinic acetylcholine receptors in midbrain dopamine neurons are poised to govern dopamine-mediated behaviors and synaptic plasticity

Authors: *J. N. BERRY[1], S. E. ENGLE[1], J. M. MCINTOSH[2,3], R. M. DRENAN[1]; [1]Medicinal Chem. and Mol. Pharmacol., Purdue Univ., West Lafayette, IN; [2]George E. Wahlen Veteran Affairs Med. Ctr., Salt Lake City, UT; [3]Departments of Psychiatry and Biol., Univ. of Utah, Salt Lake City, UT

Abstract: Acetylcholine acts through nicotinic and muscarinic acetylcholine (ACh) receptors in ventral midbrain and striatal areas to influence dopamine (DA) transmission. This cholinergic control of DA transmission is important for processes such as attention and motivated behavior, and is manipulated by nicotine in tobacco products. Identifying and characterizing the key ACh receptors involved in cholinergic control of DA transmission could lead to small molecule therapeutics for treating disorders involving attention, addiction, Parkinson's disease, and schizophrenia. Here, we used genetic, pharmacological, behavioral, and biophysical approaches to study nicotinic ACh receptors (nAChRs) containing the α6 subunit. α6-containing nAChRs are highly and specifically expressed in midbrain DA neurons, making them an attractive drug target. For many experiments, we used mice expressing mutant α6 nAChRs ("α6L9S" mice) that increase the sensitivity of these receptors to agonists such as ACh and nicotine. Taking advantage of a simple behavioral phenotype exhibited by α6L9S mice, we compared the ability of full versus partial α6* nAChR agonists to activate α6* nAChRs *in vivo*. Systemic

administration of nicotine (0.02-0.05 mg/kg, i.p.) and the partial agonists varenicline (0.01-0.03 mg/kg, i.p.) and ABT-089 (1-3 mg/kg, i.p.) increased locomotor activity in α6L9S mice. Using local infusions of both agonists and antagonists into brain, we demonstrate that neurons and nAChRs in the midbrain are sufficient to account for this behavioral response. Intra-VTA infusion of nicotine (1.7 nmol) increased locomotor activity in α6L9S mice but not their wildtype counterparts, while co-infusion with the α6* antagonist αCtxMII (10 pmol) blocked the enhanced locomotor activating effects of nicotine in α6L9S mice. Ongoing studies are investigating the role of dopamine D1 receptors in the nucleus accumbens in the locomotor activation induced by nicotine in α6L9S mice. To complement these behavioral studies, we studied the ability of *in vivo* α6* nAChR activation to support plasticity changes in midbrain DA neurons that are relevant to behavioral sensitization and addiction. By coupling local infusions of drugs and brain slice patch clamp electrophysiology, we show that activating α6* nAChRs in midbrain DA areas is sufficient to enhance glutamatergic transmission onto VTA DA neurons. Together, these results from *in vivo* studies suggest that α6* nAChRs residing on VTA DA neurons are positioned to strongly influence both DA-mediated behaviors and the induction of synaptic plasticity by the addictive drug nicotine.

Title: NRG3 modulates long-term synaptic plasticity in orbital frontal cortex

Authors: *L. ZHOU[1,2], P. ORTINSKI[2], J. TURNER[1];
[1]Dept. of Drug Discovery and Biomed. Sci., [2]Dept. of Pharmacology, Physiol. and Neurosci., Univ. of South Carolina, Columbia, SC

Abstract: Cigarette smokers have difficulty quitting, which is thought to be related to deficient impulse control. Previous studies from our lab have shown that single-nucleotide polymorphisms

across the gene for neuregulin 3 (NRG3) are linked to failed smoking cessation. A recent preclinical study indicates that NRG3 in the frontal cortex regulates certain aspects of impulsivity. However, the mechanism by which NRG3 regulates neuronal signaling in this area, and hence impulsivity, is unknown. To begin to address this, we used electrophysiological field recording to assess whether NRG3 alters long-term potentiation (LTP) in orbital frontal cortex (OFC). We developed a protocol for LTP induction in OFC and found that NRG3 attenuated the expression of LTP. This NRG3-attenuated LTP was selectively rescued by Afatinib, an ErbB4 inhibitor. These data suggest that NRG3 may influence general impulsivity through modulation of long-term synaptic plasticity in the OFC. Current studies are evaluating the effect of chronic nicotine treatment on NRG3-mediated synaptic plasticity in the OFC. This study was supported by NIH/NIDA grants DA032681 (JRT) and DA031747 (PIO).

Title: Modulation of dopaminergic neurons by endogenous acetycholine and nicotine

Authors: ***S. DIDIENNE**[1], S. TAKILLAH[2], J. NAUDÉ[3], P. FAURE[3];
[1]Cnrs_upmc, Chennevieres Sur Marne, France; [2]Biol. Adaptation and Aging (B2A), Univ. Pierre Et Marie Curie, Paris, France; [3]Neurosci. Paris-Seine lab, Univ. Pierre et Marie Curie, Paris, France

Abstract: Dopaminergic (Daergic) system is linked to a wide range of brain functions, including motivation, attention, decision making and reinforcement. The release of DA is modulated by a number of factors, and its deregulation has been implicated in multiple psychiatric disorders, such as addiction. In particular, nicotinic acetylcholine receptors (nAChRs) has been shown to be a key modulators of DA cells. However to date there are no electrophysiological recordings of the VTA DA cells in awake nicotinic mutant mice. To understand how the activity of DAergic

neurons in the ventral tegmental area (VTA) is modulated by endogenous ACh and nicotine, we recorded in awake wild type and mutant mice lacking the β2 subunit of nAChRs (β2 - /-), i) the spontaneous activity of DA neurons, ii) their response to nicotine injections, and iii) their activity in different behavioral context. Our results showed that in awake animals, the absence of β2-/- modify the bursting patterns but more importantly seems to change the synchrony among neurons. Changing the dynamics of the DA neurons activity could explain modification of DA release in the target structure and the loss of behavioral flexibility observed in the β2 - /- mice.

Title: Does nicotine speed up subjective time or induce impulsivity?

Authors: C. W. DANIELS[1], C. C. HERRERA[1], *F. SANABRIA[2];
[1]Psychology, [2]Arizona State Univ., Tempe, AZ

Abstract: Systemic nicotine induces premature responses when timing in the seconds-to-minutes range. It has been suggested that this effect reflects a nicotine-induced acceleration of the internal clock. An alternative explanation for this evidence posits that nicotine induces impulsive behavior by reducing the threshold for responses that result in more reinforcement. The clock-speed and response-threshold hypotheses were tested in rats in two experiments using a novel timing task. In this task, rats were trained to seek food at one location after 8 s since trial onset and at a different location after 16 s. In Experiment 1, rats either received the same reward at both times (group SAME) or received a larger reward at 16 s (group DIFF). In Experiment 2, rats either received a larger reward at 8 s (group SHORT) or received a larger reward at 16 s (group LONG). Steady baseline performance was followed by 3 days of subcutaneous nicotine administration (0.3 mg/kg), baseline recovery, and, in Experiment 1, an antagonist challenge (mecamylamine, 1.0 mg/kg). Empirical and modeling analysis revealed that nicotine induced an immediate reduction in latencies to switch (LTS) between locations in all groups, but this effect

was more prominent in groups DIFF and LONG than in groups SAME and SHORT. This effect was sustained throughout nicotine administration. Mecamylamine pretreatment and nicotine discontinuation rapidly recovered baseline performance. Additionally, the modeling analysis suggested that anomalous effects of nicotine on LTS dispersion may be due to a general loss of temporal control of behavior. Taken together, these results support the response-threshold hypothesis of nicotinic effects on timing, and suggest that the response threshold may be mediated by central nicotinic acetylcholine receptors.

Title: Catecholamine neurons in the nucleus of the solitary tract become hypersensitive to nicotine during spontaneous nicotine withdrawal

Authors: *S. PAGE[1], M. ZHU[1], S. M. APPLEYARD[2];
[2]Integrative Physiol. and Neurosci., [1]Washington State Univ., Pullman, WA

Abstract: Nicotine is a highly addictive drug that has broad effects throughout the brain. One site of action is the nucleus of the solitary tract (NTS), where nicotine initiates a stress response and modulates cardiovascular and gastric function through nicotinic acetylcholine receptors (nAChRs). Catecholamine neurons in the NTS influence both stress responses and cardiovascular reflexes, making them potential targets of nicotine; however the effect of chronic nicotine on these neurons is not known. Here we examined the effect of chronic nicotine and spontaneous nicotine withdrawal on NTS catecholamine neurons using patch-clamp electrophysiology in horizontal brain slices from transgenic mice that express enhanced green florescent protein driven by the tyrosine hydroxylase promoter (TH-EGFP). TH-EGFP mice were implanted with osmotic minipumps which contained either nicotine or saline. Pumps delivered nicotine at a rate of 24 mg/kg/day. Implanted mice were split into ‘chronic’ and ‘withdrawn’ treatment groups. Mice in the chronic group were sacrificed 14 days after pump

insertion and horizontal brain slices were prepared for patch-clamp recording. Mice in the withdrawn group were also treated for 14 days, but underwent a 24-hour abstinence from nicotine/saline prior to sacrifice. Neurons positive for EGFP were recorded in voltage-clamp mode. A puff of nicotine (200μM) applied to the soma of TH-EGFP neurons induced both a direct post-synaptic current mediated by α4β2-nicotinic acetylcholine receptors (nAChRs) and an increase in the frequency of spontaneous glutamatergic excitatory post-synaptic currents (sEPSCs), a pre-synaptic effect mediated by α7 nAChRs. The average amplitude of post-synaptic nicotine currents recorded in chronic nicotine-treated animals was not statistically different from control animals that received chronic saline. The pre-synaptic effect of nicotine to increase sEPSC frequency was also not significantly altered. However, both direct post-synaptic nicotine current, and pre-synaptic effect of nicotine to increase sEPSC frequency, were significantly increased in chronic nicotine-treated animals 24 hours after the pump was removed (nicotine-withdrawn animals) compared to chronic saline-treated animals whose pumps were removed. The baseline sEPSC frequency was not changed across all treatment groups. These results indicate that NTS catecholamine neurons undergo adaptation to chronic nicotine treatment that renders them hypersensitive, both pre- and post-synaptically, to acute nicotine during nicotine withdrawal, but not during continued chronic treatment.

Abstract: A growing body of evidence suggests that GABAB receptors modulate the addictive properties of nicotine, the main component of tobacco that produces dependence. In our study, complementary genetic and pharmacological approaches were used to test the hypothesis that the GABAB receptors modulate aversive motivational states associated with nicotine dependence in mice. For this purpose, the expression of the conditioned place aversion induced by mecamylamine-precipitated nicotine withdrawal was investigated in baclofen (GABAB agonist) and 2-OH-saclofen (GABAB antagonist) pretreated mice (pharmacological approach) and in GABAB1 knockout mice (genetic approach). Interestingly, baclofen prevented ($p<0.001$) the expression of conditioned place aversion induced by mecamylamine-precipitated nicotine withdrawal. Similarly, conditioned place aversion induced by nicotine withdrawal was not observed in GABAB1 knockout mice ($p<0.05$). In contrast, the antagonist 2-OH-saclofen increased ($p<0.01$) the conditioned place aversion induced by nicotine withdrawal. These findings would indicate that GABAB receptors could play a role in the conditioned place aversion of nicotine withdrawal. Taken together, these results support the hypothesis that GABAB receptor agonist may offer therapeutic advantages to treat tobacco dependence.

Title: Age-dependent effects of nicotine or fluoxetine on 5-HT1A receptor activity

Authors: *S. J. CROSS[1], M. YUAN[2], J. O. AFAGA[1], D. LARRY-SAR[2], M. T. PHAN[2], F. M. LESLIE[1,2];
[1]Anat. & Neurobio., [2]Pharmacol., Univ. of California, Irvine, Irvine, CA

Abstract: Adolescence is a sensitive developmental period when the initiation of smoking and the onset of psychiatric disorders typically occur. Clinical data indicate that teen smokers are more likely to develop substance abuse and psychiatric disorders. Preclinical data support these

findings, demonstrating that adolescent exposure to nicotine, the main psychoactive constituent in tobacco, produces lasting changes in neuronal signaling, brain development, and motivated behavior. Our lab has shown that nicotine enhances behavioral sensitivity to cocaine reward in adolescents but not adults (Dao et al., 2011). This effect is mimicked by fluoxetine, a selective serotonin reuptake inhibitor commonly prescribed for teen depression. Additionally, both co-administration of the 5-HT_{1A} receptor antagonist WAY-100,635 during drug exposure and acute administration of WAY-100,635 after drug exposure blocks the enhancing effects of nicotine and fluoxetine on cocaine self-administration. Since this indicates that these drugs increase endogenous 5-HT_{1A}R signaling in adolescents but not adults, the current study examines whether nicotine or fluoxetine age-dependently alter 5-HT_{1A}R activity, particularly in brain regions important for drug reward and motivated behaviors. Adolescent or adult rats received saline, nicotine (60 µg/kg, i.v.), or fluoxetine (1 mg/kg, i.v.) for 4 consecutive days. The next day, brains were collected and processed for agonist stimulation of [^{35}S]GTPγS binding to determine 5-HT_{1A}R activity. Our data indicate that adolescent nicotine or fluoxetine exposure increases 5-HT_{1A}R activity in brain regions mediating executive function and addiction-related behaviors, while adult exposure produces different patterns of regional 5-HT_{1A} activity. These results present region-specific understanding of the effects of nicotine or fluoxetine on adolescent brain development, as well as clarifying the underlying mechanisms in which 5-HT_{1A}Rs mediate sensitization of cocaine reward during adolescence. Keywords: adolescence, nicotine, 5-HT_{1A} receptor, fluoxetine

Title: Adolescent nicotine exposure enhances fear memory expression in ABA renewal

Authors: *R. C. BARNET, E. LUNER, A. HOGENMILLER;
Col. William & Mary, Williamsburg, VA

Abstract: Adolescent nicotine decreases the number of cells in the midbrain, hippocampus, and cortex (Trauth et al., 2000) and hippocampus-dependent context conditioning in rats is impaired in adulthood following adolescent nicotine exposure (Spaeth et al., 2010). Here we examined

whether adolescent nicotine would produce long-term impairments in a more complex form of context learning known as “renewal”. In renewal, an animal learns a task in one context (A) then receives extinction treatment in a different context (B). If returned to the original training context (A) the previously extinguished behavior recovers, or “renews”. Renewal implies that one form of context learning involves the ability of contextual cues to modulate memory retrieval (Bouton, 2002). If adolescent nicotine impairs complex aspects of context learning (renewal) in the same way as simpler forms of context learning (context conditioning) - presumably by disrupting hippocampus function - then adolescent nicotine should impair renewal. Adolescent rats received 2x/day intraperitoneal injections of nicotine (saline, 0.15 mg/kg, 0.40 mg/kg) from PD28-PD54 followed by a 20-day abstinence interval. Beginning on PD75 all animals were exposed to pairings of a light with footshock (Light-shock) then subsequent light extinction, presentation of the Light with no shock (L-). Extinction occurred either in the same or different context as original Light-shock training. Animals were tested for fear of the light in the original training context using fear-potentiated startle (FPS). Adolescent nicotine did not impair but actually facilitated context-dependent memory retrieval (renewal). Findings suggest adolescent nicotine may facilitate encoding or retrieval of traumatic fear memory long after the nicotine exposure period.

Title: Sex-differential effect on midbrain dopamine receptors of smoking

Authors: *M. JOHNSON[1], K. OKITA[2], N. PETERSEN[2], C. L. ROBERTSON[2], A. C. DEAN[2], M. A. MANDELKERN[3], E. D. LONDON[2];
[2]Semel Inst., [1]UCLA, Los Angeles, CA; [3]Physics, Univ. of California Irvine, Irvine, CA

Abstract: Evidence shows that female smokers have more difficulty in attaining long-term abstinence from cigarettes than male smokers. Although sex differences are important to consider when constructing a treatment plan, there still is a dearth of biological insight behind sex differences in smoking behavior. Previous studies show sex differences in dopaminergic transmission in the ventral striatum, the brain region through which nicotine produces rewarding effects. Given that, we hypothesize that cigarette smoking has a differential effect on D2-type receptors in the substantia nigra and ventral tegmental area (SN-VTA), which contains predominantly D2-short receptors having an inhibitory effect on dopamine release, between male and females. Twenty four smokers (14 men and 10 women) and 26 non-smokers (12 men and 14 women) participated. They were tested for dopamine D2-type receptor availability, indicated by binding potential (BPnd), in the SN-VTA using positron emission tomography (PET) with [^{18}F] fallypride, a radiotracer with high affinity for D2-type receptors. In an exploratory analyses, other brain regions were tested by voxel-wise analysis and volume of interest analysis, depending on voxel significance. The interaction effect between sex and group (smokers vs. non-smokers) was significant, whereas main effects were not. The data revealed a trend of higher SN-VTA BPnd in female smokers than in female non-smokers, as well as a higher SN-VTA BPnd in female smokers than in males. This highlights the sex difference in dopamine D2-type receptors in the SN-VTA, suggesting it may be have relation to dopamine release in the striatum of smokers. In addition, voxel-wise analyses uncovered an interaction effect between sex and group on D2-type receptor availability in regions other than SN-VTA, such as amygdala, insula, temporal lobe, and striatum. These results support findings in previous studies and provide a platform to extend research in biological sex-differential effect of tobacco smoking.

Title: Nicotine exposure causes parallel increases in prefrontal cortex gamma oscillations and visual attention

Authors: *L. S. BUENO-JUNIOR[1], N. W. SIMON[2], M. A. WEGENER[2], B. MOGHADDAM[2];
[1]Med. Sch. of Ribeirao Preto, Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Nicotine exposure has been shown to improve attentional performance, although the neural mechanism of this phenomenon is not well understood. To address this, we recorded local field potential (LFP) oscillations and single unit activity in medial prefrontal cortex (mPFC) of awake, behaving rats during five consecutive sessions of experimenter-administered nicotine (.2 mg/kg freebase concentration). Then, in a separate group of subjects, we tested visual attention performance during a comparable five day nicotine schedule using a well-established behavioral paradigm (McGaughey and Sarter, 1995). In the electrophysiology experiment, substantial modulations of mPFC low gamma LFP power (40-60 Hz) manifested on day three of nicotine exposure, whereas a consistent reduction of theta and beta power (5-25 Hz) was evident across all days. Nicotine induced a net inhibition of mPFC single unit activity after the first injection, but this effect was not observed in subsequent sessions. In the second experiment, we observed that nicotine did not affect visual attention on day one, then improved attentional performance beginning on day three. This time scale was remarkably similar to the progression of effects of nicotine on low gamma oscillations, with effects on both attention and gamma beginning on day three and persisting across subsequent treatment sessions. These parallel findings suggest that nicotine may improve attention via modulation of low gamma oscillations in mPFC.

Title: Subsecond modulation of dopamine release by the tobacco product flavorant menthol

Authors: *R. WICKHAM[1], E. NUNES[2], J. PARK[4], N. ADDY[3];
[1]Neurobio., [2]Psychiatry, [3]Departments Psychiatry and Cell. and Mol. Physiol., Yale Univ., New Haven, CT; [4]Dept. of Biotechnical and Clin. Lab. Sciences; Sch. of Med. and Biomed. Sc, Univ. of Buffalo, Buffalo, NY

Abstract: Flavorants, such as menthol, are commonly added to tobacco cigarettes in order to increase appeal. Therefore, it is not surprising that menthol, and potentially other added flavorants, alters smoking behavior. Specifically, menthol smokers have their first cigarette of the day earlier compared to non-menthol, have a harder time quitting, and smoke fewer cigarettes per day. We postulate that these differences in smoking behavior arise from menthol's actions in the midbrain dopamine (DA) pathway, a critical circuit in the brain for mediating the reinforcing effects of natural rewards and drugs of abuse. Here, in male Sprague-Dawley rats, we demonstrate a novel approach for examining the interaction between flavorants and nicotine on nicotine taking and subsequent effects on phasic DA release. Combining intraoral delivery of flavorants (0.2mL/infusion) with fast scan cyclic voltammetry in freely-moving rats, we found that intraoral administration of sucrose (10%) and menthol (0.005%), but not water, elevates phasic DA release in the nucleus accumbens core in naïve rats. Each rat received water, menthol, and sucrose, in blocks of 25 infusions. The order of flavorant presentation was counterbalanced across rats. Moreover, there was no effect on flavorant presentation order nor within a block of infusions. In order to test the reinforcing value of each flavorant, we examined operant behavior for intraoral flavorant delivery using a FR-1 schedule of reinforcement. Rats readily self-administered intraoral sucrose but not menthol nor water. Ongoing experiments include combining intraoral flavorant and intravenous nicotine self-administration in order to examine the effects of flavorants on nicotine taking.

Title: Age-dependent effects of nicotine on behavioral adaptations and striatal neurotransmission in Wistar rats

Authors: *A. LOTFI, J. MORUD LEKHOLM, B. SÖDERPALM, M. ERICSON, L. ADERMARK;
Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Nicotine addiction is one of the leading contributors to the global burden of disease, and users with an early onset display more severe addictive behaviour and have a lower chance of cessation than those starting at later stages in life. In addition, there appears to be an age-dependent component to the neurophysiological effects of nicotine, with adolescents being more prone to the reinforcing and rewarding effects by the drug. The striatal nucleus is a key structure in reward-guided behaviors, and integrative effects on striatal microcircuits appear to play major roles in the development of addiction. The aim of this study was to define age-dependent effects displayed by nicotine on behavior and neuronal function in striatal subregions. To this end, sensitization to the locomotor stimulatory properties of nicotine was studied in rats of three different ages (3-4 weeks, 8-10 weeks, >20 weeks). In addition, field potential recordings in brain slices determined the acute effects of nicotine on striatal neurotransmission in nicotine naïve or nicotine pretreated rats. Our data show that repeated nicotine administration produces a faster onset of behavioral sensitization in young animals (<10 weeks old). In addition, nicotine produced a depressant effect on rearing activity, to which tolerance developed faster in the younger age groups. Field potential recordings revealed that behavioral sensitization was accompanied by a decrease in input/output function in the dorsomedial striatum (DMS) of nicotine-treated rats. Acute administration of nicotine (1μM) to brain slices from nicotine naïve rats showed an age-dependent and partially subregion specific mechanism. Nicotine produced a robust decrease in evoked field excitatory post-synaptic potential (fEPSP) amplitude, which was significantly stronger in the dorsolateral striatum (DLS) as compared to the DMS. The decrease in fEPSP amplitude involved alpha4-containing nicotinic receptors, which was blocked by the GABA-A receptor antagonist, bicuculline (2-20μM), and the glycine receptor antagonist, strychnine (1μM), and was sensitive to modulation of dopaminergic neurotransmission. The acute depressant effect displayed by nicotine on evoked fEPSPs was reduced in brain slices from older rats, as was the acute effect by the dopamine D2 receptor agonist quinpirole. The data presented here suggests that nicotine modulates behavior and striatal neurotransmission in an age-dependent manner, which might be important in understanding the underpinnings of higher risks of developing nicotine addiction in adolescents.

Title: Environmental tobacco smoke (ETS) in the early postnatal period decreases the endocannabinoid related enzymes and receptors in the brainstem

Authors: ***T. MARCOURAKIS**, N. T. BALESTRIN, N. N. MONTEIRO, R. C. T. GARCIA, S. OLIVEIRA, T. ANDRIOLI, A. C. C. S. DURAO, L. H. L. TORRES;
Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Introduction: Environmental tobacco smoke (ETS) in the early postnatal period induces impairment in brain development, evidenced by disturbs synaptic proteins and spatial learning and memory from late infancy to early adulthood. Moreover, ETS disrupts myelination in brainstem, which controls the cardiorespiratory function (Torres et al. 2014). This study investigated the effects of the early postnatal ETS exposure in the endocannabinoid system that has been described as being involved in main stages of neural development and activity. Methods: C57/Bl mice were exposed to a mixture of mainstream and sidestream smoke generated from 3R4F reference research cigarettes since postnatal day (P) 3 to P14 during 2 hours/day. Animals (n=6) were euthanized in P15 (infancy), P35 (adolescence) and P65 (adult). Enzymes and receptors of the endocannabinoid system, such as CB1, CB2, NAPE-PLD (enzyme involved in anandamide synthesis) and FAAH (enzyme involved in anandamide metabolism) were evaluated by immunoblotting in the brainstem. Results: Mice exposed to ETS showed a significant decrease in CB1 ($p<0.05$), CB2 ($p<0.05$), NAPE-PLD ($p<0.05$) and FAAH ($p<0.05$) levels in infancy and a significant decrease in FAAH ($p<0.05$) levels in adulthood in the brainstem. Discussion: Decreases in elements of the endocannabinoid system levels in the brainstem are particularly relevant. The exposure to ETS is considered one of the major risk

factors for sudden infant death syndrome (SIDS). The mechanism of SIDS is still unknown, but requires immature cardiorespiratory control and impairment in sleep arousal, involving the brainstem. Title: Repeated nicotine exposure regulates BDNF expression in the dorsal striatum via stimulation of mGluRs in glia

Authors: J. KIM, I. RYU, S. SEO, K. SHIM, *E. CHOE;
Pusan Natl. Univ., Pusan, Korea, Republic of

Abstract: BDNF regulates synaptic plasticity related to drug addiction. Our preliminary study demonstrated that fourteen daily subcutaneous injections of nicotine (1.0 mg/kg) significantly increased BDNF expression in the dorsal striatum, suggesting that BDNF in glia plays a crucial role in the regulation of glutamatergic transmission in response to repeated nicotine exposure. Based on this speculation, we will determine molecular mechanisms underlying the repeated nicotine-induced BDNF releases by investigating the following hypothesis: increases in the releases of glutamate after repeated nicotine administration regulate BDNF expression in the dorsal striatum through stimulation of signaling cascades coupled to group I mGluRs (mGluR1/5) in glia. Title: Nicotine challenge-induced behavioral sensitization requires glutamate releases and MAP kinase phosphorylation in the rat dorsal striatum

Authors: *I. RYU, J. KIM, S. SEO, K. SHIM, E. CHOE;
Pusan Natl. Univ., Pusan, Korea, Republic of

Abstract: The dorsal striatum is a key structure of the basal ganglia circuitry integrating dopaminergic and glutamatergic transmission associated with drug addiction. Our preliminary studies demonstrated that nicotine challenge (0.4 mg/kg) after six days withdrawal following fourteen daily systemic nicotine injections (0.4 mg/kg/day, s.c.) significantly increased extracellular glutamate releases, ERK1/2 and p38 MAP kinase phosphorylation in the dorsal striatum, and locomotor activity as well as stereotypy movement. Based on these findings, we will also determine neuropsychopharmacological mechanisms underlying the nicotine challenge-induced behavioral sensitization via activation of calcium signaling cascades linked to glutamate receptors in the dorsal striatum of rats. *Supported by Ministry of Food and Drug Safety, Korea (Grant # 14182MFDS977, E.S.C.).*

Title: Functional upregulation of α4* nicotinic acetylcholine receptors in VTA GABAergic neurons increases sensitivity to nicotine reward

Authors: *J. NGOLAB, L. LIU, R. ZHAO-SHEA, G. GAO, P. D. GARDNER, A. R. TAPPER; BNRI - Univ. of Mass Med. Sch., Worcester, MA

Abstract: Chronic nicotine exposure increases sensitivity to nicotine reward during a withdrawal period which may facilitate relapse in abstinent smokers, yet the molecular neuroadaptation(s) that contribute to this phenomenon are unknown. Interestingly, chronic nicotine use induces functional upregulation of nicotinic acetylcholine receptors (nAChRs) in the mesocorticolimbic reward pathway potentially linking upregulation to increased drug sensitivity. In the ventral tegmental area (VTA) functional upregulation of nAChRs containing the α4 subunit (α4* nAChRs) is restricted to GABAergic neurons. To test the hypothesis that increased functional expression of α4* nAChRs in these neurons modulates nicotine reward behaviors, we engineered a Cre recombinase-dependent gene expression system to selectively express α4 nAChR subunits harboring a "gain-of-function" mutation (a leucine mutated to a serine residue at the 9′ position: Leu9′Ser) in VTA GABAergic neurons of adult mice. In mice expressing Leu9′Ser α4 nAChR subunits in VTA GABAergic neurons ($Gad2^{VTA}$:Leu9′Ser mice), sub-reward threshold doses of nicotine were sufficient to selectively activate VTA GABAergic neurons and elicit acute hypolocomotion which developed tolerance with subsequent nicotine exposures compared to control animals. In the conditioned place preference procedure, nicotine was sufficient to condition a significant place preference in $Gad2^{VTA}$: Leu9′Ser mice at low nicotine doses that failed to condition control animals. Together, these data indicate that functional upregulation of α4* nAChRs in VTA GABAergic neurons confers increased sensitivity to nicotine reward and points to nAChR subtypes specifically expressed in GABAergic VTA neurons as molecular targets for smoking cessation therapeutics.

Abstract: Many addictive drugs such as nicotine mediate reward and reinforcing mechanisms within the mesolimbic pathway involving midbrain dopaminergic (mDA) neurons via nicotinic acetylcholine receptors (nAChRs). Previously, genome-wide association analyses (GWAs) identified single nucleotide polymorphisms (SNPs) associated with increased risk of addictive phenotypes including a SNP encoding a D398N (aspartate to asparagine) variation in the CHRNA5 gene encoding the alpha 5 subunit of nAChR. Since nicotine mediates reward within mDA neurons of the mesolimbic pathway, we differentiated iPSC to mDA cultures to test functional properties and response to nicotine. Patient-derived induced pluripotent stem cell (iPSC) lines were prepared from age- and gender-matched D398 and N398 variants with clinically defined nicotine use. We generated mature, nAChR-expressing, DA-releasing neurons using published methods. Gene expression and immunohistochemistry studies confirm that the majority of cells expressed standard mDA markers in neuronal cultures derived from iPSCs carrying either N398 or D398 variants. A minor fraction of cells expressed glutamatergic or GABAergic markers. The N398 variant differentially expresses lower levels of genes associated with glutamate, serotonin, and dopamine receptor signaling, suggesting an indirect effect on signaling. While both groups exhibited physiological properties consistent with neuronal function, the N398 neuronal population responded more actively to application of nicotine in electrophysiological analyses, consistent with reports of an enhanced initial response to nicotine in N398 subjects. Our results are consistent with altered N398 signaling of DAergic neurons, possibly due to effects in presynaptic glutamatergic cells present in our cultures.

Title: α5 nAChR modulation of the effects of nicotine on ventral-striatal DA release and cue-reward learning

Authors: *W. M. HOWE, P. TIERNEY, A. ROSSI, D. YOUNG, R. KOZAK;
Pfizer, INC, Cambridge, MA

Abstract: Previous work has shown that the α5 nicotinic acetylcholine receptors (nAChR) in the habenula-interpeduncular nucleus (IPN) pathway are potent modulators of nicotine consumption. Emerging data suggests that the role of α5 control of drug seeking extends beyond nicotine intake, but also to other drugs of abuse (e.g. alcohol, Giorgio et al., 2014), a result that might be via this receptor's actions in circuits beyond the habenula and IPN. A substantial body of evidence shows that reward and drug seeking is controlled by mesolimbic circuitry and the modulation of dopamine (DA) release. Importantly, α5 is found throughout the mesolimbic system, including presynaptically on DA terminals in the ventral striatum where it is poised to contribute to cholinergic modulation of DA release. In the present studies, we sought to characterize the role of the α5 nAChR in modulating ventral-striatal DA release and behaviors controlled by this circuitry. First, we developed and validated an RNAi strategy to manipulate a5 expression in-vivo. We then selectively knocked-down α5 expression in the nucleus accumbens, or in the DA cell bodies in the ventral tegemental area using this shRNA. Fast-scan cyclic voltammetry (FSCV) was employed to monitor stimulated DA release in the core of the nucleus accumbens; both at baseline and in response to a nicotine challenge. We next assessed the functional impact of α5 modulation of mesolimbic circuitry with a Pavlovian conditioned approach task, and further probed the behavioral response to nicotine administration. Our results indicate that α5 knockdown reduces the impact of nicotine administration on DA release in the nucleus accumbens (n=5 for knockdown and luciferase control conditions). In the Pavlovian conditioned approach paradigm (n=16 for knockdown and luciferase control groups), α5 knockdown diminished the capacity of nicotine to augment probability (~20% decrease in approach behavior) and speed of cue-evoked approach behavior. Our combined results suggest that the α5 nAChR, via its ability to modulate mesolimbic circuitry, could be a critical mediator of fundamental motivation and reward processes, and that this effect is independent of its ability to modulate activity at the level of the habenula and IPN.

Title: Effects of adolescent nicotine exposure on intracranial self-stimulation behavior in rats

Authors: ***T. SUENAGA**[1], S. GAO[2], Y. ISHIDA[3], D. NAKAHARA[4];
[1]Tokyo Univ. and Grad. Sch. of Social Welfare, Tokyo, Japan; [2]The Lab. of Cell Imaging, Henan Univ. of Traditional Chinese Med., Henan province Zhengzhou City, China; [3]Dept. of Psychiatry, Univ. of Miyazaki, Miyazakishi, Japan; [4]Dept. of Psychology and Behavioral Neurosci., Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Tobacco is one of the most commonly used addictive drugs in the world. It is suggested that exposure to nicotine during adolescence affects vulnerability to nicotine abuse later in adulthood. In the present study, we investigated the effects of nicotine during adolescence on nicotine-induced self-stimulation reward threshold in adulthood. Male Sprague-Dawley rats were divided into three groups. They were intrapenetonally treated with saline (0 mg/kg), low-dose (0.1 mg/kg), or high-dose (0.4mg/kg) of nicotine for 10 days on postnatal day 34-43. Five weeks after drug administration, rats were implanted with a monopolar electrode into the medial forebrain bandle under anesthesia. After a one-week recovery period, they were trained in intracranial self-stimulation (ICSS) tests. During the preliminary session, the frequency was held constant at 65 pps and the current intensity was progressively increased until the subjects showed vigorous self-stimulation. The current-threshold of each rat was defined as the value of stimulus that evoked 50% of the maximal rate of self-stimulation. These intensity values were then held constant for the subsequent testing of the frequency-threshold. The rats were again tested using two alternating series of ascending and descending pulse frequencies. Drug tests began after the rate-frequency curve (once daily) was stable for at least three consecutive days. A base line rate-frequency curve was measured three hours before the drug

administration. Then 0, 0.4, 0.8, or 1.2 mg/kg nicotine was administered 15 min before ICSS test. The percent shift in threshold under drug conditions was analyzed using mixed-design analysis of variance. Saline-pretreated control group showed a decrease in ICSS reward threshold under 0.4 and 0.8 mg nicotine conditions and an increase under 1.2 mg nicotine condition. On the other hand, nicotine-pretreated groups during their adolescence showed decreased ICSS threshold under all nicotine conditions. Furthermore, rats pretreated with high-dose of nicotine showed a rightward-shift in thresholds compared to control rats. The number of reinforced response under nicotine did not differ between nicotine doses and groups. Thus ICSS thresholds were unaffected by nicotine-induced hyper-locomotion. The results reveal adolescent nicotine exposure induces a long-lasting alteration of the sensitivity of brain reward systems to the nicotine.

Title: Chronic toluene exposure and nicotine administration modify adrenergic responses in isolated rat heart

Authors: N. ALVARADO-GOMEZ[1], M. CARREON-GARCIDUEÑAS[1], L. ORTEGA-VARELA[2], D. GODINEZ-HERNANDEZ[1], *M. Y. GAUTHEREAU[3];
[1]Inst. de Investigaciones Quimico Biologicas, [2]Escuela de Enfermeria y Salud Publica, Univ. Michoacana de San Nicolas de Hidalgo, Morelia, Mexico; [3]Univ. Michoacana De San Nicolás De Hidalgo, Morelia, Mexico

Abstract: Toluene is a volatile solvent that can be inhaled to achieve intoxicating states. It is found in thinner, paints and adhesives. *In vitro* studies indicate that toluene inhibits nicotinic acetylcholine receptors. Nicotine is one of the alkaloids extracted from tobacco and is considered mainly responsible for cigarette addiction. There is evidence indicating that tobacco abuse is often combined with inhalation of solvents, such as toluene. Reports indicate that inhaling

solvents can induce cardiac arrhythmias and sudden sniffing death, by mechanisms not completely understood. However, there are some reports indicating that cardiac arrhythmias due to sensitization of the heart to epinephrine are probably the most common cause of death. In addition, tobacco smoking is a risk factor for the presentation of cardiac diseases and sudden death; nevertheless, the effects of the combined administration of toluene and nicotine have not been studied. The purpose of this study was to investigate the effect of chronic administration of toluene and nicotine on the reactivity of the heart to epinephrine. Male Wistar rats (250-300 g) were placed in a static exposure chamber and exposed to 6000 ppm toluene or air (control group) during 30 minutes twice a day during 30 days. Other groups of rats received nicotine (0.5 mg/kg, p.o.) and then were exposed to toluene or air as described above. On 31st day rats were anesthetized with sodium pentobarbital (50 mg/kg), and the hearts were isolated and perfused according to Langendorff method. Concentration-response curves to epinephrine were made and perfusion pressure, heart rate and strength of ventricular contraction were measured. Toluene-exposed hearts had a lower basal perfusion pressure compared to air-exposed hearts, and nicotine and toluene-nicotine treated hearts showed greater basal perfusion pressure values. In response to epinephrine, toluene produced a lower increase in perfusion pressure. Toluene exposure, nicotine and toluene-nicotine combination produced significant increases in basal heart rate and in heart rate values in response to epinephrine; this effect was more pronounced with toluene-nicotine combination. It was observed an increase in basal strength of ventricular contraction in all treated groups; in contrast, toluene exposed hearts and nicotine treated hearts had greater increases in strength of ventricular contraction in response to epinephrine and hearts that received toluene-nicotine combination showed a decrease in this parameter. Our results suggest that both toluene and nicotine alter cardiac responses and these effects are more pronounced if toluene and nicotine are administered together.

Title: Inhalation of aerosolized nicotine enhances cognitive function in aged mice using an automated aerosol delivery system

Authors: *X. S. XIE[1], C. A. LIEU[1], B. ZOU[1], C. PASCUAL[1], J. ZHANG[1], X. M. SHAO[2]; [1]Afasci Res. Laboratories, Afasci, Inc., Redwood City, CA; [2]Dept. of Neurobio., David Geffen Sch. of Med. at UCLA, Los Angeles, CA, CA

Abstract: Tobacco use is the leading cause of preventable disease and disability in the U.S. Nicotine is the key chemical causing addiction to tobacco smoking. Current smoke cessation drugs produce about 20% long-term abstinence of smoking. Therefore, understanding nicotine pharmacology, reward effects and toxicology is critical to the development of more effective pharmacotherapies. However, animal models that mimic human nicotine kinetics, such as episodic inhalation and chronic intermittent exposure are lacking. We have developed an aerosolized nicotine delivery device integrated with our SmartCage technology. The system allows researchers to deliver a controllable amount of nicotine rapidly into the animal's systemic circulation. To test the system, we examined if nicotine aerosol inhalation in the amount similar to smoking cigarettes in human enhances learning and memory in aged mice. We administered either 0.5% aerosolized nicotine or saline to free moving mice (C57BL/6, male, 16 - 20 months old) in the aerosolized chamber for 5 min daily for consecutive 5 days. There were 91 ng/ml nicotine and 101 ng/ml cotinine in mouse plasma 5 min after the last exposure. The levels of nicotine and cotinine 30 min after exposure were 57 ng/ml and 222 ng/ml in mouse plasma, respectively, which resemble levels seen in heavy smokers. Thirty minutes after nicotine inhalation, mice were subject to the Morris Water Maze test. Probe finding was trained daily for consecutive 4 days and memory retention was assessed in the probe test. Inhalation of aerosolized nicotine did not produce a significant decrease time in finding the probe; but significantly enhanced memory in aged mice manifested by an increased time (21 s) in test quadrant compared to the aerosolized saline-control group (14 s) in test quadrant during the probe test. In the Y-maze and step through passive avoidance test, nicotine-treated mice showed modest but an insignificant increase in memory compared to saline-control. Furthermore, the system enables rodents to perform self-administration of aerosolized nicotine by either nose-poking or lever pressing. Initially food pellet reward accelerated the training of nose-poking or lever-pressing behavior. Optimization and evaluation of nicotine self-administration are underway. In summary, we show that nicotine aerosol inhalation in the amount similar to smoking cigarettes in human enhance memory in aged mice. The aerosol generation system can deliver a controllable amount of nicotine, and potentially other drugs of abuse, which induce behavioral changes, pharmacological or toxicological effects in a preclinical setting similar to that occurs in human drug addicts.

Title: The role of the dynorphin-kappa-opioid system in reinstatement of nicotine-seeking in mouse self-administration

Authors: *A. M. GOMEZ[1], M. R. BRUCHAS[1,2];
[1]Dept. of Anesthesiol. Div. of Basic Research, Anat. and Neurobiology, an, [2]Div. of Biol. and Biomed. Sci., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Nicotine is the most widely used addictive substance, and its use is accompanied by a high propensity for relapse. However, the neurobiological mechanisms underlying nicotine relapse/reinstatement remain unclear. Prior studies have shown that in rodents, activation of the kappa-opioid receptor (KOR) system via stress-induced dynorphin release elicits negative affective states, and thereby triggering reinstatement of drug-seeking behaviors. Therefore, our goal is to establish the role of the dynorphin/KOR system in stress-induced reinstatement of nicotine-seeking. We first trained male C57BL/6 mice to self-administer nicotine intravenously (0.03 mg/kg/infusion, 60 min sessions) on a fixed ratio-5 schedule of reinforcement for a minimum of 14 days. After stable levels of nicotine intake were established, mice underwent extinction training until criterion was reached (≤ 20% of responding compared to last nicotine self-administration session). We then investigated whether activation of KORs were sufficient to induce reinstatement of nicotine-seeking. Indeed, mice showed a robust reinstatement response after administration of the KOR agonist, U50,488 (2.5-5.0 mg/kg, i.p., 30 mins prior to reinstatement test). This data suggests that activation of the KOR system is sufficient to cause nicotine-seeking in mice. Currently, we are exploring whether KORs are necessary for stress-induced reinstatement of nicotine-seeking via administration of systemic KOR selective antagonists. Future follow-up studies will focus on dissecting the specific neural circuitry underlying KOR-mediated reinstatement of nicotine-seeking.

Title: Partial inhibition of monoamine oxidase (MAO) increases nicotine self-administration in rats

Authors: T. T. SMITH[1], S. N. CWALINA[1], L. E. RUPPRECHT[1], M. J. OMINUS[1], S. E. MURPHY[2], E. C. DONNY[1], *A. F. SVED[1];
[1]Univ. Pittsburgh, Pittsburgh, PA; [2]Univ. of Minnesota, Minneopolis, MN

Abstract: Monoamine oxidase (MAO) is inhibited in the brains of chronic cigarette smokers by approximately 40%. While some compounds in cigarette smoke that inhibit MAO have been identified, it is not clear to what extent these compounds are responsible for the MAO inhibition seen in smokers. Prior studies examining the significance of the MAO inhibition to smoking behavior have used known MAO inhibitors to examine their effect on nicotine self-administration in rats. These studies have shown that MAO inhibitors can enhance responding for intravenous (i.v.) infusions of nicotine, especially at low doses of nicotine. However, these studies have relied on large doses of MAO inhibitors that produce near complete inhibition of MAO, and in some studies the doses are large enough to produce substantial off-target effects. The goal of the present study was to examine the effects of doses of tranylcypromine (TCP) that produce partial inhibition of MAO on i.v. nicotine self-administration in adult rats. Rats responded for a low dose of nicotine (10 ug/kg/infusion) in daily 1-hr sessions and received an i.p. injection of 0, 0.1, 0.3, or 1.0 mg/kg of TCP 1-hr prior to each self-administration session. TCP produced a dose-dependent increase in the rate at which rats acquired stable nicotine self-administration, as well as the rate of nicotine self-administration during stable maintenance. The average number of infusions earned during the final three days of self-administration on a fixed-ratio 2 schedule of reinforcement was 7.75 in the saline group (SEM=1.59, n=21). Rats receiving 0.3 mg/kg TCP earned an average of 18.48 infusions (SEM=2.08, n=21), and MAO activity, measured in the dorsal striatum from a subset of brains collected at the end of the final session, was 20% of that in control animals. Across all doses of TCP, there was a significant correlation between nicotine self-administration and MAO inhibition. These data suggest that in the range of partial MAO inhibition seen in cigarette smokers, MAO inhibition increases responding for nicotine. Therefore MAO inhibition caused by cigarette smoking may interact with nicotine to

promote smoking behavior, and this may be particularly relevant at low doses of nicotine. These data may be important for the FDA as they consider a mandated reduction in the nicotine content of combustible products. These data suggest that cigarette constituents that inhibit MAO are likely to shift the reinforcing value of low-nicotine products.

Title: Individual differences in nicotine self-administration and approach to nicotine cues

Authors: *C. P. KING, C. L. VERSAGGI, L. JACKSON, P. J. MEYER;
Psychology, Univ. At Buffalo, Buffalo, NY

Abstract: Drug cues are important in the regulation of drug taking and relapse behaviors, and can produce craving and elicit cue-directed approach. Individual differences in the response to these drug cues may be related to the responses to food cues. To test this, we preformed two experiments examining the relationship between food- and nicotine cue responsivity. In the first experiment, the response to food predictive cues was measured in Sprague-Dawley rats during a Pavlovian conditioned approach procedure. Rats categorized as “sign-trackers” (n=6) approached a food-paired cue, and “goal-trackers” (n=5) approached the food delivery location. We then examined whether sign- and goal-tracker rats had different patterns of intravenous nicotine self-administration, extinction, and cue-induced reinstatement. Specifically, rats were trained to nose poke for a cue light and either saline or intravenous nicotine (.03mg/kg/infusion) on a FR5 schedule of reinforcement. We found that nicotine self-administering rats performed more responses and received more infusions than controls. Responding was then extinguished and rats were tested for cue-induced reinstatement of operant responding. During this test, sign-trackers responded more than goal-trackers when nicotine-paired cues were returned. In a second experiment, we examined whether a cue predictive of an intravenous nicotine infusion could produce a sign-tracking response in rats during Pavlovian conditioning. Rats (n = 13) received infusions of intravenous nicotine (0.03 mg/kg/infusion) on a variable interval schedule. Nicotine infusions were either paired with a lever cue immediately preceding the infusion, or presented in an unpaired fashion. We found that the paired group showed higher nicotine cue directed

approach compared to the unpaired group, showing that a nicotine cue can elicit approach behavior in rats. Taken together, these results suggest that sign-tracking and nicotine cue-induced reinstatement are subserved by common neurobehavioral processes. Further, we demonstrate that nicotine cues can also acquire incentive motivational properties, as measured by approach behavior. These cues may influence drug-taking during addiction but the effect of these cues may vary among individuals.

Title: Histamine and Nicotine Self-administration

Authors: ***E. D. LEVIN**[1], K. YANG[2], S. JUNAID[2], K. MURGAS[2], C. WELLS[2], S. SLADE[2]; [1]Duke Univ. Med. Ctr., Durham, NC; [2]Duke Univ., Durham, NC

Abstract: Histamine is a neurotransmitter in the brain as well as a modulator in the periphery. As such, it does more than control secretions in the stomach and sinuses. Histaminergic neural circuits play important roles in a variety of behavioral functions. Histamine H1 receptors have been found in our earlier studies and others' to play critical roles in a variety of behavioral functions from sensorimotor modulation, to cognition to maintenance of reinforced behavior. Concerning reinforced behavior, we found that acute or chronic dosing of the histamine H1 antagonist pyrilamine significantly reduced nicotine self-administration in rats. H1 antagonist treatment may be useful as an aid for smoking cessation. To further the characterization of histaminergic involvement in nicotine self-administration, we investigated the effects of an H1 histamine receptor agonist, betahistine. Female young adult Sprague-Dawley rats were trained to self-administer nicotine (FR1, 0.03 mg/kg/infusion) in one-hour sessions. In the first study, betahistine (0, 2, 4, 8 and 16 mg/kg) was acutely administered to determine the dose-effect range for potentially increasing nicotine self-administration. Trends were found that 8 mg/kg of betahistine increased nicotine self-administration. This dose was not found to affect locomotor activity. In the second study a different set of rats were trained in the same way to self-administer nicotine. The rats were divided into two groups matched for baseline nicotine self-

administration. One group was given 8 mg/kg of betahistine before every subsequent nicotine self-administration session (N=17), while the other group was given control saline injections (N=19). Chronic betahistine significantly ($p<0.05$) escalated increasing nicotine self-administration. This further shows that histamine plays important roles in the level of nicotine self-administration, particularly further elevating higher levels of nicotine self-administration. Histaminergic system involvement in nicotine self-administration may be related to stress effects increasing tobacco addiction.

Title: Imaging CA1-hippocampal neuronal ensembles during nicotine-dependent contextual associations

Authors: ***L. XIA**[1], S. K. NYGARD[2], B. ACLAND[4], N. J. HOURGUETTES[2], G. SOBCZAK[3], M. BRUCHAS[3];
[1]Dept. of biomedical Engineering, Washington Univ. in St. Louis, [2]Dept. of Anesthesiology, Washington Univ. in St. Louis, Washington Univ. In St. Louis, saint Louis, MO; [4]the division of biological & biomedical science, Washington Univ. in St Louis, Saint Louis, MO

Abstract: Learned associations between environmental cues and the rewarding properties of addictive drugs are a major cause for relapse among drug addicts. The hippocampus (HIP) is therefore a likely key player in the development of addictive behaviors. The link between learning and memory systems, contextual cues, and reward circuitry is largely unknown. The conditioned place preference (CPP) paradigm attempts to model this aspect of drug reward-

associations and can be useful in examining the underlying neural circuitry involved in the formation of drug-associated memories. Here we combine *in vivo* calcium imaging of CaMKIIa CA1 HIP neurons with CPP to study the role of the HIP in nicotine-induced behaviors. We injected AAV5-CaMKIIa-GcAMP6f-eYFP into the HIP CA1 area and, implanted a 1 mm diameter and 4 mm length GRIN lens is 100 microns above the injected region. After another 1-2 weeks, we use a microscope camera from INSCOPIX to observe this the neuron activity in the CA1 area can be observed from the microscope. We then used a standard unbiased, counterbalanced CPP protocol to observe neuronal activity during the development of nicotine CPP. Mice were pre-tested in the CPP boxes on day 1, and days 2-3, they received saline in the AM and nicotine (0.5mg/kg, s.c.) in the PM for a 20 min session. On day 5, they were tested for nicotine place preference, as determined by the time they spent in the drug-paired chamber post-test minus pre-test. After collecting all data from each session, Mosaic™ is used to preprocess the data by reducing dataset, meaning filer, motion correction. By PCA/ICA, single neuron activity was separated and sorted manually. Each session retrieved one dataset for single neuron spatial filters and one dataset set for their time course. After comparing neuron activity between two CPP chamber within posttest section, we found distinct patterns of neuronal activity when a mouse enters the nicotine-paired chamber compared to the saline-paired chamber potentially indicating that cue-reward neuronal activity is potentiated during conditioning and formation of preference.. Follow-up studies were conducted in which AAV5-CaMKIIα-HA-hM4D(Gi)-IRES-mCitrine was injected into the CA1 HIP region to show that silencing CA1, CAMKII+ cell activity in this is sufficient to block the development of nicotine-induced CPP. Taken together, our data provide unique evidence for a key role of the CA1 HIP region in nicotine-contextual associations and begin to dissect the circuitry mediating the development of drug-reward cue associations.

Title: Nicotine self-administration is enhanced in obesity-resistant rats

Authors: *L. RUPPRECHT, T. T. SMITH, E. C. DONNY, A. F. SVED;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cigarette smoking and obesity represent the largest challenges to public health. Smokers with higher body mass index (BMI) smoke more cigarettes per day and may be more nicotine dependent than lean smokers. However, very little is understood about the relationship between obesity and nicotine reinforcement. Furthermore, the FDA is considering a policy of markedly reducing the allowable nicotine content in cigarettes; obese smokers may respond differently to nicotine reduction in cigarettes. To model obese smokers, adult male Sprague-Dawley rats (Charles River; Kingston facility) were maintained on high fat diet (HFD; 31.8 kcal from fat) for two weeks. Body weight gain distributed into distinct tertiles: diet-induced obese (DIO), DIO-resistant (DR), and a middle group, which was maintained on chow for the remainder of the experiment, as a diet control (Chow). Rats learned to self-administer 60 μg/kg/infusion nicotine on a fixed-ratio (FR) 2 for ten days before the schedule was escalated to FR5. To establish a nicotine dose response curve, and to model nicotine reduction policy, nicotine dose was halved every seven days to reach 3.75 μg/kg/infusion, a dose previously reported to be sub-threshold for nicotine reinforcement in rats eating a restricted standard chow diet. The Chow group took more nicotine than DR and DIO rats at 60 μg/kg/infusion, although there were no differences in the frequency or proportion to acquire self-administration behavior across groups. Together, these data indicate that at a population level, there are no differences in the probability that rats will acquire self-administration, but that Chow rats respond at higher rates, at least for high doses of nicotine. At all other doses, however, the dose response curve for the DR group was shifted upwards, such that the rats took more infusions than the DIO group ($p < 0.05$). The increase in infusions in the DR group was not explained by increased activity, as measured by inactive responding. The differences between groups are also not explained by differences in body weight, as there is no relationship between nicotine consumption or infusions earned and body weight. Together, nicotine self-administration, particularly at moderate and low doses, is enhanced in rats resistant to diet-induced obesity. These data indicate that current lean smokers eating a densely caloric diet may continue to smoke at high rates following the reduction of nicotine in cigarettes, prolonging the exposure to the harmful chemicals in cigarette smoke.

Title: Activation of the kappa-opioid receptor system is both necessary and sufficient for reinstatement of nicotine place preference

Authors: *S. K. NYGARD[1,2], N. J. HOURGUETTES[1,2], R. AL-HASANI[3,1], G. SOBCZAK[1], M. R. BRUCHAS[1,2,3];
[1]Anesthesiology/Psychiatry, [2]BP-Endure Neurosci. Pipeline, [3]Anat. and Neurobio., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The Kappa-opioid receptor (KOR) system plays a conserved role in stress-induced behavioral responses including reinstatement of drug seeking behavior for nearly every major drug of abuse. Due to nicotine's high propensity for stress-induced relapse, we hypothesized that stress would also induce reinstatement of nicotine seeking behaviors in a KOR-dependent manner. We used a standard unbiased, counterbalanced conditioned place preference (CPP)/reinstatement protocol in mice to investigate the role of KORs in mediating stress-induced behavioral responses to nicotine. Mice were pre-tested in the CPP boxes on day 1, and on days 2-3 mice were conditioned, receiving saline in the AM and nicotine (0.5mg/kg, i.p.) in the PM for 20 min sessions. On day 5, mice were tested for nicotine CPP, determined by the time they spent in the drug-paired chamber post-test minus pre-test. Animals were extinguished for two days using saline pairings, prior to the reinstatement phase. We found that the widely used pharmacological stressor Yohimbine (Yoh) (2mg/kg, i.p.) 5 minutes prior to reinstatement post-testing causes reinstatement of nicotine CPP. This reinstatement of nicotine CPP is NorBNI sensitive, indicating that KOR activity is necessary for Yoh-induced nicotine CPP reinstatement. To determine if KOR activation alone is sufficient for reinstatement of nicotine CPP, we injected the KOR agonist U50,488 (5mg/kg) 30 minutes prior to reinstatement, and found that KOR activation was sufficient to reinstate nicotine place preference. Two hours following the reinstatement test, mice were perfused to examine the effects on Yoh on neuronal activation (c-fos) in the presence and absence of KOR signaling. We visualized robust c-fos expression in the Basolateral Amygdala (BLA) following Yoh treatment, which was significantly reduced in mice pre-treated with norBNI prior to Yoh-exposure. Follow-up studies were conducted to locally inactivate KOR or neuronal activity in the BLA, to assess the influence of KOR-expressing cells and neural circuits on nicotine CPP. NorBNI injected locally into the BLA blocked Yoh-induced nicotine-CPP reinstatement without affecting the acquisition of nicotine CPP. In a separate experiment, we found that activation of hM4D(Gi) DREADDs in the BLA by CNO is sufficient to reinstate nicotine CPP. These data suggest a role for BLA KORs in stress-induced nicotine

seeking. Future studies will attempt to further dissect this BLA circuitry to identify cell type-specificity of these KOR circuits involved with stress-induced reinstatement of nicotine CPP.

Title: Trans-generational effects of paternal nicotine self-administration

Authors: ***J. MAURER**, D. VAN NEST, H. SCHMIDT;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Recent evidence indicates that paternal smoking is associated with nicotine dependence and increased incidence of childhood cancer in offspring. These findings indicate that voluntary nicotine taking influences behavioral phenotypes in future generations. The goal of this study is to establish a novel rodent model in which nicotine-experienced sires confer enhanced/increased vulnerability to nicotine reinforcement in their offspring and grand offspring. Male Sprague Dawley rats were allowed to self-administer nicotine (0.03 mg/kg/infusion) on a fixed-ratio 1 (FR1) schedule of reinforcement for 60 consecutive days. Each nicotine-experienced rat was paired with a yoked saline control rat that received the same number and temporal pattern of infusions. Following nicotine self-administration, nicotine-experienced and yoked saline control rats were allowed to mate with drug-naïve dams. When the offspring (F1) reached 60 days of age, acquisition and maintenance of nicotine self-administration were assessed. Both female and male nicotine-sired offspring self-administered significantly more nicotine than saline-sired offspring. Based on these results, drug-naïve, nicotine- and saline-sired male and female F1 littermates were bred with drug-naïve counterparts in order to produce an F2 generation (grand offspring of nicotine- and saline-experienced sires). Acquisition and maintenance of nicotine self-administration was then assessed in the male and female grand-offspring. Our preliminary results indicate that F2 males of nicotine-sired F1 females had a

propensity to self-administer more nicotine than controls. Taken together, these data are consistent with human epidemiological studies and indicate that voluntary paternal nicotine taking increases susceptibility to nicotine taking in subsequent generations. Identifying novel epigenetic mechanisms underlying the transmission of enhanced vulnerability to nicotine dependence will aid in the development of novel smoking cessation medication in generations at high risk for chronic smoking behavior.

Title: Azacytidine regulates socially-acquired nicotine intravenous self-administration (IVSA) in rats

Authors: ***W. HAN**, H. CHEN;
Pharmacol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Social environment is a critical factor in cigarette smoking. Previous studies demonstrated that social learning reversed conditioned flavor aversion (CFA) induced by self-administered nicotine in rats. We first determined the effect of 5-Azacytidine (5-Azac), a DNA methyltransferase inhibitor, on socially-acquired nicotine IVSA. Carbon disulfide (CS2), a component of the rodent breath, was used as a surrogate for the demonstrator rat to mediate social learning as reported. Licking on the active drinking spout in operant chambers meeting a fixed-ratio 10 reinforcement schedule resulted in the concurrent delivery of nicotine (i.v.) and an olfactogustatory (OG) cue containing CS2 (0 or 500 ppm), 0.4% saccharin and 0.1% unsweetened grape KoolAid. CS2 did not enhance the acquisition of nicotine SA in the three daily training sessions. However, CS2 significantly increased the number of active licks on CFA tested on day four (OG + CS2 vs OG: p0.05). However, it significantly diminished the effect of CS2 (5-Azac vs aCSF, $p<0.01$). In saline rats, CS2 enhanced the operant response during both the acquisition and test sessions. This effect was inhibited by 5-Azac (i.c.v., training: $p<0.01$; testing: $p<0.05$). Similarly, bilateral infusions of 5-Azac (5 ng/ul, 0.2 ul/side) into the infralimbic cortex (IL) reduced the number of active licks on the CFA test (OG+CS2 vs OG, $p<0.01$). In

contrast, a low dose of 5-Azac (1 ng/ul, 0.2 ul/side) elevated the number of active licks on the first day of IVSA training (aCSF vs 5-Azac: $p<0.01$) and on CFA test (aCSF vs 5-Azac: $p<0.001$) in rats received OG+CS2. These data indicated that the effect of 5-Azac on social transmission of nicotine preference is region and dose specific. While i.c.v. administration and high dose IL administration reduced social learning, low dose application limited to the IL enhanced social learning. Thus, DNA methylation in IL is an important mechanism via which social learning promotes voluntary nicotine intake.

Title: Gene expression and alternative splicing changes in infralimbic cortex (IL) underlies socially-acquired nicotine self-administration

Authors: *H. CHEN, T. WANG, W. HAN;
Dept Pharmacol, Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Social environment plays a critical role in the initiation of cigarette smoking among adolescents. We modeled this social effect in rats. We found adolescent rats developed conditioned aversion when an appetitive flavor cue was used for intravenous nicotine self-administration. However, this aversion was reversed by interacting with a conspecific consuming the same flavor cue (but not nicotine). We also have shown that infralimbic cortex (IL) is a critical brain region for the effect of social learning in reversing nicotine conditioned aversion. We used RNA-seq to further investigate the role of infralimbic cortex in socially acquired nicotine self-administration. Rats were trained to self-administer intravenous nicotine with contingent olfactogustatory cues in either an inducing or a neutral social environment for three days. Conditioned aversion were tested on day four. RNA extracted from IL were prepared for transcriptome sequencing. Approximately 15-20 million reads were mapped to the reference genome (rn5) per sample, which accounted for ~80-90% of the total reads. Average read length were approximately 150 bp. Gene expression levels were estimated based on Ensembl gene annotations. DESeq2 was used for data normalization and the identification of differential gene

expressions. Sixteen genes were detected with a false discovery rate of 0.1, including Egr1, Egr3, Nr4a3, etc. We also found ~ 60 genes significantly changed their splicing patterns. Many of these genes were involved in the glutamate receptor signaling pathway, such as Shisa9, Nfkb1, Dnm1, Fyn, etc. Further, GESA analysis showed that genes involved in transcription regulation, synaptic plasticity are unregulated by social learning. These data supported the hypothesis that social learning modulates nicotine intake via regulating gene expression in the infralimbic cortex.

Title: Genetic factors contribute to nicotine intravenous self-administration (IVSA) with menthol cue and sensation seeking

Authors: *T. WANG, H. CHEN;
Dept. of Pharmacol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Menthol is the most widely used tobacco additive and is preferred by ~25% of US smokers. We previously reported a rat model of nicotine IVSA with orally delivered menthol as a sensory cue (Front Behav Neurosci 2014). We found that although taste and odor were associated with the aversive effect of nicotine, the cooling sensation of menthol was a conditioned cue for the reinforcing effect of nicotine. Genetic factors contributing to the preference for menthol-flavored tobacco products were difficult to ascertain from human studies, partly because of targeted advertisement in the minority populations. We studied the amount of nicotine intake with menthol cue in eight inbred strains of rats. These strains included the Brown Norway, Buffalo, Copenhagen, Dahl salt sensitive, Fisher 344, Lewis, Spontaneous hypertensive rat, and Wistar-Kyoto. All rats were implanted with jugular catheter on approx. postnatal day 38. Daily 2.5 h nicotine IVSA sessions were conducted in operant chambers equipped with two lickometers. Licking on the active spout completing a fixed-ratio 10 schedule trigged the concurrent delivery of 60 µl menthol solution (0.01%) to the spout and iv nicotine (30 µg/kg). No audio or visual cue was used. Rats were not food or water deprived. Nicotine intake was

highest in the Dahl salt sensitive strain (9.6 ± 1.1 infusions per session) and lowest in the Buffalo strain (0.55 ± 0.22 infusions per session) during the last 3 sessions. The estimated heritability (h2) was 0.68. Each rat was also trained in an operant sensation seeking (OSS) protocol. These 1 h sessions were conducted in operant chambers fitted with two nose poke holes. Activating the active hole (fixed-ratio 2) turned on one of the two randomly chosen cue lights at a random frequency (0.5, 1, 2, 4 Hz) for a random duration (2, 4, 6, 8 s). Heritability for the number of rewards earned during the last three OSS sessions was 0.87. There was a moderate correlation between nicotine intake with menthol cue and reward earned during OSS sessions (Pearson = 0.53, p = 0.18). These data suggested that both nicotine intake with menthol cue and sensation seeking are heritable, and that sensation seeking is likely contributing to voluntary nicotine intake with menthol cue.

Title: Hypothalamic involvement nicotine self-administration in rats

Authors: *B. J. HALL, C. WELLS, E. D. LEVIN;
Dept. of Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC

Abstract: The hypothalamus is a brain region that has typically been overlooked regarding its potential contributions to processes of drug addiction. Classic literature has shown hypothalamic involvement in consummatory behavior. Drug addiction shares with feeding regulation key behavioral aspects of the appetitive urge. In addition to its primary role as a regulator of metabolic and autonomic function, the hypothalamus is a limbic structure composed of several distinct nuclei that both project to and receive input from several regions of the brain, including areas involved in memory, attention, emotion, and reinforcement learning. The functional output of these projections is responsive to, and regulated by, dopaminergic, serotonergic, noradrenergic, and cholinergic activity. We are investigating the contributions of hypothalamic nuclei to nicotine addiction in a rat model of nicotine self-administration. The first series of experiments targeted D1 dopamine receptors located in the supramammillary nucleus (SuM) of

the hypothalamus; a region that has been implicated in the process of positive reinforcement. Young adult female Sprague-Dawley rats were fitted with jugular catheters and given access to self-administer nicotine (0.03 mg/kg) on an FR1 schedule of reinforcement. Each self-administration session lasted 45 min. Bilateral infusion cannulae were implanted in the SuM to allow local infusion of the D1 receptor antagonist SCH23390. Infusions of SCH23390 occurred 5 min prior to the start of each session. Doses of SCH23390 (1, 2, and 4 μg/side) were infused in a repeated measures, counterbalanced design two times for each rat. Bilateral infusions of SCH23390 into the SuM caused significant reductions in the number of nicotine infusions per session at the 2 ($p<0.05$) and 4 ($p<0.01$) μg/side doses when compared to infusions of the aCSF vehicle. These results demonstrate that hypothalamic D1 dopaminergic innervation plays an important role in the process of nicotine self-administration. Hypothalamic mechanisms may be key components of the neural circuitry underlying addiction. Future experiments will examine the contributions of other transmitters innervating hypothalamic nuclei to nicotine addiction including the involvement of serotonergic and cholinergic receptor mechanisms to this process.

Title: Effect of the dual orexin receptor antagonist tcs1102 on intravenous nicotine self-administration and reinstatement in the rat

Authors: *S. Y. KHOO, G. P. MCNALLY, K. J. CLEMENS;
Sch. of Psychology, Univ. of New South Wales, Sydney, Australia

Abstract: Background: Smoking is the leading preventable cause of morbidity and mortality worldwide. Animal models have shown orexin antagonists reduce alcohol, cocaine and opioid seeking behaviour. Recent evidence also shows that nicotine promotes orexin release. We therefore examined impact of a dual orexin antagonist on nicotine self-administration and reinstatement. Method: Male Sprague-Dawley rats (n = 16) were implanted with chronically indwelling jugular vein catheters and intracranial guide cannulae targeting the lateral ventricle. After recovery, they received 10 days of self-administration training where each active nosepoke

(FR1) was reinforced with a 30 µg/kg/100µL infusion of nicotine. On separate test days, rats received i.c.v. infusion of 1, 3 or 10µg TCS1102 or vehicle 10min prior to self-administration. After self-administration testing and a total of 29 days of nicotine self-administration, they underwent extinction (at least 6 days until 2 consecutive days of ≤30% active nosepoke responding), during which time active nosepokes had no consequences. Relapse-like behaviour was precipitated by presentation of drug-associated cues, a priming injection of nicotine (0.3mg/kg, s.c.) or both the cue and prime, with extinction sessions in between. Rats received i.c.v. infusion of 10µg TCS1102 or its vehicle prior to each reinstatement session. Results: Central administration of 10 µg TCS1102 prior to self-administration had no significant effect on responding for nicotine. Reinstatement was precipitated by drug-associated cues, a priming injection of nicotine or a cue+prime compound. Compound reinstatement was significantly lower in TCS1102 treated animals relative to vehicle controls but there was no significant difference between the vehicle and TCS1102 treatment groups for cue-induced or nicotine-primed reinstatement sessions. Importantly, there was no effect on locomotor activity. Conclusion: The dual orexin antagonist, TCS1102, selectively reduced compound reinstatement over other nicotine-seeking and self-administration behaviours. This suggests that dual orexin antagonists, like the recently approved suvorexant, may have limited clinical utility for nicotine addiction.

Title: Effects of menthol on nicotine-taking and -seeking behavior in rat models of nicotine dependence: implications for tobacco product control policy making

Authors: *X. LIU, L. BISWAS, E. HARRISON, J. LEE;
Psychiatry and Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Tobacco smoking is a leading preventable cause of premature death in the US. Menthol is a significant additive in tobacco products. Clinical evidence suggests that menthol

may promote tobacco smoking and nicotine dependence. However, it is not clear whether menthol enhances the reinforcing actions of nicotine and thus facilitates nicotine consumption. Investigating how menthol influences nicotine-addictive behavior may provide important information for making policies to regulate tobacco products. This study employed rat models of nicotine use to examine effects of menthol on nicotine-taking and -seeking behavior. Male Sprague-Dawley rats were trained in daily 1-h sessions to press a lever for intravenous nicotine self-administration under a fixed-ratio 5 schedule. A nicotine-conditioned cue was established via association of a neutral sensory stimulus with each nicotine infusion. In the subsequent extinction sessions, responding was extinguished by withholding nicotine delivery. On the following day after extinction, reinstatement tests were performed. Menthol administration (5 mg/kg, intraperitoneal or intraoral) was given 5 min prior to sessions. The preliminary results showed that menthol increased self-administration of nicotine at 0.015 mg/kg/infusion, a dose on the ascending limb of the inverted "U" shaped nicotine dose-response curve. Continued administration of menthol sustained active lever responses in the extinction sessions. Moreover, re-administration of menthol after extinction effectively reinstated active lever responses. These data demonstrate a facilitative effect of menthol on nicotine-taking and -seeking behavior, suggesting that menthol in tobacco products may promote consumption of nicotine and contribute to the perseverance of tobacco-seeking behavior.

Title: Nicotine enhances responding for a conditioned reinforcer via α4β2 nicotinic acetylcholine receptors in the ventral tegmental area

Authors: *R. I. TABBARA[1,3], P. J. FLETCHER[1,3,2];
[1]Psychology, [2]Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [3]Biopsychology, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Environmental stimuli associated repeatedly with natural or drug reward can acquire incentive value and elicit reward-seeking behaviors. Nicotine, the main psychoactive component

in tobacco smoke, enhances the motivational properties of conditioned stimuli (CSs) previously paired with reward, such that rodents respond more for presentations of these CSs following exposure to nicotine. This enhanced responding suggests that these CSs function as conditioned reinforcers (CRfs) and that nicotine potentiates responding for CRfs. This work examined whether the response-enhancing effect of nicotine is mediated within the ventral tegmental area (VTA), as this dopamine cell body region has been heavily implicated in nicotine reinforcement. Male Long-Evans rats were implanted with a bilateral guide cannula aimed at the VTA. Next, thirsty rats received a nicotine injection (0.4 mg/kg; s.c.) prior to 12 sessions of Pavlovian conditioning. Each session consisted of 30 trials in which a 5-sec tone-light CS was paired with 0.05 ml of water. Tests for conditioned reinforcement were then conducted during which presses on a 'CR' lever produced the CS without the US, whereas presses on an 'NCR' lever had no consequences. To determine whether the enhancing effect of systemic nicotine on responding for a CRf is acting via the VTA, experiment 1 involved infusing the α4β2 nicotinic antagonist Dihydro-β-Erythroidine (DHβE; 10 nmol) into the VTA prior to a nicotine injection (0.2 mg/kg; s.c.) at test. Results indicated that nicotine systemically enhanced responding for a CRf and DHβE infused into the VTA selectively blocked the response-enhancing effect of nicotine. Next, to determine whether stimulation of nicotinic acetylcholine receptors (nAChRs) in the VTA is sufficient to enhance responding for conditioned reinforcement, experiment 2 involved infusing nicotine into the VTA at doses of 8, 16 or 32 nmol at test. Results indicated that nicotine infused into the VTA dose-dependently enhanced responding for a CRf, with the greatest enhancement produced at the 32 nmol dose. Together, these findings suggest that nicotine enhances the motivating properties of reward-paired CSs via α4β2 nAChRs in the VTA.

Title: Cotinine: a critical player in nicotine addiction?

Authors: *Z. DING, C. M. INGRAHAM, A. M. SENTIR, E. A. ENGLEMAN, R. A. CHAMBERS, W. J. MCBRIDE;
Indiana Univ. Sch. of Med., IPR, Neurosci. Res. Building, Indianapolis, IN

Abstract: Nicotine (NIC) addiction exerts an enormous heath and economic burden to both individuals and society. Limited effectiveness of current NIC-cessation treatments warrants development of new targets and therapeutics. Cotinine (COT) is the major metabolite of NIC and is mainly used as a bio-marker for NIC usage due to its long half-life. Limited research suggests that COT is biologically active. However, it remains unknown whether COT contributes to NIC effects. The objectives of this study were to test the hypotheses that COT itself can produce rewarding effects and COT interacts synergistically with NIC. Four experiments were conducted in the rat. The 1st experiment examined the rewarding effects of COT with an intra-venous (IV) self-administration procedure. The 2nd experiment tested the local rewarding effects of COT in the posterior ventral tegmental area (pVTA) with an intra-cranial self-administration (ICSA) procedure. The 3rd experiment used a microdialysis procedure to examine the effects of COT on the mesolimbic dopamine projections from the pVTA to the nucleus accumbens shell (NACsh). The 4th experiment used the ICSA procedure to examine the synergistic interaction of COT with NIC in the pVTA. The results demonstrate that: 1) rats readily acquired IV self-administration of COT (0.03 mg/kg/infusion, n = 5), responded significantly more on the active than inactive lever ($p < 0.05$). COT self-infusions gradually increased and reached approximately 0.9 mg/kg/session (~ 30 infusions / session) toward the end of the experiment. Blood COT levels immediately after the last session were 435 ± 110 ng / ml, which are within levels observed in human heavy smokers. 2) COT (0, 0.44, 0.88, 1.76 ng/100 nl/infusion, n = 3-5/group) was dose-dependently self-infused into the pVTA (10 ± 1, 11 ± 2, 26 ± 4 and 35 ± 8 infusions/session, respectively). In addition, lever discrimination was observed with the 2 higher COT concentrations. 3) Intra-pVTA microinjection of COT (1.76 ng/100 nl/infusion) significantly increased dopamine release in the NACsh by ~ 60-70% above baseline (n = 5). 4) A mixture of sub-threshold concentrations of COT (0.44 ng/100 nl/infusion) and NIC (0.16 ng/100 nl/infusion) was readily self-infused into the pVTA (~ 35 infusions/session), whereas each compound alone was not self-infused (9 - 11 infusions/session). Taken together, these results indicate that 1) COT produces its own rewarding effects; 2) activation of the mesolimbic dopamine system may mediate, at least in part, these effects; 3) COT and NIC interact synergistically to produce rewarding effects in the pVTA. Thus, COT may play a critical role in NIC reinforcement, abuse and addiction.

Title: Role for Tcf7l2 in regulating nicotinic acetylcholine receptor function and nicotine intake

Authors: *A. D. DUNCAN[1], M. P. HEYER[1], A. GEURTS[2], H. O'NEILL[3], P. J. KENNY[1]; [1]Mt. Sinai Sch. of Med., New York, NY; [2]Med. Col. of Wisconsin, Milwaukee, WI; [3]Univ. of Colorado Boulder, Boulder, CO

Abstract: Tobacco smoking is a major cause of premature death and disease, resulting in a significant economic burden on the United States healthcare system. Nicotine is the major psychoactive component of tobacco responsible for sustaining the tobacco smoking habit. Nicotine acts in the brain by stimulating neuronal nicotinic acetylcholine receptors (nAChRs). The positive reinforcing effects of nicotine are related to activation of high-affinity α4β2 nAChRs in the midbrain dopamine system. Conversely, aversive effects of nicotine are regulated by nAChRs containing α5, α3 and/or β4 subunits in medial habenula (MHb) neurons that project to interpeduncular nucleus (IPN), with these subunits highly enriched in the MHb-IPN circuit. The molecular mechanisms that restrict α5, α3 and/or β4 subunit expression to the MHb-IPN system, and the thereby control nicotine intake, are unknown. Here, we report that components of the Wnt signaling cascade, including Wnt glycoproteins, Fzd receptors and Tcf7l2, show remarkable enrichment in the MHb-IPN pathway in adult brain. We find that Wnt signaling is constitutively active in MHb neurons. Genetic disruption of Wnt signaling in the brains of rats, accomplished by genetic deletion of the Wnt transcription factor Tcf7l2, decreased α5 subunit gene expression in the MHb. Moreover, we found that nAChR-mediated transmission in the MHb and IPN were disrupted in the Tcf7l2 knockout rats, measured using 86Rubidium [86Rb+] efflux from synaptoneurosomes. As nAChR transmission in MHb and IPN is known to dependent largely on nAChRs that contain α5 subunits, these data further support a role for Wnt signaling in regulating nAChR function in the MHb-IPN system. Finally, we found that Tcf7l2 knockout rats consumed significantly more nicotine than their wildtype counterparts. Together, these data identify a key role for Wnt signaling, mediated through the transcription factor TCF7L2, in regulating the function of α5 subunit-containing nAChRs in the MHb-IPN system. Moreover, Wnt signaling in this system appears to play a key role in controlling the motivational properties of nicotine. *The first two authors contributed equally to this work

Title: Nicotine-induced behavioral sensitization is not affected by early-life methylphenidate exposure in adolescent male and female rats

Authors: S. SENG, A. SU, A. MCELROY, *A. R. ZAVALA;
Psychology, California State Univ., Long Beach, CA

Abstract: The long-term consequences of early use of methylphenidate (MPH) to treat ADHD in preschool age children are not fully understood. Preclinical studies suggest that MPH exposure during postnatal days (PD) 11-20, a period of rat development analogous to preschool age children, enhances the rewarding effects of morphine and the reinforcing effects of cocaine in adult rats. Surprisingly, the functional consequences of early MPH on other drugs of abuse commonly used during adolescence (e.g., nicotine) have not been examined. Thus, the present study examined whether MPH exposure modulates nicotine-induced locomotor sensitization in adolescent rats. Male and female rats were pretreated twice-daily with MPH (0 or 4 mg/kg, intraperitoneally) from PD 11-20. Beginning on PD 32, rats underwent daily nicotine injections (0, 0.2, or 0.6 mg/kg, subcutaneously) for 7 consecutive days, during which locomotor activity was recorded. On PD 40 all rats were then challenged with nicotine (0.2 mg/kg, intraperitoneally) and locomotor behavior was assessed. Nicotine increased locomotor activity and induced sensitization in all rats, but MPH pretreatment during PD 11-20 did not modulate the development of sensitization. The inability of MPH to enhance nicotine's sensitization effects may be due to modulation of different neurocircuitry associated with drug reward- from that of drug-induced locomotor behavior.

Title: Chronic nicotine exposure alters cue-evoked reward strategy in rats

Authors: *N. W. SIMON[1], C. C. PATTERSON[2], B. MOGHADDAM[2];
[1]Neurosci., [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Nicotine exposure enhances the salience of reward associated cues, which increases the prevalence of cue induced nicotine relapse. Therefore, it is important to understand how nicotine affects the behavioral patterns and neural processing induced by cue presentation. To begin to address this, we exposed rats to 16 days of repeated experimenter-administered nicotine at either a high dose (.3 mg/kg freebase concentration), low dose (.1 mg/kg), a reduced nicotine schedule (8 days of .3, 8 days of .1), or saline vehicle. Following this chronic nicotine exposure, rats were administered nicotine, then run in a Pavlovian conditioning task for 7 consecutive days. This task utilized a 10 second compound cue consisting of a light and extension of a lever directly beneath the light, followed by pellet delivery. We observed that the high-dose nicotine group preferred a "sign-tracking" strategy during the cue, reflected by increased contact with the lever. This strategy is typically indicative of enhanced cue incentive salience, and is correlated with increased sensitivity to drugs of abuse. Conversely, the saline vehicle group demonstrated a "goal-tracking" strategy during the cue, reflected by increased time in the food trough anticipating reward delivery. Surprisingly, both the low and reduced dose groups consistently failed to develop a strong preference for either behavioral strategy throughout training. To elucidate how nicotine influences the neural processing of reward cues, we are currently recording neuronal activity in orbitofrontal cortex during sign- and goal-tracking behavior following nicotine exposure. Collectively, these data will provide novel insight on both the role of nicotine in cue-evoked reward strategy and the neural correlates of sign- and goal-tracking behavior.

Title: Time-dependent nicotine-induced condition place preference in female and male adolescent rats

Authors: *K. HERNANDEZ[1], B. J. SALINAS[1], *N. SOLLENBERGER[1], S. E. FOX[1], S. D. IÑIGUEZ[2], N. S. PENTKOWSKI[3], A. R. ZAVALA[1];
[1]Psychology, California State University, Long Beach, Long Beach, CA; [2]Psychology, The Univ. of Texas at El Paso, El Paso, TX; [3]Psychology, Univ. of New Mexico, Albuquerque, NM

Abstract: Research investigating the rewarding properties of nicotine, using the condition place preference (CPP) paradigm, has produced varying results with the degree to which place conditioning is observed. One factor that may mediate these differences is the duration of the conditioning session post nicotine exposure, as studies employ 10-30 min conditioning sessions. Thus, the present study examined whether conditioning session length (15 vs. 30 min) results in varying expression of nicotine-induced CPP in female and male adolescent Sprague-Dawley rats. Specifically, rats were assessed for nicotine-induced CPP beginning on postnatal day (PD) 27 using a 14-day CPP procedure. On day 1, rats were habituated to the CPP apparatus by confining them to one side of the two chamber CPP apparatus for 7.5 min followed by immediate confinement to the other side for equal duration, with order of exposure counterbalanced. On days 2 and 14, rats were tested for their preconditioning and postconditioning place preferences, respectively, during 15-min sessions. On days 5-12, rats were conditioned for 15- or 30-minutes per day with either nicotine (0, 0.022, 0.067, 0.2 or 0.6 mg/kg, subcutaneously) or saline on alternating days. Days 3, 4, and 13 were rest days. Preliminary results reveal sex differences in the rewarding effects of nicotine in rats that were conditioned for 15 or 30 min, as well as differences in the strength of CPP between the two conditioning durations. Overall, these results suggest that the length of the conditioning sessions may be important in interpreting the rewarding effects of nicotine.

Title: One-trial nicotine-induced locomotor sensitization in male and female adult rats

Authors: *B. P. SCHUESSLER, A. SU, R. MERCER, A. R. ZAVALA;
Psychology, California State University, Long Beach, Long Beach, CA

Abstract: One-trial locomotor sensitization is the process by which a single exposure to a drug leads to a progressively higher locomotor behavioral response during a subsequent drug exposure. Adult rats readily exhibit one-trial locomotor sensitization to cocaine, but only within the context, or the environment where the initial drug administration took place. However, one-trial locomotor sensitization to nicotine has not been well characterized and little is known about potential sex differences. Thus, the present study examined sex differences in one-trial nicotine-induced locomotor sensitization. For the context-dependent condition, separate groups of male and female rats were injected with nicotine (0.6 mg/kg) immediately before being placed in a novel test chamber for 45 min on PD 75. Following pretreatment, rats were brought back to their home cage and after 45 min received a saline injection. For the context-independent condition, separate groups of male and female rats were injected with saline immediately before being placed in the novel test chamber, followed by an injection of nicotine (0.6 mg/kg) 45 min after being returned to their home cage. Control rats were injected with saline immediately before being place in the novel test chamber, followed by another injection of saline 45 min after being returned to their home cage. After 24 hours, rats from each pretreatment group were randomly assigned to receive a challenge injection of nicotine (0, 0.15 or 0.3 mg/kg, SC) immediately before being placed in the test chamber for 45 min. Results show that female rats exhibit nicotine-induced context-dependent locomotor sensitization, given that female rats pretreated with nicotine in the novel test chamber and challenged with either 0.15 or 0.3 mg/kg nicotine exhibited more robust locomotor responding compared to control rats and rats receiving nicotine for the first time during the challenge test day. Conversely, male rats failed to exhibit any nicotine-induced locomotor sensitization. The results demonstrate sex differences in nicotine-induced locomotor sensitization. These results are not in agreement with a recent study that demonstrated nicotine locomotor sensitization in male mice pretreated with nicotine and tested 7 days later with a challenge injection of nicotine. The number of days between the two nicotine injections may be an important factor mediating one-trial nicotine-induced sensitization in males.

Title: Effects of chronic stress on nicotine-seeking behavior and reinstatement

Authors: *J. J. CORTRIGHT, H. KLIMEK, M. ERB, A. MILLER, A. JANKE, T. HARMAN; Psychology, Univ. of Wisconsin River Falls, River Falls, WI

Abstract: Drug addiction is a major public health and serious economic concern in the United States costing taxpayers billions of dollars annually. Experimental evidence shows that exposure to stress is not only a factor in the development of addiction; but also a trigger for drug relapse, or reinstatement. As tobacco use has been linked to a number of cancers and represents the leading cause of preventable death in the United States, elucidation of the effects of stress on nicotine-seeking behavior and relapse is critical. A critical role of chronic stress in the compulsion to seek tobacco and other nicotine delivering products has long been suspected. Although many studies have provided compelling evidence for a role of chronic stress in the enhanced sensitivity to cocaine-seeking behavior and relapse, few have assessed the contribution of chronic stress on nicotine-seeking behavior. In fact, stress induced cross-sensitization to nicotine remains controversial. Additionally, there have been no studies investigating the effects of chronic stress on nicotine-seeking relapse, or reinstatement. Thus, these experiments assess the ability of repeated exposure to variable stress to augment nicotine-seeking behavior and relapse in an animal model of drug addiction. Male Long-Evans rats were exposed to variable stress that consisted of the exposure to different stressors twice a day in random order for 14 days. During this period the control group was left undisturbed except for cage cleaning. Rats were allowed to self-administer nicotine (0.03 mg/kg/infusion) under fixed ratio schedules of reinforcement across 15 consecutive daily sessions. Responding under a progressive ratio schedule of reinforcement was assessed over the following six daily sessions. This schedule allows for break points to be analyzed, a measure that reflects the motivation to self-administer nicotine. Following up to 20 days of extinction training, rats were tested for nicotine-seeking behavior reinstatement by a non-contingent injection of nicotine (0.4 mg/kg, IP). Rats exposed to chronic stress acquired nicotine self-administration at a faster rate relative to controls and exhibited enhanced motivation to obtain the drug. Further, we hypothesize that exposure to chronic variable stress will lead to resistance to nicotine self-administration extinction and

enhancements in nicotine-primed reinstatement, or relapse. Collectively, these findings indicate that chronic stress can enhance the motivational effects of nicotine.

Title: Predatory behavior predicts high motivation to self-administer nicotine in rats

Authors: *A. BROWN, E. WILLIAMS, C. A. BRADLEY, C. N. SWYMER, M. I. PALMATIER;
East Tennessee State Univ., Johnson City, TN

Abstract: The etiology of tobacco dependence derives from predispositional (i.e., genetic) and ontological (i.e., environmental) influences. Tobacco related death and illness may be prevented or reduced by determining predispositional factors that predict nicotine reinforcement and dependence. One method for investigating predispositional influences is by using phenotypic markers that correlate to drug reward - one of these is a tendency to engage in predatory behaviors in an artificial prey paradigm. In rats, predatory behavior is mediated by the same central nervous system circuits that become disregulated in substance dependence. We hypothesized that a 'high predation' endophenotype would be associated with increased nicotine self-administration. Predatory behavior was measured in 30 male Sprague Dawley rats in an 'artificial prey' chamber. The artificial prey item (marble) was allowed to roll through a trough in the chamber floor. The marble traversed the chamber in approximately 5 s and a sucrose reward (20% w/v) 5 s after the start of each trial. Predatory behavior was operationally defined as marble contacts and chasing and was measured during five sessions (12 trials per session). Third splits were used to separate the high and low predation groups (HPr and LPr, respectively) prior to nicotine self-administration. Both groups were then shaped to lever press in an operant chamber and subsequently instrumented for intravenous nicotine self-administration. There was no difference between HPr and LPr groups in acquisition of self-administration under a fixed ratio (FR) 1, 2, and 5 schedule of reinforcement. However, subsequent tests under a progressive ratio (PR) schedule, a measure motivation to obtain nicotine, the HPr's earned more infusions relative to the LPr's, indicating that predatory aggression is a predictor of the motivation to self-

administer nicotine. This expands the scope of endophenotypes associated with nicotine dependence to ethologically relevant behaviors that rely on midbrain dopaminergic function.

Title: Inhibition of aldehyde dehydrogenase-2 (ALDH-2) suppresses nicotine self-administration in rats

Authors: *A. H. REZVANI[1], M. P. AROLFO[2], M. GRAUPE[2], E. D. LEVIN[1], I. DIAMOND[2]; [1]Dept. of Psychiatry, Duke Univ., Durham, NC; [2]Gilead Sci., Palo Alto, CA

Abstract: ALDH-2 inhibitors have been shown to reduce cocaine and alcohol self-administration in rats by reducing drug-induced dopamine (DA) production in the VTA and DA release in the nucleus accumbens (Arolfo et al, 2009; Yao et al., 2010). The main goal of this study was to explore the potential of a selective ALDH-2 inhibitor for reducing nicotine self-administration. Rats were trained to self-administer nicotine intravenously (iv) via their jugular vein. After acquiring a stable baseline for nicotine self-administration, rats were given an oral administration of one of the three doses (5, 10 or 30 mg eq/kg, calculated based on parent drug) of the pro-drug GS-6637 or vehicle 1 hr before nicotine self-administration session. Results showed that the acute administration of GS-6637 at 10 and 30 mg eq/kg significantly reduced nicotine-self-administration when compared with vehicle treatment (46% and 67%, respectively). Similarly, chronic oral administration of GS-6637 for 7 consecutive days showed a significant effect by reducing nicotine self-administration at 10 and 30 mg eq/kg g (39% and 61 % inhibition, respectively) without the development of tolerance. In order to make a direct comparison with varenicline (Chantix®), one of the few therapies approved as an aid to smoking cessation , a separate group of animals was administered single doses of varenicline at 1.6, 3.2 and 6.4 mg/kg. Consistent with previous reports (Rollema et al., 2007), significant inhibitions of

nicotine self-administration was observed at the 3.2 and 6.4 mg/kg doses (52% and 49%, respectively). In conclusion, GS-6637 administered orally either acutely or chronically, can reduce nicotine self-administration without development of tolerance suggesting its promise as an aid for smoking cessation (Supported in part by NIDA P50 DA027840 and Gilead Sciences Inc.).

Title: Investigating risk and reward based decision making in nicotine dependent subjects

Authors: *L. E. CURLEY[1,2], R. R. KYDD[3,2], I. J. KIRK[4,2], B. R. RUSSELL[1], R. HESTER[5]; [1]Sch. of Pharm., [2]Ctr. for Brain Res., [3]Dept. of Psychological Med., [4]Sch. of Psychology, The Univ. of Auckland, Auckland, New Zealand; [5]Sch. of Psychological Sci., Univ. of Melbourne, Melbourne, Australia

Abstract: To date, studies investigating regional brain activation associated with risk-based decision making in drug users have not typically dissociated probability of risk from magnitude of reward, i.e. the increase in reward has been associated with an increase in the risk-associated decision. In addition, research investigating whether the outcome of a previous decision effects future decision-making has been limited. This study aimed to determine functional changes in response to risk in nicotine dependent participants using functional magnetic resonance imaging (fMRI). Two novel tasks were developed to investigate aspects of risk and reward-based decision making. The passive task attempts to dissociate probability of risk from magnitude of reward, by modulating the risk based on the difficulty of the task. The active (“choice”) task allowed

subjects to choose their own level of risk for each trial based on the monetary gamble that they select. Subjects could win or lose money which allowed the evaluation of whether outcome (i.e. whether subjects won or lost) affected future selection. Nicotine-dependent subjects and healthy control subjects, aged 18-40 years, underwent fMRI whilst completing these two tasks. Echo-planar images were collected using a Siemens 3.0 Trio scanner and were analysed using SPM8. Behavioural results (reaction time (RT) and accuracy) were compared between group using a oneway ANOVA in SPSS. The influence of previous outcomes on future decision making was also assessed. Regional brain activation was identified during the tasks when high risk trials were compared to low-risk trials. Data analysis showed a significant change in activation for the nicotine-dependent subjects in comparison to the controls in the medio-frontal regions. There were no significant differences in either RT or accuracy between groups. The effect of a positive or negative outcome on future decision-making was also different between nicotine-dependent subjects and controls. This study shows clear differences in functional activation in medio-frontal regions during the evaluation of risk between nicotine-dependent and healthy control subjects. The medio-frontal regions alongside the nucleus accumbens are affected by drugs of abuse and are involved in the development of drug-dependence. These findings in combination with the differences in reward selection after positive/negative feedback reflect changes in reward processing and decision-making in those with nicotine dependence.

Title: Nicotine reinforcement and relapse are prevented by pharmacological enhancement of kynurenic acid in rats and squirrel monkeys

Authors: ***M. SECCI**[1], A. AUBER[1], L. V. PANLILIO[1], G. H. REDHI[1], E. B. THORNDIKE[1], C. W. SCHINDLER[1], R. SCHWARCZ[2], S. R. GOLDBERG[1], Z. JUSTINOVA[1];

Abstract: Tobacco smoking remains one of the leading causes of illness and death in the United States. Current anti-smoking medications, such as bupropion and varenicline, have limited effectiveness and are associated with high rates of relapse. Therefore, there is a pressing need for newer, more effective treatment strategies. Recently, we demonstrated that enhancing brain levels of kynurenic acid (KYNA)_which is an endogenous neuroinhibitory product of tryptophan metabolism and an allosteric modulator of alpha-7 nicotinic receptors_selectively counteracts the abuse-related behavioral and neurochemical effects of cannabinoids. However, there have been no studies examining whether increasing endogenous levels of KYNA can decrease nicotine reinforcement and relapse to nicotine seeking after a period of abstinence. In the present study, we enhanced KYNA levels by administering the kynurenine 3-monooxygenase (KMO) inhibitor Ro 61-8048. We investigated the effects of this treatment on: (1) nicotine self-administration in squirrel monkeys and rats; (2) drug-induced and cue-induced relapse to nicotine-seeking behavior in abstinent rats and monkeys; and (3) nicotine-induced elevation of dopamine levels in the nucleus accumbens shell (NAcS) of freely-moving rats. In these experiments, enhancing endogenous KYNA levels blocked nicotine self-administration and attenuated nicotine-induced dopamine release in the NAcS. Moreover, it prevented relapse-like effects induced by re-exposure to either nicotine or cues that had previously been associated with nicotine. These findings suggest that KMO inhibition should be further investigated as a promising new approach for the treatment of nicotine addiction.

Title: Effects of single and repeated N-acetylcysteine on cue-induced nicotine-seeking behavior in rats

Authors: *F. MORO[1], G. GIANNOTTI[2], C. MARZO[1], A. DI CLEMENTE[1], F. FUMAGALLI[2], L. CERVO[1];
[1]Irccs-Mario Negri Inst. For Pharmacol. Re, Milan, Italy; [2]Dept. of Pharmacol. and Biomolecular Sci., Univ. of Milan, Milan, Italy

Abstract: The inability of smokers to control relapse to drug-seeking behavior is a key feature of nicotine addiction. A large body of evidence indicates that the cysteine pro-drug N-acetylcysteine (N-AC) may have beneficial therapeutic effects in the treatment of drug addiction. In humans, pilot studies have shown that N-AC decreases drug cues-induced craving for cocaine, number of cigarettes smoked, and marijuana use and craving. Pre-clinically N-AC reduced conditioned cues-induced cocaine- and heroin-seeking by restoring cystine-glutamate exchange system Xc- and the glial glutamate transporter GLT-1, normalizing extracellular glutamate in the nucleus accumbens (Nacc), thus blunting the activation of glutamatergic neurons associated with drug cues-induced reinstatement. Although nicotine-associated cues reinstate drug-seeking, it is still not clear whether N-AC can inhibit cue-induced reinstatement in abstinent rats after nicotine self-administration. It is also not clear whether restoring Glu homeostasis by chronic N-AC treatment can enhance the outcome of cue-exposure therapy (CET) for smoking cessation. To gain this information we used rats trained to associate discriminative stimuli (SDs) with intravenous nicotine or oral saccharin self-administration vs. no-reward in two-lever operant cages. Reinforced response was followed by cue signaling 20-second time-out (CSs). Re-exposure to nicotine or saccharin SD+/CS+, but not no-reward SD-/CS-, revived responding at the previously reinforced lever. A single dose of N-AC (100 mg/kg) induced a short-term reduction of cues-induced nicotine-seeking that was completely prevented by pre-treatment with the selective mGluR2/3 antagonist LY341495 (1 mg/kg i.p.). Chronic treatment with N-AC (100 mg/kg) during 14 days of CET, but not forced abstinence, induced lasting anti-relapse activity that was still present 50 days after the end of treatment. To provide a molecular mechanism underlying behavioral results, separate groups of rats that underwent nicotine self-administration and treated either with N-AC or vehicle in combination with CET were killed at different time points for molecular analysis. Interestingly, western blot analysis of brain punches containing Nacc-core and Nac-shell revealed that chronic N-AC reverted changes in the levels of the catalytic subunit of system Xc- and GLT-1 found in vehicle-treated rats. These results, provided they could be extrapolated to smokers, suggest the potential therapeutic use of N-AC for acute cue-controlled nicotine-seeking and to promote extinction of nicotine-cue conditioned responding.

Title: Effects of nicotine and minor tobacco alkaloids on intracranial-self-stimulation in rats

Authors: *A. C. HARRIS[1,2], L. TALLY[1], P. MUELKEN[1,2], A. BANAL[1,2], C. SCHMIDT[1,2], Q. CAO[2], M. LE SAGE[1,2];
[1]Med., Minneapolis Med. Res. Fndn., Minneapolis, MN; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: While nicotine is the primary addictive compound in tobacco, other tobacco constituents including minor alkaloids (e.g., nornicotine, anabasine) may also contribute to tobacco addiction by mimicking or enhancing the effects of nicotine. Further evaluating the behavioral effects of minor alkaloids is essential for understanding their impact on tobacco addiction and informing development of tobacco product standards by the FDA. This study compared the addiction-related effects of nicotine and the minor alkaloids nornicotine, anabasine, myosmine, anatabine, and cotinine on intracranial self-stimulation (ICSS) thresholds in rats. Acute injection of nicotine produced reinforcement-enhancing (ICSS threshold-decreasing) effects at low to moderate doses, and reinforcement-attenuating/aversive (ICSS threshold-increasing) effects at high doses. Nornicotine and anabasine produced similar biphasic effects on ICSS thresholds, although with lower potency compared to nicotine. Myosmine only elevated ICSS thresholds at relatively high doses, while anatabine and cotinine did not influence ICSS thresholds at any dose. None of the alkaloids significantly influenced ICSS response latencies, indicating a lack of nonspecific motoric effects. These findings indicate that some minor tobacco alkaloids can either fully (nornicotine, anabasine) or partially (myosmine) mimic nicotine's addiction-related effects on ICSS, albeit at reduced potency. These findings emphasize the need for further study of the abuse potential of minor alkaloids, including evaluation of their effects when combined with nicotine and other tobacco constituents to better simulate tobacco exposure in humans. Such work is essential for informing FDA regulation of tobacco products and could also lead to the development of novel pharmacotherapies for tobacco addiction.

Title: Effect of α4β2 and α3β4 nAChR-directed compounds on nicotine and alcohol co-addiction

Authors: A. CIPPITELLI[1], G. BRUNORI[1], N. T. ZAVERI[2], J. WU[1], M. GIULIANOTTI[1], C. ARMISHAW[1], *L. TOLL[1];
[1]Torrey Pines Inst. For Mol. Studies, Port Saint Lucie, FL; [2]Astraea Therapeut., Mountain View, CA

Abstract: Alcohol and nicotine addiction are highly co-morbid, indicating overlapping neural substrates. Recently, considerable interest has been attributed to the habenular/interpeduncular (MHb/IPN) cholinergic pathway, thought to play a role in nicotine addiction as well as addiction to other drugs of abuse. The MHb and IPN highly express nicotinic acetylcholine receptors (nAChR), particularly the α3β4 nAChR subtype, which is thought to be implicated in both nicotine and alcohol taking behaviors. Also, it has been proposed that the smoking cessation medication varenicline, commonly considered a α4β2 nAChR partial agonist, blocks alcohol self-administration by stimulating α3β4 nAChR. We examined the effect of α3β4 and α4β2 nAChR-directed compounds in an operant co-administration procedure in which rats concurrently self-administer nicotine (30 μg/kg through a jugular catheter) and alcohol (10% orally). The tested compounds were the α3β4 partial agonist AT-1001, the α4β2 partial agonist varenicline, TPI-202, a selective α4β2 antagonist; and TPI-2212-59, a selective α3β4 antagonist. Results demonstrated that the two α3β4 nAChR compounds, AT-1001 and TPI-2212-59, both attenuated nicotine self-administration at doses that did not alter alcohol self-administration whereas the α4β2 ligands, varenicline and TPI-202, both attenuated the self-administration of both reinforcers. When alcohol was used as the only reinforcer, AT-1001 was found to affect self-administration only at doses that also reduced food-maintained responding. However, a dose of AT-1001, which had no effect on alcohol or food self-administration (1.5 mg/kg), essentially eliminated reinstatement of alcohol seeking induced by yohimbine (0.625 mg/kg) whereas, reinstatement induced by alcohol-associated cues was not altered, nor did AT-1001 induce reinstatement of extinguished self-administration on its own. These data suggest that partial activation/functional inhibition at α3β4 receptors would primarily act on decreasing nicotine-reinforced behavior, while targeting α4β2 appears to modulate both alcohol and nicotine taking. However, α3β4 nAChR plays a role in mediating stress-related alcohol disorders.

Title: Behavioral and neural effects of cigarette craving regulation using a proximal/distal reappraisal strategy in young-adult smokers

Authors: C. M. COX, *D. G. GHAHREMANI, P. FAULKNER, E. D. LONDON;
Dept. of Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: Tobacco smoking is a leading preventable contributor to death and disease with an estimate of over 500,000 smoking-related, premature deaths in the U.S. alone. Craving for nicotine-containing products, such as cigarettes, is a major factor in the maintenance of use. Behavioral strategies to help with regulation of craving may be helpful for reducing cigarette smoking, yet remain underexplored. The current fMRI study uses behavioral and brain measures to examine craving regulation in young smokers. Fifteen, young-adult cigarette smokers (11 males, 18-25 years old), who abstained overnight from smoking, underwent fMRI scanning before and after smoking a cigarette. We adapted a regulation strategy, often used in emotion regulation studies and based on proximal/distal self-positioning, to the context of cigarette craving. Prior to viewing video clips of people either smoking cigarettes (smoke) or not smoking (non-smoke), participants were instructed to either imagine themselves immersed in the scene, allowing themselves to experience any sensations that arose ("close", i.e., reactivity), or to imagine themselves at a distance from the scene ("far", i.e., regulation), making factual, objective observations of the content of the scene (e.g., indoors/outdoors). Participants rated their craving after each video. Behavioral results indicated main effects of smoking, proximity (close/far), and video type (smoke/nonsmoke videos) on cue-elicited craving – lower craving ratings were given after smoking, following the "far" versus "close" instructions, and viewing the non-smoke versus smoke videos. For the far-versus- close contrast (index of regulation), fMRI activation was greater after smoking a cigarette in brain regions associated with cognitive control, including right inferior frontal gyrus, bilateral anterior insula, anterior cingulate, bilateral putamen, and bilateral posterior parietal cortex. These preliminary results suggest that reappraisal strategies have an impact on cue-elicited self-reported craving, and that smoking a cigarette after a period of abstinence may increase capacity for neural processes related to cognitive control that are important for craving regulation.

Title: D1 and D2 receptors in the infralimbic and medial orbitofrontal cortices differentially mediate the reinstatement of cocaine seeking in rats

Authors: ***C. V. COSME**, A. L. GUTMAN, A. PEPPLES, R. T. LALUMIERE;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Prior work indicates that the medial prefrontal cortex (mPFC) plays a crucial role in mediating drug-seeking behaviors. Specifically, the infralimbic cortex (IL) within the mPFC has been shown to suppress cocaine-seeking behaviors. Despite the established dopaminergic innervation of this structure, the specific role that infralimbic dopamine plays in mediating the reinstatement of cocaine seeking is unknown. Moreover, whether the medial orbitofrontal cortex (mOFC), a separate, more anterior region of the mPFC, regulates cocaine-seeking behaviors is not clear. Thus, the current set of experiments examined whether D1 or D2 receptor activation within the IL and the mOFC is involved in cocaine seeking during a variety of reinstatement tests. Male Sprague-Dawley rats underwent surgery for implantation of bilateral cannulas aimed at either the mOFC or the IL and insertion of an intravenous jugular catheter. After recovery, all animals underwent cocaine self-administration training for at least 12 days (2 h daily) followed by extinction training for a minimum of 7 days. After rats met extinction criteria, reinstatement testing began, which consisted of cued, cocaine-prime, and cue + cocaine-prime reinstatement tests. Immediately prior to reinstatement testing, rats received microinjections of the D1 antagonist SCH 23390, the D2 antagonist sulpiride, or their respective vehicles. Results indicated that D1 receptor blockade in the IL reduced cued reinstatement but had no effect on cocaine-prime and cue + cocaine-prime reinstatement. In contrast, D1 receptor blockade in the mOFC resulted in a blockade of all 3 reinstatement types. Additionally, blocking D2 receptors in the mOFC had no effect on any reinstatement type. Ongoing experiments have found that D2 receptor blockade in the IL reduces cocaine-prime reinstatement. These findings suggest that D1 receptor activation in the mOFC is required for all types of reinstatement examined whereas, in

the IL, such activation is involved in cued, but not cocaine-prime, reinstatement. Additionally, although D2 receptor blockade in the mOFC had no effect on cocaine-seeking behaviors, blocking these receptors in the IL appears to alter cocaine-prime reinstatement. Moreover, in contrast to previous work suggesting that IL activity is involved in suppressing cocaine seeking, our findings suggest that D1 and D2 receptor activation in the IL promotes cocaine seeking. Ongoing studies will further elucidate the role of D2 receptors in the IL to determine whether D1 and D2 receptors within the IL play discrete roles in mediating cocaine-seeking behaviors.

Title: Optogenetic inhibition of the infralimbic cortex following unreinforced lever presses increases cocaine seeking in rats

Authors: *A. L. GUTMAN[1], C. V. COSME[1], R. VASQUEZ[2], R. T. LALUMIERE[1]; [1]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA; [2]Psychological and Brain Sci., rachel-vasquez@uiowa.edu, Iowa City, IA

Abstract: The infralimbic cortex (IL), a region of the medial prefrontal cortex, is a component of the neural circuitry that mediates extinction learning and the active suppression of cocaine-seeking behavior. IL inactivation and activation immediately after extinction training impairs and enhances, respectively, the retention of extinction learning for cocaine seeking. However, the precise temporal relationship between IL activity, lever pressing, and extinction learning is unclear. Therefore, we examined whether selective IL inhibition immediately following each unreinforced lever press during extinction affected ongoing and subsequent cocaine-seeking behavior. The light-sensitive outward proton pump eArchT3.0 was selectively expressed in glutamatergic pyramidal neurons by injecting the adeno-associated virus encoding for eArchT3.0 under the CaMKIIα promoter bilaterally into the IL of male Sprague-Dawley rats. Rats underwent a minimum of 12 days of cocaine self-administration, during which each active (right) lever press resulted in an infusion of cocaine and the presentation of a light and tone cue. After

each right lever press, the lever was retracted for 20 s. Rats then underwent 5 days of shortened (30 min) extinction sessions, during which active lever presses did not produce cocaine infusions or cues. During these shortened extinction sessions, the IL was optically inhibited for 20 s following each unreinforced active lever press. This was followed by 7 days of full-length (2 hr) extinction sessions that served as retention tests for the extinction learning. Optical inhibition increased active lever pressing during the 5 sessions in which the inhibition occurred but had no effect on lever pressing during the 7 full-length extinction sessions. In a control experiment, similar 20-s periods of optical inhibition were provided, but in a manner not contingent upon lever pressing. In this case, IL inhibition did not increase lever pressing during the session itself or on the subsequent extinction sessions. Following extinction, rats underwent cue-induced reinstatement tests, in which active lever presses resulted in the delivery of a light and tone cue but no optogenetic manipulations were given. Rats that had received IL inhibition during extinction showed potentiated cue-induced cocaine seeking, whereas rats that had received non-contingent IL inhibition did not show any change in cue-induced reinstatement. These results suggest that IL activity immediately following an unreinforced lever press contributes to the suppression of ongoing cocaine-seeking behavior and is important for the suppression of subsequent cue-induced reinstatement.

Title: Glucagon-like peptide-1 receptor activation in the ventral tegmental area or the nucleus accumbens attenuates cocaine seeking in rats

Authors: *N. S. HERNANDEZ, E. G. MIETLICKI-BAASE, J. J. MAURER, D. S. VAN NEST, M. R. HAYES, H. D. SCHMIDT;
Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Glucagon-like peptide-1 (GLP-1) receptor signaling in the CNS is pharmacologically and physiologically relevant for energy balance control. The GLP-1 receptor agonist exendin-4 decreases intake of palatable food when administered into the ventral tegmental area (VTA) and nucleus accumbens (NAc) core. Since the VTA and the NAc mediate the reinforcing effects of food and drugs of abuse, we hypothesized that GLP-1 receptor activation in these two nuclei would attenuate cocaine reinstatement, an animal model of relapse in human addicts. Initially, rats were allowed to self-administer cocaine (0.25 mg/infusion i.v.) for 21 days on a fixed-ratio 5 (FR5) schedule of reinforcement. Cocaine self-administration was then extinguished by replacing cocaine with saline. Once cocaine taking was extinguished, rats received an acute priming injection of cocaine (10 mg/kg, i.p.) to reinstate cocaine-seeking behavior. During subsequent reinstatement test sessions, rats were pretreated with intra-cranial infusions of the GLP-1 receptor agonist exendin-4 (0, 0.005 and 0.05 μg) prior to a priming injection of cocaine. Here, we show that administration of exendin-4 directly into the VTA, NAc core or NAc shell dose-dependently attenuated cocaine priming-induced reinstatement of drug-seeking behavior. To determine if the suppressive effects of exendin-4 in the VTA and NAc on cocaine seeking were due to drug-induced motor impairments, we also examined the effects of intra-cranial exendin-4 infusions on the reinstatement of sucrose seeking. Administration of exendin-4 directly into the VTA, NAc core or NAc shell had no effect on sucrose reinstatement. Taken together, these results indicate that increased activation of VTA and NAc GLP-1 receptors is sufficient to reduce cocaine seeking and that these effects are not due to general motor suppressant effects of drug treatment. Thus, these findings support re-purposing GLP-1 receptor agonists, which are FDA-approved for treating diabetes type II and obesity, for treating cocaine addiction.

Title: Hippocampal inputs to lateral septum drive context-induced, but not cue-induced cocaine seeking

Authors: *E. M. MCGLINCHEY[1,2], G. ASTON-JONES[2];
[1]Neurosciences, Med. Univ. of South Carolina, Charleston, SC; [2]Brain Hlth. Inst., Rutgers University/Rutgers Biomed. and Hlth. Sci., Piscataway, NJ

Abstract: Stimuli associated with drug experiences can trigger relapse in drug addicts. Drug-associated contexts and discrete drug cues initiate relapse by activating distinct brain regions. However, neural circuits distinctly involved in these different relapse modalities have not been fully characterized. Using a modified self-administration model, all rats self-administered cocaine with light/tone cues in one context, extinguished this behavior in an alternative context (without light/tone cues), and reinstated in either the training context without light/tone cues (context reinstatement, ABA) or in the extinction context with light/tone cues (cued reinstatement, ABB) to dissociate context vs. cued reinstatement of cocaine seeking. We then used Fos expression as a marker of neural activation in brain regions, a retrograde tracer combined with Fos to determine activated circuits, and pharmacologic and chemogenetic approaches to examine the role of hippocampal inputs to lateral septum (LS) in these reinstatement modalities. Based on the involvement of the hippocampus in contextual processing, its dense projections to LS, and previous results from our lab showing a functional CA3-LS-VTA circuit, we hypothesized that this circuit is important specifically for context-induced cocaine seeking, but not seeking driven by discrete cues. Results revealed that both dorsal hippocampus (CA1, CA3, and dentate gyrus) and LS (caudal and rostral LS) expressed a greater number of Fos cells during context compared to cued reinstatement. Furthermore, a greater percentage of CA3 neurons that project to LS express Fos during context compared to cued reinstatement or extinction, indicating this circuit is specifically activated during re-exposure to drug-associated contexts. Interestingly, pharmacological inhibition of LS attenuated both context and cued reinstatement. We then used DREADDs (Designer Receptors Exclusively Activated by Designer Drugs) to specifically inhibit hippocampal (CA3) terminals in LS. Inhibitory (hM4Di) DREADDs virally transduced into CA3 were transported to terminals in LS and activated by local microinjections of the ligand clozapine-N-oxide (CNO). Inhibition of hM4Di-expressing CA3 terminals in LS attenuated context, but not cued reinstatement. Together these findings highlight the importance of LS in cocaine-seeking behavior, and that hippocampal inputs to LS drive context-induced reinstatement, whereas other inputs to LS likely drive cue-induced reinstatement. Elucidating the circuitry involved in different relapse modalities will identify therapeutic targets for specific relapse triggers in recovering drug addicts.

Title: Drug seeking during initial abstinence is driven by hippocampal β-adrenergic and serotonergic receptors in a sex-dependent manner

Authors: *A. S. KOHTZ[1], A. CASON[2], G. ASTON-JONES[1];
[1]Neurosci., Brain Hlth. Inst., Piscataway, NJ; [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: Studies indicate that female rats exhibit greater drug seeking than male rats during initial drug abstinence. Moreover, females are more sensitive to the effect of stress to drive drug seeking than males. Locus coeruleus norepinephrine (LC-NE), dorsal raphe serotonin (DR-5HT) and corticotropin releasing factor (CRF) neurons are involved in stress responses, including the ability of stress to drive drug relapse. Notably, LC-NE neurons are more sensitive to CRF in females compared to males, and conversely, DR-5HT neurons are more sensitive to CRF in males compared to females. Dorsal hippocampus (DH) is a prominent focal point in the stress response that receives strong inputs from both LC-NE and DR-5HT neurons. DH has a number of structural and biochemical sex differences that modulate stress responsivity, including substantial differences in CRF receptor binding affinity, de novo serotonin synthesis, cholinergic enzyme activity as well as adrenergic, corticosterone, and GABA receptor expression. Notably, DH is required for context-dependent reinstatement of drug seeking, and drug relapse often occurs when addicts are re-exposed to drug-associated contexts. Thus, we hypothesized that β-adrenergic and serotonergic neurotransmission in DH is involved differentially in male and female rats in drug seeking during extinction day 1 (ED1), i.e., the initiation of abstinence when animals are re-exposed to the drug-associated context. Drug-seeking during this initial abstinence test was decreased by S-propranolol (β-adrenergic and 5-HT1A/1B receptor antagonist), R-propranolol (5-HT1A/1B receptor antagonist), and racemic (R/S mixture) propranolol in both male and female rats (10mg/kg, IP). We observed that hippocampal, locus coeruleus, and dorsal raphe Fos expression was increased on ED1 in both male and female rats, and that hippocampal Fos was decreased by systemic S-propranolol. Utilizing intrahippocampal infusions of S-propranolol, a Betaxolol/ICI-118,551 cocktail (selective β-adrenoceptor antagonists, β-AR), or a WAY-100635/GR-127935 cocktail (5-HT1a & 1b receptor antagonists), we investigated the role of hippocampal 5-HT and β-adrenergic neurotransmission in ED1 drug-seeking behavior. ED1 responding was reduced by 5-HT but not β-AR antagonists in males, and reduced by both 5-HT and β-AR antagonists in females. Thus, drug seeking during initial abstinence requires hippocampal 5-HT and β-AR neurotransmission in females, but only 5-HT neurotransmission in

males. Additional studies are underway to test if manipulations of hippocampal serotonergic or adrenergic systems during ED1 influences later relapse to cocaine seeking.

Title: Attenuation of orexin/hypocretin signaling decreases cocaine seeking and increases cocaine taking in rats with a history of self-administering cocaine and ethanol

Authors: *B. A. ZIMMER, G. ASTON-JONES;
Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: Abuse of psychostimulants such as cocaine has a high comorbidity with heavy use of alcohol with 85-88% of cocaine-dependent individuals engaging in co-use of alcohol. Such co-use is problematic given findings that the alcohol-cocaine combination is the most common substance use pattern reported in emergency rooms. The prevalent co-abuse of alcohol and cocaine leads us to hypothesize that alcohol abuse aggravates cocaine abuse, and facilitates the transition to cocaine addiction. Male, Sprague-Dawley rats were initially trained to drink ethanol in their home-cage using the intermittent access (IA) paradigm in which liquid ethanol (20%) was available every other day. Following two weeks of IA, subjects were trained to self-administer cocaine on a within-session threshold behavioral economics (BE) procedure. A median split was performed on voluntary drinking behavior to sort animals into high drinkers (HD) and low drinkers (LD). Results showed that HD rats had significantly higher baseline demand elasticity for cocaine, indicating lower motivation to self-administer cocaine relative to the LD rats. Over time this difference between groups decreased, such that initial LD rats maintained the same demand elasticity for cocaine, whereas HD rats decreased their cocaine demand elasticity (increased motivation) over the course of the experiment. These results imply that HD rats are initially resistant to cocaine, but with repeated exposure to both cocaine and ethanol this demand for cocaine increases. We hypothesize that this may reflect trait differences

in anxiety that are mitigated by alcohol consumption over time. To assess the roles of orexin signaling in free consumption and motivation for cocaine in cocaine-alcohol exposed subjects, rats from the above experiment were given an i.p. injection of the orexin 1 receptor antagonist SB334867 (30 mg/kg) 30 min prior to a cocaine BE self-administration test session. Results showed a significant increase in cocaine demand elasticity indicating a significant decrease in motivation for cocaine. Interestingly, a significant increase was also found in cocaine free consumption, indicating an increase in the desired level of cocaine in brain, or hedonic set point. These results indicate that attenuation of orexin signaling decreases motivation for cocaine (as observed previously in cocaine-only subjects) but increases cocaine free (low effort) consumption. Thus, alcohol plus cocaine exposure elicits adaptations in the orexin system not seen in subjects exposed to cocaine alone. Possible clinical implications of these adaptations deserve further study. Title: Long access self-administration increases cocaine demand: Dependence on orexin 1 receptor signaling

Authors: *C. M. STOPPER, G. ASTON-JONES;
Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: Orexin/hypocretin plays a key role in stimulus-driven drug-seeking. Blockade of the orexin 1 receptor (Ox1R) impairs cue-, context-, and stress-induced reinstatement. Using a novel behavioral economics procedure, our lab recently demonstrated that the selective Ox1R antagonist SB-334,867 decreases demand for cocaine, but only in high-demand animals trained with drug-paired cues (Bentzley & Aston-Jones, 2015). These results highlight the contribution of orexin to trait-based motivation for cocaine. Yet, cocaine dependence often results from state factors, rather than innate individual variations. The current experiment uses this rationale to test if Ox1R antagonism can also attenuate motivation for cocaine in rats exhibiting escalated intake following long access self-administration. Male Sprague-Dawley rats were implanted with

jugular catheters for i.v. cocaine self-administration. After initial FR1 self-administration training, subjects were trained until stable on the behavioral economics demand procedure (Bentzley et al., 2013). Rats were then trained for 14 days on long access (LgA; 6 Hrs) or short access (ShA; 1 Hr) FR1 self-administration. Following LgA or ShA self-administration, rats were given counterbalanced systemic injections of vehicle or two doses of the Ox1R antagonist SB-334,867 (SB; 10 and 30 mg/kg). Animals then went through extinction training followed by reinstatement tests with SB. As has been previously observed, LgA self-administration caused escalation of cocaine intake, particularly in the first hour. LgA also decreased demand elasticity and increased free consumption of cocaine (alpha and Q0 parameters), reflecting increased motivation and desired brain level for cocaine, respectively. SB altered these cocaine demand parameters in a dose-dependent fashion, towards pre-LgA values. These results demonstrate that the OxR1 is necessary for elevated cocaine demand following long access escalation. Whereas previous data from our lab show that OxR1 antagonism attenuates cocaine demand in animals with innate "trait-based" demand, the findings of the current experiments indicate that OxR1 blockade also decreases "state-based" demand following prolonged cocaine exposure. These findings have translational implications for cocaine addiction, wherein extended use triggered by environmental factors leads to a state of dependence that is difficult to treat. As LgA cocaine self-administration is anxiogenic and OxR1 blockade is known to be anxiolytic, we hypothesize that OxR1 blockade decreased cocaine demand by decreasing the anxiety involved in escalation of intake.

Title: Effects of central and peripheral oxytocin on reinstated cocaine seeking in male and female rats

Authors: *L. R. FREEMAN[1], K.-C. LEONG[2], S. M. GHEE[2], C. R. BERINI[2], T. A. STUBBS-STROUD[3], B. M. BROWN[3], M. C. AMEY[3], C. M. REICHEL[2];

[1]Biol. and Neurosciences, Furman Univ., Greenville, SC; [2]Med. Univ. of South Carolina, Charleston, SC; [3]Col. of Charleston, Charleston, SC

Abstract: Background: Oxytocin has gained increasing attention as a possible treatment for multiple neuropsychiatric disorders, including addiction. Oxytocin impacts natural and drug reward due to extensive innervation of central reward pathways. Sex differences clearly exist in psychostimulant addiction patterns. However, the underlying neurobiology and potential addiction therapies have typically only been studied in males. The oxytocin system is sexually dimorphic with a greater number of oxytocin receptors expressed throughout the addiction circuit in males relative to females. Here, we determined that oxytocin decreased reinstated cocaine seeking in males and females following systemic oxytocin treatment. We are currently investigating effects of intracerebroventricular (icv) administration of oxytocin with this paradigm. Methods: Male and female rats underwent 2 weeks of cocaine self-administration followed by extinction and reinstatement tests after systemic (1 mg/kg, i.p.) oxytocin or vehicle treatment in the presence of conditioned cues. Following testing, rats were perfused and the brains were processed for c-Fos staining and c-Fos/oxytocin double-labeling in the paraventricular nucleus of the hypothalamus (PVN). A separate group of rats received oxytocin treatment during extinction and were tested with vehicle or oxytocin in response to cocaine-conditioned cues. Results: An acute oxytocin injection (i.p.) reduced reinstated cocaine seeking in both males and females. Likewise, repeated oxytocin during extinction also reduced responding on a cue test in males and females. However, oxytocin during extinction had no lasting impact on a cued reinstatement test. Currently, we are double labeling c-Fos and oxytocin cell bodies in the PVN to determine whether oxytocin reduced reinstated cocaine seeking via similar mechanisms. To date, we found males have a higher number of oxytocin and Fos-positive neurons in the PVN relative to females. Additionally, we are quantifying c-Fos expression in terminal areas. Discussion: Oxytocin impacted reinstated cocaine seeking similarly in both sexes. This similarity is in contrast to the well-known sex differences in the role of oxytocin on peripheral organ sites of actions and the sexually dimorphic distribution of central oxytocin receptor cites in females, relative to males. This study will determine if similar behavioral outputs may be mediated by a different underlying neurobiology.

Title: Treatment with the M1-selective muscarinic antagonist trihexyphenidyl attenuates cocaine-reinforced behavior

Authors: *K. W. GRASING, F.-C. YANG;
Kansas City Veterans Affairs Med. Ctr., Kansas City, MO

Abstract: Medications that modify cholinergic tone can have pronounced effects on behaviors reinforced by natural and drug reinforcers. Systemic treatment with M1-preferential muscarinic agonists decreases self-administration across a broad range of cocaine doses. In contrast, M1-selective antagonists can enhance the discriminative-stimulus effects of cocaine. When administered with cocaine, M1 antagonists can potentiate increases in dopamine in the nucleus accumbens shell but not the core or prefrontal cortex. The present study examined effects of the M1-preferential muscarinic antagonist trihexyphenidyl (TXP) on cocaine- and food- reinforced behavior. METHODS: Rats were trained to respond for either cocaine or liquid food under a fixed-ratio-5 (FR-5) schedule during two-hour multiple-component sessions. Across components, either cocaine dose (0.1, 0.2, and 0.4 mg/kg per injection) or amount of 20% liquid food (30, 60, or 120 µl) was varied. Pretreatment with TXP was administered intraperitoneally at low, intermediate, or high doses (1.0, 3.2, or 10 mg/kg-injection). RESULTS: TXP decreased cocaine-reinforced responding by 10 to 30% relative to baseline, with similar actions at different doses of TXP, as well as different cocaine doses. Responding for 30 µl of liquid food was attenuated by high-dose TXP, but was otherwise unaffected. TXP increased spontaneous sniffing, rearing, and digging; without modifying inactive lever responding under any of the conditions tested. CONCLUSION: TXP can decrease drug self-administration across a broad, 10-fold range of cocaine doses. Effects on spontaneous behavior are less pronounced than for cholinergic agonists, and include increases in some normally observed scored behaviors. These behavioral effects may be mediated by increases in dopamine in the nucleus accumbens shell.

Title: Pathological persistence of the brain response to "unseen" 33 msec cocaine cues as a marker of relapse vulnerability

Authors: *A. R. CHILDRESS[1], K. JAGANNATHAN[1], Z. MONGE[1], J. SUH[1,2], K. YOUNG[1], P. REGIER[1], T. FRANKLIN[1], D. LANGLEBEN[1,2], Z. WANG[1], Z. LI[1], K. KAMPMAN[1,2], R. WETHERILL[1], R. EHRMAN[1,2], M. GAWRYSIAK[1], R. SZUCS-REED[1], C. P. O'BRIEN[1]; [1]Dept Psychiat, Univ. PENN Perelman Sch. Med., Philadelphia, PA; [2]Mirecc, Philadelphia Dept. of Veteran's Affairs Med. Ctr., Philadelphia, PA

Abstract: Aims: Our laboratory has shown that even "unseen" (subliminal) 33 msec drug cues can trigger the brain's subcortical motivational circuitry. Does this early brain response to drug cues constitute a relapse vulnerability? In a new cohort of treatment-seeking cocaine patients, we are examining whether the "pathological persistence" of the brain response to cocaine cues is linked to poor clinical outcome.**Methods:** In a "fast" event-related BOLD fMRI paradigm, cocaine inpatients were exposed to cocaine-related and to comparison (sexual, aversive and neutral) cues of 33 msec duration. Each cue (48 presentations of each cue category) was "backward-masked" by a 467 msec neutral stimulus to prevent conscious recognition. Pre-planned contrasts to characterize "persistence" (comparing the brain response during the first half vs. the second half of the task, for each cue category) were calculated within SPM 8 for two outcome subgroups "GOOD" ($\leq$30% cocaine-positive urines, n=9) vs. "POOR" (>90% cocaine-positive urines, n=15).**Results:** As hypothesized, cocaine patients with "POOR" clinical outcome evidenced a greater (e.g., drug2 > drug1; $p<0.05$) response to 33 msec cues in the **second** half of the task, for 3 (cocaine, aversive and neutral) of the 4 cue categories – among *a priori* limbic regions, this "persistence" was reflected in amygdala/v. pallidum, and in temporal pole. "GOOD" outcome patients lacked this pattern. **Conclusions:** The current data highlight the relapse relevance of the early brain response to "unseen" cues": patients with POOR outcome had cue-triggered brain responses that tended to persist -- despite the multiple, unreinforced presentation of the cues. "Pathological persistence" may be a sensitive predictor of relapse, complementing conventional "magnitude" measures in BOLD fMRI. These findings underscore the potential utility of the "unseen" cue paradigm, both as a tool for screening anti-relapse medications and for identifying the "cue-vulnerable" patients who need these medications most.

Title: The group 1 metabotropic glutamate receptors regulation of cocaine seeking is receptor-selective and intake-dependent: Role of anatomical substrates

Authors: *M. GHASEMZADEH, P. HEASLIP, R. DIDOMINICIS, M. VUONCINO, C. SZEWCZYK, J. MANTSCH;
Dept Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: A major obstacle in the treatment of addiction has been the propensity to relapse, often mediated by drug-associated cues, even after prolonged period of abstinence from drug use. Repeated exposure to cocaine leads to enduring alterations in glutamatergic signaling in the brain reward circuitry that play an important role in long-lasting molecular, cellular and behavioral neuroadaptations. Therefore, glutamate signaling has been investigated as a target for the development of treatment for addiction. Recent studies have suggested that the group I metabotropic glutamate receptors (mGluR1/5) play important roles in drug reinforcement and seeking and, therefore, have been pursued as promising targets for drug development. Here, we examined the role of mGluR1/5 receptors in abstinence drug seeking using animal models of cocaine self-administration. Sprague-Dawley rats were trained to self-administer cocaine (FR1; 1.0 mg/kg/200 µl/inf) during either 2-hr (ShA) or 6-hr sessions (LgA) for 14 days. Subsequently, animals were left undisturbed in home cage for 3, 10, or 60 days. Following abstinence period, rats were tested under extinction condition for cocaine seeking after either saline or an mGluR1/5 receptor antagonist administration (MTEP or JNJ16259685). Following a short abstinence period (3 or 10 days), the blockade of mGluR5 receptor reduced drug seeking only in ShA subjects without affecting the LgA animals, while mGluR1 receptor blockade were equally effective in reducing drug seeking in both groups. However, after a long abstinence period (60 days), the blockade of either of receptors significantly reduced drug seeking in ShA and LgA rats.

Furthermore, mGluR5 blockade was effective in reducing drug taking (cocaine self-administration) in a dose dependent manner by ShA subjects but not by LgA animals. The results suggest that exposure to cocaine produced a transient intake dependent plasticity in mGluR5 signaling in the brain. The observed plasticity is specific to mGluR5 signaling since blockade of mGluR1 receptors reduced drug seeking similarly in both ShA and LgA animals. In order to identify the anatomical substrates contributing to the selective modulation of mGluR5 signaling, site-specific blockade of mGluR5 receptors in the nuclei of motive circuit will be performed. The selective, intake dependent, and transient plasticity in brain mGluR5 signaling mediated by exposure to cocaine suggest an important role for mGluR5 in cocaine mediated neuroadaptations and addiction behaviors. Understanding the mechanism of cocaine mediated effects may reveal new molecular targets for therapeutic development for the treatment of cocaine addiction.

Title: Orexin-A/hypocretin-1 in the paraventricular nucleus of the thalamus fails to reinstate cocaine-seeking behavior in animals with a history of cocaine dependence following a prolonged period of abstinence

Authors: *A. MATZEU, F. WEISS, R. MARTIN-FARDON;
The Scripps Res. Inst., La Jolla, CA

Abstract: Growing evidence implicates a role for orexin/hypocretin (Orx/Hcrt) neurons originating in the lateral hypothalamus (LH) and projecting to the paraventricular nucleus of the thalamus (PVT) in drug addiction. We previously reported that intra-PVT administration of orexin-A/hypocretin-1 (Orx-A/Hcrt-1) after 2 weeks of abstinence from cocaine or sweetened condensed milk (SCM) self-administration reinstated (primed) cocaine-seeking behavior in animals with short cocaine access (ShA, 2 h/day) or long cocaine access (LgA, 6 h/day, an

animal model of cocaine dependence), as well as SCM seeking-behavior, but with different dose-response profiles. Specifically, in LgA rats a left-upward shift of the dose-response function compared with SCM group and an upward shift compared with the ShA group were observed. This suggests that a history of cocaine dependence leads to neuroadaptive changes at the level of the PVT, resulting in the "sensitization" of PVT-Orx/Hcrt transmission, reflected by increased sensitivity (i.e., a leftward shift) and exacerbated behavioral responses (i.e., an upward shift) to the to the effects of Orx-A/Hcrt-1. The present study's aim was to investigate whether the intra-PVT priming effect of Orx-A/Hcrt-1 is preserved following 4 weeks of abstinence in animals that had a cocaine self-administration history. Male Wistar rats were trained to self-administer ShA cocaine, LgA cocaine, or SCM for a total of 21 days. After completion of the training procedure, the animals were maintained in their home cage for 2 weeks and then subjected to extinction training for 2 weeks (2 h/day). The following day, the rats received intra-PVT microinjections of 0.5 μg Orx-A/Hcrt-1 (a dose that produced equivalent reinstatement at 2 weeks of abstinence in all groups), or the respective vehicle, and then placed into operant chambers under extinction conditions for 2 h. At 4 weeks of abstinence, intra-PVT Orx-A/Hcrt-1 produced reinstatement of both SCM and ShA that was identical to what was observed at 2 weeks of abstinence. Surprisingly, Orx-A/Hcrt-1 did not trigger cocaine-seeking behavior in LgA rats. The data suggest that following cocaine dependence (i.e., LgA), functional changes in PVT Orx/Hcrt transmission occurred, reflected by a change in the pharmacological profile of Orx-A/Hcrt-1 at 2 weeks ("sensitization" to the effects of Orx-A/Hcrt-1) and 4 weeks (lack of Orx-A/Hcrt-1's priming effects) of cocaine abstinence. One tentative explanation is that the expression and/or functionality of Orx/Hcrt receptors fluctuates during cocaine withdrawal following dependence, as reflected by decreased sensitivity to Orx-A/Hcrt-1's priming effects.

Title: Orexin-A/hypocretin-1 in the paraventricular nucleus of the thalamus induces Fos expression in the medial prefrontal cortex in animals with a history of cocaine dependence

Authors: *R. MARTIN-FARDON, F. WEISS, A. MATZEU;
MCND, The Scripps Res. Inst., La Jolla, CA

Abstract: Orexin/hypocretin (Orx/Hcrt) projections from the lateral hypothalamus (LH) to the paraventricular nucleus of the thalamus (PVT) are implicated in drug addiction. We previously reported that administration of orexin-A/hypocretin-1 (Orx-A/Hcrt-1) in the PVT reinstates extinguished cocaine-seeking behavior in animals with short access (ShA, 2 h/day) or long access (LgA, 6 h/day, a model of cocaine dependence) to cocaine and sweetened condensed milk (SCM) seeking, but with different dose-response profiles. Specifically, in the LgA group a left-upward shift of the dose-response function compared with the SCM group and an upward shift compared with the ShA group were observed. This suggests that a history of cocaine dependence leads to neuroadaptive changes at the level of the PVT, resulting in "sensitization" of PVT-Orx/Hcrt transmission, reflected by increased sensitivity (i.e., a leftward shift) and exacerbated behavioral responses (i.e., an upward shift) to the effects of Orx-A/Hcrt-1. The present study sought to investigate whether the neural activation pattern following intra-PVT Orx-A/Hcrt-1 administration in animals that self-administered cocaine (ShA, LgA) or SCM is different and could partially explain the different Orx/Hcrt dose-response functions. Male Wistar rats were trained to self-administer short-access cocaine (ShA), long-access cocaine (LgA), or SCM for a total of 21 days. After completion of the training procedure, the animals underwent extinction training for 2 weeks in 2 h daily extinction sessions. Rats received intra-PVT microinjections of Orx-A/Hcrt-1 (0.5 μg) or the respective vehicle (saline) and then placed into operant chambers under extinction conditions for 2 h. At the end of the behavioral tests, the brains were prepared for Fos immunohistochemistry and analyzed for Fos expression in the medial prefrontal cortex (mPFC), nucleus accumbens (NAC) core, and shell (i.e., brain regions receiving inputs from the PVT and well known to regulate cocaine-seeking behavior). Intra-PVT administration of Orx-A/Hcrt-1 induced strong activation of the mPFC (i.e., increased Fos-expressing neurons) only in animals that had a history of cocaine dependence. In contrast, no significant activation was found in the NAC shell and core, with no differences between groups. These data suggest that the LH→PVT→mPFC pathway, through Orx/Hcrt transmission at the PVT interface, is a neuronal circuits that drives cocaine-seeking behavior in cocaine-dependent animals.

Title: Experience-dependent changes in calcium-permeable AMPA receptors in the mPFC following cocaine conditioned place preference versus cocaine self-administration

Authors: *J. I. PEÑA BRAVO, C. M. REICHEL, A. LAVIN;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Relapse to cocaine seeking involves corticostriatal neurotransmission. Plasticity of glutamatergic synapses is a fundamental mechanism through which experience changes neural function to impact behavior. Here, we tested whether experience-dependent changes in levels of cortical Ca2+-permeable AMPA receptors (Cp-ARs) depend on re-exposure to a cocaine-associated context. AMPA receptor rectification index (RI) was calculated as [RI = (eEPSC amplitude at -70mV)/(eEPSC amplitude at +40mV)] from either prelimbic (PL-mPFC) or infralimbic (IL-mPFC) medial prefrontal cortex deep layer pyramidal neurons. We found that the RI was significantly decreased in PL-mPFC neurons and trended towards an increase in IL-mPFC neurons of rats that underwent cocaine self-administration, extinction and cue-induced reinstatement. However, this methodology does not allow for a distinction between discrete cues versus contextual mediated effects. To address this distinction we used a cocaine conditioned place preference (CPP) model to establish a contextual associative memory and address whether Cp-ARs are modulated by re-exposure to a cocaine-associated environment. In the first experiment, rats underwent conditioned place preference. On day 1, rats received a 10 minutes pre-conditioning test were they had free access to the entire apparatus. During the 8 days of conditioning, rats received daily single injections of either cocaine (20mg/kg i.p.) paired with a distinct compartment or saline paired with another compartment for 25 minutes. On the test day, animals were given free access to both compartments in a drug-free state and their preference was assessed for 10 minutes. After the first CPP test, animals were split into two groups: 8 days or 30 days of abstinence. These groups are further subdivided into rats that are either tested or not tested and killed 15 minutes later for whole-cell voltage clamp experiment. Our results show a increase in RI after 8 days of abstinence, 8 days of abstinence followed by a CPP test and 30 days of abstinence compared to saline controls. Interestingly, testing the rats for CPP after 30 days of abstinence lead to a decrease in RI. In the second experiment, rats underwent 10 days of cocaine self-administration (2mg/50µL). Following 2 weeks of abstinence, rats were killed without testing and we found no difference between saline controls RI values in PL and IL-mPFC neurons. This was not surprising given that the rats did not re-experience the drug associated context or discrete cues. Future work will parse apart the importance of the cue vs context association as well as the influence of abstinence vs extinction.

Title: Involvement of the dorsal hippocampus and HDAC3 in cocaine drug-seeking

Authors: *L. N. HITCHCOCK[1], J. D. RAYBUCK[1], R. G. WILLIAMS, Jr[1], M. A. WOOD[2], K. M. LATTAL[1];

Abstract: Substance use disorder is a chronic, often relapsing disease that leads to a loss of behavioral inhibition and compulsive drug-seeking. Cues that are paired with acquisition of drug-seeking are thought to influence subsequent extinction (animal model of exposure-based therapy) and relapse-like behavior, both in humans and animals. Our previous work has implicated the dorsal hippocampus for developing and retrieving memories in a drug-seeking context. By inactivating the dorsal hippocampus, we found that extinction was impaired in a contextual learning paradigm (cocaine-induced conditioned place preference). In addition, the epigenetic enzyme histone deacetylase 3 (HDAC3), has been shown to be a negative regulator of cocaine-associated learning and memory. Here, we further investigate this hippocampal-based extinction model and determine whether inhibition of HDAC3 can enhance extinction after cocaine self-administration. Despite the fact that extended extinction does not eliminate contextual renewal or cue-induced reinstatement, we find that a systemic injection of a synthetic HDAC3 inhibitor creates persistent extinction and weakens renewal and cue-induced reinstatement. In addition, we test whether inhibition of HDAC3 in the dorsal hippocampus alone is sufficient to impair extinction. In contrast to our systemic manipulation, it appears that dorsal hippocampus-specific HDAC3 inhibition does not alter drug-seeking behavior. Results suggest that regions outside of the dorsal hippocampus likely contribute to HDAC3-mediated enhancements in extinction after cocaine self-administration.

Title: Inhibitory influence of basolateral amygdala cannabinoid CB1 receptors in instrumental cocaine memory reconsolidation

Authors: *J. A. HIGGINBOTHAM, N. MAHAN, K. HARMON, A. ARGUELLO, R. FUCHS;
Washington State Univ., Pullman, WA

Abstract: Exposure to a cocaine-associated context can reinstate extinguished drug-seeking behavior and trigger the reactivation of contextual cocaine memories. Reactivated cocaine memories are labile and sensitive to manipulation until they are re-stabilized into long term memory stores through the process of memory reconsolidation. Our laboratory has shown that cannabinoid 1 receptors (CB1R) play a role in instrumental cocaine memory reconsolidation. In the present study, we evaluated the specific contribution of CB1R populations in the basolateral amygdala (BLA) to this phenomenon. We trained rats to lever press for cocaine infusions in a distinct environmental context followed by extinction training in a different context. In order to reactivate cocaine memories, the rats were re-exposed to the previously cocaine-paired context for 15 min. The selective CB1R antagonist, AM251 (300 ng/hemisphere), or vehicle was microinfused bilaterally into the BLA either immediately or 6 h following memory reactivation (i.e., outside of the time window of memory reconsolidation). Seventy-two h later, cocaine-seeking behavior (i.e., non-reinforced active lever presses) was assessed in the previously cocaine-paired context. Remarkably, intra-BLA AM251 administration immediately, but not 6 h, following cocaine memory reactivation *facilitated* subsequent cocaine-seeking behavior. This suggests that the stimulation of CB1Rs in the BLA *inhibits* instrumental cocaine memory reconsolidation. Thus, BLA CB1Rs may be novel therapeutic targets for disrupting the salience or intrusiveness of maladaptive drug memories and for preventing relapse.

Title: Time-dependent, opposite effects of glucocorticoid receptor antagonism in the basolateral amygdala on drug context-induced cocaine-seeking behavior

Authors: *R. A. FUCHS[1], S. J. STRINGFIELD[2], A. A. ARGUELLO[1], K. M. HARMON[1], J. A. HIGGINBOTHAM[1];

Abstract: Drug context-induced relapse to cocaine-seeking is dependent on the integrity of context-cocaine associative memories and the recruitment of these memories and other processes that trigger goal-directed behavior. Here, we investigated the role of basolateral amygdala (BLA) glucocorticoid receptors (GR) in A) contextual cocaine memory reconsolidation, a process responsible for long-term memory maintenance, and B) the drug context-induced reinstatement of cocaine-seeking behavior. Rats were trained to lever press for cocaine infusions in a distinct context followed by extinction training in a different context. In Exp. 1, rats received bilateral intra-BLA microinfusions of the GR antagonist, RU038486 (3, 10 ng/hemisphere), or vehicle following exposure to the previously cocaine-paired context, a procedure that elicits cocaine memory reactivation and reconsolidation. Controls were exposed to an unpaired context (no reactivation control). Non-reinforced lever presses were assessed 72 h later in the cocaine-paired context. In Exp. 2, rats received the same pharmacological manipulations immediately prior to testing. Intra-BLA RU038486 administration dose-dependently increased cocaine-seeking behavior 72 h later. This effect did not depend on memory reactivation; therefore, it did not indicate enhancement in memory reconsolidation. This RU038486-induced increase in cocaine-seeking behavior was associated with a paradoxical decrease in BLA glutamate GluN2a and GluN2b subunit activation, which in turn positively correlated with GR levels and ERK1/2 activation, respectively. Intra-BLA RU038486 administration at test dose-dependently attenuated drug context-induced cocaine-seeking behavior. Furthermore, intra-BLA RU038486 failed to

alter locomotor activity immediately or 72 h after administration. Together these findings suggest that BLA GR stimulation is necessary for drug context-induced motivated behavior. However, compensatory changes precipitated by BLA GR antagonism can result in a protracted increase in cue reactivity.

Title: Optogenetic inhibition of the dorsal hippocampus: effect on reconsolidation of cocaine-associated contextual memories and subsequent cocaine-seeking behavior

Authors: *A. A. ARGUELLO, J. A. HIGGINBOTHAM, P. N. BUSHANA, J. L. BARNES, R. WANG, R. A. FUCHS;
Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Cocaine addiction is a chronic relapsing disorder. Relapse can be triggered by drug-associated environmental stimuli, suggesting that maladaptive cocaine-associated memories contribute to the addiction cycle. The maintenance of these memories over time depends on their reconsolidation into long-term memory stores following reactivation-induced de-stabilization. We have shown that tetrodotoxin (TTX)-induced inactivation of, but not protein synthesis inhibition in, the dorsal hippocampus (DH) impairs cocaine memory reconsolidation and subsequent cocaine-seeking behavior. Accordingly, the DH may maintain labile memories prior to their re-stabilization at another site, such as the amygdala. Therefore, the DH may be more critical during the initial stages of the 4-hour memory reconsolidation window. We have begun to examine the temporal dynamics of DH recruitment for cocaine memory reconsolidation and hypothesized that optogenetic inhibition of the DH during the first hour following memory reactivation would impair memory reconsolidation. Sprague-Dawley rats received bilateral infusions of AAV5-hSyn-eArch3.0-YFP plus optic fibers into the DH. Rats were trained to lever

press for un-signaled cocaine infusions in a distinct context and underwent extinction training in a different context. Following extinction training, rats were re-exposed to the previously cocaine-paired context for 15 minutes in order to de-stabilize cocaine-associated memories and trigger memory reconsolidation. Rats were then placed in a third context, where they received bilateral laser stimulation (532 nm, 1 second on/off) or no stimulation for 1 hour. After 2 additional extinction training sessions, cocaine-seeking behavior (i.e., non-reinforced lever presses) was assessed in the cocaine-paired context. Optogenetic inhibition of the DH during the first hour following re-exposure to the cocaine-paired context was sufficient to impair subsequent cocaine-seeking behavior. This suggests that the DH plays a critical role in the early stages of cocaine memory reconsolidation.

Title: Retrograde contextual learning induced by cocaine in a conditioned place preference paradigm

Authors: R. A. SHETTY, M. A. RUTLEDGE, *M. J. FORSTER;
Pharmacol. and Neurosci., Univ. North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: The purpose of these studies was to evaluate the magnitude of appetitive trace conditioning of context that could be induced by cocaine when presented at different interstimulus intervals (ISI) following a contextual S+. Swiss-Webster mice were tested using a standard conditioned place preference (CPP) procedure in which simultaneous pairing of 15 mg/kg cocaine with a distinctive, non-preferred floor type (S+) (composed of stainless steel rods or perforated holes) yielded a CPP. Mice were assigned to either a cocaine control condition (receiving simultaneous pairing with the S+ floor), or to trace pairing, with cocaine administered in the home cage after an ISI of 0.25, 4, or 8 h following exposure to the S+ floor. Additional mice were assigned to a saline control (null) condition in which no cocaine was administered. On two consecutive days, all mice were injected with saline before a morning session on the S-

floor. During an afternoon session on the S+ floor, the mice received either saline (saline control and trace pairing groups) or 15 mg/kg cocaine (cocaine control group). Following each afternoon session, mice were returned to their home cages in the vivarium where they received a third injection of either saline (saline control, cocaine control) or cocaine (0.25-h ISI, 4-h ISI, 8-h ISI). A preference test was conducted on the next day in which all mice were injected with saline and placed in the apparatus with split floors consisting of rods and holes, and the time spent on each floor was recorded. A positive shift in preference for the S+ floor was considered to reflect appetitive conditioning to the context. Three of the groups of mice exposed to cocaine (cocaine control, 0.25-h ISI, 4-h ISI) expressed a strong preference for the initially non-preferred floor. However, the shift in preference for S+ was absent in the 8-h ISI group. These studies suggest that retrograde appetitive conditioning of cocaine may occur to a salient context that was present up to 4 hours prior to cocaine exposure. The unusually long time-frame of this retrograde interaction is similar to that observed in studies of conditioned taste aversion, and this property may account for the important role of context in psychostimulant addiction and relapse.

Title: Extinction of cocaine craving is associated with a shutdown of neuronal activity in the insula-prefrontal cortex circuit

Authors: *P. GIRARDEAU[1,2], S. NAVAILLES[3,2], A. DURAND[3,2], K. GUILLEM[3,2], S. H. AHMED[3,2];
[1]Inst. of Neurodegenerative Dis., Bordeaux, France; [2]CNRS UMR5293, Bordeaux, France; [3]Univ. de Bordeaux, Bordeaux, France

Abstract: Relapse is often preceded by a strong desire for the drug of choice or craving. Preventing the expression of craving represents thus a major goal in the research and development of new addiction therapies. We recently developed and validated in rats a behavioral procedure that durably abolishes cocaine-primed reinstatement of cocaine seeking - a robust model of drug craving. This procedure consists of exposing rats with a long history of cocaine self-administration to repeated, passive drug priming in the absence of cocaine reinforcement. The efficacy of this procedure is thought to result from the extinction of the interoceptive stimuli of cocaine that have been conditioned to cocaine reinforcement during cocaine self-administration. Here we report using this procedure that the extinction of cocaine-primed craving is associated with a complete loss of neuronal responses to cocaine in the insular and prelimbic cortex. To obtain a more dynamic picture, we also recorded neuronal responses in the prelimbic (PL) cortex to repeated drug primings using *in vivo* electrophysiology. We found that most PL neurons fired in responses to the first cocaine priming but that this initial response eventually disappeared with repeated cocaine priming in parallel with the extinction of cocaine-primed craving. Overall, these findings show that extinction of cocaine craving is associated with a progressive extinction of neuronal responses to cocaine in the insula-prefrontal cortex circuit.

Title: Subthalamic nucleus markers of compulsive cocaine seeking

Authors: *C. BAUNEZ, A. TIRAN-CAPPELLO, Y. PELLOUX;
INT CNRS & Aix-Marseille Univ., Marseille, France

Abstract: Loss of control over drug intake and compulsive drug seeking are key features of drug addiction. Uncovering neurobiological markers of these disorders may help refine our understanding of the disease and reveal new potential therapeutic strategies. Most theories regarding neurobiological substrate of addiction have focused on dopaminergic alterations. In patients suffering from dopaminergic neurodegeneration inherent to Parkinson's disease, the subthalamic nucleus (STN) exhibits pathological oscillations in the low frequency range (beta band between 13 to 30Hz) that disappear concomitantly to motor symptoms after L-DOPA or STN high frequency stimulation. In order to assess the presence of STN oscillations in a dopamine related disorder affecting more motivation processes, we measured local field potentials (LFPs) in animal models of addiction exhibiting aberrant responding for the drug. For this aim, rats were first trained under the seeking taking schedule of reinforcement for cocaine. Then, some animals were given the opportunity to escalate their cocaine intake across 15 sessions of long access to the drug (6-hour sessions). STN LFPs were recorded 15 minutes before (that is during acute withdrawal) and 15 minutes just after (that is under the effect of cocaine) long access sessions across the 15 days. Then, all animals were returned to the seeking taking task after which intermittent punishment upon seeking responding was introduced. As previously shown, a subpopulation of animals after escalation showed persistent responding despite intermittent punishment. Only these compulsive animals exhibited a progressive increase in low frequency oscillations (6-12 Hz) during acute withdrawal, which disappeared under the effect of cocaine. These results evidence a participation of STN low frequency oscillations in the development of compulsive cocaine seeking and suggest potential benefit of manipulation aiming at reducing low frequency stimulation such as L-DOPA or STN high frequency stimulation.

Title: Cocaine motivational value is enhanced when co-administered with caffeine: relevance of adulterants in reinforcement

Authors: *J. P. PRIETO[1], C. SCORZA[2], G. SERRA[4], V. PERRA[4], G. PIRAS[4], M. GALVALISI[2], A. ABÍN-CARRIQUIRY[3], G. DI CHIARA[4], V. VALENTINI[4];

Abstract: It is widely known that illicit drugs of abuse, such as cocaine hydrochloride, are usually sold adulterated. Adulteration implies the intentional addition of a pharmacologically active substance. Forensic data provide information about the common adulterants found in drugs of abuse. It has been reported that phenacetine, caffeine, lidocaine and levamisol are the most commonly substances detected in street cocaine samples. However, it is unusual that the influence of adulterants in the psychoactive effect of cocaine is considered. Animal studies have demonstrated that particularly caffeine is able to potentiate cocaine actions, although the enhancement of the cocaine reinforcing property by this adulterant is less reported, and the results depend on the paradigms and experimental protocols used. In the present study we examined the ability of caffeine to enhance the motivational and rewarding properties of cocaine using the intravenous self-administration paradigm in rats. Additionally, the role of caffeine as a primer cue during extinction was evaluated. To this end, we assessed in naïve Sprague-Dawley rats: 1) the ability of the combination of cocaine (0,125 mg/kg/infusion) and caffeine (0,0625 mg/kg/infusion) to maintain self-administration in fixed ratio 1 (FR 1) and progressive ratio 3-4 (PR 3-4) schedules of reinforcement compared with cocaine and caffeine alone; 2) the effect of caffeine in the maintenance of responding in the animals exposed to the combination of the drugs during cocaine extinction. Cocaine and the combination of cocaine and caffeine were self-administered on a FR 1 and PR 3-4 schedules of reinforcement, being the breaking point of the combination of the drugs higher than cocaine alone. Caffeine was not reliably self-administered, but was able to maintain a drug-seeking behavior in rats previously exposed to cocaine plus caffeine. These findings suggest that the presence of caffeine enhances the reinforcing effects of cocaine and the motivational value of the drug. Our results highlight the role of active adulterants commonly used in illicit street drugs. Finally, the permanent identification of substances used as adulterants can really contribute to identify the acute or chronic toxicity and dependence induced by drugs of abuse.

Abstract: In human addicts, environmental contexts associated with previous drug use can provoke relapse to drug use after prolonged abstinence. Previous studies indicate that specific patterns of sparsely distributed neurons, called neuronal ensembles, mediate and likely encode learned associations between drug-associated contexts and drug-taking. In the present study, we investigated whether context-induced reinstatement of cocaine seeking is mediated by activation of neuronal ensembles in the ventral hippocampus. Rats were trained to self-administer cocaine (0.5-1.0 mg/infusion) 3 h/day for 12 days; drug infusions were paired with a discrete tone-light cue. Subsequently, lever responding was extinguished over 12 days in the presence of the discrete cue in a non-drug context with different sensory and circadian features than the drug self-administration context. Rats were then re-exposed to the cocaine-associated context (or the non-drug extinction context as the control condition) and lever-pressing was assessed under the same extinction conditions for 90 min as a measure of cocaine seeking. Neuronal ensembles in ventral hippocampus that were activated during context-induced reinstatement were identified using Fos immunohistochemistry. Re-exposure to the cocaine-associated context, but not the non-drug context, increased lever pressing as well as Fos-immunoreactivity in ventral hippocampus (lever pressing: 78±16 and 12±3, respectively; $p<0.05$), (Fos positive nuclei: 552±102 and 102±25, respectively; $p<0.05$). These data suggest that activation of ventral hippocampus neuronal ensembles might mediate context-induced reinstatement of cocaine self-administration

Title: Altered capacity for cellular remodeling and neurotransmission in the hippocampus underlie memory deficit in a mouse model of perinatal hyperoxia

Authors: *J. ABBAH[1], L.-J. CHEW[1], C.-M. VACHER[1,2], V. GALLO[1];
[1]Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., Washington, DC; [2]Mol. Neuroendocrinology of Food Intake Lab., NeuroPSI - Univ. Paris Sud 11 - CNRS, Orsay, France

Abstract: Survivors of preterm birth are susceptible to brain injury due to perinatal hypoxia-ischemia, infection and hyperoxia (HO). These injuries result in neurological sequeleae such as cognitive impairment and learning disability, which frequently occur in this population. The cellular and physiological mechanisms underlying the deficit in memory and learning behavior in this population are still largely unknown, in particular hippocampal abnormalities that may potentially predispose to development of a disease phenotype. Our lab developed a mouse model of perinatal brain injury using short-term (48 h) exposure to hyperoxia (80-85% oxygen) from postnatal age 6 to 8 (P6 - P8), in which impaired white matter development was previously demonstrated. Here we evaluated the impact of perinatal hyperoxia (HO) on the proliferative capacity of dentate gyrus (DG) of the hippocampus using BrdU pulse-chase in proopiomelanocortin-EGFP (POMC-EGFP) transgenic mice. Perinatal HO leads to biphasic impairment in cell proliferation within the hippocampus. Specifically, HO causes an initial decline (P8) in the number of BrdU+ cells followed by recovery at P12 - P14. In parallel with reduction in all newly generated cells, we also found that the number of Sox2+ cells that represent the pool of stem/progenitor cells, and those of neuronal neuroblasts that are POMC+ were also reduced after HO treatment. However, the apparent recovery of cell proliferation in the DG following HO is not sustained, as the numbers of BrdU+, POMC+ and doublecortin positive cells are significantly reduced again at P60. HO also caused a significant reduction in the number of parvalbumin positive (PV+) interneurons within the CA1, and of the expression levels of PV mRNA. Protein levels of CaMKII and the α1 and α3 subunits of GABAA receptors were also reduced. Patch-clamp recordings revealed regional-specific reduction in inhibitory postsynaptic currents (IPSCs) in the CA1 at both P8 and P20, and an increase in excitatory postsynaptic currents (EPSCs) at P20. Mice exposed to HO also displayed impaired memory and learning ability in the water T-Maze and novel object recognition tests. These data indicate that HO selectively impairs the proliferation of neuronal-lineage cells in the SGZ and alters the balance of excitatory and inhibitory neurotransmission in the CA1. Impaired hippocampal remodeling

coupled with dysregulated GABAergic neurotransmission caused by HO contributes to deficits in learning and cognitive ability.

Title: Early administration of cord blood cells reduces preterm brain injury following hypoxia-ischemia

Authors: ***J. LI**, T. YAWNO, A. SUTHERLAND, J. LOOSE, I. NITSOS, F. Y. WONG, G. JENKIN, S. L. MILLER;
The Ritchie Ctr., MIMR-PHI Institute, Monash Univ., Clayton, Australia

Abstract: Background: Preterm infants, particularly infants born <32 weeks gestational age, are at high risk for cerebral palsy and other neurological deficits. There is increasing evidence that umbilical cord blood (UCB) may have therapeutic potential in reducing brain injury in cases of term neonatal asphyxia. However, there is limited information on the potential benefits of UCB treatment for the preterm brain. Aim: This study examined the effectiveness and mechanism of action of allogeneic UCB mononuclear cell administration to preterm fetal sheep following umbilical cord occlusion (UCO). Methods: UCO or sham was performed for 25 minutes to fetal sheep at 100d gestational age (~0.7 gestation). 50 million CFSE-labelled UCB cells, derived from term lambs, or saline were administered intravenously to the fetus at 12 h or 5 d after UCO. Regular fetal plasma samples were collected, and brains obtained at 10 d after UCO, for analysis. Results: Brain histology revealed that CFSE-labelled cells when given i.v were detected in the fetal brain. UCO reduced the number of oligodendrocytes (olig2+) and myelinated axon density (CNPase+) in white matter, while UCB cells administered at 12 h, restored white matter development (Figure). UCO animals showed a significant increase in TUNEL- and Ki67-positive cells in the white matter, co-localised with olig2, while UCB cells, administered at 12 h, prevented these effects. The number of activated microglia (Iba1+) was also increased in the

white matter in UCO fetuses, whereas UCB cell administration at 12 h provided an anti-inflammatory effect. However, UCB cell administration at 5 d failed to show these, potentially, therapeutic effects (Figure). Additionally, UCB cell administration at 12 h reduced systemic oxidative stress that occurred in response to UCO. Conclusion: Early UCB mononuclear cell administration at 12 h after hypoxia-ischemia reduces white matter injury through its anti-inflammatory, anti-apoptotic, and antioxidant effects.

Title: Perinatal tetrahydrobiopterin biosynthesis is changed in fetal brain in a chorioamnionitis animal model

Authors: *Z. SHI[1], K. LUO[1], A. DROBYSHEVSKY[1], J. VASQUEZ-VIVAR[2], S. TAN[1]; [1]Pediatrics, Northshore Univ. Hosp., Evanston, IL; [2]Biophysics, Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Aim: Tetrahydrobiopterin (BH_4) is an essential cofactor for nitric oxide (NO) formation in many organs. BH_4 levels in fetal rabbit brains are at very low levels at premature gestation and decreases with hypoxia-ischemia. We have developed a new model of chorioamnionitis in maternal rabbits using lipopolysaccharide (LPS) injection into the endocervix. **Methods:** LPS (0.5 ml, 200 μg/kg/ml, Escherichia coli O22:B55, Sigma) or sterile saline (0.5 ml, control) was injected into the endocervix of E28 (89% term) rabbit dams (New Zealand White) under hysteroscopy guidance. Brain tissues were collected 24h afterwards, and snap-frozen. Rabbit genes, which were previously unknown, were cloned using RACE-based techniques by lab-designed gene-specific primers, and confirmed by alignment with the predicted sequences at GenBank. Primers were designed by Primer-Blast programs. Quantitative RT-PCR was used for gene expression of enzymes in the tetrahydrobiopterin pathways. **Results:** We compared two key biosynthetic enzymes involved in the tetrahydrobiopterin pathway, GTP cyclohydrolase I (GTPCH) and sepiapterin reductase (SPR) between the LPS and saline groups. We found no change in neuronal nitric oxide synthase (nNOS) expression. However, a significant increase in GTPCH was observed in all brain regions from fetuses irrespective of the position of the uterus, with a trend to increase more in the fetuses at the uterine poles compared to the uterine base. There was a decrease in SPR expression in cortex of the pole samples. **Conclusions:** For the first time we can study the gene expression of biosynthetic enzymes of tetrahydrobiopterin in the rabbit. Different biosynthetic enzymes of the tetrahydrobiopterin pathway respond differently to an inflammatory insult with opposing results. Further studies are underway to characterize the other biosynthetic enzymes. **Key words** Lipopolysaccharide, Chorioamnionitis, Tetrahydrobiopterin, Neuronal nitric oxide synthase, GTP cyclohydrolase I

Title: Transcranial motor-evoked responses in children with perinatal stroke involved in an intensive leg training program

Authors: *A. SMITH[1], E. ZWEDIE[1], D. LIVINGSTONE[1], K. BRUNTON[1], C. HURD[1], A. MOIR[1], A. KIRTON[2], J. YANG[1], M. GORASSINI[1];
[1]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [2]Univ. of Calgary, Calgary, AB, Canada

Abstract: The sensorimotor regions of the brain are common sites of damage early in development. Individuals with cerebral palsy (CP) experience a reorganization of sensorimotor pathways in the developing brain resulting in limited limb activity and motor impairment. Over 70% of children with CP experience difficulties with walking. While current therapy interventions aimed at improving walking are still very broad, there is a growing shift from passive movements initiated by a therapist to an emphasis on more activity-based learning initiated by the child. These intensive practice programs in early infancy have shown promising functional results; however, the degree to which they influence underlying motor systems is unknown. Here we investigated the effects of intensive training to the affected leg in children with perinatal stroke to mainly one side of the brain. The strength of the corticospinal pathways involved and the latency of leg muscle responses at different ages were investigated before and after the training period. We examined the amplitude and onset latency of motor-evoked potentials (MEPs) evoked by transcranial magnetic stimulation (TMS) over the motor cortex supplying the lower limb muscles (vastus lateralis, tibialis anterior, hamstrings, and gastroc-soleus). Data will be presented from an on-going, 2-centre, randomized trial with a delayed-treatment group acting as controls. Intensive leg training was provided by physical therapists to improve walking function in children between 8 months and 3 years old. In 19 children, we examined if MEPs could be evoked in leg muscles when applying TMS over the less affected cortex. In this condition, ipsilateral MEPs could be evoked in 14 children in at least one of the four muscles tested, whereas contralateral MEPs were less prevalent, occurring in 13 children. In contrast, MEPs could only be evoked from the more affected cortex in 9 of the children, all of which showed contralateral responses and only 7 of which showed ipsilateral responses in at least one of the four muscles tested. The onset latency of both ipsilateral and contralateral MEPs evoked from the less affected cortex progressively decreased with age across the sample size, typically with latencies of 60 ms at 8 months of age to 30 ms at 54 months of age. Additionally, a strengthening of descending pathways was observed in 10 children where there was an increase in consistency and amplitude of MEPs in at least one of the muscles following the training period. These preliminary results suggest a reorganization of underlying motor systems in response to an early intensive training program.

Title: Perinatal brain injury in a chorioamnionitis model in rabbits

Authors: *K. LUO[1], Z. SHI[2], A. DROBYSHEVSKY[2], S. TAN[2];
[2]Pediatrics, [1]Northshore Univ. Healthsystem, Evanston, IL

Abstract: Introduction: Chorioamnionitis, an ascending infection from the vagina into the amniotic cavity, is believed to be a risk factor for perinatal brain injury. Previous animal models have used bacterial injection into the endocervix or lipopolysaccharide injection into the myometrium in rabbits. Rodent models that use postnatal intraperitoneal injection of lipopolysaccharide may not exactly mimic the human condition. **Objective:** Our objective was to develop a clinically relevant animal model by intra-cervical administration of the endotoxin, lipopolysaccharide (LPS), in pregnant rabbits to induce intrauterine inflammation. The study determined the postnatal neurobehavioral deficits and cytokine response in fetuses. **Methods:** Pregnant rabbits at 28 days gestation were anesthetized. A flexible cannula was inserted under hysteroscopy guidance 1-2 cm into the cervix. Saline or 0.5 ml of LPS (Escherichia coli O22:B55) in a dose 200 µg/kg/ml was injected in each cervical opening. One cohort of animals was allowed to deliver and a neurobehavioral battery of tests conducted at postnatal days 1 and 11 (P1, P11). Caesarean section was done on another cohort at 24 hours after LPS injection. Fetal cortex (CO), basal ganglia (BG), thalamus (TH), and cerebellum (CE) various regions of the uterus were assayed with RT-PCR for cytokines. Statistical significance was defined as $P < 0.05$ (Student t test). **Results:** LPS exposure caused a significant locomotion deficit at P1. The degree of hypertonia was mild. By P11 most animals had recovered and looked almost normal. The neurobehavioral deficits were transient compared to hypoxia-ischemia. Since some of the newborn kits looked normal we determined if the cytokine response was any different in the fetuses between the base and pole position in the uterus after 24 hours. TNF-α, IL-1β, IL-2, IL-6, IL-8, IL-10 and TGF-β expressions were not different between the base and pole (n=3 in each group). Most cytokines showed increase in the LPS treated group except TNF-α, which showed a decrease. **Conclusions:** This is the first study to show neurobehavioral changes in kits and cytokine changes in fetal brain tissues in a LPS induced ascending chorioamnionitis model in rabbit. LPS inflammation affects fetuses to varying degrees, probably not depending on the

position of the fetus in the uterus. **Key words**: LPS; intra-cervical injection; RT-PCR; cytokine; IL-1β; IL-2; IL-6; TGF-β; TNF-α, IL-8; IL-10

Title: Development of an LPS-sensitized mouse model of very preterm brain injury

Authors: A. MIKHAILOVA[1], S. RANASINGHE[1], *P. S. MCQUILLEN[2];
[1]Pediatrics, UCSF, San Francisco, CA; [2]Pediatrics and Neurol., Univ. California, San Francisco, San Francisco, CA

Abstract: Evidence supports a role for both infection/inflammation and hypoxic-ischemic (HI) injury in the pathogenesis of brain injury in premature human newborns. The Rice-Vannucci model (unilateral carotid ligation followed by hypoxia) has been combined with lipopolysaccharide (LPS) administration at P7 to either sensitize or precondition against brain injury depending upon timing of administration. However, this model has not been performed before P5. We have used the Rice-Vannucci procedure at P2 in rats to model brain injury in the very preterm human newborn (26-30 weeks) with injury to lower cortical layers including subplate and developing white matter. However, we have not been able to reproduce similar cortical injury in mice. We aim to develop a mouse model of very preterm brain injury (< P5) combining LPS sensitization with Rice-Vannucci procedure for cerebral hypoxia-ischemia. C57Bl/6 mice at P3 or P4 received subcutaneous injections of LPS 4 hours before unilateral right carotid artery ligation and subsequent exposure to 8% O2 for 30-40 min. Procedural and post-procedural mortality was recorded. At 10 days post-HI, injury was assessed by histology and immunohistochemistry. Infarct volume was measured using Cavalieri method and calculated as (hypoxia hemisphere area - HI hemisphere area)/(hypoxia hemisphere area). LPS (doses 0.1-1mg/kg) or HI alone did not cause detectable cortical injury. Surgical mortality for HI procedure was 14% (N=8/56). Mice pretreated with LPS doses of 0.3 and 1 mg/kg prior to HI all died 1-3 days after HI (N= 8). At a dose of 0.1 mg/kg, no mice survived a hypoxia duration of 40 minutes (N=5) performed at P4. When LPS-HI was performed at P3 with 30 minutes of 8% oxygen, post-

procedural mortality was 19% and at P4 mortality was 40%. At both ages, a range of injury was observed from mild (no histologically detectable injury) to severe (cortical injury with lateral cyst formation). Mild/moderate injury was found in 76% at P3 (N=16/21) and 91% at P4 (N=10/11). For P3 animals, infarct volume increased with categorical injury score: mild- (1.8 +/- 0.5%, N=3), moderate- (8.5+/-5.5%, N=2), severe- (25.6+/-5%, N=3). Immunofluorescence with layer specific markers is being analyzed for difference in subplate and lower cortical layer cell number in injured animals. Cortical injury with acceptable mortality can be produced by combining LPS pretreatment with HI at early ages in mouse. A mouse preterm brain injury model will facilitate utilization of genetically modified mouse strains for imaging, cell fate tracking and gain/loss of function experiments.

Title: Graded restoration of normocapnia blocks pathophysiological suppression of sharp waves in a rat model of birth asphyxia

Authors: *E. PROKIC, A. ALAFUZOFF, J. VOIPIO, K. KAILA;
Lab. of Neurobio., Helsinki Univ., Helsinki, Finland

Abstract: Spontaneous periodic network events are a characteristic feature of developing neuronal networks, and they are thought to play a crucial role in the maturation of neuronal circuits. In the rodent hippocampus *in vivo*, sharp waves (SPW) are the first and only population event during early postnatal development. Birth asphyxia is associated with pathophysiological changes in the EEG, including either seizures or suppression of EEG activity during and immediately following asphyxia, which are often predictive of a poor neurodevelopmental outcome. The mechanisms underlying brain trauma and developmental disorders following birth asphyxia remain unknown. Here, we studied the short term EEG outcome following experimental asphyxia. We use a model of infant rats that mimics the alterations in systemic

CO2 and O2 levels during and after birth asphyxia. Infant rats (P5-7) were exposed for 45 minutes to asphyxic conditions (20% CO2, 4% O2) and left to recover either in room air for 2 hours (rapid restoration of normocapnia, RRN), or by a graded restoration of normocapnia (GRN, 10% CO2 for 30minutes, followed by 5% CO2 for 30 minutes, and subsequently room air for 1 hour). The impact of asphyxia and recovery on SPW activity was assessed 24 hours post-asphyxia. We recorded SPW activity along the CA1-dentate gyrus axis using multi-site silicon probes under urethane anaesthesia. Rats exposed to RRN showed strong and prolonged suppression of SPW activity. Strikingly, frequency and amplitude of SPW showed no significant changes when asphyxia was followed by GRN. There is a widely recognised lack of therapeutic interventions to effectively ameliorate pathophysiological effects caused by birth asphyxia. Our work suggests that GRN may turn out to be one effective strategy for intervention.

Title: Postnatal erythropoietin modulates excess calpain activation following prenatal hypoxia-ischemia in rats

Authors: *L. L. JANTZIE[1], S. ROBINSON[2];
[1]Neurol., Dept. of Pediatrics, UNM, Albuquerque, NM; [2]Neurosurg. & Neurol., Boston Children's Hospital/Harvard Med. Sch., Boston, MA

Abstract: Preterm infants suffer central nervous system (CNS) injury termed encephalopathy of prematurity from hypoxia-ischemia and inflammation. Caspases and calpain activation are two major mediators of mature CNS injury. Previously it has been shown that Erythropoietin (EPO) limits apoptosis mediated by activated caspases, but its role in limiting calpain activation has not been investigated extensively in immature CNS injury. Here, we examined the impact of calpain degradation in encephalopathy of prematurity in detail by defining the extent and time course of calpain degradation of molecules essential to perinatal neurodevelopment. We hypothesized that excess calpain activation degrades developmentally-regulated molecules essential for CNS circuit formation, myelination and axon integrity, including neuronal potassium-chloride co-

transporter KCC2, myelin basic protein (MBP), and phosphorylated-neurofilament (pNF), respectively, and that post-injury EPO treatment could mitigate CNS calpain-mediated degradation. Using prenatal transient systemic hypoxia-ischemia (TSHI) in rats at E18 to mimic CNS injury from extreme preterm birth, and postnatal EPO treatment with clinically-relevant dosing, we found excess cortical calpain activation, as shown by cleavage of αII-spectrin into 145kDa αII-spectrin-degradation products (αII-SDPs) and p35 into p25. Specifically, cortical SDP ratios were significantly elevated in TSHI animals compared to sham (n=12-15, p=0.007) at P2. To confirm excess calpain activity, we also quantified the degradation of p35 to p25 at P2, and found more p25 in TSHI than sham cortex (n=10-11, p=0.026). Compared to shams at P11 αII-SDP ratios were significantly elevated in cortex following TSHI (n=14, p=0.002, Fig. 2E) concomitant with reduced expression the endogenous calpain inhibitor calpastatin. Postnatal EPO treatment reversed increases in αII-SDP ratios (p=0.016) and loss of KCC2, MBP and NF following prenatal TSHI. Together, these data indicate that postnatal EPO treatment can mitigate excess calpain activity and attenuate degradation of molecules essential to neurodevelopment and the pathogenesis of encephalopathy of prematurity.

Title: Decrease of white matter projections in spinal cord after antenatal hypoxia-ischemia in rabbit cerebral palsy model

Authors: *A. DROBYSHEVSKY, K. LUO, Z. SHI, S. TAN;
Pediatrics, Northshore Univ. Hlth. Syst. Res. Inst., Evanston, IL

Abstract: Newborn rabbit kits after global antenatal hypoxic-ischemic (H-I) injury exhibit motor deficits similar to human infants with cerebral palsy, including muscle hypertonia. We have previously shown that decrease of descending corticospinal projections in internal capsule and cerebral peduncles after antenatal brain injury may play a key role in development of hypertonia. We hypothesized that a decrease of descending corticospinal projections will affect the development of spinal cord from the moment of injury in fetuses till development of hypertonia. Alternatively, direct cell injury in spinal cord after antenatal global hypoxia -ischemia is hypothesized. Rabbit dams underwent global fetal H-I at E22 for 40 min. At P1 fixed neonatal

brains and spinal cord were scanned *ex vivo* on 14T magnet with isotropic 0.15 mm resolution with diffusion tensor imaging. Fractional anisotropy (FA) in brains of hypertonic, non-hypertonic and control kits (n=5,6,9) were compared using Tract Based Spatial Statistics (TBSS) approach. Significant reduction in FA was found in cortico-spinal tract, external capsule, fimbria hippocampi bilaterally in hypertonic group only. There was significant reduction in white and gray matter in spinal cords in only hypertonic group at cervical, thoracic and lumbar levels. Amount of TUNEL and FluoroJade C positive cells was not significantly different between the groups in spinal cord 24 and 72 hours after H-I. We conclude that significant loss of spinal white matter and gray matter in hypertonic kits 10 days after fetal H-I injury is likely to result from degenerative changes or disrupted development due to upstream injury to corticospinal tract and not due to the axonal and cell loss immediately after H-I.

Title: Neuroprotective effect of hypothermia in a model of neonatal encephalopathy resulting from E. coli-induced inflammation plus hypoxia-ischemia

Authors: *M. CHEVIN[1], C. GUIRAUT[2], G. SÉBIRE[2,3];
[1]Dept. de Pédiatrie, Univ. De Sherbrooke, Sherbrooke, Canada; [2]Dept. de Pédiatrie, Univ. De Sherbrooke, Sherbrooke, QC, Canada; [3]Child neurology division, Mc Gill Univ., Montréal, QC, Canada

Abstract: Introduction: Neonatal encephalopathy (NE) which affects 2-9/1000 full term newborn leads to life threatening symptoms and can cause permanent brain damage such as cerebral palsy (CP). The two main risk factors of NE are perinatal infection-inflammation and hypoxia-ischemia (HI). The standard treatment is therapeutic mild hypothermia (body cooling of 33-34°C for 72h) providing a partial neuroprotection in moderate to severe NE. Such neuroprotective effect of hypothermia remains unclear when NE result from pathogen-induced inflammation combined to HI. Otherwise, the anti-inflammatory interleukine-1 receptor antagonist (IL-1ra) has a well-proved neuroprotective effect in preclinical models of perinatal inflammation induced by pathogens and/or HI. We hypothesize that the combination of mild hypothermia plus IL-1ra results in additive or synergistic neuroprotection. Objectives: We characterised the impact of hypothermia on the expression of cerebral inflammatory markers (cytokines, chemokines) and on the prevention of cerebral injuries. Material and methods: We used an animal model of rat pups (Lewis) at postnatal day 12 (P12). P12 corresponds to the level of cerebral development of the human full term newborn. Inflammation is induced by injecting the rat pups intraperitonealy with 200 µg/kg of lipopolysaccharide (LPS) from E.coli. Four hours (h) later, the right common carotid artery is ligated, then hypoxia is induced (8% O2, 1 h 30 min). Finally, rat pups are submitted to hypothermia (32° +/- 0.5°C for 4 h). Pups are euthanized at different time points in order to perform histological analysis and cytokine titration. Results: Our results show that hypothermia alleviated brain damage in the LPS+HI-exposed cerebral cortex and hippocampus. This protective effect only occurred in the brain areas affected by ischemic penumbra, but not core injuries; penumbra corresponds histologically to an association of pyknotic and healthy neurons, without destruction of extracellular matrix or ischemic cavitation. This neuroprotective effect did not result from a down-regulation of the neurotoxic response mediated by IL-1β or TNF-α. Conclusion: Our results demonstrate a neuroprotective effect of hypothermia on LPS+HI-induced brain damage in a model of NE. This beneficial effect of hypothermia is not mediated by IL-1β down-regulation meaning that IL-1ra administration might reinforce the hypothermic neuroprotective effect. This project could open new therapeutic avenues to prevent CP.

Title: Using neuroimaging biomarkers to study tetrahydrobiopterin pathways critical to hypertonia in antenatal hypoxia-ischemia

Authors: *S. TAN[1], K. LUO[1], Z. SHI[1], A. DROBYSHEVSKY[1,2], J. VASQUEZ-VIVAR[2]; [1]Northshore Univ. Healthsystem, Evanston, IL; [2]Med. Col. of Wisconsin,, Milwaukee, WI

Abstract: Introduction: Previously, there has been a paucity of relevant animal models of cerebral palsy (CP). We were the first to show sustained hypertonia, a pathognomonic feature of CP, in a rabbit model following antenatal hypoxia-ischemia. Furthermore, we have developed sensitive and specific MRI biomarkers to identify which fetuses are critically injured and will develop hypertonia postnatally. This allows the study of early events that are causative of hypertonia. We have previously also shown that maternal tetrahydrobiopterin supplementation ameliorates motor deficits postnatally. **Objective:** Our objective was to investigate tetrahydrobiopterin pathways with hypertonia caused specifically by oxidative stress and not by other pathways such as energy failure or endoplasmic reticulum involvement. **Methods**: Pregnant rabbits at 25 days gestation (79% term) were subjected to uterine ischemia for 40 min under a clinical magnet with MRI monitoring. MRI biomarkers delineated four groups of brain injury: Hypoxic injury alone, Reperfusion-Reoxygenation injury, Mild and No injury. Caesarean section was done at 48 hours after the insult. Cortex, basal ganglia, thalamus, and cerebellum from fetuses located in different regions of the uterus were assayed for biopterin using a fluorescent HPLC method. Statistical significance was defined as $P < 0.05$ (Student t test). **Results:** Biopterin, a surrogate for tetrahydrobiopterin levels, was decreased in the cortex and cerebellum in the Reperfusion-Reoxygenation group compared to other groups. Those fetuses showing only hypoxic injury did not have significant change from Mild or No injury groups. The changes in the basal ganglia and thalamus were not different between the groups. **Conclusions:** Tetrahydrobiopterin levels are decreased 48 hours in the group specifically associated with oxidative stress only, i.e. Reperfusion-Reoxygenation group. This could be due to a secondary decrease in biosynthesis or breakdown of tetrahydrobiopterin from free radicals. Another possibility could be that those fetuses which are unable to increase tetrahydrobiopterin may be vulnerable to the critical pathogenetic event leading to hypertonia.

Abstract: Diabetes mellitus is intense metabolic disorder with multiple complications that include deterioration of learning and memory, which leads to cognitive impairment and dementia. Although adult hippocampal neurogenesis is reduced in chronic diabetes, the effect of acute diabetes on hippocampal neurogenesis has not been studied. Herein, we investigated the effects of acute diabetes on adult hippocampal neurogenesis in pharmacologically-induced diabetic models. This study also investigated the role of the trace metal zinc in adult neurogenesis. In the present study, we hypothesized that administration of zinc with histidine and proline may increase hippocampal neurogenesis in diabetic rats. To induce type 1 diabetes, rats were injected with streptozotocin (STZ, 50 mg/kg, i.p.). One-month-old male Sprague Dawley rats were given STZ by intraperitoneal injection once per day for two consecutive days. Diabetes was defined as fasting blood glucose levels above 200 mg/dl at two days after the first injection. Zinc plus cyclo-(His-Pro) contains 20 mg of zinc. To test the effects of zinc supplementation on neurogenesis in diabetic rats, 5'-Bromo-2'deoxyuridine (BrdU) was injected twice daily for four consecutive days starting 3 days after the STZ injection. For the experimental group, zinc (30mg/kg) plus cyclo-(His-Pro) was injected by oral gavage for seven days starting at one day after the second STZ injection. For the control group, cyclo-(His-Pro) was injected without zinc for seven days. The present study found that acute streptozotocin-induced diabetes increases progenitor cell proliferation in the subgranular zone of the dentate gyrus at seven days post-injection in diabetic rats. Interestingly, we also found that zinc plus cyclo-(His-Pro) supplement further increased hippocampal neurogenesis in diabetic rats. The present study suggests that supplementation of zinc with cyclo-(His-Pro) promoted hippocampal neurogenesis in early stages of diabetic pathophysiology.

Title: Glutamate oxaloacetate transaminase a therapeutic target against periventricular leukomalacia in neonates

Authors: *N. ZAGHLOUL[1,2], H. L. PATEL[3], M. N. AHMED[3,4];
[1]Pediatrics, Cohen's Children Med. Ctr., Manhasset, NY; [2]Feinstein Inst. for Med. Res., Manhasset, NY; [3]The Feinstein Inst. for Med. Res., Manhasset, NY; [4]Pediatrics, cohen's Children Med. Ctr. of NY, Manhasset, NY

Abstract: BACKGROUND: Periventricular leukomalacia (PVL) is the most common cause of cerebral palsy in premature infants and often a consequence of hypoxia ischemia (HI) leading to excessive neuroexcitotoxic glutamate accumulation.Glutamate oxaloacetate transaminase (GOT-1) catalyzes transfer of the amino group from Glutamate (Glu) to oxaloacetate which will clear toxic extracellular Glu from the ischemic site while also feeding cellular respiration. OBJECTIVE: To delineate the physiologic protective role of GOT and its mechanisms of action in PVL. DESIGN/METHODS: Human premature brain autopsy specimens (23-28 weeks gestation) with PVL and age matched controls were stained for GOT-1. PVL neonate mouse model (HI) was established by temporary bilateral carotid ligation at P5 for 10min, followed by hypoxia exposure 8% for 20 min. Immunostaining for GOT1,neuronal (GAP 43, Doublecortin, NeuN), microglia (Iba1) and astrocyte marker(GFAP).To delineate the physiologic role of GOT-1, neuronal cell culture subjected to oxygen glucose deprivation challenge (OGD) with overexpression of GOT-1 using Lentivirus and suppression of GOT-1 using siRNA were studied. RESULTS: Our mice model of PVL exhibited hind limb paresis, in coordination and feeding problems. MRI and histopathological findings showed both lateral and 3rd ventriculomegally caused by white matter loss and neuronal apoptosis. GOT-1 was significantly over expressed in human premature autopsy brain tissue with PVL and mouse model of PVL as compared to controls. Immunostaining for both human and mice brain showed high colocalization of GOT expression to neurons. Interestingly glutamate receptors are also highly expressed on neurons. In our *in vitro* neuronal cell culture when using GOT Lentivirus overexpression there was a statistically significant increase in neuronal cell viability and a statistically significant decrease in Glu level in OGD as compared to non transfected cells. Using GOT siRNA trasfected neuronal cell culture, there was a statistically significant decrease in neuronal cell viability and statistically significant increase in Glu levels in OGD as compared to non transfected cells. CONCLUSIONS: Based on our *in vitro* findings, GOT may have a significant protective role in neonate mice model with PVL and human neonateswith PVL. As a compensatory mechanism to HI, GOT levels increase in an attempt to decrease serum glutamate levels. This increases the

glutamate gradient between blood and brain, thus decreasing brain glutamate. Recombinant GOT-1 or a small molecule that targets GOT-1 expression and activity could be a potential therapeutic approach for PVL.

Title: Impact of hypoxia-ischaemia and dopamine treatment on Dopamine 2-like receptors in the preterm lamb brain

Authors: ***N. BREW**[1,2], S. INGELSE[2], U. RATNAYAKE[3], F. WONG[2,4,5];
[1]Childrens Res. Inst., Washington, DC; [2]The Ritchie Centre, MIMR-PHI Inst. of Med. Res., Melbourne, Australia; [3]Florey Inst. of Neurosci. and Mental Hlth., Melbourne, Australia; [4]Monash Newborn, Monash Med. Ctr., Melbourne, Australia; [5]Dept of Paediatrics, Monash Univ., Melbourne, Australia

Abstract: Background: Hypoxic-ischaemic (HI) brain injury is a major concern for preterm infants. Dopamine is a neurotransmitter and inotrope commonly used to raise blood pressure in preterm infants. After HI in term babies reduced dopamine receptor density is associated with adverse outcomes. The effect of dopamine treatment on the immature brain and dopamine receptors remains unknown. Aim: Determine the effect of HI and dopamine treatment on Dopamine-2 receptors (D2R) in the preterm fetal lamb brain. Methods: D2-receptor density was measured with *in vitro* autoradiography using [3H] Spiperone. Treatment groups (99 days of gestation, term =147days) were (A) unoperated control fetuses (n=6), (B) fetuses exposed to a severe HI insult using umbilical cord occlusion and saline infusion (HI-saline, n=5) and (C) HI insult with dopamine infusion (HI-dopamine, 10µg/kg/min, n=4) for 74 hours. The caudate, putamen and globus pallidus were identified on cryostat cut sections using H&E and adjacent sections underwent autoradiography. Results: D2R density was decreased in HI-saline brains compared to controls in the caudate (53.3±10.4 vs. 98.2±13.3 fmole/mg), putamen (90.5±13.9 vs. 150.6±11.6 fmole/mg) and globus pallidus (38.1 ± 2.0 vs. 64.2 ± 14.0. fmole/mg, $p<0.05$). In HI-dopamine brains D2R density in the caudate and putamen (53.2 ± 2.2 and 101.7±6.6 fmole/mg,

respectively) was not different to HI-saline levels. In the globus pallidus of HI-dopamine brains D2R density was not different to controls (53.4±5.0 fmole/mg). Conclusions: HI decreases D2R density of in the basal ganglia of the fetal lamb brain. Dopamine treatment may protect D2R expression in the globus pallidus, and be potentially neuroprotective.

Title: Neurodevelopmental effects of caffeine on neonatal neurons

Authors: *H.-L. LI[1], I. AHMED[2], T. ADAMS[1], U. ADEN[3];
[1]Dept. of Physiol. and Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY; [2]Biol., CUNY, Medgar Evers Col., Brooklyn, NY; [3]Women's and Children's Hlth., Karolinska Inst., Stockholm, Sweden

Abstract: Apnea of prematurity (AOP), defined as cessation of breathing for more than 20 seconds, is commonly seen in preterm infants. Caffeine is widely used to treat AOP for its safety and effectiveness. Caffeine releases the respiratory arrest by competing with adenosine for binding to A1 and A2 receptors. The plasma concentration of caffeine in preterm infants during AOP treatment is 10-100 times higher than that in infants receiving breast milk from mothers who drink moderate doses of coffee. Caffeine has long been known as a psychostimulant in adult brains. However, the effect of caffeine on developing brains, especially in the high concentrations used for AOP treatment, remains unclear. We first sought to ask 1) whether neonatal brains express A1 and A2 receptors and 2) how these receptors are modulated in response to prolonged caffeine treatment. Using immunostaining and confocal microscopy, we found A1 and A2 receptors are differentially expressed in rodent neonatal brains; A1 receptors are synaptically localized whereas A2 receptors are primarily enriched in soma. The estimated serum concentration of caffeine in preterm infants receiving caffeine therapy is about 25-103 uM. We tested the molecular effects of caffeine within this concentration range in primary

neuronal culture isolated from neonatal rodent brains. Using RT-PCR, we found the expression of A1 receptors was upregulated in neurons treated with 100 uM of caffeine in 5 days, whereas the upregulation of A2 receptor expression was observed using lower doses of caffeine (50 uM). We are currently investigating the underlying mechanisms of upregulation of the expression of A1 and A2 receptors and their consequences on the development of both normal and injured neonatal brains in rodents.

Title: Metformin promotes sensorimotor recovery and activation of endogenous neural precursor cells following a hypoxic/ischemic insult

Authors: ***P. DADWAL**, N. MAHMUD, L. SINAI, A. AZIMI, M. FATT, F. D. MILLER, C. MORSHEAD;
Univ. of Toronto, Toronto, ON, Canada

Abstract: A Hypoxic/Ischemic (H/I) insult to the immature brain is thought to play a role in the development of cerebral palsy pathology. Our goal is to design therapeutically relevant methodologies to enhance the activation of endogenous subependymal (SE)-derived neural precursor cells (NPCs, composed of stem and progenitor cells) to promote self-repair following a perinatal H/I insult. The widely prescribed drug, metformin (met), used to manage type II diabetes has been shown to promote neural differentiation by activating aPKC-CBP pathway. However, it is unknown if the enhanced differentiation is due to met acting on the neural stem cell and/or the downstream progeny. Using the neural stem cell (NSC) colony-forming assay, we first examined the effect of met in the absence of injury. Postnatal 8 (PND 8) SE-derived NPCs

exposed to met resulted in an 2-fold expansion in the size of the NSC pool, and a 3-fold and 2-fold increase in the numbers of neurons and oligodendrocytes, respectively, upon differentiation, *in vitro*. Next we examined the effects of met following H/I injury. PND 8 mice pups received a unilateral carotid artery ligation followed by 1 h hypoxia. Pups received met at 24 h post-injury via their lactating mothers and for one week (PND 9 – PND 15). To examine the impact of met and H/I injury on endogenous NPCs, a group of mice were sacrificed at PND 12. We observed a 2-fold increase in the size of the NSC pool in met-only pups and a 4-fold increase in H/I injured pups. A separate group of mice were sacrificed at PND 23 (1 week post-met treatment) and most striking, one week of met treatment was able to completely rescue sensorimotor impairments in the cylinder test. To understand the cellular basis for this recovery, we performed lineage-tracking experiments using *Nestin-CreER^{T2}/R26R-YFP* transgenic mice. At two weeks post-injury H/I + met treated pups had significantly more SE-derived YFP+ cells (ranging from 4 to 23 fold increases) in the striatum, motor cortex, corpus callosum, in both the ipsilateral and contralateral hemispheres (relative to the ischemic insult). We examined the fate of SE-derived YFP+ cells and observed increased number of YFP+ neurons and oligodendrocyte (striatum, motor cortex, corpus callosum) in H/I + met treat pups. Interestingly, we observed no difference in the relative percentage of YFP+ neurons or YFP+ oligodendrocytes between H/I and H/I + met treated pups suggesting that the observed recovery following met treatment was due to the increased absolute number of NPCs and not due to preferential differentiation. Hence, met activates endogenous NPCs and promotes endogenous repair of injured postnatal brain.

Title: L3 auditory interneuron responses to dual-frequency calling songs in female crickets (Acheta domesticus)

Authors: *J. LEE[1], B. NAVIA[2];
[1]Behavioral Sci., [2]Biol., Andrews Univ., Berrien Springs, MI

Abstract: Female crickets exhibit phonotactic behavior, by selectively walking towards the source of calling songs with specific carrier frequencies (4-5 kHz), syllable periods (SP; 50-70 ms), and other temporal parameters.Such selective behavior is the result of complex processing by a number of neurons. Of the previously identified ascending prothoracic auditory neurons, only L3 has been proposed to be involved in SP selective phonotaxis. Previous tests have shown that females respond more selectivity to calling songs with intensities above L3's threshold than those above L1's threshold and below L3's threshold. Furthermore, L3 responds with selective decrement to 5 kHz calling songs with attractive syllable periods and such decrement has been correlated with selective phonotaxis. In addition, L3 is also tuned to 16 kHz auditory stimulus, which has been suggested to influence aversive phonotactic behaviors. Based on such studies, L3's cellular responses to simultaneous 16 kHz and 5 kHz calling songs will be examined through extracellular recording, thereby further establishing the connection between L3's selective decrement responses and selective phonotatic behavior. We hypothesized that in response to simultaneous 16 kHz and 5 kHz calling songs, L3 will show a decrease in selective decrement. Preliminary results from the current study showed a decrease in decrement pattern in responses to dual frequency auditory stimulus, thereby supporting the hypothesis.

Title: The effect of varying sound intensities on phonotactic selectivity in Female

Authors: R. GREENE, *B. A. NAVIA;
Dept. of Biol., Andrews Univ., Berrien Springs, MI

Abstract: The intensity of the calling songs to which a female cricket Acheta domesticus is most likely to start responding phonotactically has been reported to be around 55dB at a carrier frequency of 4 - 5 kHz. These reports, however, have not shown selective phonotaxis to occur at such low intensities. Preliminary data from behavioral experiments have demonstrated that i) in response to calling songs with intensities above 75dB, females are more likely to exhibit

selective phonotaxis in response to a full sequence of calling songs with varying syllable periods (30 - 90 ms); ii) in response to calling songs with intensities below 75 dB the same females are less likely to respond selectively to identical stimuli. By testing all three intensities, 85dB, 75dB, and 60dB, at various syllable periods, we intend to find the threshold intensity at which a female cricket will exhibit selectivity in their phonotactic choices.

Title: Spike threshold adaptation enhances temporal fluctuation coding in the avian cochlear nucleus

Authors: *S. T. LUBEJKO[1], B. FONTAINE[3], K. M. MACLEOD[2];
[2]Dept. of Biology, Neurosci. and Cognitive Sci. Program, [1]Univ. of Maryland, College Park, MD; [3]Univ. of Leuven, Leuven, Belgium

Abstract: Depending on their intrinsic properties, single neurons operate in functional modes which range on a spectrum from coincidence detection (CD) to broad time scale integration. These properties determine a neuron's input-output functions and how information, particularly temporal information, is transformed or transmitted. In the auditory system, highly specialized CD neurons require rapidly fluctuating inputs to fire. However, we have recently shown that a subset of repetitively firing neurons in the avian cochlear nucleus are also sensitive to the timing of input fluctuations, responding with increased firing rates to larger fluctuations and more reliable firing (Kreeger et al. 2012). The intrinsic properties underlying this sensitivity is not clear, but may arise from the dynamics of spike initiation, specifically spike threshold adaption. We assessed the hypothesis that spike threshold adaptation is related to the operating modes of cochlear nucleus neurons by recording from avian cochlear nucleus angularis (NA), the brainstem area responsible for early sound intensity and spectrotemporal coding. To directly investigate intrinsic mechanisms, we made whole cell patch clamp recordings in brain stem

slices *in vitro* and used direct current injection into the repetitively firing NA neurons. The injected stimuli were white noise ('fluctuating') currents, simulating synaptic bombardment but with controlled mean level and variance. Two neuronal groups were determined: those that responded to increased stimulus variance with increased firing (coincidence detectors, CDs) and those that did not (integrators) as determined from their FI curves. The voltage at which the spike threshold occurred was measured for all the action potentials for each stimulus set. Spike threshold adaptation was widely observed, in that the mean voltage threshold increased with firing rate and mean stimulus level. The CD neurons, however, showed greater adaptation than the integrators, with greater changes in the median threshold and threshold variance. Threshold was inversely correlated with the rate of rise in the voltage and with the interspike interval. We applied a model of sodium channel inactivation to explain the threshold adaptation and whether differences in inactivation parameters could explain the differences between response types. This finding demonstrates that spike threshold adaptation could contribute to the increased activity of coincidence detector neurons in response to a fluctuating stimulus, and more generally contribute to the ability of neurons in NA to encode temporal envelope variations found in complex sound stimuli.

Title: Frequency tuning in the songbird auditory cortex: topographical distribution and relation to species-typical vocalizations

Authors: *J. M. MOORE, S. M. N. WOOLLEY;
Psychology, Columbia Univ., New York, NY

Abstract: Tonotopy is a principle organizational feature of the vertebrate auditory system. Increasing evidence supports the hypothesis that avian and mammalian primary auditory cortices are homologous, but the extent to which their functional configurations are shared is unclear.

Primary auditory cortex in mammals is mapped tonotopically with isofrequency columns traversing layers. A similar layout in avian primary auditory cortex has not been shown definitively. Moreover, in both birds and mammals, it is unknown how well tone-evoked cortical responses can explain spiking patterns in response to more complex stimuli, such as spectrotemporally modulated synthetic sounds or vocalizations. Here, we measured the frequency tuning of single neurons throughout the auditory cortex of two songbird species with acoustically distinct songs, the zebra finch (Taeniopygia guttata) and long-tailed finch (Poephila acuticauda). We presented pure tone stimuli and recorded physiological responses extracellularly in awake birds. High resolution mapping of best frequencies in Field L subdivision L2, the thalamo-recipient region, showed a systematic tuning gradient from low-to-high frequencies along the caudodorsal-to-rostroventral axis and along the lateral-to-medial axis. Isofrequency columns extended from L2 dorsally into subdivision L1 and caudal mesopallium and ventrally into subdivisions L and L3. Units in the lateral extents of these regions were heterogeneously tuned and not organized spatially. We also compared topographical patterns of response properties such as best frequency, excitatory and inhibitory bandwidths, and spectrotemporal modulation tuning to song acoustics. Species differences in tuning generally correlated with their disparities in song; some differences existed throughout the cortex while others emerged in specific subdivisions. These results suggest a shared functional architecture in the primary auditory cortex of birds and mammals.

Title: Organization of auditory cortex in the Nine-banded Armadillo (Dasypus novemcinctus)

Authors: B. MOFFITT, B. SKINNER, *J. J. PADBERG;
Dept. of Biol., Univ. Central Arkansas, Conway, AR

Abstract: This comparative study is one of a series aimed at characterizing the organization of sensory systems in members of Xenarthra, an early superclade in the mammalian class. Here we explore the functional and anatomical characteristics of auditory cortex in the nine-banded

armadillo, (Dasypus novemcinctus), the only extant xenarthran species found in North America. Historically, this armadillo is well known for its armored carapace, its potential as a zoonotic reservoir of Mycobacterium leprae, and its behavioral reliance upon olfaction. Anecdotally, the armadillo has been described as having very sensitive hearing, however, its auditory sensitivity and the range of frequencies it can detect remain poorly described. An early study of evoked cochlear potentials suggests that armadillos are capable of detecting frequencies into the ultrasound range, but may have less sensitive auditory responsiveness than guinea pigs (Peterson and Heaton, 1968). While the general location of auditory cortex has been described using evoked potentials (Royce et al., 1975), the full extent of this field in this animal has not been explored using microelectrode recordings. To this end, we recorded multiunit responses in the auditory cortex of nine-banded armadillo to broadband auditory stimuli in order to determine the functional extent of the field, and later matched the locations of these recordings to series of sections stained for cytochrome oxidase (CO) histochemistry, myelin, or Nissl substance in order to identify the anatomical location. The primary auditory cortex stained intensely for myelin, and was notable for the presence of many large lattice-like features. Adjacent series stained for Nissl showed the inverse of these features, with clusters of cells located inside the myelin lattice. Based on both the electrophysiological responses and staining patterns, the extent of auditory cortex is nearly the entire caudolateral third of the armadillo brain. Experiments using a range of toneburst frequencies will clarify whether the tonotopy of xenarthran auditory cortex more closely resemble those of monotremes, marsupials, or euarchontoglires.

Title: Acoustic features contributing to 1/f temporal modulation spectra of vocalization sequences and speech

Authors: *F. KHATAMI[1,2], M. WÖHR[4], H. L. READ[1,2], M. A. ESCABI[1,2,3];
[1]Biomed. Engin., Storrs, CT; [2]Psychology, Behavioral Neurosci., [3]Electrical Engin., Univ. of

Connecticut, Storrs, CT; [4]Behavioral Neuroscience, Exptl. and Physiological Psychology, Philipps-University of Marburg, Marburg, Germany

Abstract: In vision, natural scenes exhibit 1/f power spectrum where visual edges are main contributors and cortical neurons are tuned to effectively extract edge related information (Field, 1987). Similarly, in audition, temporal modulations in vocalized sounds exhibit 1/f modulation power spectrum (Voss and Clark, 1975) and central auditory neurons can respond efficiently to such statistics (see discussions, Escabi et al., 2003; Rodriguez et al., 2010). Numerous factors contribute to temporal fluctuations in vocalized sounds including articulatory gestures, vocal tract filtering, and vocal fold vibration. Yet how such factors contribute to 1/f structure is unclear. Vocalized sounds contain a variety of temporal cues, including rhythmic fluctuations (< 20 Hz), onsets and offsets at the beginning and end of vocalizations (e.g., isolated words, species specific calls), and periodic structure such as from vocal fold vibrations (e.g., periodicity pitch) and these vary extensively over several orders of magnitude (from a few Hz for rhythmic information to ~800 Hz for pitch). It is plausible that 1/f structure arises from the combined contribution of such physical cues. We used vocalization sequences from a variety of animals, including nonhuman primates, mice, birds, infant cries, and speech to evaluate the role of vocalization transients, duration and amplitude variation in the sound temporal envelope. First, the modulation spectrum from isolated vocalization and vocalization sequences was compared. Synthetic vocalization sequences were generated based on statistics of the vocalization duration, timing, and amplitude variation of natural sequences and artificially perturbed to investigate contributing factors. In all instances, the presence of onsets and offsets at the beginning and end of isolated vocalizations predicted the observed 1/f modulation spectrum observed in vocalization sequences. Though timing, duration, and amplitude variation shaped the modulation power spectrum these only accounted for small amount of residual variation around the observed 1/f trend. The results demonstrate that acoustic “edges” are largely responsible for 1/f modulation structure found in vocalization sequences including speech. This is similar in principle to visual edges being main contributors to 1/f spectrum of visual images. Since central auditory neurons are particularly sensitive to temporal onsets and are adapted for 1/f structure, the findings imply that temporal edge detection is a major determinant for neural coding of vocalizations sequences.

Title: Auditory midbrain processing is differentially modulated by auditory and visual cortices

Authors: *P. P. GAO[1,2], J. W. ZHANG[1,2], S.-J. FAN[1,2], D. H. SANES[3], E. X. WU[1,2]; [1]Lab. of Biomed. Imaging and Signal Processing, [2]Dept. of Electrical and Electronic Engin., The Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The cortex contains extensive descending projections, yet the impact of cortical input on brainstem processing remains poorly understood. In the central auditory system, the auditory cortex contains direct and indirect pathways (via brainstem cholinergic cells) to nuclei of the auditory midbrain, called the inferior colliculus (IC). While these projections modulate auditory processing throughout the IC, single neuron recordings have samples from only a small fraction of cells during stimulation of the corticofugal pathway. Furthermore, assessments of cortical feedback have not been extended to sensory modalities other than audition. To address these issues, we devised blood-oxygen-level-dependent (BOLD) functional magnetic resonance imaging (fMRI) paradigms to measure the sound-evoked responses throughout the rat IC, and investigated the effects of bilateral ablation of either auditory or visual cortices (auditory cortex ablation: n=12; visual cortex ablation: n=12; normal control: n=12). Auditory cortex ablation increased the gain of IC responses to noise stimuli (primarily in the central nucleus of the IC), and decreased response selectivity to species-specific vocalizations (most prominently in the external cortex of the IC). In contrast, visual cortex ablation decreased the gain, and induced a much smaller effect on response selectivity. The results suggest that auditory cortical projections normally exert a large-scale and net suppressive influence on specific IC subnuclei, while visual cortical projections provide a facilitatory influence. Meanwhile auditory cortical projections enhance the midbrain response selectivity to species-specific vocalizations. We also probed the role of the indirect cholinergic projections in the auditory system in the descending modulation process by pharmacologically blocking muscarinic cholinergic receptors (normal animals, n=6). This manipulation did not affect the gain of IC responses, but significantly reduced the response selectivity to vocalizations. The results imply that auditory cortical gain modulation is mediated primarily through direct projections and they point to future investigations of the differential roles of the direct and indirect projections in corticofugal modulation. In summary, our imaging findings demonstrate the large-scale descending influences, from both the auditory and visual

cortices, on sound processing in different IC subdivisions. They can guide future studies on the coordinated activity across multiple regions of the auditory network, and its dysfunctions.

Title: In search of the origins of a central auditory deficit in gap-in-noise sensitivity

Authors: ***J. MATTLEY**[1], L. A. ANDERSON[1], J. F. LINDEN[2];
[1]UCL Ear Inst., London, United Kingdom; [2]UCL Ear Inst. & UCL Dept. Neurosci., Physiol. & Pharmacol., London, United Kingdom

Abstract: BXSB/MpJ-Yaa mice are a powerful animal model in which to study the neural mechanisms of auditory temporal processing and gap-detection deficits. These mice have long been used as an animal model for developmental disorders thought to affect auditory temporal processing in humans (Ramus, TINS 2004), such as dyslexia, specific language impairment, and central auditory processing disorder. Approximately 30-50% of BXSB/MpJ-Yaa mice have localised disruptions of neocortical lamination (ectopias) which are considered a hallmark of thalamocortical developmental abnormalities, and which resemble those observed in humans with auditory processing and developmental language disorders. Intriguingly, although the ectopias occur in frontal cortex and not in auditory cortex, ectopic BXSB/MpJ-Yaa mice have greater difficulty than their non-ectopic littermates with behavioural tasks involving detection of brief gaps in noise (Clark et al., Neuroreport 2000). Previous work has shown that neural responses to brief gaps in noise are abnormally weak in the auditory thalamus of ectopic mice (Anderson and Linden, SFN 2012), due to a reduction in the proportion of auditory thalamic neurons with sound-offset responses (Linden and Anderson, SFN 2015). To determine whether these thalamic deficits in gap-in-noise and sound-offset sensitivity arise “bottom-up” from

abnormalities lower in the ascending auditory pathway, we recorded from neurons in the inferior colliculus (IC) in ectopic and non-ectopic BXSB/MpJ-Yaa mice. Extracellular recordings were obtained from urethane-anaesthetised mice during presentations of gap-in-noise stimuli, click trains, tones, and clicks following noise. All recordings were conducted blind to the ectopic status of the animal, which was determined from post-mortem histology. In experiments on 8 ectopic mice (341 recordings) and 7 non-ectopic mice (267 recordings), we found no significant differences in IC responses to brief gaps in noise or noise offsets, even though responses to the same stimuli are abnormal in the auditory thalamus of ectopic animals. In IC, the median "neural gap-detection threshold" (minimum gap duration evoking a significant change in firing rate) was 2.8ms for both ectopic and non-ectopic mice; in auditory thalamus, the median neural gap-detection thresholds were 3ms for non-ectopic mice and 5ms for ectopic mice. Our results indicate that thalamic deficits in gap-in-noise sensitivity in ectopic BXSB/MpJ-Yaa mice may arise above the level of IC, either in auditory thalamus or in auditory cortex.

Title: Functional connectivity for spectrotemporal processing of neighboring neurons in inferior colliculus

Authors: ***L. SHEN**, Y. YAN, N. GUO, B. HONG;
Dept. Biomed. Engin, Sch. Med. Tsinghua Univ., Beijing, China

Abstract: Natural sounds are rich in spectrotemporal attributes and their processing is important for auditory perception. Inferior colliculus (IC) is sensitive to specific spectrotemporal features and is the first site emerging frequency sweep direction selectivity and envelope periodicity rate-tuning. However, it is still unclear how the neighboring neurons are functionally connected with each other and how this connectivity play roles in spectrotemporal processing. Here, we used tetrodes (inter-tetrode separation < 100 μm) to simultaneously record the responses of neighboring neurons in IC to dynamic moving ripple which had structurally rich time-varying spectrum. Spectrotemporal receptive field (STRF) was obtained using reverse correlation. We

analyzed the cross-covariance function between simultaneously recorded neuron pairs and only pairs with significant correlation with 10 ms delays ($p<0.01$) with respect to an independent Poisson assumption were analyzed further. We found that the activities of many neighboring neurons were temporally correlated. We separated the causal spikes from the activities of the source neuron and the target neuron to obtain causal spikes evoked STRF (causal STRF). We found that the neighboring neurons exhibited three types of functional connectivity: feature integrating, feature extracting and time-delay. In the first case, the target neuron integrated several simple spectrotemporal patterns to shape a complex feature selectivity and the causal STRF resembled the source STRF rather than the target STRF. The function role of this kind of connectivity approximated the "OR" operation. In the second case, only the spikes triggered by certain spectrotemporal features of the source neuron could drive the target neuron and the similarity between the causal STRF and the target STRF was higher. And the function role of this kind of connectivity approximated the "AND" operation. In the last case, the target neuron generally inherited the spectrotemporal properties of the source neuron except with various time-delay. Accordingly, the causal STRF was almost equally similar with the source STRF and the target STRF if the delay was wiped out. These results suggest that the spectrotemporal feature selectivity of IC neurons can be developed and refined via functional connectivity within local circuits.

Title: Sound evoked afterdischarge in the auditory midbrain

Authors: ***M. ONO**[1,2], D. BISHOP[1], D. OLIVER[1];
[1]Univ. of Connecticut Hlth. Ctr., Farmington, CT; [2]Kanazawa Med. Univ., Kanazawa, Ishikawa, Japan

Abstract: Hearing is normally associated with neural activity caused by sound stimulation. We have discovered a previously unobserved phenomenon where excitatory and inhibitory neurons in the auditory midbrain exhibit a sound-evoked afterdischarge (SAD) that continues long after sound stimulation ceases. To distinguish GABAergic from glutamatergic neurons *in vivo*, we used VGAT-ChR2-EYFP mice in which inhibitory neurons specifically express Channelrhodopsin-2 in all parts of the neuron. When a light stimulus was delivered to the IC from the brain surface, it evoked spikes in GABAergic neurons, but it suppressed firing in glutamatergic neurons that lacked GAD67. To evoke SAD, we used long duration, 30 - 60 s, one-octave noise (60 dB) for 44 GABAergic neurons and 48 presumed glutamatergic neurons. We found that 20% of GABAergic and 17% of glutamatergic neurons continued to fire after the sound termination. The discharge after sound was stronger when the response during sound (RDS) was higher and the sound duration was longer. The minimum sound duration required to induce SAD was around 30 s. The RDS had to be sustained to evoke the SAD since a SAD was not seen when the RDS was transient. The number of spikes in the SAD and RDS responses were positively correlated (R = 0.51). SAD+ neurons had less adaptive firing during sound than SAD- neurons. In response to 30 s sound, both GABAergic and nonGABAergic SAD+ neurons showed more sustained firing during sound than SAD- neurons. Some SAD+ neurons had build-up firing which was not seen in SAD- neurons. The time course of SAD was variable. A peak firing rate occurred 1.0 - 50.1 s after the sound termination. There was no correlation between the peak times and the number of SAD spikes (R = 0.29), but the duration of the decay of the SAD was strongly correlated with the number of SAD spikes. The decays ranged from 0.4 - 235.6 s. SAD was also evoked by discontinuous sound (1 s narrowband noise bursts presented every 2 s, 50 repetitions). Interestingly, there was a gradual increase in interstimulus spikes not seen in neurons lacking SAD. These results suggested a form potentiation that might allow SAD neurons to overcome synaptic adaptation during long duration sounds. These results also suggested that SAD might be a substrate for an auditory afterimage or phantom sound.

Title: Thalamocortical forward suppression of field excitatory postsynaptic potentials in the auditory cortex

Authors: *C. XIONG, L. KONG, J. YAN;
Dept. of Physiol. and Pharmocology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Auditory forward masking is a common perceptual phenomenon of hearing and the neurophysiological observations of masking in the auditory cortex are that temporally adjacent sounds result in attenuation of neuronal cortical responses to the second sound. The thalamocortical system is the primary input to the auditory cortex, and thus is a likely source of this cortical forward suppression. Recent recordings from our group, with a novel two-stimulus paradigm in the mice mouse auditory cortex, have shown clear suppression of spike rates to the second thalamocortical input. We substituted one or both tones of the conventional two-tone suppression paradigm with electrical stimulation of the ventral medial geniculate body (ESMBGv). We found that tone stimulus strongly suppressed the ESMGBv-induced field excitatory postsynaptic potentials (fEPSPs) and vice versa in the auditory cortex. This cortical suppression occurred consistently at an inter-stimulus interval (ISI) threshold of 80-120 ms, which is notably shorter than ISI thresholds recorded in mice midbrain and auditory nerve fibers. One possibility is that suppression in the auditory cortex has unique cellular properties that induce greater suppression. It remains unclear what the exact mechanisms of cortical suppression are but it is evident that the thalamocortical system can induce suppression autonomously. Here we present recordings of cortical fEPSP showing the suppression of pure thalamocortical inputs. Only present during the suppression time interval was a post-excitatory group "hyperpolarization" effect. These data suggests that thalamocortical circuits have intrinsic mechanism(s) underlying suppression.

Title: Nicotine narrows receptive fields and increases gain in A1 via distinct actions at several subcortical auditory regions

Authors: *C. E. ASKEW, I. INTSKIRVELI, R. METHERATE;
Univ. of California, Irvine, Irvine, CA

Abstract: Nicotine is thought to enhance sensory-cognitive function by way of increased attentional filtering and processing capacity. The neural basis of this effect is unknown. Previously, we have shown in rat and mouse primary auditory cortex (A1) that systemic nicotine increases responses to characteristic frequency (CF) stimuli and decreases responses to spectrally-distant (2 octaves) non-CF tones, thus appearing to increase response gain within a narrowed frequency receptive field (RF). However, the use of pure tones does not mimic situations when multiple frequency channels are activated simultaneously. Here we recorded local field potentials evoked by notched-noise stimuli (white noise stimuli filtered with a spectral notch centered on the CF of the recording site) in mouse A1, medial geniculate (MGv) and inferior colliculus (IC). We first found that varying notch width can be used effectively to measure frequency RFs. Systemic nicotine (0.7 mg/kg i.p., free base) produced two effects in A1: reduced response amplitude at wider notch widths and increased amplitude at smaller widths, indicating increased gain within narrowed RFs . Surprisingly, muscimol (100um) application in A1 prior to systemic nicotine resulted in qualitatively similar effects, implying a subcortical locus of action. In IC and MGv recordings, systemic nicotine reduced amplitudes at multiple notch widths, demonstrating that nicotine only narrows RFs in these regions. These results suggest that nicotine narrows RFs at various levels in the ascending auditory pathway and enhances gain at least partly due to enhancement in the thalamocortical pathway. Nicotine modulation of RFs plausibly can be the neural basis for nicotine's effects on sensory-cognitive function.

Title: Augmentation of A1 responses is reproduced by a recurrent circuit model combining strong excitation with synaptic depression

Authors: *P. J. GONCALVES[1], J. F. LINDEN[2], M. SAHANI[1];
[1]Gatsby Computat. Neurosci. Unit, [2]Ear Inst. and Dept. Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Cortical responses to dynamic stimuli display a temporal complexity reflecting the rich repertoire of recurrent cortical circuitry. For instance, primary auditory cortex (A1) responses to the second of a pair of tones are largely suppressed when the inter-tone interval is shorter than 500ms, even though most membrane currents are not sustained for that long (Wehr and Zador, Neuron 2005). This suppression may reflect thalamocortical or intracortical synaptic depression (Loebel et al., Front. Neurosci. 2007). However, in some cells the response to the second tone may be augmented, particularly at intermediate intervals around 300ms. Similarly, some cells in supragranular layers of A1 show augmented responses to the second and later stimuli within a regular train of noise bursts spaced by 300-400ms (Christianson et al., J. Neurosc. 2011) but not at lower or higher inter-burst intervals. In the same layers, an isolated noise burst leads to suppression of neural activity below spontaneous rates for about 300ms followed by a slight rebound above the spontaneous rate; this rebound was hypothesised to be related to the observed augmentation. How might this diversity of responses arise in the absence of long-lived membrane currents? We explored the hypothesis that suppression and augmentation both stem from intracortical synaptic depression. We characterized analytically the response of a network of excitatory and inhibitory neurons with depressing synapses between the excitatory cells, when stimulated by periodic drive of different frequencies, thus extending a study of Ledoux and Brunel (Front. Comp. Neurosci. 2011) on networks with static synapses. Although synaptic depression usually leads to suppressed responses, we found that networks with synaptic depression also exhibited a novel response regime in which low-frequency stimuli could be resonantly amplified. In this regime, with sufficiently strong excitatory recurrence, simulations of network activity showed a long-delay rebound following pulsed stimulation, in agreement with the A1 data. The same mechanism also led to an augmented response to a second input at intervals close to 300ms. This augmentation was driven entirely by network effects, without any mechanism for hyperpolarisation-induced membrane rebound or synaptic facilitation. In the augmentation parameter regime, a network with static and fully replenished

synapses would be unstable. Thus the supragranular layers of A1 might operate in a regime where transient sensitivity to sound onsets is maximised, while runaway activity is prevented by the short-term depression of intracortical synapses.

Title: Distinct time-scales for neural discrimination of sound envelope shape in three auditory cortical fields

Authors: A. F. OSMAN[1], C. M. LEE[2], M. A. ESCABI[1,3,2], *H. L. READ[4,1];
[1]Biomed. Engin., [2]Psychology, Behavioral Neurosci., [3]Electrical Engin., Univ. of Connecticut, Storrs, CT; [4]Univ. of Connecticut, Storrs Manfld, CT

Abstract: Changes in the sound envelope amplitude over time provide perceptual shape cues to identify and discriminate sounds (Iverson and Krumhansl 1993; Irino and Patterson 1996, Drullman, Festen et al., 1994; Geffen et al., 2011). Mammals need cortex to detect many temporal sound cues; however, the underlying cortical circuits and neural coding mechanisms for this ability remain unknown. Sound shapes can be represented with a shape-specific spike rate increase in primary (A1) auditory cortex (Wang et al., 2008). In addition, auditory cortical neurons can represent sound shape with variations in spike-timing (i.e. jitter, Lee et al., 2014). Here we ask whether spike-timing patterns can be used to discriminate sound shape in primary (A1), ventral (VAF) and caudal suprarhinal (cSRAF) auditory fields of the rat. To probe cortical single neuron sensitivities to sound shape, we generated a stimulus set with 55 unique shaped envelope noise sequences. Single neuron response spike trains were recorded from layer 4 neurons in A1, VAF and cSRAF where the physiology and corresponding thalamocortical pathways have been well described (Polley et al., 2007, Storace et al., 2010, 2011, 2012, Higgins et al., 2010). The spike train analysis temporal resolution was varied by convolving spike trains with an exponential kernel having a time constant, tc (van Rossum, 2001). The spike train

distance between responses to different shapes was estimated using the sensitivity index (d-prime; Green and Swets, 1966) for comparing responses across pairs of sounds in our stimulus set (Gai and Carney, 2008). For each pair of spike trains, the slope of time constant, tc, is varied between 1 and 256 ms to determine the tc yielding the maximal discrimination value, i.e. the "best d-prime". In all fields, we find a rank order increase in the response duration with A1 < VAF < cSRAF to any given sound shape (Lee et al., 2015). Similarly, here we find a rank order increase in tc yielding best d-prime with: A1 < VAF < cSRAF (logarithmic means: A1: 33 ms (1.03), VAF: 39 ms (1.02), cSRAF: 44 ms (1.03), $p < 0.001$). A1 neurons discriminate small differences in sound envelope shape (e.g. 2Hz vs 4Hz). Whereas, VAF and SRAF outperform A1 for discrimination of large differences in sound envelope shape (e.g. 2Hz vs 64Hz). This data supports the notion that neural discrimination of shaped periodic sound sequences relies upon the temporal patterns of spiking. Furthermore, distinct response time-scales allow for complementary shape discrimination abilities in primary and non-primary auditory cortices.

Title: Contributions of synaptic inhibition to forward-masking in awake mouse auditory cortex

Authors: E. A. K. PHILLIPS[1], C. SCHREINER[2], *A. R. HASENSTAUB[3];
[1]Otolaryngology / Head and Neck Surgery, [2]Otolaryngology / Head and Neck Surgery and Physiol., [3]Otolaryngology / Ctr. for Integrative Neurosci., UCSF, San Francisco, CA

Abstract: Sensory systems continually receive sequences of complex stimuli, and our ability to interpret particular components of such stimuli is dependent on the temporal relationships between many stimulus components. In line with this, neural responses are generally modulated by recent stimulus history. A simple and robust example of history dependence in auditory cortex (AC) is forward-masking, in which recent sound exposure suppresses responses to a

subsequent sound, depending on the spectral and temporal distance between the two sounds. Within AC, synaptic inhibition is thought to enhance forward-masking, but the relative contributions of inhibition versus other potential mechanisms (such as intrinsic adaptation or short-term synaptic depression) remain unclear. This question is complicated by the existence of multiple types of cortical inhibitory interneuron, with markedly different intrinsic and synaptic properties. For instance, while SST+ interneurons tend to receive facilitating synapses, activate GABA receptors with relatively slow kinetics, and have relatively slow intrinsic membrane properties, PV+ interneurons tend to receive depressing synapses, activate GABA receptors with relatively fast kinetics, and have relatively fast intrinsic membrane properties. This suggests that these two networks of interneurons are likely recruited by different temporal patterns of cortical activity and modulate history-dependence in distinct ways. In order to test how different populations of interneurons contribute to history dependence, we recorded from the AC of awake mice (since interneuron activity is differentially suppressed by anesthesia) in which either SST+ or PV+ interneurons expressed archaerhodopsin. We used a two-tone stimulus to elicit forward-masking, and randomly interleaved trials in which inhibition was optogenetically suppressed with trials in which inhibition was unaffected. We found qualitative differences in the tendency of SST+ and PV+ interneurons to modulate responses to masked vs unmasked and preferred vs non-preferred stimuli. Moreover, by comparing trials with equal firing rates to the first tone under the two conditions, we found that these modulation effects are independent of changes in firing to the first tone, counter to intrinsic adaptation models of forward-masking. Results will be discussed in the context of the hypothesis that history-dependent modulation of temporally complex stimuli is not just inherited from subcortical structures, but that it is enhanced within the cortex, and is selectively mediated by cortical interneurons that suppress activity forward in time.

Title: Entrainment of neuronal oscillations by repetitive complex auditory patterns

Authors: *A. BARCZAK[1], M. N. O'CONNELL[1], T. MCGINNIS[1], D. ROSS[1], P. LAKATOS[1,2]; [1]Nathan S. Kline Inst. For Psychiatric Res., Orangeburg, NY; [2]Psychiatry, NYU Sch. of Med., New York, NY

Abstract: Previous studies have shown that ongoing neuronal oscillations in auditory cortex can entrain to rhythmically-presented auditory stimuli. However, most stimuli used in these studies have been simple tones or noise bursts. Since our auditory environment is composed of a continuous flow of complex, multi-timescale information (e.g. speech/species specific communication) it is important to understand how the brain parses this information into chunks of fused elements to be further processed (e.g. interpreted or counted). The main purpose of our study was to expose a possible neural mechanism for the perceptual parsing and grouping of repeating complex random tone sequences amidst a continuous flow of auditory stimuli. Human psychophysical studies suggest that the recognition of a novel auditory pattern occurs automatically about 1.5 cycles into the pattern if repeated. We hypothesized that if low frequency neuronal activity in primary auditory cortex (A1) plays a role in parsing and grouping, it would entrain to these repeating patterns such that the low excitability phase would segregate each pattern by marking their beginning and end points. In line with human psychophysical findings, we anticipated the onset of this low excitability delta phase concentration to first occur at the end of the second pattern and reoccur after each iteration. To examine pattern-related oscillatory effects in A1, we used linear array multielectrodes to record laminar neuroelectric activity while subjects passively listened to an auditory stimulus stream consisting of pure tones and pure tones embedded in varying amounts of noise presented randomly at a 20 Hz rate. At random intervals we repeated the preceding 11 random sounds 5 times, resulting in the perception of 5 repeating complex auditory patterns. The pattern repetition rate was 1.7 Hz. As predicted, in our initial results we observed an increase in phase concentration at the rate of pattern repeat. However, the onset of the pattern-related effect appeared later than anticipated and the phase of entrainment at the "junction" of patterns was not always the low excitability phase. We interpret these results as an indication that activity in A1 can respond to and track complex auditory patterns even without these "gaps" marking the beginning and end of patterns. However, the observed pattern-related oscillations in A1 may be a consequence of - rather than a mechanism for - the segregation of auditory patterns. Current analyses are focusing on the implications of the laminar differences in the observed entrainment effect as well as variances in the effect timing across hierarchical nodes of thalamocortical information processing.

Title: Sustained spiking patterns discriminate sound envelope shape in ventral non-primary auditory cortices

Authors: *C. M. LEE[1], A. F. OSMAN[2], M. A. ESCABI[3,2], H. L. READ[1,2];
[1]Psychology, [2]Biomed. Engin., [3]Electrical and Computer Engin., Univ. of Connecticut, Storrs, CT

Abstract: Mammals, including humans and rats, have multiple auditory cortical fields with segregated thalamic pathways but it remains unclear if these cortices support distinct temporal sound cue processing (Storace et al., 2010; Hackett 2010). In many species, onset responses and first spike latencies change with the sound envelope shape in A1 providing one potential means for discriminating this cue (Heil, 2004). In rat, spike-timing precision (jitter) changes with sound envelope shape in A1, ventral (VAF) and caudal suprarhinal (cSRAF) auditory cortical fields providing another potential means for discriminating this cue (Lee et al., SFN 2014). Here we separate onset and sustained responses and examine whether the latter can discriminate sound shape cues in A1, VAF and cSRAF. First we characterize onset and sustained responses to each sound shape by quantifying the peak latency, peak magnitude, and half-amplitude duration of the sound cycle peri-stimulus time histogram (cPSTH) response. We find a rank order increase in PSTH peak delay with: A1 < VAF < cSRAF (means (standard error), A1: -41 (4), VAF: -32 (3), cSRAF: -17 (3) ms, $p < 0.001$) and a rank order increase in duration with: A1 < VAF < cSRAF (logarithmic means and standard error, A1: 19 (1.01), VAF: 27 (1.02), cSRAF: 33 (1.05) ms, $p<0.001$). In addition, the PSTH peak amplitude is greater in A1 than VAF or cSRAF (means A1: 53 (0.5), VAF: 54 (0.4), cSRAF: 40 (0.3) Hz, $p<0.001$). These findings suggest that A1 neurons have primarily a brief robust “onset” response; whereas, VAF and cSRAF neurons have an additional sustained spike response that follows the sound envelop shape. We developed a neurometric discrimination index based on a spike distance (van Rossum, 2001) between spike trains to periodic noise sequences of different shapes. To investigate the role of onset and sustained activity in shape discrimination, onset spikes were removed from the response spike trains. The perturbed spike trains yielded better shape discriminability in rank order with: A1 < VAF < cSRAF as compared to A1. Together, these findings indicate that sound shape is primarily encoded during the onset of the sound in A1; whereas, in ventral fields, shape is also encoded by the sustained response. These distinct primary and non-primary cortical forms of

spike-timing response will have unique contributions to sound envelope shape coding at the next level of sound processing.

Title: Frequency selectivity of neurons in the ferret auditory cortex

Authors: *D. MERRY, T. WELLS, P. ADJAMIAN, A. R. PALMER, C. SUMNER;
Inst. of Hearing Res. MRC, Nottingham, United Kingdom

Abstract: Frequency selectivity describes the ability to resolve the individual frequency components in sound, and is a fundamental feature of hearing. It is crucial for most auditory tasks such as identifying sounds, separating auditory objects, and understanding speech. The ability of the auditory system as a whole can be measured through the behaviour of a subject, whereas the ability of neurons to be informative can be measured by observing their spiking activity when presented with an external stimulus. We examine the neural correlates of frequency selectivity using the power spectrum model. Although typically associated with behavioural measurements we instead utilised it to examine multi-unit neuronal response in the ferret's primary auditory cortex (A1). Neuronal responses to stimuli were recorded while the ferret was anaesthetized or awake, and results were compared to previous behavioural studies. In addition, these were compared to peripheral measurements of tuning in the auditory nerve (AN). Awake behaving neuronal tuning in A1 closely resembles behavioural results while the ferret undertakes a frequency specific sound localisation task. These are also broadly similar to prior results from anaesthetised recordings in AN, although AN bandwidths are more homogenous across units of similar characteristic frequency (CF). These would suggest that frequency selectivity is established at the periphery, is maintained to the level of A1, and this ability is reflected in perception. However, units recorded in the ferret A1 under anaesthesia had better frequency selectivity, or sharper tuning, compared with units recorded under awake behaving conditions, and also behaviour and AN. This would imply that the ability to resolve frequency improves along the auditory system, but is then combined using sub-optimal coding to produce a perceptually poorer representation. Further study would be required to understand the factors behind these divergent results.

Title: Optogenetic silencing of the ferret primary auditory cortex in a behaviorally- and physiologically-relevant model of lesion-induced tinnitus

Authors: J. R. GOLD, F. R. NODAL, A. J. KING, *V. M. BAJO-LORENZANA;
Univ. of Oxford, Dept. of Physiology, Anat. and Genet., Oxford, United Kingdom

Abstract: Tinnitus is the subjective perception of a sound in the absence of an environmental source. A key step to facilitate clinical progress is the development of animal models that capture relevant features of the condition in humans - in particular, the links between the patient's percept and the complex network of physiological changes correlated with the condition. Our aims were first to develop a model of trauma-induced tinnitus in the ferret, a species well known for its utility in auditory research, and to interrogate the animal model using longitudinal behavioral and physiological approaches. Second, we wished to investigate a possible causal role for the primary auditory cortex (A1) in tinnitus by optogenetically silencing A1 activity during gap-in-noise behavior (Gold et al., 2015, Behav. Neurosci.) in a mixed group of tinnitus (T) and non-tinnitus (NT) ferrets. In a cohort of ferrets (N=10), a partial, unilateral mechanical lesion of the spiral ganglion (SG) was performed that replicated certain aspects of the peripheral pathology noted in human tinnitus patients. Prior to and following this lesion, animals were tested on an auditory gap-in-noise detection task, to examine whether temporal processing was affected in a manner consistent with the presence of tinnitus. Mixed lesion-mediated effects were seen across the cohort, with a subset of animals showing reductions in psychometric gap detection threshold, slope and asymptote. Within the same (T & NT) cohort, pre- and post-lesion auditory brainstem responses (ABRs) were obtained using clicks, narrowband chirps and masked click stimuli. The data indicated complex lesion-mediated changes, with latency increases and shifts in amplitude-level functions, particularly in late-wave ABR components. Multi-unit

recordings made bilaterally in A1 of a subset of animals showed tonotopic remapping, neural hyperactivity and hypersynchronicity following SG lesion. In a smaller mixed (T & NT) ferret cohort (N=6), the light-sensitive proton pump archaerhodopsin T (ArchT) was expressed in A1 neurons by bilateral viral vector injections (AAV8-CAG-ArchT-GFP), allowing suppression of neural excitability during behavior with 532 λ green laser light via fiber optic implants. Laser illumination modified gap detection behavior differentially according to side of illumination (bilateral, or ipsi/contralesional), acoustic stimulus type, and each ferret's tinnitus status. Our initial results suggest a possible approach to alleviating tinnitus through manipulation of mal-adaptively affected neural circuitry.

Title: Single-unit responses in lateral belt auditory cortex of the behaving marmoset monkey

Authors: *D. GAMBLE, X. WANG;
Johns Hopkins Univ., Baltimore, MD

Abstract: The current working model of primate auditory cortex comprises the hierarchical arrangement of a series of functionally distinct information processing stages: a primary 'core' region, a secondary 'belt' region, and a tertiary 'parabelt' region. Combined anatomical, physiological, and imaging data have subdivided core and belt into multiple tonotopic subfields (Kaas & Hackett 2000, Petkov et al. 2006). While previous studies have shown that lateral belt neurons prefer band-pass noise stimuli over pure tones (Rauschecker et al. 1995, Rauschecker and Tian 2004), knowledge of the functional properties of the lateral belt region is still limited. We have studied single neuron responses in the lateral belt region of marmosets under both passive and behaving conditions. The effects of arousal on firing rates were quantified by comparing responses in both conditions. Responses in the passive condition were further split into an 'eyes open' and 'eyes closed' state on the basis of the monitoring via an eye-tracker video camera. Analysis revealed that while arousal could modulate firing rates either up or down,

the eyes-open passive state was usually intermediate between the behaving and eyes-closed passive states. Consistent with previous findings, many lateral belt neurons displayed preferences for restricted spectral bandwidth. However, by using a two-noise stimulation paradigm, we revealed diverse nonlinear interactions extending outside of the single-noise receptive field, suggesting extensive spectral integration in the lateral belt region. We also found that most neurons preferred temporally modulated stimuli, with heterogeneous preferences for amplitude or frequency modulation.

Title: Harmonic processing in primary auditory cortex of awake marmoset revealed by intracellular recordings

Authors: *L. GAO, X. WANG;
BME, The Johns Hopkins Univ., Baltimore, MD

Abstract: Numerous natural and man-made sounds, such as species-specific animal vocalizations, human speech and sounds from many musical instruments, contain rich harmonic structures. However, little is known about how our brain processes harmonic sounds. The peripheral auditory system functions as overlapping band-pass filters which segregate complex sounds into narrow frequency channels, whereas the central auditory system functions to reassemble these channels into a coherent representation for perception. Extracellular recording studies in our lab have shown that the primary auditory cortex (A1) of the common marmoset (callithirx jacchus), a highly vocal New World primate species, contains harmonic template neurons which encode spectral and temporal features of harmonic sounds. However, cellular mechanisms for encoding harmonic sounds are still largely unknown. In the current work, we applied a novel intracellular recording technique that we have developed for the awake marmoset to study the subthreshold properties of A1 neurons in response to harmonic complex tones (HCTs). We found that a subgroup of A1 neurons exhibited harmonically related subthreshold response peaks in their frequency tuning profiles. These subthreshold responses showed similar

or sometimes more harmonic peaks as compared to spiking responses. Moreover, the neurons that exhibited preference to HCTs contained the same harmonic peaks at both spiking and subthreshold levels. Many A1 neurons have a single peak in their pure tone frequency tuning. Some of them exhibited preference to HCTs containing the best frequency. Our results indicated that in addition to the harmonic template neurons, many A1 neurons appear to encode some features of harmonic complex tones at both spiking and subthreshold levels.

Title: Oscillatory mechanisms for the segregation and integration of auditory inputs

Authors: *B. ZOEFEL[1], M. N. O'CONNELL[2], A. BARCZAK[2], R. VANRULLEN[1], P. LAKATOS[2,3];
[1]Ctr. De Recherche Cerveau Et Cognition (CerCo), Toulouse, France; [2]Cognitive Neurosci. & Schizophrenia Program, Nathan Kline Inst., Orangeburg, NY; [3]Dept. of Psychiatry, NYU Sch. of Med., New York City, NY

Abstract: An auditory scene in everyday life rarely consists of only one source of input. Rather, multiple stimulus streams are mixed and thus, the segregation of simultaneous streams of input is an important task for the auditory system and essential for survival. Another important task that has to be simultaneously performed by the auditory system is the integration of acoustic stimuli into meaningful units that the brain can “understand”. While we have mounting evidence that segregation is performed using neuronal oscillations that track streams in the attentional focus, the neuronal mechanisms underlying integration and parsing of information remain mostly unclear. Recently, it was hypothesized that neural oscillations might be used by the auditory

system to also parse its input (e.g., Giraud and Poeppel, 2012): One oscillatory cycle might act as a “window of integration”, and stimuli falling within this cycle might be perceived as being part of the same stream (i.e. integrated). Vice versa, stimuli falling in different cycles of the oscillation might be perceived as being part of different streams (i.e. separated). Thus, the phase of neural oscillations might determine whether stimuli of two simultaneous auditory streams are perceived as one (integrated) or two (segregated) streams. We investigated this hypothesis by presenting monkeys with tone triplets (ABA paradigm) that can be heard as either a single stream or two separated streams, depending on the frequency separation between A and B tones. The monkeys listened passively to the tone sequences while current source density (CSD) profiles and single/multiunit activity were recorded in primary auditory cortex (A1) and auditory thalamus. In line with our expectation, we observed a phase shift of neural oscillations in A1 when the assumed perception changed from segregation (for large frequency separations between A and B tones) to integration (for small frequency separations), thereby shifting the low excitability phase that is hypothesized to enable parsing. Moreover, neural phases were more consistent for assumedly integrated than for segregated tone triplets, indicating the presence of one integrated stream in the auditory environment rather than two for the segregated percept. These effects were largest in the supragranular layers of A1, in line with previous reports of strongest adaption to auditory stimulation in those layers. Our results indicate that neuronal oscillations are used to facilitate multiple simultaneous operations for the meaningful interpretation of the auditory environment: segregation, parsing and integration.

Title: Isolating neural indices of continuous speech processing at the phonetic level

Authors: *G. M. DI LIBERTO, E. C. LALOR;
Trinity Ctr. for Bioengineering, Trinity Col., Dublin, Ireland

Abstract: That cortical sensory systems are organized in a hierarchical fashion is reasonably well established. While much of the work on this topic has focused on the visual system, increasing effort has been made in recent years to investigate hierarchical organization of the auditory system. In the context of human speech it has been suggested that such an organization could explain how acoustically variable inputs can be perceived as categorical speech units. A method for indexing the neurophysiology of such hierarchical processing in the context of continuous speech has recently been introduced. Specifically, the relationship between continuous speech and low-frequency EEG responses has been shown to be best described when that speech is represented using both its low-level spectrotemporal information and also the categorical labeling of its phonetic features (Di Liberto et al., submitted). Here we outline an experiment aimed disentangling low-level neural activity from that relating to phonetic feature processing. The intelligibility of 10 s speech stimuli was degraded using noise vocoding. Each stimulus was then presented twice with an intervening presentation of the original clean speech version of that stimulus. As such, the second presentation of the vocoded version of the stimulus was primed by the clean speech and was found to be significantly more intelligible on a match-to-sample task. We attempted to predict the EEG responses to the primed and non-primed vocoded stimuli using different representations of the vocoded speech stimulus. When the vocoded speech was represented as its envelope or spectrogram there was little difference in EEG prediction accuracy as a function of priming. However, when the speech was represented as a sequence of time-aligned phonemes or phonetic features, the EEG was significantly more accurately predicted for the primed stimulus than the non-primed. This difference in prediction accuracy represents a dependent measure of speech processing at the phonetic level using non-invasive, low frequency EEG.

Title: Effects of sequential comparison on the lateralization of processing of different fundamental acoustic parameters

Authors: *N. ANGENSTEIN, A. BRECHMANN;
Leibniz Inst. for Neurobiol, Magdeburg, Germany

Abstract: The perception of complex acoustic stimuli requires the evaluation of basic acoustic parameters like frequency, duration and intensity. Usually, these parameters are not judged in an absolute manner but in relation to preceding sound segments e.g. the decision as to whether a given tone is soft or loud is made relative to a reference. As acoustic information of sound sequences unfolds over time, the evaluation of these sequences requires the storage of information of individual segments until the judgment is finished and it requires a sequential update of this information. Sequential processing is suggested to mainly involve the left hemisphere. With functional magnetic resonance imaging (fMRI) we investigated the effects of sequential comparison on the lateralization of processing in the human auditory cortex (AC) for direction of frequency modulations (FM), intensity and duration. For that we used a method that reveals differential hemispheric contribution to the processing based on an increase in activity by presenting additional noise contralateral to monaurally presented task-relevant stimuli. The categorization of FM tones according to their FM direction strongly involves the right AC. However, the pairwise sequential comparison of this parameter led to an additional involvement of the left AC. For intensity, left-lateralized processing in the AC was observed irrespective of the task (without or with sequential comparison) and irrespective of the stimulus type (tones with and without FM). The categorization of tones according to their duration stronger involved the right AC for FM tones and stronger involved the left AC for tones without FM. For both intensity and duration, additional sequential comparison of tones according to these parameters led to a stronger involvement of auditory areas and a network of brain areas outside the AC in contrast to the categorization of tones according to these parameters. Analogous to the results for FM direction, the stronger activity for comparison of duration compared to categorization was lateralized to the left AC. Together with previous studies on sequential comparison, the results suggests that the left AC is additionally involved when fundamental acoustic parameters have to be sequentially compared. The stronger involvement of the right AC during comparison in contrast to categorization probably has capacity reasons. During comparison areas outside the AC are probably stronger involved because it requires sequential update of information in memory.

Title: Effects of speaking rhythm naturalness on the neural basis of speech perception

Authors: *S. HIROYA[1], K. JASMIN[2], S. EVANS[2], S. KRISHNAN[2], M. OSTAREK[2], D. BOEBINGER[2], S. K. SCOTT[2];

Abstract: Speech communication is important for our daily life. We normally understand spoken sentences in native language without effort. However, neural mechanisms for the perception of speech sounds remain unclear for more than half a century. Recent brain imaging studies of speech revealed a common cortical activation during speech production and perception. This suggests that mirror neuron system may play an important role in speech perception. Manipulation techniques of speech sound naturalness will give us a new possibility to investigate the neural correlates of speech perception. Sinewave speech and noise-vocoded speech based on reducing the frequency information have often been used. However, few studies have investigated the neural mechanisms of temporal information underlying speech perception, i.e., speaking rhythm. English is a stress-timed language which is different from a mora-timed language of Japanese. Thus, Japanese English speaking rhythm is unnatural for native English speakers. We first developed a novel method for decomposing speech signals into a speaking rhythm and phonetic information. For Japanese English speech, replacing speaking rhythm of a native Japanese speaker with that of a native English speaker would improve Japanese English speech naturalness. 16 channel noise-vocoded speech was used for controlling the intelligibility of speech. Seven native English speakers evaluated the naturalness of speaking rhythm. Results showed that naturalness was significantly improved for native English speaking rhythm. Next we performed fMRI scans during passive listening that investigated the neural basis of speech perception. Six types of stimuli such as Japanese rhythm, English rhythm, same phonetic duration, and their spectrally rotated speech were used. We scanned eleven healthy, right-handed English speakers. Result showed that left-lateralized premotor cortex and supplementary motor area (SMA) were more activated for Japanese rhythm than for English rhythm, and the areas overlapped that of vowel production. Moreover, left premotor cortex activation was shown for human articulation-related naturalness and left SMA activation was shown for native language-related naturalness. A series of our studies suggests that greater premotor cortex activation during speech perception would explain speech sound unnaturalness of both frequency and temporal information.

Title: The cortical representation of sounds with speech-like modulation rates tested with multi-dimensional scaling

Authors: *X. TENG[1], D. POEPPEL[2];
[1]Dept. of Psychology, New York Univ., New York, NY; [2]Max Planck Inst., Frankfurt, Germany

Abstract: Neural oscillations in auditory cortex can entrain to sounds over a wide range of modulations, although there appear to be preferential rates. Two such discrete regimes have been established and investigated, a low-frequency range (< 8 Hz) and a high-frequency range (> ~ 30 Hz). These regimes arguably reflect specialized temporal coding at two clearly distinct timescales in the auditory system. While cortical oscillations do not appear to be robustly entrained by sounds with intermediate modulation rates (8 – 30 Hz), such sounds are perceivable and still give people a clear sense of temporal structure. One particular question presents itself : how does the auditory system track and code the sounds with mid-range modulation rates? To address this question, we use a match-to-sample task in the context of MEG recording. Participants listen to sounds at five different modulation rates: 4-7 Hz (‘theta’ sound), 8-12 Hz (‘alpha’ sound), 13-20 Hz (‘beta1‘ sound), 21-30 Hz (‘beta2’ sound), and 31-45 Hz (‘gamma’ sound). While undergoing MEG recording, participants executed a 3-IFC match to sample study with modulation rate as the critical variable. We applied a multi-dimensional scaling analysis to the behavioral data – and further elucidate the MDS analysis with the MEG data. We observe that the representation of these different sounds is captured nonlinearly in a two-dimensional space, instead of by a one-dimensional space encoding modulation rate alone. In particular, we observe groupings of theta and gamma, on the one hand, and alpha, beta1, and beta2, on the other, suggesting that there are different coding strategies for the sounds of different modulation rates. MEG analyses of phase locking as well as classification analyses further illuminate the differential encoding. Title: Musical experience and interaural correlation processing at various interaural delays

Authors: *M. WANG[1,2], R. NING[1], Y. YANG[1], L. KONG[3];
[1]Sch. of Psychology, Beijing Normal Univ., Beijing, China; [2]the State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China; [3]Dept. of Physiol. and Pharmacology, Cumming Sch. of Medicine, Univ. of Calgary, Calgary, AB, Canada

Abstract: Interaural correlation processing is known to be based on the neural timing of the auditory system. Recently, it has been found that listeners with musical experience (musical group) usually have more precise or faster neural timing than those with no musical experience (control group). Here we show that participants in musical group behaviorally responded faster to a change in interaural correlation (IAC) than those in control group only at large interaural delays (4 ms and 6 ms). However, the response speed of musical group was the same as those of control group when the interaural delay is smaller (0 ms and 2 ms). We then recorded the cortical response to the interaural correlation change using event-related potentials. Consistent with our behavioral results, participants in the musical group had shorter P2 latency than those in the control group only when the interaural delay is large (4 ms). Thus, musical group showed an advantage over the control group for the processing of interaural correlation change with larger interaural delay. Given that interaural correlation processing at large interaural delay is closely related with speech perception accompanied by noise and reflections, listeners might benefit from their musical experience under noisy and reverberant environments.

Title: The endocannabinoid system exerts a paradoxical effect on visually-evoked responses of mouse retinal ganglion cells

Authors: *D. A. PROTTI[1,2], I. DARWISH[1], J. HUANG[2,3], C. YATES[1];
[1]Dept of Physiol., [2]Bosch Inst., [3]Biomed. Sci., Univ. of Sydney, Sydney, Australia

Abstract: The retina carries out complex and sophisticated neural computations that involve several distinct physiological mechanisms, including short and long-term plasticity phenomena similar to those described in other parts of the brain. The mechanisms responsible for modifying the strength of retinal synaptic transmission, however, are not fully understood. The endocannabinoid (eCB) system and all of its components (receptors, synthesising and degrading enzymes, and agonists) have been identified in the retina. We have previously found that the exogenous cannabinoid receptor agonist WIN55212-2 decreased the strength of synaptic transmission, whilst the eCB receptor antagonist AM251 enhanced synaptic transmission onto retinal ganglion cells (RGCs). Whether or not eCBs are tonically released in the retina and their potential physiological role, however, is still unknown. This study aimed to establish whether or not eCBs are released in physiological conditions in the retina and, if so, to unravel how they affect retinal processing of visual stimuli. We examined how the eCB system modulates the response strength of RGCs to visual stimulation and their receptive field organisation by doing whole-cell patch-clamp recordings from large ON- and OFF-RGCs in current-clamp mode. In addition, we assessed the effects of modulating the eCB system on RGC excitability by monitoring the activity of sodium channels in RGCs using voltage-clamp conditions. We recorded visual-evoked responses and voltage-gated sodium currents before and after bath application of either Anandamide (15 μM), an endocannabinoid, or URB597 (1 μM), an inhibitor of the enzyme that degrades Anandamide. Bath application of either Anandamide or URB597 reduced the peak amplitude of visual-evoked postsynaptic potentials and the spatial tuning of ON- and OFF-RGCs. Paradoxically, both drugs increased RGC peak spike count of visual-evoked responses. We also found that Anandamide and URB597 increased the occurrence of sodium currents for any given voltage-step and that the current voltage curve of the sodium current was shifted to the left. Finally, accommodation to high frequency visual stimulation was increased by both Anandamide and URB597, in line with the more classical modulatory role of eCBs. We conclude that eCBs are tonically released in the retina and they modulate retinal synaptic transmission, consistent with their function in other central nervous system areas. Their

net effect on retinal output, however, will depend on the balance of their effects at the circuit level and directly on RGCs sodium channels.

Title: Ultraviolet and long-wavelength excitation combine with mid-wavelength inhibition to generate multiphasic spectral patterns in the ganglion cells of larval zebrafish retinas

Authors: *R. F. NELSON[1], V. P. CONNAUGHTON[2];
[1]Neural Circuits Unit, NINDS, NIH, Bethesda, MD; [2]Biol., American Univ., Washington, DC

Abstract: Larval zebrafish possess 4 cone types with opsin absorbances spanning the spectrum from red to ultraviolet wavelengths. The wavelength processing performed by larval ganglion cells (GCs) on this rich spectral substrate is not yet known. We measured light-evoked GC impulse discharges in the optic nerves of *in vitro*, superfused 5-6 dpf larval eyes. 'Loose-patch' recordings of GC spike discharges were obtained penetrating the optic nerve stump of eyes placed cornea side down in the recording chamber, while stimulating through the sclera with 9 wavelengths of light (330-650nm), each at 7 light intensities (0.5 ND interval). Peri-stimulus time histograms (PSTH) were qualitatively scored for spectral properties. A spectral model based on the integrated ON discharges interpolated spectral sensitivities and extracted the amplitudes of individual cone signals contributing to the spectral patterns. Receptive fields were mapped with 20μm slit stimuli. 89% of 36 characterized cells were spectrally multiphasic (color opponent) types. Spectrally triphasic GCs were the most common type (64%). These GCs were excited by long and short wavelengths and inhibited by mid wavelengths. Green, blue, or green and blue cones could be inhibitory, with the remaining cones being excitatory. Pentaphasic GC's were the next most common (11%). These cells were excited by UV, far red, and mid-spectral stimuli, and inhibited by blue and near red stimuli. Examples of biphasic and tetraphasic spectral patterns were also encountered. In all except the tetraphasic GC's, where UV was inhibitory, ultraviolet stimulation (330,370nm) evoked the greatest discharge of impulses, and the maximum spectral peak. Receptive field space constants of less than 10μm were observed. The cone-

dominated retina of larval zebrafish produces a GC output that is almost entirely color opponent. The common triphasic spectral pattern would appear to send a dominant signal of 'small' and 'not green' to the larval brain. This pattern, also seen in the H3 horizontal cells of adult zebrafish, likely represents the color-opponent output of UV cones. This suggests that UV cone pathways to GCs mature early in zebrafish development.

Title: SIRT6 deficiency causes neurotransmission defects in the mouse retina

Authors: *D. M. SILBERMAN[1], K. ROSS[2], P. H. SANDE[1], S. KUBOTA[3], R. S. APTE[3], S. RAMASWAMY[2], R. MOSTOSLAVSKY[2];

Abstract: The retina is one of the major energy consuming tissues within the body and its energetic source for normal functioning comes mainly from glucose metabolism. This necessity for glucose is evidenced by alteration in electroretinogram (ERG) responses and altered neurotransmitter release as described in ischemic and hypoglycemic conditions. Upon activation of photoreceptors, G-coupled glutamate receptors (mGluR) regulate transmitter release by ON bipolar cells ultimately converting visual stimulation to patterns of activity of retinal ganglion cells (RGCs) leading to visual perception in the visual cortex. The synaptic transmission is a highly energy demanding event and it has been shown that a decline in energy supply and a disruption in bioenergy homeostasis play a critical role in multiple neuropathological conditions. It is therefore of physiological significance to have synaptic activity coupled with glucose

homeostasis. SIRT6, a chromatin- bound enzyme member of a conserved family of NAD(+)-dependent deacylases, regulate various metabolic pathways and have emerged as an important sensor of energy status in mammals. SIRT6 has been shown to regulate glycolitic genes as the glucose transporter GLUT1 and has been described as a tumor suppressor factor and as a critical modulator of DNA repair. Given the importance of glucose availability for retina function, the critical role for SIRT6 in modulating glycolysis and the lack of information about this sirtuin in the retina, the goal of this study was to provide a functional characterization of SIRT6 in this tissue. We found that SIRT6 is expressed in the nuclei of cells in all retinal layers and is highly active, as shown by the significant increased levels of acetylation of it substrates, H3K9 and H3K56, in the SIRT6-KO retina compared to the WT. In SIRT6 deficient mice (strain 129/J), the structure of the retina remained unchanged and no significant differences in the thickness of the layers between WT and KO mice were observed. However, SIRT6 deficient retinas exhibited increased apoptosis in the inner layers determined by TUNEL, downregulation of the G0-coupled type 6 metabotropic glutamate receptor (Grm6) gene and upregulation of the glucose transporter GLUT1, indicating that both neurotransmission and glucose levels in the retina might be regulated by SIRT6. Functionally, ERG analysis showed that both scotopic and photopic a- and b-wave amplitudes were severely altered for all the light intensities analyzed in the retina of SIRT6-KO mice, indicating a unique role for SIRT6 as a modulator of retinal function.

Abstract: Retinal ganglion cells (RGCs) comprise a small portion of the vertebrate retina, yet they are the sole communication between retina and brain. This population of neurons is composed of more than 25 different types, as defined by morphology, responsible for responding to different light stimuli and coordinating with visual reflex centers. Despite studies

characterizing the distinct morphologies of RGC subtypes, the transcriptomic profiles of many of these cells have remained elusive. Specifically, there has not been a definitive study that links morphological and physiological properties of ganglion cells to their transcriptome. Our project aims to uncover the genetic networks operating within subsets of retinal ganglion cells identified by different characteristics, including their physiology and morphology. Individual retinal ganglion cells were isolated from adult mouse retinas based upon morphology and physiology. After isolating the RNA and amplifying the cDNA for each individual cell, the resulting cDNA was hybridized to microarrays and analyzed. Gene clusters have been identified that correlate with specific morphologies/electrophysiological properties of ganglion cells. This method has also revealed transcriptomic variation between individual cells, which we have validated using a combination of *in situ* hybridizations and immunohistochemistry. The analysis of single cells allows for in-depth studies regarding the genetic profile responsible for a particular cell's function. Our studies have yielded multiple genetic networks corresponding to subsets of RGCs that we will utilize in the future to better understand the unique roles of these cells and how retinal ganglion cells are specified during development.

Title: Delineating retinal ganglion cell subtypes in macaque monkey using large scale morphometric cluster analysis coupled with immunohistochemistry

Authors: D. VAN DER LIST[1], *K. D. MURRAY[2], W. M. USREY[3];
[1]Univ. of California, Davis, Davis, CA; [2]Psychiatry & Behavioral Sci. and Ctr. for Neurosci., Univ. California Davis, Davis, CA; [3]university of California, Davis, Davis, CA

Abstract: All visual information must pass to the central nervous system along sets of axons emanating from a diverse set of retinal ganglion cells (RGCs). In primates, where molecular

markers of RGC subtypes are less well defined, definitive categorization of RGCs has to rely on physiological, connectional and morphological properties. To date, no useful reference database exists that can be harnessed for classifying monkey RGC subtypes. To address this we conducted a large-scale survey of over 300 monostratified RGC's in the adult macaque monkey with the goal of identifying a morphological reference database of functional cell classes using a set of readily quantifiable morphological parameters coupled with antibody staining. All RGC's were filled by direct application of DiI crystals to wholemount retina followed by antibody labeling using several candidate RGC markers including HCN1, SMI-32, Kv1.2 and calbindin. Confocal imaging and Neurolucida software were used to make morphometric measurements of each labeled RGC. A hierarchical cluster analysis was performed using various morphometric features including soma area, dendritic field area and number of branches. In addition, for each cell, eccentricity was recorded at 1mm intervals from the fovea to peripheral edge and depth of stratification within the inner plexiform layer (IPL) was measured. A diverse set of cells were identified using this approach including midget, parasol, wide field, large and giant sparse, broad and narrow thorny cells. Unsupervised hierarchical clustering successfully segregated DiI labeled RGCs into functionally distinct groups that correlated with the known parasol marker, HCN1, along with positively labeled SMI-32 cells. Surprisingly, other purported markers of RGC's, Kv1.2 and calbindin did not correlate with distinct morphological subtypes of RGC suggesting they may label a broader range of RGC 's. These results illustrate that by using a defined set of minimal morphological parameters in combination with antibody staining, we are able to classify RGCs into functionally distinct subtypes in the macaque monkey. The resulting set of morphological features will be an important reference database for future studies identifying RGC subtypes in monkey.

Title: Classification and characterization of twenty functional subtypes of ganglion cells in the mouse retina

Authors: *A. MANI[1], G. W. SCHWARTZ[2];
[1]Dept. of Ophthalmology, [2]Departments of Ophthalmology and Physiol., Northwestern Univ., Chicago, IL

Abstract: Classification of neurons into distinct, functional, morphological, and genetic classes is essential in extending our understanding of the nervous system to the level of individual circuits. We have developed a novel strategy for classifying retinal ganglion cells (RGCs), which form the parallel outputs of the retina, carrying all visual information to the rest of the brain. Far from the textbook camera-like representation of the visual world, in recent years it has been found that intricate computational processing already occurs in the retina. Parallel information channels, carried by the different RGC types, each extract specific features from the visual scene, including contrast, motion, orientation and color. A necessary step in understanding the different computations done in the retina, and characterizing the circuits responsible for them, is classification of RGCs into their different types. Previous attempts to classify RGC types have relied on unique gene expression profiles of subsets of RGCs or on large-scale clustering of dendritic morphology or electrophysiological properties. The different classification schemes have yet to arrive at a definitive, unified typology, and less than half of the ~20 RGC types suggested by morphological studies have been found in functional classifications. Here we present a novel functional classification of RGCs in the mouse retina, using spiking response to a set of light stimuli. We combine clustering and principal component analysis techniques with an efficient method based on a decision tree to probe a large number of parameters of the light response. We have achieved reliable, online classification of 20 RGC types, and our algorithm can be used across labs to standardize RGC typology. Our classification includes all functional RGC types previously identified in mouse, as well as types previously identified only in other species, and types that were previously unknown in any mammalian retina.

Title: Toward a complete functional classification of ganglion cells in the mammalian retina

Authors: *S. RAVI[1], D. AHN[2], M. GRESCHNER[2], A. M. LITKE[3], E. J. CHICHILNISKY[4], G. D. FIELD[1];
[1]Neurobio., Duke Univ., Durham, NC; [2]Systems Neurobiology, Salk Inst., Univ. of California San Diego, San Diego, CA; [3]Santa Cruz Inst. for Particle Physics, Univ. of California Santa Cruz, Santa Cruz, CA; [4]Neurosurg. and Ophthalmology, Stanford Univ., Stanford, CA

Abstract: Retinal ganglion cells (RGCs) are the exclusive source of visual signals to the brain. Morphological studies suggest that 15-20 types tile the retina with their dendritic fields. This implies that each RGC type provides a uniform sampling of the visual scene. However, functional classifications have found 5 - 12 types, and in some cases RGCs that appear to lie along a functional continuum, in apparent contradiction to the numerous types found in anatomical studies. The purpose of this study is to design a robust classification paradigm that will establish the extent to which visual information is processed in distinct parallel channels. This paradigm will be standardized across animals, so that it can serve as a platform to be used in different labs, animal models, and transgenic lines. We also aim to determine whether looming detectors (LD) and/or orientation selective (OS) cells observed in previous studies sample visual space uniformly. A large-scale multi-electrode-array (MEA) was used to record the action potentials of RGCs in an isolated rat retina preparation. Several visual stimuli were used to drive RGC responses: spatiotemporal white noise, drifting sinusoidal gratings, and full field flashes. Recorded spikes were sorted offline to identify distinct RGCs. A quantitative classification procedure was designed using parameters extracted from responses to visual stimuli. The classification procedure was tested across preparations to ensure reproducibility. The receptive field properties of OS and LD cells were measured to determine their spatial arrangement. Individual recording sessions identified 400-500 RGCs over the MEA, from which we consistently classified 12 functional types, in addition to several others that were less reliably identified. The receptive fields of each type were arranged in a tiling pattern, or “mosaic”, indicating that these RGC types sample space uniformly and that each identified RGC type was not further divisible. Distinct functional channels of LD and horizontal and vertical OS cells in the retina appeared to sample space with a mosaic organization similar to other types of RGCs with center-surround receptive fields.

Title: Genetic identification of a novel bistratified intrinsically photosensitive retinal ganglion cell

Authors: *D. J. BERG, S. SABBAH, D. BERSON;
Brown Univ., Providence, RI

Abstract: Intrinsically photosensitive retinal ganglion cells (ipRGCs) are rare mammalian photoreceptors that use the photopigment melanopsin. They are essential for such non-image-forming visual functions as circadian entrainment and the pupillary light reflex. ipRGCs comprise six subtypes distinguishable by morphology, physiology, and projections. We used transcriptional profiling (RNAseq) to identify dozens of genes that are much more highly expressed in murine ipRGCs than in conventional ganglion cells. One such gene, *Rbp4*, codes for a retinoid binding protein. It was strongly expressed in cells labeled in a mouse reporter for all known ipRGC subtypes (Ecker et al., 2010), but not in those labeled in another reporter that marks only the M1-M3 ipRGC subtypes. To determine which ipRGC subtype(s) expressed *Rbp4*, we obtained a transgenic Rbp4-Cre mouse (GENSAT) and fluorescently labeled Cre-expressing cells either by crossing with a Cre-reporter mouse or by intraocular injection of flexed viruses. Ganglion cells labeled in these studies appeared to belong to a single type ('Rbp4-RGCs') with intermediate dendritic field size (~165 um diameter) and a bistratified dendritic arbor. One arbor co-stratified with M1 ipRGCs at the outer limit of the inner plexiform layer (IPL), while the other stratified near the ON cholinergic (starburst) sublayer. We assessed functional properties using multiphoton microscopy and selective expression of the Ca^{2+} indicator GCaMP6f(Ai95 reporter) in Rbp4-cre mice. Rbp4-RGCs were strongly excited by increases in illumination either globally or restricted to the receptive-field center, but were strongly suppressed by drifting bars or gratings, suggesting very strong, motion-sensitive surround inhibition. A weak ON response persisted under synaptic blockade, suggesting that Rbp4-RGCs are intrinsically photosensitive. Rbp4-RGCs resemble M1, M3 and M6 ipRGCs in having a purely ON-type synaptically driven responses despite extensive arborization in the OFF sublayer; all such OFF-layer dendrites probably receive ectopic *en passant* contacts from the axons of ON cone bipolar cells. Rbp4-RGC axons innervate the dorsal and ventral lateral geniculate nuclei and superior colliculus, but

spare other major non-image-forming ipRGC targets such as the suprachiasmatic and olivary pretectal nuclei. These findings reveal the existence of a physiologically, morphologically, and molecularly distinct mouse ganglion-cell type that appears to be yet another variety of ipRGC. Its projection patterns suggest a role primarily in form vision rather than in non-image-forming functions such as circadian entrainment or pupillary light reflex.

Title: Intrinsically photosensitive retinal ganglion cells are required for proper dopaminergic amacrine cell development

Authors: *T. MUNTEANU[1], S. PAN[2], P. KOFUJI[3], T. M. SCHMIDT[1];
[1]Neurobio., Northwestern Univ., Evanston, IL; [2]Biol., Johns Hopkins Univ., Baltimore, MD;
[3]Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Retinal dopamine is known to play a crucial role in vision and is produced by the dopaminergic amacrine cells (DACs). DAC processes are found in the inner plexiform layer (IPL), where they release both dopamine and GABA. DACs have been found to co-stratify with the melanopsin-expressing, intrinsically photosensitive retinal ganglion cells (ipRGCs). These two cell types interact in a variety of ways. ipRGCs drive light-evoked depolarizations in DACs in a retrograde manner. ipRGCs also respond to dopamine, and their stratification within the IPL closely follows that of DACs. In fact, when DAC stratification is disrupted through a knockout of the semaphorin receptor PlexinA4, ipRGCs co-localize with the aberrant DAC processes. Since ipRGCs depend on DACs for proper development, we examined whether DACs also depend on ipRGCs for proper development. To test this we utilized immunohistochemistry for tyrosine hydroxylase, a marker of DACs, and then counted DACs in a variety of mouse models where ipRGCs are manipulated. When ipRGCs are ablated early in development, we see a reduction in the number of DACs. Surprisingly, this effect is absent in mice lacking melanopsin,

indicating that light signaling through ipRGCs is not likely to play a role in DAC development. Collectively, these results indicate that ipRGCs are required for proper DAC development, possibly through physical contact between these two cell types during early postnatal stages.

Title: Optogenetic responses to low-intensity light in dystrophic retinas revealed by blockade of pathological hyperactivity

Authors: ***J. M. BARRETT**, G. HILGEN, E. SERNAGOR;
Inst. of Neurosci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Retinitis pigmentosa (RP) is a hereditary progressive retinal dystrophy that causes visual impairment and eventually blindness. Presently, electrical prostheses are able to restore crude vision, but newer approaches based on optogenetics - genetic expression of light-sensitive proteins in neurons - may potentially offer higher-quality vision. However, alongside photoreceptor loss, retinal degeneration also involves significant inner retinal remodelling that leads to spontaneous, rhythmic bursting activity in retinal ganglion cells (RGCs). Recently, both our lab (Barrett et al, SfN 2014) and others (Toychiev et al, 2013) have shown that reducing spontaneous activity in dystrophic retinas improves the signal-to-noise ratio of RGC responses to photoreceptor, electrical and optogenetic stimulation. We sought to extend these results by investigating whether this approach can improve the contrast sensitivity and spatial acuity of optogenetic responses. We crossed a transgenic mouse line expressing the light-sensitive cation channel channelrhodopsin2 (ChR2) in Thy1-expressing RGCs with the rd1 model of retinal degeneration, creating a strain of mice with retinal degeneration and ChR2-expressing RGCs (ChR2rd1 mice). We recorded RGC activity from ex-vivo ChR2rd1 retinas using a large, high density, 4096-channel, Active Pixel Sensor CMOS multielectrode array (APS CMOS MEA; Berdondini et al 2009). Light stimuli were delivered with a DLP projector, providing 664x664 pixels of patterned light stimulation over a retinal area of 2.67x2.67mm^2 with 4μm resolution and sub-millisecond temporal precision. We were able to evoke ChR2-mediated responses from

hundreds of RGCs per experiment using RGB light with an intensity of around 20μW/mm^2. We presented a variety of stimuli - e.g. gratings of varying phase, spatial frequency and contrast; moving bars; Sloan letters - and used Bayesian classification to decode stimulus properties from the RGC population response (Jacobs et al, 2009). Blocking spontaneous hyperactivity using 40μM meclofenamic acid (MFA) improved the decoder performance in all conditions. Our results show that the principle of blocking spontaneous hyperactivity in the rd1 retina to improve optogenetically-evoked responses extends to a variety of stimulus classes and this enables lower luminance, lower contrast and higher spatial frequency stimuli to be correctly discriminated. This suggests that this technique might improve the quality and usefulness of vision returned by retinal prosthetics.

Title: Oscillating ON-direction selective ganglion cells induce oscillating eye movements in Nyx^{nob} mice

Authors: ***M. KAMERMANS**[1], K. M. FRANSEN[2], W. DE GRAAFF[4], J. HUISMAN[4], Ö. ÖZYILDIRIM[5], B. BRAAKMAN[5], M. A. MCCALL[3], C. I. DE ZEEUW[5,6], B. H. J. WINKELMAN[5,6];

Sci. and Neurobio., Univ. of Louisville, Louisville, KY; [4]Retinal Signal Processing, [5]Cerebellar Coordination & Cognition, Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [6]Neurosci., Erasmus MC, Rotterdam, Netherlands

Abstract: Retinal motion detection is elemental to image stabilizing eye movement reflexes. In Nyx^{nob} mice a mutation in the X-chromosomal gene encoding for nyctalopin causes defective synaptic input of retinal ON-bipolar cells, leading to congenital stationary night blindness (CSNB) and malfunction of the ON-pathway. Loss of ON-bipolar cell function specifically affects ON-direction selective ganglion cells (ON-dsGCs), which underlie the optokinetic reflex. Analysis of the eye movement response to optokinetic stimulation using sine-wave gratings

showed substantial impairment of the optokinetic reflex and defective gaze holding. Furthermore, eye movements of Nyx^{nob} mice exhibited a prominent horizontal oscillation with an average frequency of 5 Hz. To check whether this pathological eye movement behavior could be caused by abnormal anatomy, we crossed Nyx^{nob} mice with SPIG1-GFP knock-in mice, which show GFP-labeling in a subtype of ON-dsGCs sensitive to downward retinal image movement (Yonehara et al., 2008). Analysis of SPIG1-GFP expression combined with anterograde labelling of ganglion cells with CTB-Alexa 555 showed no apparent miswiring of the central projections of ON-dsGCs to the MTN of the accessory optic system. Electrophysiological recordings in the retina confirmed that ON-dsGCs of Nyx^{nob} mice are unresponsive to light stimulation. Moreover, the membrane potential of ganglion cells showed robust sub-threshold oscillations with a frequency of 5 Hz on average. These oscillations were eliminated or significantly reduced by simultaneously blocking both AMPA and NMDA, using application of DNQX and D-AP5. Intravitreal injection of this cocktail in both eyes of Nyx^{nob} mice also abolished the 5 Hz oscillation in spontaneous eye movements, recorded while the animal was awake, which strongly suggests that synchronous oscillation of dsGCs in the retina is the direct cause of the horizontal eye movement oscillation. This mechanism might also explain the small amplitude horizontal nystagmus observed in CSNB patients (Simonsz et al., 2009).

Title: Directional tuning of excitatory synaptic inputs to direction selective retinal ganglion cells revealed by optical quantal analysis

Authors: *V. JAIN, G. B. AWATRAMANI;
Biol., Univ. of Victoria, Victoria, BC, Canada

Abstract: Introduction: Whether excitatory bipolar cell inputs to direction selective ganglion cells (DSGCs) are directionally tuned is a matter of current debate. Patch-clamp analysis of light

evoked currents indicates that they are directionally tuned, implying that 'null' inhibition (known to be mediated by starburst amacrine cells) acts presynaptically at bipolar cell terminals. However, optical imaging of presynaptic bipolar cell activity using Ca2+ and glutamate sensors indicate that inputs to DSGCs are not directionally tuned implying a postsynaptic locus for null inhibition. To resolve this issue, we performed an optical quantal analysis using 2-photon calcium imaging techniques. Methods: We identified DSGCs in the mouse retina based on their directional spiking responses measured extracellularly. Subsequently, DSGCs were loaded with a Fluo-5F through a whole-cell patch-pipette. Changes in Ca2+ in individual dendritic compartments of DSGCs were measured using 2-photon laser scanning microscopy. Results: To estimate presynaptic glutamate release we measured Ca2+ responses mediated by synaptically activated NMDA receptors. In response to moving spots, spatially isolated "Ca2+ hot-spots" (FWHM ~1μm) were observed along the dendrite. These responses were abolished when a NMDA receptor antagonist (50 μM D-AP5) was added to the bath indicating that they represent activity at single glutamatergic synapses between the bipolar terminals and DSGCs. Interestingly, in about a third of synaptic sites responses were strongly directionally tuned. The tuning of the dendritic Ca2+ response matched that of the spiking response. Moreover, DS tuning at single synaptic sites was abolished when GABA receptor antagonists were applied. Conclusions: Optical imaging of synaptic activity unequivocally reveals directional tuning of the inputs to DSGCs. Thus, null inhibition mediated by SACs must act pre-and postsynaptically to shape DS in the retina.

Title: Visual information encoded by the wave of first stimulus-evoked spikes revealed in the retinal ganglion cell layer by large-scale multielectrode array recordings

Authors: *E. SERNAGOR[1], J. M. BARRETT[2], G. PORTELLI[4], G. HILGEN[3], T. MASQUELIER[5], P. KORNPROBST[4];

[2]Inst. of Neurosci., [3]INstitute of Neurosci., [1]Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [4]Inria Sophia Antipolis Méditerranée, Sophia Antipolis, France; [5]Vision Inst., CNRS – INSERM – Univ. Pierre&Marie Curie, Paris, France

Abstract: How a population of retinal ganglion cells (RGCs) encodes the visual scene remains an open question. Going beyond individual RGC coding strategies, a previous study in salamander suggested that the concerted spiking of a RGC pair encodes spatial information (Gollisch and Meister, 2008). Gollisch and Meister suggested that a population code based on such concerted spiking could be a powerful mechanism to transmit visual scenes. Here, we tested this hypothesis in the mammalian retina by recording simultaneous light-evoked responses from hundreds of mouse RGCs using a new generation of large-scale, high density multielectrode array (MEA), the Active Pixel Sensor CMOS MEA consisting of 4096 electrodes covering an active area of 7.12 mm^2. We stimulated the retina using stationary gratings (spatial frequency 0.009 to 0.075 cycles per degree) presented at 8 different phases. In contrast to the previous findings in salamander, we did not find any RGC pair exhibiting a clear latency tuning to the phase of the grating, demonstrating that in mouse, individual RGC pairs may not provide sufficient information to encode visual information (this may be partially due to strong background spontaneous activity in the mammalian retina). However, when we considered the concerted spatio-temporal spiking pattern of a large RGC population at pan-retinal level rather than just in cell pairs, we found that the wave of first stimulus-evoked spikes (WFS) provides an accurate indication of stimulus content. Moreover, we found that it outperforms classical spike count- and latency-based codes by being more efficient and faster. Overall, these novel observations suggest that already at the level of the retina, the WFS provides a reliable and fast strategy to rapidly transmit new visual scenes.

Title: Genetically identified Suppressed-by-Contrast retinal ganglion cells in mice reliably signal self-generated visual stimuli

Authors: *N.-W. TIEN[1], J. PEARSON[1], C. HELLER[2], J. DEMAS[2,3], D. KERSCHENSTEINER[1];
[1]Ophthalmology and Visual Sci., Washington Univ. in St. Louis, Saint Louis, MO; [2]Dept. of Physics, [3]Dept. of Biol., St. Olaf Col., Northfield, MN

Abstract: Spike trains of retinal ganglion cells (RGCs) are the sole source of visual information to the brain; and understanding how the approximately 20 RGC types in mammalian retinas respond to diverse visual features and events is fundamental to understanding vision. Suppressed-by-Contrast RGCs (SbC-RGCs) stand apart from all other RGC types in that they reduce rather than increase firing rates in response to light increments (ON) and decrements (OFF). Here, we genetically identify and morphologically characterize SbC-RGCs in mice, and target them for patch clamp recordings under 2photon guidance. We find that strong ON inhibition (glycine > GABA) outweighs weak ON excitation, and that inhibition (glycine > GABA) coincides with decreases in excitation at light OFF. These input patterns explain the suppressive spike responses of SbC-RGCs, which are observed in dim and bright light conditions. SbC-RGC responses lack spatial antagonism and inhibition is driven by rectified receptive field subunits, leading us to hypothesize that SbC-RGCs could signal pattern-independent global changes in the retinal image. Indeed, we find that shifts of random textures matching saccade-like eye movements in mice elicit robust inhibitory inputs and suppress spiking of SbC-RGCs over a wide range of texture contrasts and spatial frequencies. Similarly, stimuli based on kinematic analyses of mouse blinking consistently suppress SbC-RGC responses. Receiver operating characteristics show that SbC-RGCs are reliable indicators of self-generated visual stimuli that may contribute to central processing of blinks and saccades.

Title: Light adaptation changes the functional properties of direction selective retinal ganglion cells

Authors: *X. YAO[1], G. D. FIELD[2];
[2]Neurobio., [1]Duke Univ., Durham, NC

Abstract: Light adaptation enables vision to operate across an extremely wide range of light conditions. Direction selective retinal ganglion cells (DS-RGCs) respond to motion of objects moving in a preferred direction. ON-OFF DS-RGCs are thought to work at local motion detectors whereas ON DS-RGCs are thought to mediate motion-related behaviors like the optokinetic reflex and object tracking. Yet we know little about whether and how light adaptation alters DS-RGCs response properties. Here we use a large-scale multi-electrode array to record *ex vivo* and simultaneously from large population of DS-RGCs across light levels. Their response properties were probed by using a battery of visual stimuli including drifting gratings, moving bars, full-field light steps, and checkerboard white noise. We observed that direction tuning of superior preferring ON-OFF DS-RGCs was weaker and broader at lower light levels, while other subtypes exhibited more stable tuning. The speed tuning of all DS-RGC types was narrower as at lower light levels, while the peak location remained constant. Furthermore, ON-OFF DS-RGCs changed their response polarity to pure ON at rod-mediated light levels. These findings indicate that direction computations in the retina change across light levels, which likely constrains how rod signals converge onto DS RGCs and is relevant for how the downstream circuitry processes these signals from the retina.

Title: Spike time patterns in retinal ganglion cell responses convey information about stimulus shape

Authors: *S. V. GIRMAN[1,2], S. WANG[1];
[1]Regenerative Med. Inst., Cedars Sinai Med. Ctr., West Hollywood, CA; [2]Ophthalmology, OHSU, Portland, OR

Abstract: Traditionally it was thought that the modulations of mean firing rate of retinal ganglion cell (RGC) encode all information about the stimulus and that the response magnitude is the only variable which contains stimulus-relevant information. Much of our understanding of how the RGCs encode the visual world is based on studies analyzing the responses solely in terms of mean firing rate. In this study we addressed the question whether all information the RGC spike trains carry can be assessed with the rate-based coding scheme. The simplest way to answer the question is to analyze the iso-rate responses triggered by different stimuli: the responses carry identical information in the mean rate; therefore, if they can be differentiated in any way regarding the stimuli eliciting them, then the answer to the question posed above is "no". Following this approach, we recorded spike activity of RGCs in rat *in vivo* presenting a set of stimuli of different spatial configurations (shapes), while their contrast and temporal attributes were the same. The spatial parameters of the stimuli were adjusted to achieve that, in a given experiment, the stimuli elicited equal responses in terms of mean spike rate. To compare pairwise the PSTH profiles of the responses, we obtained the differential PSTH (dPSTH) by bin-wise subtraction between the two PSTHs. The more the PSTH profiles differ, the more prominent are the time intervals in the dPSTH where contiguous bins contain values of the same sign, either positive or negative, and, correspondingly, the more prominent are the low-frequency components in the Fourier spectrum of the dPSTH. Thus, we suggested quantifying the PSTHs pattern dissimilarity as a ratio of the mean amplitude of the first five harmonics of the dPSTH Fourier transform to that of the middle-spectrum harmonics. This index of pattern dissimilarity (IPD) is invariant to firing rates in the responses; therefore, IPDs obtained for individual cells can be pooled together in order to characterize how dissimilar the PSTH profiles are in the overall set of responses of all recorded RGCs. We found that the distribution of IPD values obtained for response pairs to stimuli of equal strength but having different shapes differed, with high statistical significance, from IPD distribution for the responses to stimuli of the same shape, while magnitudes of the responses under comparison were equal. We concluded that spike temporal patterns of iso-rate responses can be significantly different depending on stimulus shape. Therefore, response temporal patterns of RGCs carry information about stimulus shapes, in addition to information regarding the stimulus strength encoded in the mean spike rate.

Title: Position-dependent characteristics of retinal ganglion cell mosaics across the entire retina

Authors: ***F. FRANKE**[1], M. FISCELLA[1], R. DIGGELMANN[1], A. DRINNENBERG[2], B. ROSKA[2], A. HIERLEMANN[1];
[1]ETH Zürich, Basel, Switzerland; [2]Friedrich-Miescher-Institute, Basel, Switzerland

Abstract: The retina encodes the visual scene by means of roughly 20 parallel channels, each one represented by a specific retinal ganglion cell (RGC) type. The receptive fields of all RGCs of a certain type tile the complete visual scene with small overlap in a mosaic-like fashion. It is thought that each RGC represents the local information about a certain feature in the visual stimulus and that at each retinal position is covered by at least one cell of each type. For some cell types, the visual features they encode seem to be relatively well characterized: direction-selective ON-OFF (DS) cells, e.g., encode the presence of local movement in a certain direction. However, in the retina of many mammalians, the characteristics of individual cells of a specific type, for example their receptive field size (and thus their spatial density), change with retinal position and retinal eccentricity: The further away from the optic nerve, the larger the receptive fields. Why are receptive field characteristics position dependent? One obvious reason is the optical transfer function (OTF) of the eye: The further away from the intersection of the optical axis of the eye and the retina, the larger a point light source will appear on the retina. Thus, the maximal optical resolution of the retina is limited and position dependent. The position dependence of RGC properties is not well characterized and it is not known to which extent it reflects physical properties of the incoming light. To address this question we recorded from a large number of DS RGCs in different regions of the isolated hamster retina by means of high-

density microelectrode arrays (HD-MEA) with 30k electrodes and 1000 read-out channels while the retina was visually stimulated with moving bars. The electrodes of the array record the spiking activities of essentially all RGCs on top of the array and each RGC is recorded from by up to 50 different electrodes. To extract individual RGC spiking activity from the recorded signal mixture, individual spikes were detected by thresholding, and then fed into an automatic spike sorting algorithm. The resulting spiking activity of each cell was used to determine its direction selectivity index, which allowed us to identify the DS cells, as well as preferred direction, peak firing rate, receptive field size, and tuning function width. We then related these characteristics to a simple model of the OTF of the eye. We show that the RGC characteristics are indeed dependent on retinal position, which partially can be explained by the OTF of the eye.

Title: Circuit-based description of retinal ganglion cell computation explains the spike response at millisecond resolution

Authors: *D. A. BUTTS[1], Y. CUI[1], Y. V. WANG[2], J. B. DEMB[2];
[1]Dept. of Biol., Univ. of Maryland, College Park, MD; [2]Ophthalmology and Visual Sci., Yale Univ., New Haven, CT

Abstract: Visual processing depends on computations performed by complex neural circuits, but it is often unclear how these circuits shape processing due to relatively impoverished descriptions of visual computation. In the retina, for example, there is extensive knowledge of the feedforward circuit components underlying retinal output, but model-based descriptions are typically based on linear or mathematically abstract components. Here, we derive a novel description of ganglion cell computation based on retinal circuitry, and constrained by voltage-

clamp and extracellular recordings from the same neuron. We recorded from ON Alpha ganglion cells in the mouse retina, *in vitro*, using a temporal noise modulation (0 - 30 Hz) of a spot (1-mm diam., photopic level), centered on the ganglion cell's receptive field. First, a cell-attached recording measured spikes and then a whole-cell recording measured excitatory currents. We first demonstrate that nonlinear responses of ganglion cells are in part derived from nonlinearities present in the excitatory synaptic input. By fitting a novel nonlinear model for this current, and then extending it to explain the spike train, we offer a nearly perfect prediction of spike response at millisecond resolution. The model could also explain adaptation to stimulus contrast. The model critically depends on divisive suppression that is consistent with presynaptic inhibition of amacrine cells onto bipolar cell terminals, and its interaction with spike refractoriness. Our approach demonstrates a detailed circuit-based model of ganglion cell spike generation, and suggests novel computational components contributing to visual processing by retinal circuitry.

Title: The influence of dopamine on the temporal resolution of retinal neurons

Authors: ***M. L. RISNER**, D. G. MCMAHON;
Biol. Sci., Vanderbilt Univ., Nashville, TN

Abstract: Purpose: Dopamine is a key neuromodulator in the retina that reconfigures retinal circuitry based on the prevailing light level. To investigate how dopamine modulates vision our lab has previously generated a mouse model in which dopamine is depleted in the retina by genetically excising the rate limiting enzyme, tyrosine hydroxylase, required for producing dopamine (rTHKO). The rTHKO mouse exhibits deficits in contrast sensitivity measured both behaviorally and in acute retinal ganglion cell (RGC) recordings. The deficits we have observed

in contrast sensitivity of rTHKO are similar to those observed in Parkinson's disease patients. Parkinson's disease patients not only exhibit decreased contrast sensitivity, they also show reduced temporal resolution. The purpose of this study was to investigate temporal resolution of retinal neurons in rTHKO and control (C57Bl/6J) animals. **Methods:** We assessed temporal resolution of the electroretinogram (ERG) b-wave in whole animals and RGCs using *in vitro* multi-electrode array (MEA) recordings. To date we have assessed temporal resolution in 8 control animals and 4 rTHKO using the ERG technique and 2 control and 2 rTHKO animals using the MEA recording method. In both ERG and MEA recordings temporal resolution was probed using a square-wave broad-spectrum white light that varied from 0 to 30 cd/m^2 in luminance and 1 to 40 Hz in temporal frequency. To measure temporal resolution of the ERG b-wave and spike output of RGCs we computed the spectral density power of the first harmonic (F1). **Results:** The F1 of the ERG b-wave was not significantly different between genotypes across temporal frequencies. However, there was a significant difference in the F1 across temporal frequencies between genotypes in ON- and OFF-center RGCs. rTHKO OFF-center RGCs exhibited a decrease in the F1 across most temporal frequencies (1-34 Hz). rTHKO ON-center RGCs showed a decrease in the F1 at low and higher temporal frequencies (1, 15-40 Hz). **Discussion:** The divergent results between electrophysiological methods measuring the ERG b-wave and RGC spike output suggests temporal resolution is decreased by knocking out dopamine but only for RGCs. These results suggest that dopamine effects the response integration time of RGCs either through receptors native to RGCs or through synapses between bipolar cells and RGCs.

Title: Naturalistic visual stimuli modulate neural oscillations in the rodent ventral lateral geniculate nucleus of the thalamus

Authors: *U. M. CIFTCIOGLU[1], K. R. DING[1], V. SURESH[1], A. S. GORIN[2], F. T. SOMMER[3], J. A. HIRSCH[1];

[1]Biol. Sci., [2]Neurosci. Grad. Program, USC, Los Angeles, CA; [3]Redwood Ctr. for Theoretical Neurosci., Univ. of California, Berkley, Berkeley, CA

Abstract: There are two main routes from the eye to the brain in mammals. The pathway from the retina to the superior colliculus (SC) is directly involved with sensorimotor tasks and the pathway from the retina to the lateral geniculate nucleus of the thalamus (LGN) is associated with form vision. However the LGN is not a homogeneous structure and comprises a dorsal and a ventral subnucleus, the dLGN and the vLGN respectively. While the dLGN projects directly to the neocortex, the evolutionarily older vLGN connects with subcortical structures that coordinate movement, the SC, for example. The dLGN, which has been studied in depth, is much larger than its ventral counterpart, whose small size creates a challenge for electrophysiological studies *in vivo*. In mice, however, the two subnuclei are roughly the same size and are thus equally accessible. We have taken advantage of this species difference to explore the structure and function of the vLGN in the whole animal, using techniques of whole-cell recording with dye-filled electrodes *in vivo* in addition to computational analyses. Recently, we compared the two divisions of the murine LGN and found that neurons in the vLGN had receptive fields several times larger than those of relay cells in the dLGN, along with broader dendritic arbors. These findings were in keeping with the idea that the vLGN does not play a dominant role in form vision. Our next step was to compare neural coding in the vLGN with that in sensorimotor structures it connects to, using the literature about the SC as a starting point. In particular, experiments in both awake (Brecht et al., 2004) and anesthetized animals (Stitt et al., 2013; Sridharan et al., 2011) show that neurons in the SC encode visual stimuli in two ways, as a conventional rate code and also by means of gamma oscillations. We began our analysis using full field stimuli of different luminance values. Approximately a third of the cells in the vLGN responded both with an increase in firing rate and the initiation of gamma oscillations. The strength and frequency of the oscillations remained fairly constant once the threshold luminance value was reached. To determine if these oscillations might play a role in natural vision, we recorded responses to movies and found that gamma oscillations occured during some image sequences. The strength of the oscillations decreased with increasing stimulus contrast. These oscillations might help coordinate activity between the vLGN and subcortical visual motor networks in the execution of motor tasks.

Title: Optimizing electrical stimulation parameters in a lateral geniculate nucleus (LGN) model

Authors: *S. ELDAWLATLY, A. JAWWAD;
Computer and Systems Engin. Dept., Ain Shams Univ., Cairo, Egypt

Abstract: Restoring vision to the blind is no longer impossible thanks to recent advances in neural interfaces. Successful demonstrations of retinal implants motivate the development of more sophisticated and effective visual prostheses. However, when initial visual processing sites such as the retina or the optic nerve are completely damaged, the thalamic Lateral Geniculate Nucleus (LGN) makes the next logical interfacing site for visual prostheses. One of the main challenges in developing thalamic visual prostheses as well as other visual prostheses is optimizing the parameters of electrical stimulation. We propose a Kalman-based optimal encoder whose function is to determine the optimal electrical microstimulation parameters required to induce a certain visual sensation. In this approach, two Kalman filters are first trained: the first one relates LGN neuronal responses to visual stimuli while the second filter relates LGN neuronal responses to electrical stimuli. For a given visual stimulus, we use the first filter to predict the corresponding responses of the underlying population. The predicted responses are then decoded using the second filter to determine the electrical stimulus needed to elicit the responses predicted by the first filter. We demonstrate the performance of the proposed approach in analyzing synaptically-coupled LGN neuronal population using a probabilistic point process model. In this model, spiking of LGN neurons is modeled using a Generalized Non-linear Model (GNM) with stimulus-driven suppression which has been demonstrated to better fit LGN neuronal responses compared to other models (Butts et al., 2011, J. Neurosci., 31:31). We modeled a population of ON-center and OFF-center cells in which each ON-center cell has a corresponding OFF-center cell covering the same receptive field. Corresponding ON-center and OFF-center cells were synaptically-coupled through inhibitory interneurons. Visual stimuli driving the model were generated using a Gaussian distribution with zero mean presented at 30 Hz. We examined the performance of the proposed optimal encoder for different electrical stimulation parameters (quantization levels, stimulation duration, stimulation frequency and number of stimulation electrodes). The results demonstrate that we can achieve a significant similarity between LGN neuronal responses obtained using electrical stimulation and the responses obtained using the corresponding visual stimuli with a mean correlation of 0.61 ($P < 0.01$, $n = 54$). These results indicate the efficacy of the proposed optimal encoder in driving LGN neurons to induce visual sensations.

Title: Early maturation of trn gabaergic feedback inhibition to dlgn

Authors: *P. W. CAMPBELL[1], T. A. SEABROOK[2], G. GOVINDAIAH[2], W. GUIDO[2];
[2]Anatom. Sci. and Neurobio., [1]Univ. of Louisville, Louisville, KY

Abstract: The thalamic reticular nucleus (TRN) is a key modulator of thalamocortical activity. GABAergic neurons of TRN provide the main source of inhibitory feedback to relay cells in primary sensory thalamic nuclei such as the dorsal lateral geniculate nucleus (dLGN). Despite their role in gating retinogeniculate signal transmission little is known about how and when these inputs innervate the developing dLGN. To address this we used a GAD65 transgenic mouse in which GABAergic projections to dLGN can be visualized with GFP. We found that reticulothalamic fibers begin to innervate dLGN at early postnatal ages (P2-4). During the first postnatal week there is a rapid increase in innervation so that by P7-9 about 85% of dLGN is occupied by a dense plexus of TRN GABAergic fibers that are distributed throughout the nucleus. We also found that retinal signaling regulated the timing of TRN innervation. In transgenic mice lacking retinofugal projections (*math5 -/-*, Wang et al., 2001), reticulothalamic innervation was highly accelerated showing a two-fold increase in the rate of innervation at early ages. To assess whether these early projections form functional connections with dLGN cells, we conducted *in vitro* whole cell recordings in acutely prepared thalamic slices in transgenic mice that express channelrhodopsin in somatostatin (SST)-containing neurons of TRN (SST-Cre x ChR2). Blue light stimulation of SST containing fibers in dLGN evoked postsynaptic inhibitory activity in dLGN relay cells. Weak inhibitory responses were present as early as P2, a time when TRN terminals first arrive in dLGN. These responses matured rapidly over the first three postnatal weeks, growing in strength 50-fold, showing reliable responses to even high rates of stimulation (50 Hz) and displaying strong paired-pulse depression. By contrast, feed-forward inhibition, evoked by the electrical activation of optic tract and intrinsic interneurons, emerged at much later ages (P9-10). Thus in dLGN, feedback inhibition from TRN develops at early postnatal ages, at a time when retinal synapses onto dLGN cells are actively pruning to form adult-like patterns of connectivity. The presence of feedback inhibition in dLGN occurs well

before innervation and circuit formation of other nonretinal modulatory systems including descending input from cortical layer VI and ascending cholinergic input from brainstem.

Title: Spatial changes on LGN receptive fields by corticofugal input manipulations

Authors: ***C. RIVADULLA**, J. AGUILA, J. CUDEIRO;
Dept Medicine-Neurocom, Univ. De Coruna and INIBIC, Coruña, Spain

Abstract: Ascending sensory pathways in the brain are paralleled by descending feedback pathways, but there has been little consensus as to the role of the feedback connections in perception. The cortical feedback to the thalamus can modify how LGN neurons behave under visual stimulation, and work carried out mainly in anaesthetized animals has shown how the feedback thus affects the spatial and temporal characteristics of the visual signals to be transferred to the cortex. We have explored the effect of inactivation of V1 on LGN cell responses in the awake monkey. Transient inactivation of cortical neurons was achieved by mean of repetitive Transcranial Magnetic Stimulation (rTMS). We have recorded from 75 parvocellular cells in the LGN of two monkeys (Macaca mulatta) during visual stimulation with both, static and drifting gratings of several sizes before and after rTMS (figure-8 coil, 0.7Hz during 4 min; parameters able to induce a depression of cortical activity; (1)). 75% of the cells showed a decrease in firing rate during cortical blockade. This effect was stimulus dependent. However, the most striking result concerned the spatial location of LGN cells receptive fields (RFs). 33% of the cells (n=25) showed a significant shift in RFs position; 4.53 degrees in average. We were able to stablish a relationship between the retinotopy of the recorded cells and the direction of the shift. Since rTMS was always applied at the same cortical location, we conclude that the relative retinotopy between the affected area of the cortex and the recorded

LGN cells was critical for predicting the shift. Even when our inactivation method affects several millimeters of the cortical surface and, admittedly, we are altering an extensive part of the cortical feedback, our results are robust and suggest that RFs in awake animals are more dynamic than previously thought and are modulated by the cortico-thalamic input. (1) Ortuño, et al, Bursting thalamic responses in awake monkey contribute to visual detection and are modulated by corticofugal feedback. Front Behav Neurosci. 2014; 8: 198.

Title: Negative afterimages to a flashed spot may originate as early as in the visual thalamus

Authors: *H. LI, X. LIU, Y. LU, X. LI, I. M. ANDOLINA, W. WANG;
Chinese Acad. of Sci., Inst. of Neurosci., Shanghai, China

Abstract: The mismatch between the perceived and the physical stimulus is typically regarded as evidence for a visual illusion. The removal of a flashed spot often generates the perception of a negative afterimage. However, where the perception of such a negative afterimage is initiated in the brain remains unclear. It is well-known that ON or OFF centre neurons in dorsal lateral geniculate nucleus (dLGN) of visual thalamus respond vigorously to the removal of flashing spot stimuli with opposite signs. Considering recent progresses demonstrating visual thalamus in primates engages heavily in behavioral tasks and higher cognitive functions, we hypothesize the neuronal responses to the removal of a flashed dark or light spot in dLGN may provide the initial foundation for the generation of negative afterimages. In the current study using human psychophysical tests, electrophysiological single-unit and whole-cell recordings of cat dLGN, we found evidence to support such a hypothesis. Specifically, ON centre neurons exhibited higher firing rates with longer response duration in response to the removal of a dark spot than that of OFF centre neurons to the removal of a light spot. These results matched the observation of an asymmetry between opposite sign negative afterimages in our psychophysical experiment, as dark flashed spots generated perceptually stronger and longer afterimages than light flashed spots. Furthermore, we found that dLGN responses also showed a clear size tuning to the

removal of a flash spot of various sizes, comparable with our psychophysical test that the observed size of a negative afterimage was determined by the stimulus size. These findings suggest that the negative afterimage of a flashed spot could initiate at least as early as in the dLGN.

Title: Pretectal modulation of retinogeniculate signal transmission

Authors: ***S. P. MASTERSON**, G. GOVINDAIAH, N. ZHOU, P. S. MAIRE, W. GUIDO, M. E. BICKFORD;
Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: A projection from the pretectum (PT) to the dorsal lateral geniculate nucleus (dLGN) that utilizes gamma amino butyric acid (GABA) was previously described in cats, but the impact of PT-dLGN projections on geniculate circuitry remains poorly understood. We combined anatomical, physiological and optogenetic techniques to examine this projection in mice. Injections of cholera toxin subunit B conjugated to Alexafluor 488 (CTB-488) into the dLGN of C57/BK6 mice labeled PT cells via retrograde transport that were primarily distributed in the ipsilateral and contralateral posterior pretectal nucleus (PPT) and nucleus of the optic tract (NOT). Similar injections were placed in the dLGN of mice in which GABAergic cells express the red fluorescent protein tdTomato (GAD2-cre x Ai9 reporter mice). This revealed that GABAergic PT-dLGN cells are located in both the ipsilateral and contralateral PT. Biotinylated dextran amine (BDA) injections were placed in the PT to label PT-dLGN terminals for ultrastructural analysis. Postembedding immunocytochemical staining for GABA was used to identify the GABAergic PT-dLGN terminals and determine the GABA content of their postsynaptic targets. This revealed that GABAergic PT-dLGN terminals are relatively large

profiles that contact the dendrites of both relay cells and interneurons. To label and activate GABAergic PT-dLGN terminals, we injected a cre-dependent viral vector into the PT of GAD2-cre mice, or a non-cre-dependent virus in the PT of mice that express green fluorescent protein in dLGN interneurons (GAD67-GFP mice). These viral injections induced the expression of tdTomato and the channel rhodopsin variant ChIEF (a cation channel activated by blue light) in PT cells and their terminal projections. Whole-cell recordings were then obtained from relay cells or interneurons within the dLGN maintained *in vitro* and ChIEF-expressing PT-dLGN terminals were activated with short pulses of blue light. At holding potentials of 0 mV (with an internal solution that contained cesium), both dLGN relay cells (16 of 28) and interneurons (12 of 18) responded to activation of PT-dLGN with small amplitude IPSCs (10-120pA). In current clamp experiments at the resting membrane potential, activation of PT-dLGN terminals (50Hz) suppressed retinogeniculate EPSPs (activated via electrical stimulation of the optic tract) in 50% of the cells tested (n=10). This suggests that the PT could simultaneously suppress some visual signals (via direct relay cell inhibition) and enhance others (via disinhibition). Thus, the mouse PT may provide a powerful substrate for modulating the gain, and specificity, of retinogeniculate signal transmission.

Title: Modifications to the dorsal stream visual cortex following early-life lesions of the inferior pulvinar

Authors: *J. A. BOURNE, W. C. KWAN, I. C. MUNDINANO;
Aust. Reg. Med. Inst., Monash University, Australia

Abstract: Previous studies from our laboratory revealed that the medial portion of the inferior pulvinar (PIm) receives retinal input that normally regresses during postnatal development. PIm

also projects to the middle temporal cortex (area MT) with this connection being responsible for the early maturation of area MT. MT distributes information primarily to the dorsal stream areas of the visual cortex. Following removal of the primary visual cortex (V1), the retina-PIm-MT pathway remains unpruned, which could be the anatomical substrate for the preserved vision observed in infants rather than adults ensuing V1 lesions. To study the influence of thalamocortical input from PIm on the organization and maturation of the visual cortex, 4 neonatal (14-21 days) marmoset monkeys (Callithrix jacchus) received unilateral PIm ablations. Ablations were induced by NMDA (100 nl, 0.12M) infusions employing an MRI-guided stereotaxic surgery. The consequence of the lesion were followed up by Diffusion Tensor Imaging (DTI) analysis 6, 12, 18 and 36 weeks post-lesion. Voxel-based morphometry and region of interest analysis revealed a significant reduction of fractional anisotropy values in ipsilateral area MT, dorsal stream associated areas and posterior parietal association cortex. DTI results were further qualified with tracing experiments, and immunohistochemistry revealed morphological changes. Data presented here demonstrate that thalamocortical input from PIm in early life is critical for the correct development and maturation of dorsal stream visual areas.

Abstract: Traditionally, sensory stimuli are thought to be encoded by spike firing rate. However, stimulus features can be encoded by other schemes, such as oscillatory activity. What features

might oscillations encode? In the frog visual pathway, looming stimuli evoke gamma oscillations in retinal ganglion cells that trigger escape behavior (Arai et al, 2004). In the cat, gamma (40-80 Hz) oscillations originating in a subset of retinal ganglion cells are transmitted by thalamic relay cells to cortex, multiplexed with stimulus-locked information in the low frequency band (<30 Hz)) (Koepsell et al, 2009). While oscillations in the cat thalamus can as much as triple the amount of information sent downstream, it is not clear what visual features these oscillations encode. To investigate this question, we turned to the rodent- a model system in which experiments are economical and that offers the potential for a wide range of genetic manipulations. We used whole-cell recording *in vivo*, a technique that allows us to resolve both retinal inputs (EPSCs) and thalamic spikes during visual stimulation; Events were detected and EPSCs and spikes sorted using a support vector machine. The occurrence of retinal-based oscillations in each record was assessed using multitaper spectral analysis (Bokil et al, 2010; Thomson, 1982) and their strength was measured using the oscillation score index (Muresan et al, 2008). We found intrinsic oscillatory activity in the gamma frequency band in the EPSC and spike trains in some murine relay cells, similar to observations in cat. Furthermore, our data indicate that oscillation strength is inversely correlated to stimulus contrast, especially for naturalistic stimuli. Two interpretations arise from this result: (1) retinal oscillations are generated by distributed networks and thus might signal information about spatially extensive features and/or context. Sensitivity may increase when contrast is low; (2) retinal oscillations may form a complementary second information channel, reducing redundancy and improving the robustness of signal transmission. Our next steps will be to estimate the information rates conveyed by spike times relative to intrinsic oscillations vs the stimulus and, ultimately, to use genetic tools to determine if these oscillations are specific to particular subtypes of ganglion cells.

Title: Parallel tectothalamic pathways in the mouse lateral posterior nucleus

Authors: P. S. MAIRE, S. P. MASTERSON, N. ZHOU, *M. E. BICKFORD;
Anatom. Sci. and Neurobio., Univ. Louisville Sch. Med., Louisville, KY

Abstract: The superior colliculus (SC) contains a unique population of cells with wide dendritic fields (wide field vertical, WFV), and either bilateral (type I) or ipsilateral (type II) projections to the thalamus (Fredes et al., JCN 2012). We combined anatomical, physiological, and optogenetic techniques to examine the synaptic connections of type I and type II WFV cells in the mouse lateral posterior nucleus (LPN). Bilateral and ipsilateral WFV-LPN projections were confirmed using injections of two different viruses in the right and left LPN to label WFV cells via retrograde transport. Virus injections in the right and left SC demonstrated that ipsilateral WFV projections fill the LPN, while contralateral WFV projections are confined to a caudal/medial subdivision. Next unilateral virus injections were placed in the SC to induce the expression of tdTomato and the channel rhodopsin variant ChIEF (a cation channel activated by blue light) in WFV cells and their terminal projections. Whole-cell recordings, with biocytin-filled pipettes, were obtained from neurons in the ipsilateral or contralateral LPN maintained *in vitro*, and ChIEF-expressing WFV-LPN terminals were activated with short pulses (1-10ms) of blue light. WFV-LPN responses could be elicited in the presence of 1 μM TTX when paired with 100 μM 4-aminopyridine, and were abolished in the presence of glutamate receptor antagonists. Activation of ipsilateral WFV-LPN terminals (type I + type II) with trains of light pulses (1-20 Hz) evoked excitatory postsynaptic potentials (EPSPs, n = 38) with amplitudes that depressed at high frequencies, or with amplitudes that were frequency-independent. Activation of contralateral WFV-LPN terminals (type I) evoked frequency-independent EPSPs (n = 4). A Scholl analysis (as in Krahe et al., J Neurosci 2011) of biocytin-filled LPN neurons (n = 65) was used to calculate a direction of orientation index (DOI; high values denoting symmetry), which ranged from 0.03-1.00 (mean = 0.53). Dendritic diameters (DD, 201-436 μm) were also measured (mean = 201 μm). The arbors of LPN cells that responded to activation of ipsilateral WFV-LPN terminals (n = 13) were more oriented (mean DOI = 0.46, mean DD = 289) than the arbors of LPN cells that responded to contralateral WFV-LPN (n = 4; mean DOI = 0.71, mean DD = 268 μm). Our preliminary results suggest that a subset of LPN neurons with symmetric dendritic arbors receive convergent input from type I WFV cells, while a second subset of LPN neurons with more selective dendritic arbors receives input from ipsilateral type II WVF cells. This organization may contribute to the reliable initiation of appropriate action in response to diverse visual signals.

Title: Developmental regulation of cholinergic input to the visual thalamus

Authors: *G. SOKHADZE, G. GOVINDAIAH, W. GUIDO;
Anatom. Sci. and Neurobio., Univ. of Louisville, Louisville, KY

Abstract: Sensory nuclei of the thalamus receive extensive projections from cholinergic neurons of mesopontine brainstem as well as the basal forebrain. Such input modulates sensory transmission during different behavioral states including arousal, attention, and the sleep/wake cycle. Despite playing such a crucial modulatory role, little is known about how and when these cholinergic circuits develop in the thalamus. In the visual system two key targets include the dorsal lateral geniculate nucleus (dLGN), a primary sensory relay that transmits retinal information to the cortex; and the thalamic reticular nucleus (TRN), an area that receives indirect visual input but provides GABAergic feedback inhibition to dLGN cells. To examine cholinergic innervation, we utilized a transgenic ChAT-Cre mouse and crossed it with a reporter line (Ai9) to express tdTomato fluorescent protein in cholinergic neurons and their processes. At early postnatal ages, cholinergic axons course along the optic tract and begin to innervate the dorsolateral shell region of dLGN. Their progression through dLGN is slow and diffuse, finally innervating the entire nucleus after 3-4 weeks of age. In dorsal areas of TRN that project to dLGN, cholinergic innervation follows a similar time course. These fibers appear during the first postnatal week and become denser with age, occupying the entire region by 3 weeks of age. By contrast, cholinergic innervation of ventral TRN, in areas that project to primary somatosensory nuclei, is more advanced. To assess when cholinergic projections to TRN form functional connections, we conducted *in vitro* whole cell recordings in acutely prepared thalamic slices in transgenic mice that express channelrhodopsin in choline acetyl-transferase-containing neurons (ChAT-Cre x ChR2). Blue light stimulation of ChAT containing fibers in TRN evokes biphasic (excitation followed by inhibition) postsynaptic activity. The emergence of light evoked activity corresponded to the timing of cholinergic innervation, with responses appearing in ventral areas earlier than in more dorsal locations. We also found that retinal signaling affects cholinergic innervation of dLGN, but not TRN. In mutant mice lacking retinofugal projections (math5 -/-, Wang et al., 2001), the density of cholinergic inputs to dLGN is greatly reduced. Moreover, the spatial distribution is perturbed with cholinergic arbors showing a dense patchy clustering. These results suggest that cholinergic innervation of thalamus happens in a coordinated manner, and

that a disruption of sensory input may affect the timing and pattern of cholinergic innervation in primary relay nuclei.

Title: Developmental remodeling of intrinsic interneurons in the mouse dorsal lateral geniculate nucleus

Authors: ***N. CHARALAMBAKIS**[1], G. GOVINDAIAH[2], W. GUIDO[2];
[2]Anatom. Sci. and Neurobio., [1]Univ. of Louisville, Louisville, KY

Abstract: The dorsal lateral geniculate nucleus (dLGN) of the mouse thalamus has become a powerful model system to understand visual circuit development. Key elements of these circuits include the two primary cell types of dLGN, relay cells and intrinsic interneurons. Studies have focused primarily on relay neurons, and little is known about the development of the other principal cell type, intrinsic interneurons. Here, we used a transgenic mouse line (GAD67-GFP) in which green fluorescent protein (GFP) is expressed within dLGN interneurons. Such cell-type specific visualization allowed us to readily target interneurons for *in vitro* whole cell recordings with biocytin-filled electrodes, and test whether their form and function changes with postnatal age. At birth, interneurons begin to migrate into the dorsolateral tier of dLGN, and by the end of the first postnatal week they are evenly distributed throughout the nucleus. Between P0-7 there is a six-fold increase in the density of interneurons in dLGN. In contrast, the cell density and positioning of relay cells is well established by early postnatal ages. Confocal reconstructions of 32 biocytin-filled interneurons reveal substantial age-related changes in morphology. Overall, interneurons display type-2 morphology, with 2-3 primary dendrites that arise from opposite poles of spindle-shaped soma. Between postnatal weeks 1-3, there is a three-fold increase in soma size and a four-fold increase in dendritic field. At all ages dendritic fields are quite large, and by 3 weeks of age a given interneuron occupies as much as a third of the nucleus. Initially (P5) branching is simple and sparse. Between P8-17, interneurons undergo a period of exuberant branching, showing a four-fold increase in the total number of branches and branch order, with

some interneurons exhibiting 12-14th order branching. By P21 branch number and complexity begins to prune, as dendritic trees assume a more simple and elongated architecture. These changes are accompanied by age-related increases in resting membrane potential, input resistance, and a nine-fold increase in spike firing frequency. Thus compared to relay cells that take on adult-like features by the end of the first postnatal week, interneurons seem to mature more slowly. Such differences suggest that relay cells and interneurons are governed by separate developmental programs.

Title: Visual responses under naturalistic patterns of illumination in the mouse dlgn

Authors: *R. STORCHI;
Univ. of Manchester, Manchester, United Kingdom

Abstract: Introduction: Every day we experience a wide array of gradual and abrupt changes in background light intensity (irradiance) that encompasses several log units. Experimental evidence supports the notion that firing rate activity in the early visual system is defined by the instantaneous level of irradiance as well as by irradiance changes integrated over multiple timescales. In spite of this evidence most visual experiments focussing on neuronal responses to spatial stimuli are conducted at steady irradiance levels, therefore ignoring the effect of irradiance history. We addressed this gap by electrophysiological recordings in dorsal LGN of awake and anaesthetized mice. Results Neurons in dLGN widely differed in their relative sensitivity to instantaneous irradiance and irradiance changes. This irradiance profile was largely invariant upon presentations of uniform screens and artificial or naturalistic images. Critically, at matching levels of instantaneous irradiance, each unit could provide substantially more or less information depending on irradiance history and its irradiance profile. Conclusion Our results show that dLGN neurons exhibit a great diversity of sensitivities to irradiance history. Their irradiance profile shape responses to spatial stimuli and therefore represents an additional dimension to take into account in order to understand how spatial stimuli are encoded in real life

situations. Key Words: Irradiance; Mutual Information; Generalized Linear Models; Neuronal Variability; Overdispersion; Melanopsin; ipRGCs;

Title: Synaptic properties of the thalamocortical projections from lateral posterior nucleus to secondary visual cortex in mice

Authors: *Y.-W. LAM, C. MO, S. SHERMAN;
Univ. of Chicago, Chicago, IL

Abstract: Little is known of the synaptic properties of the pathway from the lateral posterior nucleus (LP), a higher order thalamic nucleus, to visual cortical areas. Studying the thalamocortical pathway from LP is difficult using conventional experimental techniques. We therefore attempted to study the synaptic properties of the thalamocortical pathways from LP to the visual cortices using optogenetic techniques. We stereotactically injected the adeno-associated virus carrying genes for hsyn-ChR-YFP or CamK2-ChR-YFP fusion protein into LP of 5-6 week old mice. The animals were sacrificed 3 to 5 weeks after injection and their brains were sliced coronally for whole-cell recordings. Expression of the fusion channelrhodopsin protein was much stronger in V2 than V1 and therefore, in our initial experiments, we recorded from layer 4 neurons of V2 and stimulated them optically using a UV laser at a wavelength (355 nm) that we found, at high intensity, readily activates their LP inputs. In these cells, photostimulation usually evoked biphasic responses that consisted of fast monosynaptic EPSCs followed by strong polysynaptic IPSCs, suggesting that the thalamocortical projection from LP can strongly suppress layer 4 neurons through disynaptic feed-forward inhibition. When evoked EPSCs were isolated, these monosynaptic EPSCs showed paired-pulse depression, suggesting driver properties for the synapses in this pathway. In this regard, the properties of LP input to V2 seems similar to those we have previously defined for higher order thalamic input to secondary

cortical areas, namely, the input from POm to S2 and from MGNd to A2. Supported by NIDCD grant DC008794 and NEI grant EY022338.

Title: Rapid and strong gamma oscillations in response to snakes in the monkey pulvinar

Authors: *Q. V. LE, J. MATSUMOTO, Q. V. LE, R. V. BRETAS, T. ONO, H. NISHIJO; Univ., Toyama, Japan

Abstract: Gamma oscillations (30-80Hz) have been suggested to be involved in high-level perception, and might play an important role in detecting threat-relevant objects. In the present study, we analyzed gamma oscillations of pulvinar neurons in the monkeys during delayed non-matching to sample task (DNMS), in which monkeys were required to discriminate 4 kinds of stimuli (snakes, monkey faces, monkey hands and simple geometrical patterns). Of 745 neurons recorded, 115 neurons responded to visual stimuli. Of these 115 neurons, 91 neurons were tested with all stimuli and were used to analyze gamma oscillations. Gamma oscillations were analyzed in three periods around the stimulus onset (pre500: from 500 to 0 ms before the onset; Post0-200 and Post300-500: from 0 to 200 ms, and from 300 to 500 ms after the onset, respectively). The results indicated that, although there was no significant difference in ratios of SC neurons showing gamma oscillation and frequencies of gamma oscillations among these periods, the snake images induced a significant increase of mean strength of gamma oscillations in the Post0-200 and the facial images induced an increase in the Post300-500. In the period Post0-200, strength of gamma oscillations in response to snakes was significantly larger than those to the other stimuli, while in the period Post300-500, strength of gamma oscillations in response to the faces was significantly larger than those to the snakes. These results provided neurophysiological evidence of involvements of gamma oscillations in representation of threat relevant events, including snakes in the early phase.

Title: Y-cell responses to texture stimuli predicted by a nonlinear receptive field model based on bipolar cell subunits

Authors: *A. GHARAT[1], C. BAKER, Jr[2];
[1]Integrated Program in Neurosci., [2]Ophthalmology, McGill Univ., Montreal, QC, Canada

Abstract: A prime aim of visual neuroscience is to estimate neuronal receptive field models that can predict responses to arbitrary stimuli. Y type cells of the retina and the LGN may be an important early stage for second-order processing (Demb et al., 2001b; Rosenberg et al., 2010). A linear receptive field model with static output nonlinearity (LN model) cannot account for nonlinear responses of Y-cells to high resolution texture stimuli. Recent studies have shown that retinal Y-cells receive rectified synaptic inputs from bipolar cells (Demb et al., 2001a). A model with spatial pooling of rectified inputs from several small subunit receptive fields (corresponding to bipolar cells) might better predict responses of Y-cells to arbitrary high resolution texture stimuli. We recorded single-unit responses of cat LGN Y-cells to synthetic naturalistic texture movies and to grating stimuli (drifting and contrast reversing). We estimated both a linear receptive field (LN) model as well as a nonlinear (LNLN) subunit model of Y-cells with regularized gradient descent optimization using STRFlab software (http://strflab.berkeley.edu/). The estimated subunit (LNLN) model explains a significant fraction of response variance to texture movies, while the quasi-linear (LN) model performs poorly. The subunit model also

predicts the "Y-cell signature" spatial frequency tuning to grating stimuli (Hochstein & Shapley, 1976) while the linear model fails to predict tuning to contrast reversing high spatial frequency gratings. These results demonstrate that the subunit model captures nonlinear spatial summation across the receptive fields of Y-cells, and better predicts responses to naturalistic arbitrary stimuli.

Title: A comparison of the synaptic input to visual areas v1 and v2 from primate pulvinar

Authors: *B. MOORE[1,2,3], K. LI[4], J. A. MAVITY-HUDSON[3], V. A. CASAGRANDE[3,4,5]; [2]Vanderbilt Brain Inst., [3]Cell and Developmental Biol., [4]Psychology, [5]Ophthalmology and Visual Sci., [1]Vanderbilt Univ., Nashville, TN

Abstract: Several puzzles remain about the flow of visual signals between the primary and secondary visual areas (i.e., V1 and V2) in primates. Although it is generally agreed that the lateral geniculate nucleus (LGN) provides the main sensory message to V1, newer data from our lab (Purushothaman et al., 2012) has shown that signals from lateral pulvinar (PL) to V1 can strongly gate output signals from V1 to V2. In V2, axons from V1 and PL both terminate in layer 4 and the boutons from PL are significantly larger than those arriving from V1 (Marion et al.,

2013). The latter results suggest that visual driving signals to V2 might not come directly from V1 but instead arrive via a loop through the pulvinar. The question remains exactly how does the pulvinar relate to visual processing in V1 and V2. As a first step in understanding how pulvinar interacts with the local networks of V1 and V2 we examined and compared the synaptic targets of PL in each cortical area. The retinotopic maps in PL and inferior pulvinar (PI) of adult bush babies (Otolemur garnettii) were identified using extracellular recording. Once the pericentral area of the dorsal map in PL was identified, biotinylated dextran amine (BDA) was pressure injected. After a 20 day survival period, the animals were perfused, tissue sectioned on a vibratome and the axons visualized in V1 and V2 using streptavidin-HRP/tetramethylbenzidine/diaminobenzidine-cobalt stain. Ultrathin sections containing labeled axons were then immuno-labeled with antibodies to GABA and visualized with 15nm gold particles. Results showed that in both V1 layer 1 and V2, layer 4 pulvinar axons made asymmetric single synapses with non-GABAergic dendrites on both spines and shafts. No evidence of multiple synapses was found in either area. Except for bouton size differences, our results did not identify any major differences between pulvinar axons in V1 and V2. These results suggest that pulvinar axons in both V1 and V2 can directly activate excitatory postsynaptic cells. Given the similarity in the synaptic morphology of pulvinar axons in these areas and the synaptic morphology described by Anderson and Martin (2009) for V1 to V2 axons, more detailed analysis will be required to determine the relative potency and separate functional roles of these pathways.

California, San Diego, La Jolla, CA

Abstract: Visual information is conveyed from the eye to the brain by functionally distinct parallel pathways. The output neurons of the eye are retinal ganglion cells (RGCs). There are an estimated 30 RGC types, each encoding a different and specific set of visual features such as contrast, direction, luminance, or self-motion and projecting to specific targets in the brain. A major goal of neuroscience is to understand the nature of these signals and how they contribute to central visual processing (Dhande and Huberman, Curr Opin in Neurobiol, 2014). In mice, the identification of molecular markers expressed by distinct RGC types has lead to a significant advance in understanding the organization of eye-to-brain parallel pathways and in some cases the contribution of individual parallel channels to specific behaviors. Although the primate retina also includes a rich diversity of RGC subtypes (Dacey et al., Neuron, 2003), the visual features encoded by most primate RGCs and how these signals impact visual processing within the brain remain a mystery. To bridge the gap between molecular and functional understanding of primate RGCs, we screened for molecular markers expressed in specific RGC types in mouse (Wang et al., in preparation), in the macaque monkey retina. We discovered that the transcription factor Satb2 (Special AT-rich sequence-binding protein 2), which is unique to On-Off direction selective RGCs in mouse is expressed by a quasi-mosaic of RGCs in the macaque. The density of Satb2 RGCs scales with retinal eccentricity in macaque and has a peak density of ~ 160 cells/mm2 parafoveal, suggesting that i) Satb2-expressing RGCs may represent a single RGC subtype and ii) that these cells may contribute to central vision. Next, to determine whether the Satb2 RGCs in primate project to the dorsal lateral geniculate nucleus (dLGN) and thus may be involved in the generation of "sight", we injected a modified rabies virus expressing GFP into the dLGN to infect the axon terminals of dLGN-projecting RGCs and then stained the retinas for Satb2. Indeed, Satb2-expressing RGCs synapse in the dLGN. We also confirmed the morphology of the Satb2 RGCs is uniform from cell to cell and are now exploring their physiological responses to specific light stimuli, including directional stimuli. These experiments represent our first step towards the goal of achieving a thorough understanding of the functional diversity and evolutionary conservation of parallel visual pathways in primates and other species.

Title: Diversity and layer specificity of thalamic inputs to mouse visual cortex

Authors: *K. Z. SOCHA-JANIAK, C. AYDIN, V. BONIN;
Neuro-Electronics Res. Flanders, Leuven, Belgium

Abstract: Neuronal activity in the dorsal lateral geniculate nucleus (dLGN) is functionally diverse with distinct neurons conveying information about specific features of the visual scene (Piscopo et al., 2013). This activity likely reflects the response properties of retinal ganglion cells and their inputs to dLGN (Cruz-Martin et al., 2014). While the properties of dLGN neurons have been studied extensively, little is known about how distinct dLGN populations convey distinct information to cortex. We combined chronic cellular imaging and a head-fixed locomotion assay to characterize the response properties of dLGN axons projecting to distinct layers of the primary visual cortex (V1) of mice. We performed stereotaxic injections of an adeno-associated viral vector to express the calcium indicator GCaMP6f in dLGN populations (Fig. 1A). We then used 2-photon microscopy to image the fluorescence calcium signals of dLGN axons in response to visual stimulation. We measured responses to a broad range of visual stimuli including full-field drifting sinusoidal gratings of different directions, spatial and temporal frequencies. We identified visually responsive boutons (Glickfeld et al., 2013) and investigated the boutons' tuning properties to stimulus attributes. We obtained strong GCaMP6 expression in dLGN cell bodies and their axonal projecting to cortex across layers (Fig. 1A). Consistent with a recent study of dLGN inputs to superficial V1 (Cruz-Martin et al., 2014), responses of dLGN axons were tuned to different stimulus orientations and directions (Fig. 1B). However, far from being confined to layer 1, orientation and direction selective boutons were found within all layers of V1. We observed that locomotion modulates visual responses of V1-targeting dLGN axons (Fig. 1C). Our results are consistent with recent studies (Erisken et al., 2014), showing the influence of locomotion on visual responses already at early processing stage in the visual system. Currently, we investigate how visual and movement-related outputs from dLGN are distributed and vary with depth in V1.

Title: Dissecting corticothalamic feedback during active behavior in the mouse visual system

Authors: ***S. ERISKEN**[1,2], A. VAICELIUNAITE[1], L. BUSSE[1];
[1]Univ. of Tuebingen, Tuebingen, Germany; [2]Grad. Training Ctr. of Neurosci., Tuebingen, Germany

Abstract: Causal manipulation of neural circuits has led to promising advances in understanding the neural substrates of visual perception and behavior. From local computations to long-range communication across areas, e.g. shaping of thalamic activity by cortical feedback, a broad range of circuit functions can be interrogated through activation and silencing of distinct neural cell-types. Such circuit-mapping approaches are particularly powerful if used to control not just action potential firing but rather neurotransmitter release from selective terminals. Designer receptors exclusively activated by designer drugs (DREADDs), are one set of such tools and are activated by biologically inert CNO. CNO, however, is typically delivered systemically, which limits its selectivity. To target specific brain areas and selectively manipulate transmission at specific terminals it is thus desirable to implement methods for local intracranial CNO injections. Here, we describe a method for minimally disruptive intracranial delivery of CNO during simultaneous extracellular recordings in awake behaving mice. In mice headfixed on a spherical treadmill, we recorded activity with Neuronexus linear probes and injected CNO with a glass

pipette into the same structure. To position the tip suitably close to recording sites, pipettes were pulled with ~1.5 cm long tips, and connected to a 10 uL Hamilton syringe via a glass coupler and PEEK tubing. The system was filled with silicone oil and the syringe placed in a syringe pump. We drew a drop of CNO solution on parafilm into the pipette. After electrode insertion, we put a layer of aCSF on the brain surface before we inserted the pipette to avoid leakage. During recording we delivered CNO slowly (500 uL/hr) via 25-50 uL injections at 1-10 s intervals. These injections did not cause significant distortions, as ongoing LFPs did not exhibit injection-related artifacts that were evident with higher-pressure injection methods. We are currently using this technique to investigate influences of feedback from primary visual cortex (V1) in modulating the dorsolateral geniculate nucleus (dLGN) during switches of behavioral state. L6 corticothalamic cells in V1 influence dLGN by both direct excitatory and indirect inhibitory feedback, via the reticular nucleus (TRN). By injecting CNO in dLGN or TRN of Ntsr1-Cre mice expressing Cre-dependent DREADD receptors, we can selectively silence the excitatory or inhibitory feedback at corticothalamic synapses while not disturbing L6 control over cortical gain. This approach promises to precisely dissect the influence of corticothalamic feedback with pathway-specificity and minimal damage.

Title: Estimating the response properties of the human lateral geniculate nucleus using a spatiotemporal population receptive field model

Authors: *K. DESIMONE[1], K. A. SCHNEIDER[2];
[1]Psychology, York Univ., North York, ON, Canada; [2]York Univ., Toronto, ON, Canada

Abstract: The population receptive field (pRF) model has been widely adopted in the imaging community as a quantitive approach for estimating the response properties of populations of neurons. The initial formulation of the pRF model represented the spatial tuning of each voxel in terms of a two-dimensional gaussian (Dumoulin & Wandell, 2008). This spatial pRF model has characterized the retinotopic organization of a number of cortical areas (Dumoulin & Wandell, 2008; Amano et al., 2009) and a number of patient groups (Levin et al., 2010; Hoffmann et al., 2012). More recently, the spatial pRF model has been used to estimate the retinotopic

organization of multiple subcortical nuclei (DeSimone et al., in revision), including the lateral geniculate nucleus (LGN). We sought to extend the spatial pRF model to include a temporal component for characterizing the functionally and anatomically distinct layers of the LGN. Using a flickering visual stimulus, we found evidence that the magnocellular and parvocellular layers of the LGN may be functionally differentiated using a spatiotemporal pRF model.

Title: Corticogeniculate feedback enhances temporal precision of LGN neurons in the ferret

Authors: *J. M. HASSE, F. BRIGGS;
Physiol. & Neurobio., Geisel Sch. of Med. At Dartmouth, Lebanon, NH

Abstract: An important function of the visual system is to filter relevant visual information from the noisy visual environment. The corticogeniculate pathway, which connects primary visual cortex (V1) with the visual thalamus (lateral geniculate nucleus or LGN) in the feedback direction, may play a role in this filtering process. We are investigating the functional role of the corticogeniculate pathway by optogenetically manipulating the activity of corticogeniculate neurons in anesthetized ferrets. First, we inject a modified Rabies virus expressing m-Cherry and channelrhodopsin2 (ChR2) into the LGN such that corticogeniculate neurons are infected through their axon terminals. Following surgical virus injection, we perform an *in vivo* experiment in which we place electrode arrays into retinotopically-aligned regions of the LGN and V1. Our V1 electrode is coupled to a fiberoptic cannula such that we can record responses of ChR2-expressing corticogeniculate neurons to both visual stimulation and optogenetic stimulation (via blue LED activation). We record the activity of V1 and LGN neurons in response to drifting sinusoidal gratings and m-sequence stimuli under conditions in which corticogeniculate neurons expressing ChR2 are light-activated. Our data suggest there are multiple morphological subtypes of corticogeniculate neurons that modulate feedforward LGN neurons in a stream specific manner, and that corticogeniculate feedback enhances the temporal

precision of LGN neurons. These results support the notion that corticogeniculate feedback increases the salience of information carried by discrete feedforward processing streams.

Title: Contribution of retinal mechanisms to nonlinear receptive field properties in the lateral geniculate nucleus

Authors: ***T. FISHER**[1], H. ALITTO[1], D. RATHBUN[1,2], W. M. USREY[1];
[1]Univ. of California at Davis, Davis, CA; [2]Inst. for Ophthalmic Res., Eberhard Karls Univ., Tübingen, Germany

Abstract: Extraclassical surround suppression and gain control in the lateral geniculate nucleus (LGN) are generally accepted to result from a combination of mechanisms involving feedforward and feedback circuits. Although extraclassical suppression and contrast gain control have been separately characterized for retinal ganglion cells and LGN neurons, a direct one-to-one comparison of these nonlinear response properties between synaptically coupled neurons has not been performed. This comparison would provide much needed information for understanding the cellular and circuit mechanisms underlying nonlinear processing in the LGN. To achieve this goal, we made simultaneous recordings from the retina and LGN, identified monosynaptically connected cell pairs via cross-correlation analysis, and quantified extraclassical suppression and gain control from responses to drifting grating stimuli that varied in size or contrast. Our results reveal a dynamic interplay between stimulus parameters and the communication of spikes between the retina and LGN. Additionally, our results reveal stimulus-dependent interactions between feedforward and feedback pathways. These results provide key insight into the contributions made by retinal and non-retinal inputs to visual responses in the LGN and provide important information needed to develop a comprehensive model of visual processing in the LGN.

Title: The influence of contrast on area summation in the lateral geniculate nucleus of the alert macaque monkey

Authors: ***D. ARCHER**, H. J. ALITTO, W. M. USREY;
Univ. of California, Davis, Davis, CA

Abstract: Nonlinear extraclassical suppression is a fundamental receptive-field property for neurons in the early visual system, including the retina, LGN, and primary visual cortex (V1). Previous studies examining area summation in V1 of macaque monkeys have shown that the size of the classical receptive field and the magnitude of non-linear suppression depend on stimulus contrast (Sceniak et al., 1999). Interestingly, LGN neurons do not show this effect in a preparation that involves silencing the cortex pharmacologically (Sceniak et al., 2006). To gain insight into whether corticogeniculate feedback is necessary for contrast to influence size tuning and extraclassical suppression in the LGN, we made single-unit recordings from cells in the LGN of two alert, fixating macaque monkeys. Area summation response functions were generated from neuronal responses to drifting sinusoidal gratings varying in size and contrast centered over the receptive field of the recorded cell. Response functions were fit with a difference of Gaussians (DOG) model to estimate the spatial parameters of the central excitatory and surround inhibitory subunits at various contrasts. Our results reveal a range of effects of stimulus contrast on area summation, with a subset of LGN cells demonstrating a clear influence similar to the contrast-dependent modulation found in macaque V1. When considered in the context of previous reports, results from the current study suggest that visually responsive corticogeniculate neurons may contribute to contrast-dependent area summation in the macaque LGN.

Title: Behavioral modulation of visual responses and network dynamics in the lateral geniculate nucleus

Authors: *H. J. ALITTO, W. M. USREY;
Univ. of CA, Davis, Davis, CA

Abstract: The main function of the lateral geniculate (LGN) nucleus is to transmit visual information from the retina to primary visual cortex (V1). The LGN also serves as a gate, selecting when and what retinal information is transmitted to the cortex. How this is accomplished is not entirely understood, but it is likely to involve direct and indirect modulation from a variety of cortical and subcortical regions, including, the thalamic reticular nucleus (TRN), the cholinergic brainstem, the hypothalamus, basal forebrain, and V1. This modulation affects visual responses during sleep and arousal, as well as when cognitive processes such as decision making and spatial attention are engaged. To understand how spatial attention affects the network dynamics of the LGN, we measured local field potentials and spike-field interactions with well isolated LGN units while macaque monkeys performed a spatial attention task. Recordings were made using either single electrodes or multielectrode recording arrays (V-probe, Plexon) that spanned multiple layers of the LGN and, in some cases, the TRN. During the spatial attention task, monkeys fixated on a central location while two sine-wave grating patches (typically 2^{o} in diameter, located ~4^{o} -8^{o} from fixation) were presented peripherally: one positioned over an LGN receptive field, the other positioned at a separate location. Animals were cued, in block format, to detect an increase in contrast either at or away from the spatial position of the LGN receptive field and were rewarded for making a saccade toward the grating where the contrast change occurred. For a subset of cells, these spatial attention conditions were compared to a non-attention condition where the monkey was rewarded for maintain fixation and no stimulus change occurred. Preliminary analysis indicates the firing rate of LGN neurons is invariant to changes in spatial attention; however, there is apparent modulation of the local field potentials in the in alpha and beta bands. Ongoing analysis is aimed at determining if these

changes are systematically influenced by spatial attention or may represent an inherent instability in network dynamics that is more strongly influence by other factors, such as fluctuations in task engagement, motivation, or arousal.

Title: Retinogeniculate communication during thalamic bursts

Authors: H. J. ALITTO[1], D. L. RATHBUN[2], *W. USREY[1];
[1]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [2]Inst. for Ophthalmic Res., Eberhard Karls Univ., Tübingen, Germany

Abstract: Visual information from the retina is transmitted to primary visual cortex through the lateral geniculate nucleus (LGN) of the thalamus. At a basic level, retinal information is processed by LGN neurons in two distinct modes: tonic and burst. During tonic mode, LGN neurons respond to excitatory input with regularly spaced action potentials, the rate of which is proportional to the strength of the excitatory input. By contrast, during burst mode, LGN neurons respond to excitatory input with irregular trains of action potentials at a rate that is roughly independent of the strength of the excitatory input. Burst mode occurs when LGN neurons are sufficiently hyperpolarized that T-Type Ca+2 channels are deinactivated. The subsequent activation of the T-Type channels leads to a Ca+2 plateau potential that can trigger a short sequence of high frequency, Na+ based action potentials (a burst). Given the mechanisms underlying burst mode, it is generally thought that individual spikes in a burst are less dependent on retinal activity than their tonic counterparts. However, previous experiments using S-potentials as a surrogate for retinal inputs onto an LGN neuron indicate that nearly all LGN spikes, tonic and burst, are directly triggered by retinal action potentials. To investigate the retinal contribution to LGN burst spikes, we made simultaneous recordings from monosynaptically connected RGCs and LGN neurons in the cat while cells were excited with a

variety of stimuli. LGN bursts were identified using previously established statistical criteria: a preceding interspike interval (ISI) >100 msec followed by at least one ISI <4 msec. Our results show that retinogeniculate communication changes as a function of visual stimulation and LGN response mode. In particular, the retinal contribution to burst spikes was approximately half of that for tonic spikes. This difference increased as the preceding ISI increased beyond the minimum value (100 msec) towards the longest recorded values (>400 msec). Interestingly, although LGN activity was less dependent on retinal activity during burst mode, retinal spikes were more effective in driving thalamic activity during burst events. These results provide direct insight into how retinogeniculate communication is influenced by nonvisual aspects of thalamic circuitry.

Title: Thalamus conveys diverse contextual information to layer 1 of visual cortex

Authors: *D. R. MUIR, M. M. ROTH, F. IMHOF, S. B. HOFER;
Univ. of Basel, Basel, Switzerland

Abstract: The pulvinar is a complex of higher-order visual nuclei in the thalamus. It is heavily interconnected with many cortical and subcortical areas, and has been shown to exert strong influence on visual cortical activity. The pulvinar may be important for attentional gating of visual information and integration of visual and behavioral information, but knowledge about its function is still very limited. Specifically, it is unknown what type of information this thalamic hub conveys to different cortical areas. The homologue of the pulvinar in the mouse is the lateral posterior nucleus (LP). We quantified information conveyed by LP to visual cortex, and compared it to the information arising from the dorsolateral geniculate nucleus (dLGN), the first-order visual thalamic nucleus that receives its primary input from the eye. By using *in vivo* two-photon imaging of axons labelled with genetically-encoded calcium indicators, we recorded

responses of thalamic axon terminals from LP or dLGN in layer 1 of mouse visual cortex. During imaging, head-fixed mice were free to run either in the dark or through a simple virtual corridor with variable visual patterns on the walls. In some sessions, the visual stimulus was uncoupled from the animals' locomotion to separate the visual from motor signals, and to examine the role of thalamo-cortical interactions in sensory-motor integration. We found that both LP and dLGN transmit a wide range of sensory, behavioral and contextual signals to layer 1 of visual cortex. Both dLGN and LP boutons carried information about the animals' running speed as well as visual flow speed of the virtual corridor. However, LP boutons carried significantly more running speed information in the absence of visual stimulation. Visual flow and running speed were signaled largely by separate subsets of boutons, and visual and motor signals also differed in their timing. Only LP boutons carried prominent signals representing discrepancies between expected and actual optic flow during locomotion. These results suggest that LP is engaged in sensory-motor integration, for instance to enable animals to differentiate self-generated from external visual motion. In summary, we found that layer 1 of visual cortex receives diverse contextual information from the higher order thalamic nucleus LP, including purely visual, purely motor, and combined sensory-motor interaction signals.

Title: Functional and anatomical organization of the dorsal pulvinar in humans

Authors: ***M. J. ARCARO**, M. A. PINSK, S. KASTNER;
Princeton Univ., Princeton, NJ

Abstract: The primate pulvinar is thought to facilitate communication between cortical regions. In general, directly connected cortical regions are also indirectly connected via the thalamus. Previously, we found that cortical connectivity within the ventral and posterior pulvinar reflects cortical distance even for functionally similar areas that are spatially distributed across temporal cortex (Arcaro et al. 2014 SfN). Tracer studies in non-human primates have shown that cortical connectivity greatly differs between the dorsal and ventral pulvinar (Baizer et al. 1993). Still,

little is known about the functional organization of the dorsal pulvinar and its relation to cortical connectivity. Using neuroimaging, we investigated functional response properties and cortical connectivity in the human dorsal pulvinar. Retinotopic mapping, basic response properties, and attentional modulation were measured. Functional connectivity was assessed during states of rest and movie viewing. Functional connectivity was assessed using correlation analyses. Anatomical connectivity was assessed using probabilistic tracking analyses on diffusion imaging data. Functional response properties differed between the dorsal and ventral pulvinar. Retinotopic representations were mainly found within the ventral pulvinar. Visually-evoked responses were typically weaker in the dorsal pulvinar. Attention effects were specific to contralateral space in the ventral pulvinar, but bi-lateral in the dorsal pulvinar. Activity patterns in the dorsal and ventral pulvinar were consistent across repeated movie presentations. Consistency was greatly reduced within the dorsal, but not ventral, pulvinar when movies were temporally scrambled, suggesting that the dorsal pulvinar is more sensitive to coherent structure in stimuli. During rest and movie viewing, activity in the dorsal pulvinar was strongly coupled with frontal and parietal regions that are part of the dorsal attention network. Cortical connectivity with the dorsal pulvinar reflected both cortical distance and functional similarity. There was a broad topography of anatomical connections between parietal cortex and the dorsal pulvinar with posterior areas most strongly connected with lateral portions and anterior areas most strongly connected with medial portions. We also found evidence that connectivity between functionally dissociable parietal regions converges within the dorsal pulvinar. Overall, our results suggest that the dorsal pulvinar is well situated to facilitate communication between cortical regions that are functionally related as well as regions that are in close anatomical proximity.

Abstract: Sensory adaptation serves to adjust awake brains to changing environments on different time scales. However, adaptation has been traditionally studied under anesthesia and for short time periods. Here, we demonstrate, in awake rabbits, a novel type of sensory adaptation that persists for more than one hour and acts on visual thalamocortical neurons and their synapses in the input layers of the visual cortex. Following prolonged visual stimulation (10 - 30 minutes), cells in the dorsal lateral geniculate nucleus (LGN) show a severe and prolonged reduction in spontaneous firing rate. This effect is bi-directional and prolonged visual response suppression is followed by prolonged increase in spontaneous activity. The reduction in thalamic spontaneous activity following prolonged visual activation is accompanied by increases in (a) response reliability, (b) signal detectability, and, (c) the ratio of visual signal/spontaneous activity. In addition, following such prolonged activation of an LGN neuron, the monosynaptic currents generated by thalamic impulses in layer 4 of primary visual cortex (V1) are enhanced. These results demonstrate that, in awake brains, prolonged sensory stimulation can have a profound, long-lasting effect on the information conveyed by thalamocortical inputs to visual cortex.

Abstract: Recent behavioral evidence suggests that dogs, like humans and monkeys, are capable of visual face recognition. But do dogs also exhibit specialized cortical face regions similar to

humans and monkeys? Using functional magnetic resonance imaging (fMRI) in six dogs trained to remain motionless during scanning without restraint or sedation, we found a candidate region in the canine temporal lobe that responded significantly more to movies of human faces than to movies of everyday objects. Next, using a new stimulus set to investigate face selectivity in this predefined candidate dog face area, we found that this region responded similarly to images of human faces and dog faces, yet significantly more to both human and dog faces than to images of objects and scenes. Such face selectivity was not found in dog primary visual cortex. Taken together, these findings: 1) provide the first evidence for a face-selective region in the temporal cortex of dogs, which cannot be explained by simple low-level visual feature extraction; 2) reveal that neural machinery dedicated to face processing is not unique to primates; and 3) may help explain dogs' exquisite sensitivity to human social cues.

Title: Neural encoding of shapes in the middle superior temporal sulcus (mid-STS) body patch neurons

Authors: *S. KUMAR, R. VOGELS;
Neurosci., KU Leuven, Leuven, Belgium

Abstract: In monkeys (Macaca mulatta), fMRI defined body category-selective regions ("body patches") are more strongly activated by images of bodies compared to inanimate objects, however the quantitative characteristics of the stimulus selectivity of body patch neurons still remain unclear. Mid-STS body patch neurons respond well to silhouettes, suggesting that mainly shape determines the response of these neurons. Here, we attempt to unravel the shape selectivity of mid-STS body patch neurons by finding their discriminative shape features and quantifying

their interactions by employing adaptive stimulus sampling and deriving feature-based mathematical models of these single neurons. We varied shape, including body silhouettes, parametrized with elliptical Fourier features and sampled the stimulus space of these neurons adaptively varying both local and global shape. This adaptive stimulus sampling procedure produced a large number of stimuli with a wide range of responses, which were used to derive models of the shape selectivity of each neuron, using multi-start non-linear least squares optimization with 5-fold cross-validation, providing a safeguard against overfitting. Shape tuning was quantified by 4 dimensions including curvature, orientation and relative position XY values of decomposed shape contour elements with approximately constant curvature. Statistically significant (n = 51 neurons, $p < 0.001$) parsimonious (penalized for complexity) models were reliable predictors of the response of single mid-STS neurons to complex test stimuli widely varying in shape, mean goodness of fit (r) being 0.61 (range = 0.31 - 0.88). The fitted models of most cells contained more than 3 subunits, each corresponding to a contour element at a different relative position along the outer contour of the shape. This suggests that midSTS body patch neurons receive information from a multitude of low level inputs that respond to contour features similar to those reported for area V4 neurons by Pasupathy et al. NN 2002. We observed an inhibitory influence of one or more contour subunits in the majority of fitted models, while excitatory influences being slightly higher in magnitude than inhibitory (mean E/I index = 0.55). Some neurons exhibited strong non-linear interactions between their subunits. These results suggest that at least part of the neural encoding of complex shapes in the mid-STS body patch can be described with linear and nonlinear interactions of multiple local contour features.

Title: Distinct patches for gaze following and the passive vision of faces in the macaque posterior superior temporal sulcus can be distinguished by specific local field potential fingerprints

Authors: *H. RAMEZANPOUR, I. CHONG, P. W. DICKE, P. THIER;
Cognitive Neurol., Hertie Institue For Clin. Brain Res., Tübingen, Germany

Abstract: Rhesus monkeys are able to follow their conspecific's head gaze ("sender") in order to shift their focus of attention to potential objects of interest. These are identified by the sender's gaze vector to establish joint attention, a key step in developing the theory of the other's mind. Although previous studies have shown that the posterior part of the superior temporal sulcus (pSTS) plays an important role in gaze following, how gaze information is encoded in the pSTS and its relationship to general face processing remains unclear. To answer these questions, we trained a rhesus monkey on a task requiring spatial shifts of attention based on either following the head gaze of monkey portraits or alternatively on matching their identities to the same targets. The monkey was required to single out one of four small targets by making a saccade to the target that was pointed out by the head gaze direction or matched to one of the four learned identities. In each trial the color of the fixation point indicated which of the two tasks had to be performed. A separate task required the passive viewing of face and non-face stimuli while maintaining a small fixation point. Single unit responses recorded from the right pSTS of the monkey showed a clear topographical organization of response preferences in these tasks. Among others, we were able to identify a small patch congruent with the gaze following patch (GFP) previously reported by Marciniak et al. (Elife, 2014) based on fMRI. In the GFP, neurons showed a clear response only to gaze following. On the other hand, face selective neurons responding to the passive vision of faces were found in a patch roughly 7mm away from the GFP, probably corresponding to the middle face patch (MFP) first delineated by Tsao et al. (Science, 2006). Here we report the clearly different features of local field potentials (LFPs) recorded from these two patches. The spectral analysis of LFPs recorded from the GFP exhibited a dominance of beta frequency oscillations (12-30Hz) as soon as the first facial information became available, continuing until the monkey made a saccade to the target indicated by the gaze cue in gaze following trials. On the other hand, LFPs recorded from the MFP were dominated by a broad range of high frequency gamma oscillations (30-100Hz). These clear differences in the frequency domain are in full support with the notion that the pSTS accommodates distinct neural architectures in distinct patches, i.e. the passive processing of facial attributes in face patches versus spatial shifts of attention based on directional facial information in the GFP.

Title: Recordings from macaque face patches ML and AM reveal a mechanism for view-invariant computation

Authors: *L. CHANG, D. TSAO;
Div. of Biol., CALIFORNIA INSTITUTE OF TECHNOLOGY, Pasadena, CA

Abstract: The macaque temporal lobe contains six patches of face-selective cortex. Previous experiments have explored face representation in the middle face patches using cartoon images and found that face cells are tuned to subsets of feature dimensions (Freiwald, Tsao and Livingstone, 2009), but it remains unclear how this result applies to realistic faces and other face patches. Furthermore, neurons in anterior face patch AM show face view-invariant tuning to individual identities (Freiwald and Tsao, 2010). What are the special tuning properties underlying view-invariant identity representation in AM? To address these questions, we generated a parametric real face space. We started with a database of 200 frontal faces (FEI face database), and for each face, used an "active appearance model" (Cootes, Edwards and Taylor, 2001) to extract significant facial features describing both the shape and shape-free appearance; we then computed the top 25 principal components for shape and for appearance. Thousands of faces were randomly drawn from the 50-d face space and presented during recording from face patches. We found that middle face patch neurons are better tuned to shape dimensions than appearance dimensions, while for neurons in anterior patch AM the opposite is true. Using linear regression, we decoded intensity variations at different locations of faces based on population responses. Two types of facial images were used for decoding: the original images presented to the monkey and the same set of images morphed to a standard shape template. Interestingly, we found using middle face patch population, the intensities around the eyes can be nicely decoded for the original images but not for shape-normalized images, while for AM population, the decoding is much better after shape normalization. This result suggests that AM cells are warping the face representation they receive from middle patch cells to a standard template. This provides a mechanistic explanation for how identity can be represented in a way that is invariant across small changes in view. The warping process we observed in AM neurons can be implemented in two different ways: 1) IT cortex may dynamically morph the facial images to match facial features like eyes to that of a standard face template; 2) Templates of "facial features" at different positions and scales could first be used to filter the facial image, then the outputs of the templates could be pooled together by nonlinear operations (like "max") to extract position- and scale-invariant feature values (Riesenhuber and Poggio, 1999). We are now exploring these possibilities with new experiments.

Title: Multiple object representation in the middle face patch

Authors: *P. BAO, L. CHANG, D. TSAO;
Biol., Caltech, Pasadena, CA

Abstract: In the natural environment, primates can recognize objects in the presence of the other objects and electrophysiological studies show that IT neurons reduce their response to a preferred object when presented with a non-preferred object (Zoccolan et al., 2005). It still remains unclear how the reduced responses can account for recognition invariant to the presence of multiple objects. To address this question, we performed electrophysiological recordings in the macaque middle face patch (ML). In the first experiment, to test how responses to preferred stimuli are affected by non-preferred stimuli, one face and one non-face object were presented horizontally or vertically around the fixation point. We also varied the relative contrast energy of two stimuli, while maintaining the whole contrast energy constant. In the horizontal configuration, we found when the face was in the visual field contralateral to the recording hemisphere, neurons performed a MAX operation regardless of contrast energy; when the face was presented in the ipsilateral visual field, neurons performed weighted averaging, with weight determined by contrast energy. In the vertical configuration, regardless whether the face was above or below the fixation, neurons always performed a MAX operation. In the second experiment, to test how neurons code multiple preferred objects, two faces were presented in a vertical or horizontal configuration as in the first experiment. Each face was randomly and independently sampled from a parametric real face space defined by three shape and three appearance dimensions (Chang & Tsao, 2014). In the vertical configuration, responses evoked by two-face stimuli were modulated by both faces. Moreover, the shapes of the tuning curves for each face in the two-face condition were similar, but lower in gain, than those for the single-face conditions. When two faces were presented in the horizontal configuration, the tuning curve to the ipsilateral face was flat, while the tuning curve to the contralateral face was similar to that for a single contralateral face. These two experiments reveal that neurons in the middle face patch can perform either MAX or averaging depending on the spatial configuration of the stimuli, and moreover, single cells participate in coding identity of multiple faces.

Title: Functional connectivity of category-selective patches in macaque IT cortex

Authors: *J. S. GUNTUPALLI, D. Y. TSAO;
Dept. of Biol., Caltech, Pasadena, CA

Abstract: fMRI of the macaque brain reveals six face-selective regions in the IT cortex. Electrophysiological recordings targeting these patches show that most neurons in these patches are also face-selective and the representation of faces by the neural population in these patches evolves along the posterior-to-anterior axis gradually building viewpoint invariance. Electrical stimulation within face patches revealed strong and specific connectivity among these patches suggesting that they form a network with strong connections. Similar category-specific regions for scenes and color have also been found using fMRI. Using resting state fMRI data, we found that a similar specific connectivity can be seen non-invasively among the face patches. Scene and color patches also show resting state functional connectivity within the respective networks but neither as strong nor as specific as face patches. Moreover, we found similar functionally-connected networks that do not overlap with any known category-selective regions in IT cortex. We targeted nodes within these networks for electrical stimulation to further explore the connectivity of these regions, and understand the relationship between electrical stimulation- and resting-state fMRI-defined connectivity. Overall, our results show that resting state fMRI connectivity provides a useful guide to to explore IT cortex, especially regions not yet identified as selective for any particular category.

Title: Location, location, location: face recognition critically depends on the information processing of individual face patches

Authors: *S. MOELLER[1], D. Y. TSAO[2];
[1]Dept. Animal Physiol., Tuebingen, Germany; [2]Caltech, Pasadena, CA

Abstract: We know that objects are processed by the inferior temporal cortex (IT); however, we do not know how object vision is organized within IT. There is evidence that objects are coded in a distributed fashion by large parts of IT; but face processing seems to be concentrated into six separate nodes, the face patches. While these face patches are only strongly connected within themselves, it is so far not clear whether face patch activity is necessary or sufficient for face perception or whether the activity of the surrounding cortex also supplies useful information about faces. We trained two monkeys on a delayed match to sample task, showing two images in sequence separated by a delay, followed by saccade targets, one to report images of the same identity and one to report images of different identity. We used fMRI (Siemens Tim Trio, 1 mm resolution, MION contrast agent) to localize face patches in both monkeys, and targeted 5 patches for perturbation experiments. In those experiments we perturbed the targeted face patch by electrical microstimulation (e.g.: 200 μA bipolar pulses @150 Hz for 200 ms) during the presentation of the second image. Microstimulation inside each of these 5 face patches resulted in a strong bias to report faces as different, but did not affect (most) non-face object identification. This bias appeared as a strong performance decrease in same-identity trials (performance change in % points by face patch: MF -55.35; ML -74.63; AF -44.59; AL -68.58; AM -84.65). Stimulation outside of the face patches did not affect face identification behavior. Interestingly, stimulation in the face patches also affected identification of non-face objects whose overall shape was consistent with a face (e.g., apples) albeit weaker than face identification. The magnitude of the stimulation effect on face, but not apple and citrus fruit identification significantly correlated with the stimulation site's face selectivity; showing that the large effect on faces required precise targeting to the core of a face patch, while the milder effect on face-compatible objects did not. Perturbing the activity of each individual node in the face patch network strongly disrupts face recognition behavior. Perturbed face patch activity cannot be overridden by un-perturbed activity of non-face selective IT cortex. Together this shows face

identification critically depends on information processing in the face patches but not the distributed activity of larger areas of IT cortex. The effects also indicate that while faces are encoded by face-selective regions, activity in these regions can also affect the percept of a large number of face compatible non-face objects.

Title: Dynamic relations between the left and right fusiform cortex in the spatially cued detection of faces

Authors: *M. MENG[1], B. GUO[1], J. GOOLD[1], H. LUO[2];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Peking Univ., Beijing, China

Abstract: A fundamental issue in understanding brain functions lies in the relationship between the left and right cerebral hemispheres. It is known that human face perception appears to be dominant in the right fusiform cortex, although face-selective responses have been identified bi-laterally. Moreover, activity in the left fusiform cortex was found to correlate with the perceived face semblance in non-face stimuli, whereas the right selectively responded to only faces (Meng et al., 2012). However, the question remains unknown of how the two hemispheres coordinate to form unified face representations. One possibility is that synchronized oscillatory activity across hemispheres may enable the coordination (Fries, 2005; Doron, Bassett, & Gazzaniga, 2012). To test this possibility, we combined an fMRI study with a novel experimental design that enables time-resolved sampling of brain responses across trials. This design has been successfully used to measure rhythmic behavioral effects, such as reaction time and response accuracy, in spatial and object-based attention (e.g., Fiebelkorn, Saalmann, & Kastner, 2013; Song et al., 2014). In each trial, an uninformative cue was presented in the left or right hemifield. Participants were asked to make speeded responses of whether a face or a house was presented, at either the cued or un-cued location. Critically, the cue-to-target stimulus onset asynchrony (SOA) varied trial-by-trial in small steps of 20ms, from 200ms to 1080ms. Bilateral fusiform face areas (FFA) and parahippocampal place areas (PPA) were localized with separate fMRI scans. On average, across

all SOAs, activity in the left FFA depended on whether the target had been shown in the contralateral hemifield or ipsilateral hemifield, whereas activity in the right FFA invariantly corresponded with the face/house target. More interestingly, the spatial cue led to significant theta-band (5Hz) oscillations of the activation patterns in the FFA as a function of SOA, complementing the results of another SFN2015 abstract, in which we report similar rhythmic effects of visual priming in the FFA and PPA. Together, our results suggest: 1) asymmetric response functions of visual hemifield in the left and right FFAs, and 2) reliable neural correlates of the theta-band oscillation induced by the spatial cue shown to each hemifield. These findings shed light on how the left and right cerebral hemispheres may work dynamically in tandem.

Title: Rapid, accurate detection of faces but not houses suggests a visually coarse but context sensitive subcortical face processing mechanism

Authors: ***L. M. CABRAL**, B. STOJANOSKI, R. CUSACK;
Western Univ., London, ON, Canada

Abstract: Recent neuroimaging and behavioural investigations into face processing have suggested a role for subcortical structures. Two conflicting views have emerged about the nature of the representations: subcortical structures are responsible for 1) coarse representations such as those involved in orienting to faces and 2) more fine grained representations at the level of face identification. The aim of the current experiment is to examine 1) the level at which faces are represented and 2) whether context influences the extent to which subcortical areas are recruited. We hypothesized that a rapid subcortical mechanism would facilitate face detection at fast reaction times, but that no such mechanism would be present for houses. In one block, participants (N=22) performed a face detection task, pressing a button for intact faces, but not for scrambled distractor stimuli. In another block, they performed the same task for houses. Block

order was counterbalanced. The distractor stimuli were matched for lower level visual features, but were unrecognizable. Presentation was monocular. Stimuli were randomly presented to the temporal or nasal visual field. Each participant's reaction times were divided into five bins, where bin each spanned an equal percentile range. At slower reaction times, detection accuracy was generally similar. However, at the fastest reaction times, participants were more accurate at identifying faces than houses ($p < 0.05$), supporting the idea that a rapid, subcortical mechanism facilitates face detection. No difference was found across visual fields. A second experiment (N=22) was conducted to examine the precision of the subcortical route. Less scrambled distractor stimuli were used, requiring a finer visual discrimination. In experiment 2, there was no subcortical advantage; at fast reaction times faces were not detected more accurately than houses. Finally, we tested whether the subcortical route was automatically recruited, or whether it depended on the task context. A subset of participants (N=11) completed an experiment requiring fine (cortical) visual discriminations and then completed an experiment requiring coarse (subcortical) discrimination. Under these conditions, even for coarse discriminations, faces were not detected more accurately than houses. This suggests that when participants had recently performed a task that recruited a cortical route, subcortical structures no longer effectively contributed to face processing. These results support a rapid, subcortical mechanism that exists to detect faces, which is only effectively engaged in coarse visual discriminations, and is sensitive to the task context.

Title: Information representation in monkey area TE for global categorization of faces and for upright versus inverted face categorization

Authors: ***N. MATSUMOTO**[1], Y. SUGASE-MIYAMOTO[1], K. KAWANO[2], M. OKADA[3]; [1]AIST, Tsukuba, Japan; [2]Kyoto Univ., Kyoto, Japan; [3]Univ. Tokyo, Kashiwa, Japan

Abstract: Sparse representation might be useful for improving memory storage in an artificial neural network. Some researches indicate that information is sparsely represented in the brain. We have reported that face-responsive neurons in monkey area TE represent information about a global category, namely human faces vs. monkey faces vs. simple shapes and about an upright vs. inverted face category. To examine whether the global categorization and the upright vs. inverted face categorization are sparsely represented in area TE, we analyzed activities of 119 face-responsive neurons in area TE of two rhesus monkeys (Macaca mulatta), performing a fixation task. The test stimuli were colored pictures of monkey faces (4 models with 4 expressions), human faces (3 models with 4 expressions), and inverted pictures of these faces. The population activity vectors consisting of mean spike counts across trials to each stimulus were computed in a 50-ms time window slid by 5 ms from 25 ms to 350 ms after each stimulus onset. Sparse logistic regression (SLR) was applied individually in each window to the population vectors for the upright human vs. monkey faces (GL), for the upright vs. inverted human faces (HUI), and for the upright vs. inverted monkey faces (MUI). In the 115-165 ms time window, when the Euclid distance between the gravity centers of human population vectors and of monkey vectors was the largest, the number of neurons selected to categorize GL, HUI, and MUI was 2, 2, and 5, respectively. Averaged spike counts revealed that the two neurons selected for GL by SLR also showed a significant effect of GL and that the two neurons selected for HUI by SLR showed a significant effect of HUI (one-way ANOVA, $p<0.01$). On the other hand, three out of the 5 neurons selected for MUI by SLR did not show a significant effect of MUI (one-way ANOVA, $p>0.01$). Each of the 3 neurons did not support to differentiate MUI, but a combination of one of the 3 neurons and one of the remaining two neurons did categorize MUI. In all time windows, the number of neurons selected in common for HUI and MUI was significantly larger from the number for GL and HUI (Wilcoxon signed-rank test, $p<0.01$) and for GL and MUI ($p<0.01$). The number selected in common for GL and HUI was not significantly different from the number for GL and MUI ($p>0.01$). The results suggest that only a small number of neurons in area TE are necessary to categorize human vs. monkey and upright vs. inverted faces and different members of the neuronal population contribute to categorize GL and HUI or MUI, and that HUI and MUI have contributing members in common.

Title: The face inversion effect in rhesus macaques

Authors: O. B. TOMEO, *N. LIU, S. W. LI, L. G. UNGERLEIDER;
Section on Neurocircuitry, Lab. of Brain and Cognition, Natl. Inst. of Mental Health, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Face perception plays a critical role in social communications and interactions. Given the similarities between monkeys and humans in the neural circuitry underlying social cognition, the rhesus macaque could provide an ideal animal model to study face processing. Although human and monkey neuroimaging studies have demonstrated similar face patch systems, behavioral studies exploring face processing in monkeys, unlike those in humans, have yielded inconsistent results. Here, we sought to clarify face-processing mechanisms by re-examining in macaques the face inversion effect, a phenomenon well documented in humans, which refers to greater difficulty in recognizing inverted faces compared to inverted non-face objects. Head-fixed rhesus macaques were trained to perform an oculomotor delayed match-to-sample (DMS) task. Stimuli were from six categories (faces: macaque, chimpanzee, human and sheep; objects: shoes and cars). Faces were forward facing and emotionless. All stimuli were contrast-normalized and grayscale. Faces were cropped with an oval mask to isolate central face information and exclude peripheral features that could be used to cheat. Subjects were first trained on the DMS task with simple shapes until achieving 85% accuracy, and then performed the test for each category equally per day. Reaction time (RT), accuracy and pattern of eye movement were recorded; the efficiency score (RT/accuracy) was used to account for the trade-off between RT and accuracy. We found that scan patterns were similar when viewing macaque, chimpanzee and human faces but not sheep faces. However, better efficiency scores for recognizing upright stimuli than the inverted ones were only found for macaque and chimpanzee faces but not for human faces, sheep faces or non-face objects. These results thus revealed a face inversion effect only for conspecific (macaque) and heterospecific (chimpanzee) faces, implying that macaques process both macaque and chimpanzee faces holistically. Moreover, our data support the idea that the effect is specific for stimuli for which the individual has developed expertise.

Title: The effects of crowding on the tuning and latency of neurons in human and monkey amygdala

Authors: *J. MINXHA[1], J. K. MORROW[4], C. P. MOSHER[4], A. N. MAMELAK[5], K. GOTHARD[4], R. ADOLPHS[2,3], U. RUTISHAUSER[5,3];

Abstract: The electrophysiological characteristics of primate amygdala neurons have been explored in a variety of visual tasks. While previous work in this area has shed some light on the properties of the cells in the amygdala, the electrophysiological response has typically been measured with respect to the stimulus onset, leaving the relationship with eye movements largely unexplored. To evaluate the link between cell responses and eye movements, we recorded from single neurons in the amygdalae of eight neurosurgical patients who were implanted with depth electrodes for the purpose of monitoring their seizures. In addition, we also recorded from the amygdalae of 3 rhesus macaque monkeys as they performed the same task as the human subjects. We recorded eye-movements as both monkeys and humans freely scanned an array of images arranged in a circle around a fixation point. The images depicted items from six categories: fractals, flowers, human faces, monkey faces, cars, and fruits. The competing visual targets elicited a sequence of fixations and saccades (scan path) that resembled more closely the natural pattern of eye movements. Aligned at fixation onset, the response of neurons was highly sensitive to which images were fixated. Although we found neurons responding to fixations on images of all six categories, the greatest number of cells responded to fixations on human and monkey faces. The majority of these face-selective cells were tuned to conspecifics in both the monkeys (n=78 cells, 1% fractals, 1% flowers, 47% monkey faces, 4% human faces) and humans (n=112 cells, 20% human faces, 14% monkey faces, 2% fractals, 2% flowers). The response latency of image-selective neuron in humans was on average 60 ms longer than in monkeys (relative to fixation onset). Furthermore, this response latency depended on the number of images presented simultaneously to the subject. In humans, the response latency was 348 ms for a single image and 256 ms for an array of 8 images. In monkeys, the response latency was 320 ms for a single image and 150 ms for an array of 8 images. This difference in both species

might be due to the allocation of attention that precedes fixation on the target image. Together, this data shows both similarities and differences between neural responses in the human and monkey amygdala. In both species, (a) image-selective neurons were sensitive to the number of visual targets available; b) cells were sensitive to the context in which visual targets are presented; c) higher tuning preference for the faces of conspecifics. Neurons in the human amygdala, however, responded systematically later compared to the neurons in the monkey amygdala.

Hosp., Pasadena, CA; [7]Departments of Neurosurg. and Neurol., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: The human amygdala plays a key role in processing facial emotion, as evidenced by lesion, functional neuroimaging, and human electrophysiological studies. Here for the first time we combine all three approaches to elucidate the amygdala's role in encoding emotions expressed by faces. We employed a face morph task with fear-happy morphs (ranging from 30% fear/70% happy to 70% fear/30% happy as well as 2 anchor faces of fear and happy without

ambiguity). In each trial, subjects judged whether the emotion was ‘fear’ or ‘happy’. Behavioral performance varied systematically as a function of morph levels: anchors were reliably identified whereas the most ambiguous intermediate stimuli variably resulted in a fear or happy judgment. This task is thus well suited to differentiate sensory representations from decisions. BOLD-fMRI analysis (N=19 healthy subjects) showed that our faces activated the amygdala reliably within a region of interest specified both anatomically and functionally by an independent localizer task. Both emotion identity (morph level) and emotion uncertainty (ambiguity level) modulated BOLD-fMRI amygdala activity, with happier faces and unambiguous faces resulting in the largest BOLD response. To investigate the detailed response characteristics at the cellular level, we next recorded single neurons from the human amygdala in epilepsy patients implanted with depth electrodes (235 units, recorded in 14 sessions from 9 neurosurgical patients). The response of 33 neurons (14.0%, binomial $P<1e-7$) correlated with the gradual change of emotion identity (linear regression of average firing rate across trials vs. morph levels, $P<0.05$; 21 and 17 neurons increased and decreased their activity as a function fearfulness, respectively). A separate population of 36 neurons (15.3%, binomial $P<1e-9$) signaled levels of ambiguity (trial-by-trial linear regression of average firing rate in a 1.5s time window 250ms after face onset vs. ambiguity levels, $P<0.05$). Of these, the majority of neurons (30/36) had the largest firing rate for the anchors. Population level decoding showed that during ambiguous trials, amygdala single neurons correlated with the subjective decision (fear or happy) given the same stimuli. Lastly, three patients with focal bilateral amygdala lesions who performed our task were more likely to identify stimuli as fearful compared to healthy controls and the neurosurgical patients. This confirms the amygdala’s causal role in our task. Taken together, our results reveal a significant functional role of the amygdala in making decisions about facial emotions.
