Abstract: Human observers follow another person´s eye gaze to objects and locations of interest to the other one, thereby establishing "joint attention", a first and major step towards developing a theory of the other´s mind. Previous fMRI studies agree that a small patch of cortex in the posterior superior temporal sulcus (STS) is specifically implicated in eye gaze following. This "gaze following patch" (GFP) is located in the same general region known to be part of the core face processing system that consists of several distinct patches in the STS and ventral visual cortex, the "face patch" system. Hence, the GFP might actually correspond to one of the "face patches". In order to test this hypothesis, we carried out an fMRI experiment in which we tried to clarify the spatial relationship of the GFP and the face patch system in the same subjects. In order to identify the GFP, we resorted to the paradigm introduced by Materna et al. J. Cogn. Neurosci. 2008. Subjects were asked to make saccades to distinct spatial targets based on information provided by a human portrait presented to the observer. Depending on the instruction, subjects either had to rely on the seen eye orientation to identify the correct target or, alternatively, they had to use the color of the eyes, changing from trial to trial but always matching to one of the targets, in order to make a saccade to the target having the same color. In other words, the only difference between the two tasks was the information, subjects had to exploit in order to solve the task and the performance levels achieved in both were actually not different. We localized the face patch system in a separate experiment in which subjects passively viewed images of faces as well as a variety of biological and non-biological non-face stimuli while maintaining fixation of a central cue. In correspondence with previous works (e.g. Tsao et al., PNAS, 2008) passive viewing of faces elicited BOLD activity within a distributed cortical network that included the occipital face area (OFA), the fusiform face area (FFA), as well as patches in the posterior superior temporal sulcus (pSTS) and the inferior frontal gyrus (IFG). In accordance with Materna et al., gaze following as assessed by the gaze following vs. identity matching BOLD contrast activated a distinct GFP in the pSTS, with its activation maximum separated by more than 12mm (euclidean distance) from the nearest member of the "face patch system". This segregation suggests a distinct function of the GFP beyond the elementary processing of facial information accommodated by the face patch system. On the other hand, it would of course be fully compatible with members of the face patch system serving as major input to the GFP.

Title: Role of dorsolateral prefrontal cortex in the cognitive control of gaze following

Authors: *M.-S. BREU, H. RAMEZANPOUR, P. DICKE, P. THIER;
Cognitive Neurol., Hertie Inst. For Clin. Brain Res., Tübingen, Germany

Abstract: Non-verbal communication is indispensible for successful social interactions. In humans, the face and the eyes are major sources of information on the other´s mental state. It is the direction of gaze that informs us about objects another person might be interested in. By following the other´s gaze to this object, we establish "joint attention". And by mapping our own object-associated needs, interests and aspirations onto the other, we develop a theory of her/ his mind. Human gaze following is a fast and almost reflex-like behavior, yet, it can be controlled, if not opportune, for instance in an attempt to disguise interest in the other one. As shown by fMRI studies, the major substrate of human gaze following is a well defined region in the posterior superior temporal sulcus ("pSTS") (Materna et al., J. Cogn. Neurosci., 2008; Marquardt et al., SfN 2015), arguably also the target of the executive control of gaze following. In order to identify the source(s) of the putative control signal(s), we carried out an fMRI-experiment, in which humans subjects were exposed to gaze following cues which - depending on the prevailing instruction - were used to establish joint attention or not. More specifically, the experimental subjects saw the portrait of a female ("sender"), looking with her eyes at one out of five targets in front of her. Subjects had to follow the gaze of the sender with a saccade to the target. Alternatively, they had to ignore gaze and to look at the target whose color matched the sender´s (variable) eye color. The two trial types were presented randomly interleaved. The instruction to choose the target based on gaze direction or on eye color was presented before a particular trial started. In accordance with previous work, gaze following activated the right pSTS region. Moreover, we could identify a circumscript region in the right dorsolateral prefrontal cortex, being part of Brodmann area 46, that was specifically activated in color matching trials in which gaze following had to be suppressed. This result suggests that area 46 plays a central role in the context-dependent control of human gaze following.

Title: Neural signatures of eye gaze and face identity representations in MEG data

Authors: *J. LI[1], M. FANG[2], Q. LI[5], R. CICHY[3], D. PANTAZIS[4];
[1]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [2]McGovern Inst. for Brain Res., MIT, Boston, MA; [3]Computer Sci. and Artificial Intelligence Lab., [4]McGovern Inst. for Brain Res., MIT, cambridge, MA; [5]Radiology, Massachusetts Gen. Hosp., Boston, MA

Abstract: Human face perception is a core cognitive function, crucial for social interaction, communication and cooperation. It involves two orthogonal functions: one is to identify a person's identity by analyzing the invariant features of a face while neglecting it's changeable features, the other what the person is feeling, or attending to by analyzing the state of the changeable features irrespective of identity. While the locations of brain networks involved in either function have been well described, the description of temporal dynamics within those regions has remained challenging. Neural responses to identity and gaze processing overlap in time, making singling each of them out problematic using non-invasive methods in humans that have only low spatial resolution. To address this issue we investigated the encoding of gaze or identity as a function of task context: We reasoned that a task requiring attention to either identity or gaze would specifically boost function-specific neural activity, allowing dissociation of identity and gaze processing. We recorded magnetoencephalography data (MEG) while participants conducted either a gaze or identity 1-back repetition detection task on a set of images (3 individuals with 3 eye gaze directions each, i.e. 9 images). Trials were ordered in blocks by task. We then used multivariate pattern classification to decode facial identity and gaze direction dependent on task. In line with our prediction, we found that eye gaze was discriminated by visual representations during the eye gaze task for several hundred milliseconds after the stimulus, while decoding fluctuated around baseline for the identity task. Unexpectedly, we did not find the reverse effect for identity: identity was discriminated by visual representations in the eye gaze task but not in the face identity task. Taken together, these results indicate that while eye gaze representations are readily captured by MEG, face identity representations are more challenging to measure. Our results also suggest that face identity representations might highly dependent on the attended area of the face.

Title: Task differentially modulates the spatial extent of category-selective regions across anatomical locations

Authors: *L. BUGATUS[1], K. WEINER[1,2], K. GRILL-SPECTOR[1,2];
[1]Psychology, [2]Stanford Neurosciences Inst., Stanford Univ., Stanford, CA

Abstract: The human brain contains separate functional networks consisting of multiple regions across occipital, temporal, and prefrontal cortices that are involved in processing faces and words. Prior research shows that cognitive tasks performed by subjects while viewing these stimuli modulate neural responses. However, it is unknown if task effects vary by (a) macroanatomical location, (b) stimulus category, and (c) hemisphere. To address these gaps in knowledge, we examined how different tasks affect representations of faces and words across the cortex. We scanned 12 subjects using fMRI at 3T. Subjects viewed stimuli from five categories (faces, bodies, houses, cars, and pseudo-words) while performing one of three tasks. In the oddball task, subjects detected a randomly presented phase-scrambled image. In the working memory task, subjects indicated when a stimulus repeated after an intervening image (2-back). In the selective attention task, subjects indicated when an attended image of two superimposed images was upside down. We examined how these tasks affected category-selective representations in three anatomical regions: lateral occipitotemporal cortex (LOTC), ventral temporal cortex (VTC), and ventrolateral prefrontal cortex (VLPFC). We report three main findings. First, multivoxel pattern (MVP) analyses revealed differential effects of task across anatomical regions: in LOTC and VTC, MVPs for a category were similar across tasks (LOTC: $r = 0.45 \pm 0.08$; VTC: $r = 0.5 \pm 0.08$), while in VLPFC, MVPs for a category differed across tasks ($r = 0.09 \pm 0.09$). Second, quantifying the consistency of category-selective voxels ($t>3$) across tasks revealed a triple-interaction among hemisphere, category, and task ($F(5,672) = 5.55$, $p < 0.001$): in LOTC and VTC, the same voxels displayed category-selectivity across tasks, whereas in VLPFC, different voxels displayed category-selectivity in different tasks, with word-selective voxels lateralized to the left and face-selective voxels lateralized to the right VLPFC. Third, we observed selectivity differences for faces and words across tasks ($F(2, 230) = 11.73$, $p < 0.001$): for faces, the highest selectivity was during working memory, while for words, the highest

selectivity was during selective attention, except for left VLPFC in which it was highest during working memory. Together, these results reveal a complex interaction of stimulus, hemisphere, and task, affecting representation of category-selective responses. In turn, this suggests that the multiplicity of face- and word-selective regions may be related to task-relevant functional differences of separate components of these functional networks.

Title: The representation of semantic content and attentional state in medial temporal lobe during visual processing of natural scenes: an ECoG study

Authors: Z. SABRA, J. BREEDLOVE, L. BONILHA, *T. NASELARIS;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Brain areas within the medial temporal lobe (MTL) are critical for a variety of cognitive functions, most notably declarative memory. MTL is also anatomically and functionally connected to areas within the ventral visual stream. However, the role of MTL in ventral stream visual processing is currently unclear. MTL may act primarily as a source of purely cognitive, top-down signals that modulate visual processing; it may also be possible that it has a more purely sensory role in the ventral stream representation of the semantic content of scenes. To address this issue, we recorded electrocorticographic (ECoG) potentials from hippocampus and surrounding MTL cortical areas with the goal of answering a simple question: Is variation in neural activity in MTL driven more by changes in attentional state or by changes in stimulus content? Two patients implanted bilaterally with depth electrodes in MTL viewed a stream of natural scenes that prominently featured a face, a building, or a car. Subjects were instructed to fixate a small dot at the center of each image while attending to one of the stimulus categories (i.e., attend to either face, building, or car). Image presentation was divided into blocks of 50 images. The attended category was fixed during each block, while the stimulus category was randomly interleaved. Subjects demonstrated compliance by performing a simple identification task. Image and inter-stimulus interval durations were randomized. For each

attentional/stimulus condition (for example, attend face/view car) we estimated a distinct finite impulse response function (FIR). We then quantified the amount of variation in the FIR due to changes in the attended category, as well as the amount of variation due to changes in the stimulus category. We found that variation in the FIR due to changes in attended category was significantly larger than variation due to changes in stimulus category for more than 70% of the electrode contacts in MTL. These preliminary results suggest that variation of activity in MTL is driven more by variation in attended category than by variation in stimulus category.

Title: Increased distinctiveness of visual face representations during memory retrieval compared to perception

Authors: *S.-H. LEE[1,2], B. A. LEVY[2], C. I. BAKER[2];
[1]Dept. of Bio and Brain Engin., Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [2]Lab. of Brain and Cognition, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: Despite the high similarity of human faces, we can easily discriminate and recognize face identity, and can retrieve how people look. Here, we asked how individual face information is represented in the visual cortex during perception and retrieval. To address this question, we performed an event-related functional magnetic resonance imaging (fMRI) experiment, comprising separate perception, learning and retrieval sessions. During the perception session, which took place inside the scanner, participants were presented with fixed pairings of six auditory cues (pseudowords) with six face images (e.g. ‘greds’- man1, ‘drige’-man2), and six auditory cues with six shoe images. During the learning session, which took place on a separate day outside the scanner, participants were trained to memorize the pseudoword-image associations for about one hour. Finally, one day after the learning session, participants were

scanned again and instructed to retrieve each image in response to auditory presentation of the paired pseudoword cue. To test the veracity of the retrieved visual information, participants were asked to perform forced-choice tests, in which they heard one of the pseudoword cue and chose the paired category or image, after the retrieval scan session. Every participant showed near perfect performance in the forced-choice test (> 95% correct). We focused on the patterns of response in face-selective cortical areas. Using multivoxel pattern analyses, we found that anterior face-selective areas showed more discriminable patterns of response to individual faces during retrieval compared to those elicited during perception whereas those areas did not show any significant difference between perception and retrieval for individual shoe images. To determine whether the increased discrimination reflected a difference between perceived and retrieved face information and not an effect of learning, we conducted a similar fMRI experiment in which the second session was also perception and not retrieval. Importantly, there was no difference in face discrimination between the first and second perception sessions in anterior face-selective areas. Taken together, these results suggest that retrieval of face information generates more discriminative neural responses for individual faces than that evoked by perception of the very same faces.

Title: Temporal dynamics and quantification of face-selective responses to natural images

Authors: T. L. RETTER, *B. ROSSION;
Univ. of Louvain, Louvain-la-Neuve, Belgium

Abstract: Despite a wealth of research in human vision, the quantification and temporal dynamics, i.e., the onset, evolution, and duration of complete face-selective responses to briefly visible images remains largely unknown. Here, we present various nonface object images at a fast periodic rate (one image every 80 ms, i.e., 12.5 Hz), with natural face images inserted every

3, 5, 7, 9, or 11 stimuli (240 to 880 ms, i.e., 4.17 to 1.14 Hz) during electroencephalographic (EEG) recording. This fast periodic visual stimulation allows for quantification of complete face-selective responses in the frequency domain, identified at the various pre-defined face stimulation rates objectively and directly (without subtraction). These responses are the largest over the right occipito-temporal cortex and are significantly reduced below 400 ms of face onset asynchrony (i.e., at 240 ms), indicating that the duration of a face-selective response exceeds that amount of time. In the time domain, face-selective responses emerge shortly after 100 ms following stimulus onset and, despite a brief stimulus duration, they possess a succession of components with slightly different spatio-temporal signatures over the occipito-temporal cortex until shortly after 500 ms. These observations clarify a number of key issues related to investigations of human face categorization, such as the quantification of face-selective responses in the human brain, the distinction between evoked EEG responses to slow and fast, periodic repetitive stimulation (i.e., "ERPs" vs. "SSVEPs"), and the exact projection of a fixed onset delay to each successive temporal response. More generally, they go a long way towards understanding the temporal dynamics of face-selective responses to natural images in the human brain, paving the way for investigating its neural basis and relationship to face categorization behavior.

Title: Face-evoked visual field potential generators in the macaque temporal lobe

Authors: *Y. KAJIKAWA[1], C. E. SCHROEDER[2,1];
[1]Nathan Kline Inst., Orangeburg, NY; [2]Columbia Univ., New York City, NY

Abstract: When we communicate with others, we look at their faces that trigger a sequence of sensory activation in occipital and temporal lobes. fMRI studies in humans show face selective

cortices in those regions: the fusiform face area (FFA), the occipital face area (OFA) and the superior temporal sulcus (STS). Electrophysiologically, viewing face evokes visually evoked potential (VEP) that contains occipito-temporal positive peak at 100 ms (P1) followed by occipito-temporal negative peak at 170 ms (N170). N170 is the largest peak and is widely used to study the mechanisms of face perception and to index social cognitive dysfunction. In contrast, the face-evoked VEP has not been studied well in macaques. We trained macaque monkeys to perform audiovisual (AV) vocalization discriminations. They pulled a lever to initiate trials, and in each trial, monitored a repetition of AV vocalizations (brief videos) to detect oddballs (e.g., change from a "bark" to a "coo") in either auditory or visual modalities. Upon detection of an oddball, monkeys had to respond by releasing the lever quickly to obtain reward. The behavioral requirement ensured that animals pay attention to both modalities. Stimulus sequences contained 3-6, 500 ms audiovisual movie clips of a conspecific vocalization interleaved with 600~1200 ms of silence with a static image. During the tasks, scalp potentials over the temporal lobe were recorded along with intracortical electrophysiological activity, recorded using linear array electrodes straddling the auditory cortex, and/or underlying superior temporal sulcal regions. Face-evoked VEPs on the macaque scalp started with a vertex positive peak near 70 ms (P1) followed by larger vertex negative peak at 110 ms (N1). Face-evoked field potentials with peaks near 110 ms, like the scalp N1, were recorded in the auditory cortex, the superior temporal polysensory area (STP), and the inferior temporal cortex (IT). Current source density analysis revealed local contributions to the scalp N1 that were consistent in IT, sporadic in STP, and weak or absent in the auditory cortex. These results indicated that face-evoked field potentials concurrent with scalp potentials are present in wide cortical regions of the temporal lobe. However, cortical activity generating face-evoked VEP is largely confined to the cortices in the superior temporal sulcus.

Title: Attention shifts and Microsaccades in dynamic bubbled faces

Authors: *H. XU, H. YING;
Nanyang Technological Univ., Singapore, Singapore

Abstract: We recently showed that adapting to dynamic bubbled faces generated significant facial expression aftereffect, but adapting to static bubbled faces did not (Xu et al., VSS 2013, Luo & Xu, APCV 2013). It thus renders the question whether attention plays a role in the above difference. Microsaccade, a kind of unconscious eye movement typically occurs during prolonged visual fixation reflecting covert attention (Engbert & Kliegl, 2003), has been suggested to indicate attention shifts. Five subjects were tested in our study. The task was to judge the emotions (happy vs. sad) of 580 faces from three categories: static full faces, static bubbled faces, and dynamic bubbled faces. We recorded their judgment accuracy of these faces and reaction time. Simultaneously we recorded their eye movement by eye tracker (EyeLink II), and analyzed their microsaccades patterns in particular. We found that although there was no significant difference between judgment accuracy in the three face categories, the subjects spent more time on judging bubbled faces, and more frequent microsaccades toward bubbled faces, with larger amplitude of microsaccades to static bubbled faces. It thus suggests attention shifts in bubbled faces are different than in full faces, and the attention difference in dynamic and static bubbled faces. Our findings may shed light on the mechanism of attention in incomplete face perception.

Title: Word and text processing in developmental prosopagnosia

Authors: *C. RUBINO[1], J. C. CORROW[1], J. J. S. BARTON[2], S. L. CORROW[1];
[1]Ophthalmology and Visual Sci., [2]Ophthalmology and Visual Sciences, Med. (Neurology), Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Word and text processing in developmental prosopagnosia Cristina Rubino Jeffrey C Corrow Jason J S Barton Sherryse L Corrow Human Vision and Eye Movement Laboratory,

Departments of Medicine (Neurology) and Ophthalmology and Visual Sciences, University of British Columbia, Vancouver, Canada Objective The recent 'many-to-many' hypothesis asserts that multiple cortical regions participate in processing multiple object types[1]. Studies of subjects with impaired face or word recognition provide an opportunity to test predictions of this hypothesis, that prosopagnosic subjects would have minor impairments in word processing, while alexic subjects would have subtle impairments in face perception. In this study, we evaluate whether subjects with developmenta*l* prosopagnosia have deficits in processing aspects of written text. Methods In a first experiment we evaluated the word-length effect for reading time in subjects with developmental prosopagnosia (n=9). In a second experiment we assessed their sorting of written text by word content across variations in font or handwriting style, and their sorting of text by handwriting or font style across variations in word content. Results In Experiment 1, prosopagnosic subjects had normal word-length effects. In Experiment 2, sorting time and accuracy for processing word content across stylistic variations was normal, When sorting text by stylistic properties two of the nine showed a mild reduction in accuracy for handwriting but not for computer font. Interpretation Subjects with developmental prosopagnosia have efficient single-word reading and can extract word identity across stylistic variations. Only a minority demonstrate mild difficulty processing stylistic properties of text, which contrasts with the frequent impairment of this process recently reported in acquired prosopagnosia. This may suggest a difference in either severity or selectivity between the acquired and developmental forms of prosopagnosia. Key Words: face, agnosia, words Footnotes [1] Behrmann M, Plaut DC. Title: Tone deafness in developmental prosopagnosia - is there a common cause?

Authors: *S. CORROW[1], S. BUSS[3], H. LI[3], G. SCHLAUG[3], J. J. S. BARTON[2]; [1]Ophthalmology and Visual Sci., [2]Neurology/Ophthalmology and Visual Sci., Univ. of British Columbia, Vancouver, BC, Canada; [3]Neurol., Beth Israel Deaconess Med. Ctr. and Harvard Med. Sch., Boston, MA

Abstract: OBJECTIVE: Developmental prosopagnosia is a disorder of face recognition that is believed to reflect impairment of high-level visual mechanisms. Recent work has shown differences between those with prosopagnosia and control subjects in matter connectivity of the inferior longitudinal fasciculus. Amusia (e.g. tone deafness) is another developmental disorder which has been shown to have grey matter abnormalities in several non-primary perisylvian regions and is also associated with white matter connectivity in the arcuate fasciculus (Loui et al, 2009). Based on anecdotal reports of some subjects, we hypothesized that there may be instances in which these two disorders overlap. **METHOD:** Subjects with developmental prosopagnosia were compared to healthy control subjects on two measures. The Montreal Battery of Evaluation of Amusia examined melodic organization (scale, contour, and interval), temporal organization (rhythm and meter), and memory (DP n=7, Control - normative data from 160 healthy adults). In addition, subjects completed a pitch discrimination threshold task (DP n=8; Control n=10). For details of these test batteries, see Loui et al (2009) and Fujii and Schlaug (2014). **RESULTS:** On pitch discrimination, as a group, subjects with developmental prosopagnosia were impaired relative to controls [$p<0.05$], and at the individual level, 5 of 8 subjects with developmental prosopagnosia exceeded the mean for control subjects by at least 10 standard deviations. On the Montreal Battery of Evaluation of Amusia, the prosopagnosic sample was impaired relative to normative controls on their overall score [$p<0.01$] as well as specific scores for pitch interval perception [$p<0.001$] and tune memory [$p<0.05$]. At the individual level, 2 of 7 subjects with prosopagnosia were impaired on their global score and several were impaired specifically on contour (1), interval (2), scale (3), meter (1), and memory (1). **CONCLUSION/DISCUSSION:** At least some cases of developmental prosopagnosia have not only impaired face recognition but also show deficits found in congenital amusia, particularly impaired pitch discrimination. One possible explanation is that focal cortical abnormalities and connectivity profiles of brain regions in different domains could be abnormal, resulting in a co-occurance of amusia and prosopagnosia. Whether this is a primary white matter disconnection or secondary to a cortical migration disorder is not yet clear. Our future work will include high resolution MRI to reveal neural substrates that are common between both disorders to determine the anatomic substrate of this behavioral observation.

Title: Getting lost: Topographic skills in acquired and developmental prosopagnosia

Authors: *J. CORROW[1], S. L. CORROW[2], E. LEE[2], F. BURLES[3], R. PANCAROGLU[1], B. DUCHAINE[4], I. GIUSEPPE[3], J. J. S. BARTON[2];
[1]Ophthalmology and Visual Sci., [2]Med. (Neurology), Univ. of British Columbia, Vancouver, BC, Canada; [3]Psychology, Univ. of Calgary, Calgary, AB, Canada; [4]Psychology and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Previous studies report that acquired prosopagnosia is frequently associated with topographical disorientation. However, whether this is associated with a specific anatomic subtype of prosopagnosia, how frequently it is seen with the developmental variant of this disorder, and what specific topographical function is impaired to account for this problem are not known. We studied ten subjects with acquired prosopagnosia from either occipito-temporal or anterior-temporal lesions and seven with developmental prosopagnosia. Subjects were given a battery of tests assessing cognitive processes important for topographical orientation, including house and scene recognition, the road map test, a test of path integration from optic flow, and cognitive map formation and use. House and/or scene recognition were frequently impaired after either occipito-temporal or anterior-temporal lesions in acquired prosopagnosia. Subjects with occipito-temporal lesions were also impaired in cognitive map formation: an overlap lesion analysis identified right fusiform and parahippocampal gyri as a likely correlate of this deficit. Path integration was intact in all participants, and only one subject with acquired prosopagnosia had mild difficulty with directional orientation on the road map test. Only one subject with developmental prosopagnosia had difficulty with cognitive map formation, and none were impaired on the other tests. We conclude that topographical disorientation in acquired prosopagnosia reflects impaired place recognition, with a contribution from poor cognitive map formation when there is occipito-temporal damage. Topographical impairments are less frequent in developmental prosopagnosia.

Title: Behavioral study of trpa1 and trpv1 channels inactivation by nsaids

Authors: ***M. G. TSAGARELI**[1], I. NOZADZE[2], N. TSIKLAURI[2], G. GURTSKAIA[2], E. ABZIANIDZE[2];

Abstract: Transient receptor potential (TRP) cation channels have been extensively investigated as targets for analgesic drug discovery. Because some non-steroidal anti-inflammatory drugs (NSAIDs) are structural analogs of prostaglandins, we examined three widely used non-steroidal anti-inflammatory drugs (NSAIDs) (clodifen, ketorolac, and xefocam) on the activation of TRPA1 and TRPV1 channels using thermal paw withdrawal (Hargreaves) test and mechanical paw withdrawal (von Frey) test in male rats. Thermal withdrawal latencies and mechanical thresholds for both hind paws were obtained with 5, 15, 30, 45, 60, and 120 min intraplantar post-injection of TRPA1 agonists' cinnamaldehyde (CA) from cinnamon and allyl isothiocyanate (AITC) a natural compound of mustard oil, and TRPV1 agonist capsaicin a natural compound of chili pepper, or vehicle. Twenty minutes prior to the start of the experiment, ketorolac or xefocam were pre-injected in the same hindpaw and animals were examined by these two tests. After pretreatment of all three NSAIDs in the ipsilateral (injected) hindpaw that produced strong antinociceptive effects, CA, AITC, and capsaicin caused significant decreases in latency of the thermal withdrawal reflex compared with vehicle or the contralateral hindpaw. The same findings were observed for the paw withdrawal threshold. In approximately 30 min the effects of CA, ITC, and capsaicin returned to baseline. The findings in this study are different from our previous results, where TRPA1 agonists CA and AITC and TRPV1 agonist capsaicin produced hyperalgesia for nearly 2 h and resulted in facilitation of these withdrawal reflexes. Thus, we show for the first time an inactivation of TRPA1 and TRPV1 channels by NSAIDs to channel agonists in behavioral assays.

Title: TRPA1-protein complexes: tuning a noxious stimuli detector

Authors: ***L. AVENALI**, P. NARAYANAN, T. ROUWETTE, I. CERVELLINI, M. W. SEREDA, O. ABATE FULAS, J. SONDERMANN, O. JAHN, D. GOMEZ-VARELA, M. SCHMIDT;
Max Planck Inst. For Exptl. Med., Goettingen, Germany

Abstract: The transient receptor potential A1 (TRPA1) channel is essential for vertebrate pain. TRPA1 plays a fundamental role as a primary detector of noxious stimuli of physical and chemical nature, and is critically involved in different pain states. Even though TRPA1 activation modalities have been studied extensively, the network of protein interactions regulating TRPA1 (the so-called TRPA1 interactome) is only poorly understood. Considering the crucial role of TRPA1 in pain signaling, it is mandatory to shed light on the elusive molecular machinery regulating TRPA1 channels in sensory neurons. To this end we established a mass spectrometry-based proteomics approach to identify and characterize proteins interacting with native TRPA1 channels from mouse sensory neurons. In this way we have recently uncovered

the physical association of Annexin A2 (AnxA2) with native TRPA1. Functional studies suggest that AnxA2 limits the availability of TRPA1 channels at the plasma membrane and furthermore regulates TRPA1-dependent nociception in mice. These results demonstrate a role for AnxA2 as an endogenous modulator of TRPA1 activity and define a mechanism capable of controlling TRPA1-mediated nociception in vertebrates. In addition, these findings underscore the idea that TRPA1 surface availability and function are controlled by protein-protein interactions and pave the way for a more thorough investigation of the dynamic changes in TRPA1-associated protein complexes. To accomplish this we used an established inflammatory pain mouse model and identified changes in TRPA1 interactome by state-of-the-art quantitative mass spectrometry. This work revealed TRPA1-protein complexes specifically altered in the context of inflammatory pain. New players in the development or maintenance of inflammatory pain might be uncovered, and their characterization is the focus of our current investigations. We anticipate that this study will contribute to our molecular understanding of the processes which give rise to TRPA1-dependent nociception and open the possibility to develop targeted therapeutics for specific TRPA1-related pain disorders.

Title: Possible contribution of TRPA1 to capsaicin-induced analgesia in deep tissue pain

Authors: *D. SUGIYAMA[1], S. KANG[1], H. GU[1], T. J. BRENNAN[2];
[1]Dept. of Anesthesia, Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [2]Dept. of Anesthesia and Pharmacol., Univ. of Iowa Hosp. and Clinics, Iowa CIty, IA

Abstract: We have previously shown that peripheral nerve block with a selective TRPV1 agonist capsaicin (CAP) significantly inhibited non-evoked guarding pain behavior after deep tissue incision in rats. On the other hand, TRPV1 antagonist had limited analgesic efficacy on guarding pain. This suggests that TRPV1-expressing afferents, rather than the TRPV1 itself, are

crucial for non-evoked pain behavior after deep tissue incision. TRPA1 is mostly co-localized with TRPV1 in primary afferents, and recent studies suggest that TRPA1 may play a role in postoperative pain. Therefore, perineurally applied CAP may exert its analgesic effect, at least in part, via blocking pain signals transmitted by TRPA1 in deep tissue. Our preliminary data indicate that injection of H2O2 into deep tissue induced spontaneous pain behavior through TRPA1. We hypothesized that TRPV1-expressing afferents mediate spontaneous pain behavior evoked by activation of TRPA1 in deep tissue, and that nerve block with will inhibit this pain behavior. H2O2 (100 μM- 5 mM) induces Ca2+ influx via TRPA1 receptors in rat DRG neurons (L3-5) in a concentration-dependent manner. H2O2 elicited Ca2+ transients in 15-25% of DRG neurons, all of which also responded to TRPA1 agonist AITC (100 μM). The H2O2-evoked Ca2+ transients were inhibited by TRPA1 antagonists, HC-030031 (100 μM) and AP-18 (100 μM). We studied the relationship between H2O2- and CAP-responsive DRG neurons: the majority (92%) of H2O2-responsive neurons also responded to CAP (0.5 μM), and 52% of CAP-responsive neurons responded to H2O2. We examined the effect of nerve block with CAP on spontaneous pain behavior induced by injection of H2O2 into deep tissue in rats. Percutaneous sciatic nerve block was performed using the following drugs: (1) 0.05% CAP plus 0.5% bupivacaine (BUP) or (2) 0.5% BUP only (control). H2O2 (100 mM, 0.6 ml) was injected into the gastrocnemius muscle at various time points (1-7 days) following the nerve block, and the total time spent flinching, lifting, and licking was recorded for 60 minutes. Compared to control, CAP+BUP group showed significantly decreased H2O2-induced spontaneous pain behavior throughout the testing period ($p < 0.05$): duration of H2O2-induced pain behavior in CAP+BUP vs. control groups were 69 ± 74 vs. 2212 ± 1119 sec at 1 day after nerve block, and 1060 ± 1241 vs. 2337 ± 213 sec at 7 days after nerve block. Our results suggest that H2O2 causes deep tissue pain via TRPA1 receptors, and that interfering with TRPA1 activation may contribute, at least in part, to the CAP-induced analgesia in deep tissue pain. Blockade of TRPA1 receptors in deep tissue might provide an effective therapy for postoperative pain conditions.

Title: Hydrogen peroxide (H2O2) induces pain via TRPA1 receptors in deep tissue

Authors: ***S. KANG**, D. SIGIYAMA, H. GU, T. J. BRENNAN;
Universit of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: TRPA1 receptors mediate inflammatory and nerve injury pain, making them key targets for pain therapies. TRPA1 may have a role in postoperative pain. While various endogenous chemicals that activate TRPA1 have been identified, the endogenous TRPA1 ligand that mediates postoperative pain is currently unknown. Hydrogen peroxide (H2O2) activates TRPA1 in organs and is generated in wounds to recruit leukocytes and support the wound healing process. Previously, we have shown that incised deep tissue rather than skin has a central role in the genesis of spontaneous activity in pain transmitting pathways and non-evoked guarding behavior after plantar incision in rats. Therefore, we hypothesized that H2O2 exerts its nociceptive effects, particularly spontaneous pain, via TRPA1 in the deep tissue. To evaluate H2O2-induced spontaneous pain behavior, various concentrations (10-100 mM) and volume (0.4-1.0 ml) of H2O2 was injected into the gastrocnemius muscle or subcutaneous (S.C.) tissue overlying the gastrocnemius muscle in SD rats, and the total time spent flinching, lifting, and licking was recorded for 60 minutes. The control group was injected with same volume of synthetic interstitial fluid (SIF) instead of H2O2. Intramuscular (I.M.) injection of H2O2 produced spontaneous pain behavior in a concentration- and volume-dependent manner. I.M. injection of H2O2 (0.6 ml, 100 mM) produced greater spontaneous pain behavior (1675 ± 378 sec), compared to S.C. injection (83 ± 74 sec; $p=0.0045$). I.M. injection of SIF did not produce pain behavior (27 ± 19 sec). Pre-treatment with locally injected TRPA1 antagonists, HC-030031 or AP-18 (0.3 ml, 50mM each), significantly reduced pain behavior after I.M. injection of H2O2 (0.3 ml, 100 mM), ($p < 0.0001$). To further evaluate spontaneous pain behavior induced by H2O2, Conditioned Place Aversion (CPA) test was conducted in three separate groups of animals: (1) I.M. and (2) S.C. injection of H2O2, and (3) I.M. injection of SIF. CPA score was calculated by subtracting time spent in the drug-paired chamber during baseline from time spent in the drug-paired chamber during testing. After conditioning, rats developed aversion to the chamber paired with I.M. injection of H2O2 (0.6 ml, 30 mM) (CPA score 203 ± 133), but not to the chambers paired with either S.C. injection of H2O2 (CPA score 10 ± 108) or I.M. injection of SIF (CPA score 28 ± 99) ($p < 0.05$). Our results strongly indicate that H2O2 induces spontaneous pain when injected into deep tissue, but not into S.C. tissue. The reduction of pain behavior in rats given TRPA1 antagonist HC-030031 and AP-18 prior to I.M. injections of H2O2 suggests that H2O2-induced pain behavior is mediated via TRPA1.

Title: TRPA1 in lung innervating nodose neurons

Authors: ***M. M. KAELBERER**[1,2], S.-E. JORDT[2];
[1]Pharmachology, Yale Univ., New Haven, CT; [2]Anesthesiol., Duke Univ. Med. Ctr., Durham, NC

Abstract: Life sustaining airways through which we inhale oxygen are also paradoxically, the same avenues whereby harmful irritants enter our bodies. To detect these irritants our lungs are innervated pain sensing neurons, or C-fibers, which are part of a vast network of sensory neurons. These sensory fibers are derived from cell bodies in the nodose ganglia of the vagus nerve. The nodose is a diverse population of nerves that extend not only to the lungs but also the heart, and gut, and controls many vital functions such as respiration, heart rate food intake, and sensory pain. Pain sensing neurons throughout the body contain the noxious heat and mechanical pain transducing channel TRPV1. Of these neurons, a subset also have the wasabi activated channel TRPA1 which is sensitive to many known airborne environmental irritants. Given the diversity of sensory function serviced by the nodose ganglia of the vagus nerve, it is important to isolate specific sub-populations within the nodose to address their different contributions. In this study we focus on the unique identity of pain sensing C-fibers in the lungs, specifically the abundance TRPV1 and TRPA1.

Title: Transient receptor potential cation channel A1 (TRPA1) is a sensory nociceptor in a rodent model of ocular pain

Authors: *A. M. SCHUMACHER[1], M. GADD[2], J. LAO[3], H.-S. CHOI[3], J. WATSON[3], D. TULLY[3], A. PATAPOUTIAN[4], M. PETRASSI[3];
[1]Novartis, San Diego, CA; [2]Alcon, Fort Worth, TX; [3]Genomics Inst. of the Novartis Res. Fndn., San Diego, CA; [4]The Scripps Res. Inst., San Diego, CA

Abstract: Ocular pain can occur as a result of corrective surgery, injury, or exposure to smoke and noxious, reactive chemicals. Current standard of care largely consists of topical corticosteroids and NSAIDs, with a focus on control of inflammation. Use of topical anesthetics is limited due to inhibition of corneal wound healing, short duration of action, and abuse potential. The identification of additional nociceptive targets and associated therapeutic modalities to treat ocular pain and irritation without inducing ocular anesthesia is therefore of great interest. The non-selective cation channel Transient Receptor Potential A1 (TRPA1) is expressed in sensory neurons and activated by endogenous inflammatory compounds as well as exogenous chemical compositions, such as smoke and tear gas. TRPA1 activation has also been implicated in the release of pro-inflammatory peptides that play a role in pain transmission. In this study we report the expression of TRPA1 protein in both rodent and human eyes, and the robust induction of a TRPA1-dependent blinking response to formalin-induced irritation in the rat eye. This pain response was blocked by topical pre-treatment of the rat eye with a potent, selective antagonist of the TRPA1 channel activity. This analgesic effect was observed up to 30 min following administration of the antagonist. Significantly, we did not observe any concurrent anesthetic effect of TRPA1 antagonism using Cochet-Bonnet esthesiometry. This suggests that TRPA1 plays a role in transmitting chemically-but not mechanically-induced pain in the eye.

Title: Characterization of toll-like receptors and TRPA1 in human primary sensory neurons

Authors: *T. BERTA, Y. KIM, F. TANG, K. KWAK, R.-R. JI;
Dept. of Anesthesiol., Duke Univ. Med. Ctr., Durham, NC

Abstract: Although significant progress has been made in revealing the molecular and cellular mechanisms of pain and itch in rodents, it has been difficult to translate these basic findings to new therapeutics in humans, in part due to the limitations of animal models. Our recent studies have shown that toll-like receptors (TLR3 and TLR7) are expressed by primary sensory neurons in mouse dorsal root ganglion (DRG) and play an important role in itch and pain sensation in mice. We have also identified functional coupling between TLR7 and TRPA1 in mouse DRG neurons. In particular, we found that microRNA let-7b is an endogenous ligand of TLR7 and activates TRPA1 in mouse DRG neurons via a non-canonical signaling mechanism (Park et al., Neuron, 2014). In this study, we investigated whether human DRG neurons also express functional TLRs using histochemical, molecular, and electrophysiological approaches. We obtained fresh non-diseased human DRG tissues from National Disease Research Interchange (NDRI). Immunohistochemistry revealed the expression of TLR7 in small-sized (<60 micrometers) neurons of human DRGs. Single-cell PCR analysis in dissociated small-sized neurons showed that TLR7 is completely co-localized with TRPA1 in human DRG neurons. Notably, the percentage of TRPA1 expressing human DRG neurons (80%) is much higher than that of mouse DRG neurons (40%). Patch-clamp recordings also confirmed that a very high percentage (~73.3%) of small-sized human DRG neurons responded to the TRPA1 AITC with inward currents. Notably, Let-7b was sufficient to induce inward currents in small-sized human DRG neurons (~62.5%), and these inward currents were completely blocked by the TRPA1 antagonist HC030031. Our results indicate that (1) TLR7 is also present in human DRG neurons and (2) there is functional coupling of TLR7 and TRPA1 in human DRG neurons. Currently, we are investigating if functional TLR3 and TLR4 are also present in human DRG neurons. These studies will validate TLRs in human DRG neurons as novel targets for pain and itch treatment. Future studies will also be designed to test the efficacy of novel TLR and TRPA1 inhibitors in human DRG neurons before these compounds are tested in clinical trials.

Title: Epigenetic regulation of TRPA1 in trigeminal ganglia under inflammatory muscle pain condition

Authors: *J. ASGAR, K. LEE, Y. ZHANG, M.-K. CHUNG, J. RO;
Neural and Pain Sci., Univ. of Maryland Sch. of Dent., Baltimore, MD

Abstract: Inflammation and injury produce rapid and reversible changes in the methylation status of genes and thereby regulate gene transcription, and these changes have been implicated in the development or maintenance of persistent pain. Transient receptor potential cation channel, subfamily A, member 1 (TRPA1) plays an important role in acute and persistent mechanical hyperalgesia in craniofacial muscles. However, the role of epigenetic regulation of TRPA1 gene in persistent muscle pain condition has not been studied. We have shown that Complete Freund's Adjuvant (CFA)-induced inflammation of the masseter muscle leads to the upregulation of TRPA1 expression in TG. Here we provide evidence that TRPA1 gene in TG is under epigenetic regulation and that DNA methylation plays a critical role in the transcriptional regulation of TRPA1. We first showed that the CFA-induced masseter inflammation was associated with a significant decrease in global DNA methylation in TG. Furthermore, CFA-induced masseter inflammation led to the downregulation of DNA methyltransferases (DNMTs) in TG. More specifically, masseter inflammation significantly reduced the methylation of specific CpG sites within the TRPA1 promoter in TG. Using the chromatin immunoprecipitation assay, we obtained the evidence that two DNMTs (1 and 3a) bind to the CpG region of the TRPA1 promoter. Consistent with these findings, the inhibition of DNMTs with 5-Aza-2′-deoxycytidine induced a significant increase in TRPA1 expression in TG cultures. Treatment of TG cultures with reactive oxygen species, such as H2O2, induced a significant increase in TRPA1 expression. We confirmed that TG cultures treated with H2O2 led to significantly less DNMT3a binding to the TRPA1 promoter region, suggesting that oxygen-derived free radicals that are produced during inflammation can alter DNMTs from binding to the TRPA1gene. In summary, this study provides evidence of the epigenetic regulation of TRPA1 in TG under a myositis condition and suggests the role of DNA methylation as a key epigenetic mechanism. The functional role of such epigenetic regulation of TRPA1 in persistent muscle pain conditions is now being investigated.

Title: Electrophysiological characterization of internal and external ligands on human TRPA1

Authors: A. BRUGGEMANN[1], M. RAPEDIUS[1], T. GOETZE[1], C. HAARMANN[1], I. RINKE[1], M. VOGEL[1], T. STENGEL[1], J. STIEHLER[1], *J. L. COSTANTIN[2], R. HAEDO[2], J. OESTREICH[2], C. BOT[2], G. OKEYO[2], M. GEORGE[1], N. FERTIG[1];
[1]Nanion Technologies, Munich, Germany; [2]Nanion Technologies, Livingston, NJ

Abstract: The bottle neck for drug discovery on ion channels are usually electrophysiological assays. Nanion's SyncroPatch® offers a high-throughput gigaseal platform that records from up to 384/768 cells at the same time, and therefore helps fill the gap. TRPA1 is a member of the TRP (Transient Receptor Potential) family of ion channels that is thought to play a predominant role in the sensation of noxious cold and inflammatory pain (1,2). TRPA1 is activated by a range of environmental irritants causing pain, pungent compounds found in food (mustard oil, garlic, cinnamon) or low temperatures (3). Consistent with its proposed function in nociception, TRPA1 has been shown to be primarily expressed in sensory neurons (1). Further, due to the increasing role in physiology and pathophysiology, TRPA1 has also been considered as an important potential therapeutic target in drug discovery for the treatment of pain, respiratory diseases, cancer and immune disorders (4). Preclinical data and data from a recent human genetic study indicate TRPA1 antagonists as a promising new approach for the treatment of acute and chronic pain (5). Indeed, a TRPA1 antagonist has been shown positive results in a proof of concept study for diabetic neuropathic pain (6). Our results show activation of hTRPA1 by Supercinalaldehyde (SCMA) and specific inhibition by A967079. Furthermore, we also show the activation of TRPA1 by intracellular activation using the automated internal perfusion feature. Reliable pharmacology on hTRPA1 expressing HEK cells will be shown, allowing an in-depth biophyiscal characterization of the protein. References: 1. Story G.M., et al. 2003. Cell. 112(6): 819-29.; 2. Title: Agonist-induced sensitization of the irritant receptor ion channel TRPA1

Authors: ***J. E. MEENTS**[1,2], M. J. M. FISCHER[3,2], P. A. MCNAUGHTON[4,2];
[1]Inst. of Physiol., Uniklinik RWTH Aachen, Aachen, Germany; [2]Dept. of Pharmacol., Univ. of Cambridge, Cambridge, United Kingdom; [3]Inst. of Physiol. and Pathophysiology, Univ. of Erlangen-Nürnberg, Erlangen, Germany; [4]Wolfson Ctr. for Age-Related Dis., King's Col. London, London, United Kingdom

Abstract: The TRPA1 ion channel is expressed in nociceptive neurons and responds to a wide variety of chemical irritants, such as acrolein in smoke or isothiocyanates in mustard. In this

study we show that TRPA1 is sensitized by repeated agonist application in mouse DRG neurons as well as heterologously expressed. Activation by an agonist is essential, because repeated activation by depolarization did not sensitize the channel. Agonist-induced sensitization is independent of the site of action of the agonist, because covalent and non-covalent agonists were equally effective. Mutating N-terminal cysteines, the target of covalent agonists, did not affect sensitization by non-covalent agonists. Sensitization is unaffected by agents blocking ion channel trafficking or signalling pathways involving ATP, protein kinase A or the formation of lipid rafts, and does not require ion flux through the channel. Examination of the voltage-dependence of TRPA1 activation shows that sensitization is caused by a slowly developing shift in the voltage dependence of TRPA1 towards more negative membrane potentials. This shift reverses very slowly and is partly conserved upon repeated agonist stimulation. Sensitization is therefore intrinsic to the TRPA1 channel. Agonist-induced sensitization may represent a slowly developing gain in function and may play a role in exacerbating the pain caused by prolonged activation of TRPA1.

Abstract: Chronic itch, like chronic pain, is a major clinical problem. Despite the similarities between itch and pain, the underlying neural circuitry for itch is poorly understood, as is the mechanism by which itch is suppressed by pain. Profound analgesia occurs with stimulation of the periaqueductal gray, however the precise role of the PAG in itch is unknown. We

hypothesized that specific subsets of neurons within the PAG could suppress itch and provide a neural substrate for the inverse interaction between itch and pain. To determine the role of PAG in mediating itch and pain, we activated or inhibited PAG neurons using engineered G-protein coupled receptors (GPCRs) activated exclusively by synthetic, systemically administered small molecules (i.e., DREADD technology). Engineered excitatory (Gq) or inhibitory (Gi) GPCRs were expressed in PAG neurons via adeno-associated viral vectors. We found that chemogenetic activation of non-specific PAG neurons produced a reduction of both itch and pain, whereas inhibition of non-specific PAG neurons resulted in enhanced itch and pain. In contrast, when only the GABAergic neurons in the PAG were targeted using VGAT Cre mice, activation resulted in decreased itch, but increased behaviors. Conversely, inhibition of PAG GABAergic neurons resulted in increased itch, but decreased pain behaviors. When glutamatergic neurons in the PAG were selectively targeted we found that activation led to enhanced itch and decreased pain, while inhibition neurons produced decreased itch and increased pain. We conclude that the PAG bidirectionally modulates itch and pain signaling and is a neural control center for pruritus.

Title: A possible neural mechanism for photosensitivity in chronic pain

Authors: *M. M. HEINRICHER[1], M. E. MARTENSON[2], N. HAMMACK[2];
[1]Dept Neurol Surgery, Mail Stop L-472, [2]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Abnormal sensitivity to light is a symptom associated with a range of neurological and neuro-ophthalmic disorders, including migraine, various eye conditions, traumatic brain injury, and some chronic pain disorders. Although candidate pathways by which light could interact with nociceptive transmission pathways have been described, these circuits do not adequately explain the general intolerance to light unaccompanied by localized light-induced pain seen in many clinical conditions. The photosensitivity seen in patients with some chronic pain disorders is often part of a more general sensory hypersensitivity. Here we show, in lightly anesthetized

rats, that a subset of pain-modulating neurons in the rostral ventromedial medulla unexpectedly responds to light. ON-cells (known to exert a net facilitating effect on spinal nociceptive processing) and OFF-cells (known to exert a net inhibiting effect on spinal nociceptive processing) were recorded in the rostral ventromedial medulla (RVM). These neurons have historically been defined by changes in activity during noxious somatic stimulation. Approximately half of the pain-facilitating ON-cells sampled, and a similar proportion of pain-inhibiting OFF-cells showed a change in firing with light. Light exposure also resulted in a measurable decrease in the threshold for heat-evoked paw withdrawal. We also investigated three possible relays through which information about ambient light could reach the RVM: the olivary pretectal nucleus, posterior thalamus, and trigeminal pathways. Light-evoked changes in ON- and OFF-cell firing were prevented by inactivation of the olivary pretectal nucleus, but did not require a trigeminal or posterior thalamic relay. These data demonstrate integration of information about ambient light intensity with somatic nociceptive input at the level of single pain-modulating neurons in the brainstem. These data provide a novel mechanism for photosensitivity in chronic pain states. Since activation of RVM pain-facilitating neurons is known to induce an aversive state, our findings suggest that ambient light could modulate sensory processing such that normally innocuous inputs are perceived as aversive or even painful.

Title: Sex differences in glial activation and subsequent cytokine release affect morphine efficacy in the rat

Authors: *H. H. DOYLE[1], A. Z. MURPHY[2];
[2]Neurosci. Inst., [1]Georgia State Univ., Atlanta, GA

Abstract: Morphine continues to be one of the most widely used analgesics for pain management in the US; unfortunately, clinical and animal models show that morphine is a less potent analgesic in females than in males. The midbrain periaqueductal gray (PAG) is a central

locus in pain signaling and opioid action. Recent studies suggest that morphine binds to the innate immune receptor toll-like receptor 4 (TLR4) on glia, resulting in increased activation of microglia and astrocytes, increased cytokine release, and paradoxical opposition of morphine analgesia. Here we test the hypothesis that males and females have dissimilar patterns of glial activation in the brain, specifically within the PAG, that may contribute to observed sex differences in morphine analgesia. To test this hypothesis, lipopolysaccharide (LPS), an immunoreactive component of gram negative bacteria and a known TLR4 agonist, was administered either peripherally, (i.p., 1mg/10ml/kg) or centrally (bilateral intra-PAG, 5ug/.5ul/side) in male and female rats, and body temperature, glial activation and morphine efficacy were determined. Peripheral LPS did not sex-specifically affect febrile responses, however, significantly more activated glia were observed within the PAG of LPS-treated females compared with LPS-treated males. Similar effects on glial activation were observed following intra-PAG administration of LPS. Current experiments are testing the hypothesis that sex differences in glial activation result in disproportionate release of pro-inflammatory molecules in females. mRNA levels of IL-1β, IL-6, IL-9 and TNFα, as well as TLR4, will be quantified for the PAG of male and female rats given LPS or morphine. Together, these results suggest that microglial activation in the PAG of males and females is innately different, and contribute to the dimorphic effects of morphine.

Title: Investigating the role of the anterior cingulate cortex in opioid-sensitive descending pain modulatory pathways

Authors: *L. GOMTSIAN[1], E. NAVRATILOVA[1], A. OKUN[1], C. QU[1], X. YUE[1], D. LU[1], D. ROBLES[1], F. PORRECA[1], J. OYARZO[2];
[1]Pharmacol. Dept., Univ. of Arizona, Tucson, AZ; [2]Mayo Clin., Scottsdale, AZ

Abstract: Pain is a multidimensional phenomenon composed of sensory and affective features. Opioids such as morphine are used for treatment of moderate to severe pain and have been

suggested to act primarily by alleviating the aversive aspects of pain. However, they have many harmful side effects. There is an urgent medical need to elucidate the mechanisms and opioid-sensitive circuits by which pain and pain relief is modulated. Cortical regions may contribute to descending pathways modulating pain through projections to the peri-aqueductal gray (PAG) and the rostral ventromedial medulla (RVM). We explore the effect of morphine administration at different areas of the anterior cingulate cortex (ACC) and its effect on mechanical hypersensitivity in a rodent model of neuropathic pain. Adult, male Sprague-Dawley rats received nerve injury by ligation of the L5/L6 spinal nerves (SNL injury). Evoked tactile allodynia was evaluated following microinjection of morphine into the ACC and RVM. Rats with SNL developed tactile hypersensitivity that was not reversed by morphine injection into various regions of the ACC. In contrast, morphine injection in the RVM reversed evoked thresholds in SNL animals, as shown previously. We have demonstrated that sites in the ACC can modulate the affective aspects of neuropathic pain without altering the sensory component. The primary goal of this research is to understand the nature of the neuroanatomical contributions of the ACC and its role in descending pain modulatory pathways. Further studies exploring other sites within the ACC may ultimately lead to a better understanding of opioid-sensitive circuitry.

Title: What the young brain tells the spinal cord: the changing developmental profile of top down serotonergic modulation of dorsal horn sensory circuitry

Authors: F. SCHWALLER, *M. FITZGERALD;
Univ. Col. London, London, United Kingdom

Abstract: The development of postnatal sensory circuits is shaped by central modulation of sensory inputs. Experimental evidence in rodents has shown that adult descending modulation of dorsal horn activity is both inhibitory and facilitatory, whereas in the first weeks of life,

descending facilitation is dominant. In adults, serotonergic neurons in the rostroventral medial medulla (RVM) are an important contributor to descending controls. Here we have investigated the contribution of this system, and specifically 5HT3 receptors, to descending facilitation in young animals. Mapping the postnatal maturation of 5-HT terminals in the lumbar spinal dorsal horn using 5-HT transporter (5-HTT) immunoreactivity revealed a marked increase after postnatal day (P) 14, suggesting the arrival of descending serotonergic fibres in the third postnatal week. Ablation of descending serotonergic neurons with intrathecal 5,7-DHT resulted in increased dorsal horn neuron pinch-evoked firing activity at P40, but a strong decrease in brush and pinch-evoked firing activity at P21. Mapping 5-HT3 receptor expression in the dorsal horn revealed an adult-like distribution from postnatal day 7 (P7). Spinal administration of the 5-HT3 receptor antagonist ondansetron did not change neuron activity in naive adults, but dose dependently decreased brush and pinch-evoked firing at P21. Weaker reduction of facilitation of pinch evoked neuron responses was observed following ondansetron application at P10. These findings show that when descending serotonergic terminals first arrive in the lumbar spinal dorsal horn in the third postnatal week, they strongly facilitate both low and high threshold input via dorsal horn 5-HT3 receptors. In adulthood, the profile of descending serotonergic modulation changes. We suggest that this is due to the late maturation of inhibitory interneuronal circuits, recruited via different classes of spinal 5-HT receptors.

Title: Dose dependent conditioned place aversion following chemogenetic activation of the locus coeruleus

Authors: ***S. HIRSCHBERG**[1], Y. LI[1], A. RANDALL[2], A. PICKERING[1];
[1]Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom; [2]Med. Sch., Univ. of Exeter, Exceter, United Kingdom

Abstract: The Locus coeruleus (LC) is the principle noradrenergic (NA) nucleus in the CNS. Dysfunction of the NAergic system has been associated with pathologies such as major

depression, Alzheimer's disease and neuropathic pain. We have therefore been interested in developing means to produce long term activation of the NA system. We describe here the use of an engineered excitatory receptor-ionophore (PSAM) to manipulate LC activity. We developed a lenti-viral vector (lenti-PRS-EGFP2aPSAM-HA) with catecholaminergic promoter (PRS) to allow expression of a traceable (HAtagged) excitatory ion channel (PSAM-HA) in NAergic LC neurons. Expression was evaluated using immunofluorescence for EGFP and dopamine beta hydroxylase (DBH) after vector delivery into the LC of Wistar rats (P19-21). Cell properties and effects of agonist application were investigated using patch clamp recordings from acute pontine slices and *in vivo* spike recordings with multi-barrelled electrodes. To assay for behavioural effects Wistar rats (250-300g) were transduced with either lenti-PRS-EGFP2aPSAM-HA (N=11) or a control vector lenti-PRS-EGFP (N=7) and tested in a conditioned place preference (CPP) protocol with intraperitoneal (i.p.) dosing of 5mg/Kg and 10mg/Kg PSEM308 (selective agonist). After behavioural testing, transduced animals were dosed with PSEM308, culled 2.5 hours later and pontine tissue processed for c-Fos expression. After LC injection of lenti-PRS-EGFP2aPSAM-HA, fluorescence (285+/-75 cells per LC, N=3) was restricted to DBH-positive neurons and PSAM-HA was only detected in membranes of EGFP-positive cells. Patch recordings showed functional expression of PSAM that was well tolerated by the LC neurons. *In vivo*, four out of ten LC neurons were reversibly excited by local PSEM308 pressure application (1mM) with a dose dependency. Mean increase in baseline firing was 4.5+/-0.74 Hz,. Conditioning with 10mg/Kg PSEM308 caused aversion to the drug paired chamber in PSAM-HA transduced rats (N=8; $P<0.05$, Bonferoni post-test saline vs drug, 20% difference; Interaction: $P=0.052$ $F(1.14)=4.47$ Two way repeated ANOVA) whilst 5mg/Kg (N=11) had no effect. No effect of PSEM308 was seen in control animals at either dose. The percentage of transduced neurons that were double labelled with c-Fos was increased by PSEM308 from 18.4+/-5.9% in EGFP and 29.8+/-9.4% in PSAM-HA transduced animals. Our findings show that chemogenetic LC activation causes a dose-dependent aversive effect. It remains to be determined whether targeting of subsets of LC neurons (such as the pontospinal group) will produce the same aversive behaviour.

Title: Time-frequency EEG analysis of pain modulation by hypnosis, suggestions and distraction

Authors: *B. HOUZÉ[1,2], A. STREFF[1,2], M. PICHÉ[1,3], P. RAINVILLE[1,2];
[1]CRIUGM, Montreal, QC, Canada; [2]Univ. de Montréal, Montréal, QC, Canada; [3]Univ. du Québec à Trois-Rivières, Trois-Rivières, QC, Canada

Abstract: Pain modulation by hypnosis is well documented but the specific brain mechanisms underlying the effects of hypnotic suggestions on acute pain are not fully understood. To investigate this issue, we examined pain-related time-frequency (TF) electroencephalographic responses elicited by noxious electrical stimulation under various modulatory conditions. In 18 subjects (SHSS hypnotisability score 7.9 ±3.4), hypnotic hypoalgesia (HypnoHypo) and hypnotic hyperalgesia (HypnoHyper) were assessed in a hypnotic modulation session. Non-hypnotic suggestions of hypoalgesia (SuggHypo) and distraction hypoalgesia (DT) were assessed in a non-hypnotic session. In both sessions, stimulus intensity was set individually at 120% RIII-reflex threshold, producing moderate pain. Stimuli were administered in 5 successive blocks in the target experimental conditions (2 blocks of 9 stim), alternating with neutral control conditions (3 blocks of 6 stim). After trial-averaging of TF decomposition activity using a Morlet wavelet transform, 3 regions of interest were defined on TF maps: somatosensory-evoked potential (SEP:0-500 ms, 3-7 Hz, ROI1), event-related synchronisation in beta band (ERS β: 0-250 ms, 13-17 Hz, ROI2) and event-related desynchronisation in alpha band (ERD α: 350-1000 ms, 8-12 Hz, ROI3). The means of the 10% highest amplitude values were computed for each ROI and compared between the 3 hypoalgesic conditions, and between the 2 hypnotic pain modulation conditions. All modulatory conditions produced robust pain modulation compared to control blocks ($p<.00005$). HypnoHypo suggestions produced a marginal decrease in frontal ROI1 activity compared to DT ($p=.053$) and a context effect was observed on parietal ROI3 activity, with a more ERD α elicited under hypnosis (HypnoHypo), in both the control and experimental conditions compared to DT ($p=.009$). HypnoHypo and HypnoHyper conditions increased frontal ROI1 activity, indicating a generalized effect of hypnotic suggestions independent of the direction of suggestions. HypnoHypo further decreased activity in frontal ROI2 ($p=.034$) and ROI3 ($p=.014$). Parietal ROI3 activity was also reduced by HypnoHypo suggestions and was increased by HypnoHyper suggestions ($p=.032$). The SHSS-scores was associated with changes in pain ratings in the hypnosis and suggestion conditions ($p<.05$) but not in DT. However, SHSS-scores were not associated with changes in brain activity for any ROI, although a trend was observed for the HypnoHypo condition ($R2 > 0.17$, $p <.09$). Altogether, these results suggest that hypnosis, suggestions and distraction modulate pain through partly distinct brain mechanisms.

Title: Extrasynaptic GABAA signaling in the ventrolateral periaqueductal gray differentially affects morphine antinociception in male and female rats during persistent inflammation

Authors: *K. J. TONSFELDT[1], K. L. SUCHLAND[2], S. L. INGRAM[2];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The ventrolateral periaqueductal gray (vlPAG) is a key structure in the descending pain modulatory circuit. Activation of the circuit is dependent on removing GABAergic inhibition or disinhibition of vlPAG output neurons. Mu-opioid receptors (MOPrs) reduce GABA-mediated inhibition of vlPAG output neurons to activate the descending pain modulatory system and induce antinociception. Both tonic and phasic GABAA-mediated currents are observed in the vlPAG. Tonic GABAA currents are reduced in vlPAG neurons from female rats pretreated with Complete Freud's Adjuvant (CFA) for 5-7 days to induce chronic inflammatory pain, but similar changes were not observed in male rats (Two-way ANOVA, Effect of Sex; $F(1,31) = 5.681$, $p < 0.05$; Sidak's multiple comparison, * $p < 0.05$). However, mIPSCs are increased in females following CFA treatment (Mann-Whitney $U = 21$, $p = 0.003$). The mRNA and protein levels of the GABAA delta subunit, known to mediate tonic currents in other brain areas, are unchanged in the vlPAG of female pretreated with CFA, but the mRNA expression is reduced compared to males (Main Effect of Sex; $F(1,16) = 16.89$, * $p = 0.008$) . The selective agonist of GABAAδ receptors THIP (gaboxadol) induced similar amplitude currents in naïve and CFA-treated rats (Effect of Concentration, $F(1,23) = 33.87$, $p < 0.0001$). In addition, a positive allosteric modulator of the GABAAδ subunit DS2 increased tonic currents and revealed a contribution of GABAAδ receptors to evoked GABAergic IPSCs (Paired t-test; $t(8) = 2.518$, * $p < 0.05$), indicating that GABAAδ receptors remain on the cell surface after CFA treatment. Finally, we explored the role of the GABAA δ subunit in morphine-induced antinociception. Importantly, opioid inhibition of mIPSC frequency was increased selectively in CFA-treated female vlPAG neurons suggesting that opioid activation of the descending pain circuit is

facilitated during persistent inflammation (Effect of Pretreatment, $F(1,23) = 9.016$, $p = 0.006$; Sidak's multiple comparison, * $p < 0.05$). Indeed, systemic morphine antinociception was enhanced in female rats pretreated with CFA and this effect was reversed with microinjections of DS2 directly into the vlPAG (Effect of Pretreatment, $F(1,23) = 9.016$, $p = 0.006$; Sidak's multiple comparison, * $p < 0.05$). Together, these data suggest that decreased activation of GABAAδ receptors is a compensatory mechanism to enhance descending inhibition of pain in persistent inflammation in females.

Title: Sex differences in the lateral hypothalamus-induced descending noradrenergic system in nociceptive and hyperalgesic pain types

Authors: B. N. MANTHA[1], M. A. WAGNER[1], T. BANERJEE[1], Y. JEONG[2], *J. E. HOLDEN[1];
[1]The Univ. of Michigan, Ann Arbor, MI; [2]Kyung Hee Univ., Ann Arbor, MI

Abstract: The lateral hypothalamus (LH) modifies nociception at the level of the spinal cord dorsal horn. In a model of nociception, LH stimulation produces antinociception when norepinephrine (NE) binds to alpha2-adrenoceptors and pronociception when NE binds to alpha1-adrenoceptors. Stimulating the LH with 500 nmol of carbachol produces antinociception in male and female rats for both nociceptive and hyperalgesic pain types. The purpose of this study was to determine whether LH-induced alpha-adrenergic modulation occurs in hyperalgesic as well as nociceptive pain conditions. Male and female Sprague-Dawley rats were randomly assigned to either nociceptive or hyperalgesic pain groups (n = 12 - 15 rats per group). The hyperalgesic group received chronic constriction injury (CCI) with left sciatic nerve ligation to induce hyperalgesia. Fourteen days later, carbachol (500 nmol in 0.5 µl normal saline [NS]) was microinjected into the LH and paw withdrawal latency (PWL) from a thermal stimulus was measured at 1, 5, and 10 min. At 10 min rats were then given IT infusion of either the alpha1-adrenoceptor antagonist WB4101, the alpha2-adrenoceptor antagonist yohimbine (97 nmol each)

or normal saline for control. PWL was then measured at 1 min and then every 5 min for 45 min. Results from generalized estimating equation (GEE) analysis showed no difference in PWL between pain types. Female rats had a 3.29 sec increase in PWL ($Z = 4.61$, $p < 0.0001$) over controls after blocking alpha1-adrenoceptors with WB4101 and a 2.47 sec decrease from controls after blocking alpha2-adrenoceptors with yohimbine ($Z = -3.52$, $p = 0.0004$). Male rats showed a 2.06 sec increase over controls in PWL after WB4101 ($Z = 2.91$, $p = 0.0036$) and a 2.44 sec decrease from controls after yohimbine ($Z = -3.69$, $p = 0.0002$). The findings of this study suggest that stimulating the LH modulates nociception in part at both alpha1 and alpha2-adrenoceptors, but the extent of modulation depends on sex of the rat.

Title: Relationship of activation of phenotypically-distinct neuronal populations in the extended centromedial amygdala with the expression of acute pain, conditioned fear, and fear-conditioned analgesia

Authors: ***R. K. BUTLER**[1], S. EHLING[2], M. BARBAR[1], J. M. THOMAS[1], M. A. HUGHES[1], A. E. THOMSON[1], S. J. WALL[1], V. ZARIC[1], B. CASE[1], D. KNAZOVICKY[1], M. E. GRUEN[1], W. BÄUMER[2], R. M. RODRIGUIZ[3], V. M. POGORELOV[3], D. K. ARYAL[3], W. C. WETSEL[3], B. D. X. LASCELLES[1];
[1]Clin. Sci., [2]Mol. Biomed. Sci., North Carolina State Univ. Col. of Vet. Med., Raleigh, NC;
[3]Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC

Abstract: Fear-conditioned analgesia (FCA) is a survival response whereby an organism suppresses nociceptive behaviors in an environment previously paired with an aversive stimulus. FCA is facilitated through activation of the descending inhibitory pain pathway which originates in brain regions including the amygdala. The amygdala can be broadly divided into two

components: the basolateral amygdala complex (BAC) and the extended centromedial amygdala (ECMA). Previously, we investigated the role of phenotypically-distinct neuronal populations in the BAC in the expression of acute pain, conditioned fear, and FCA; in these experiments, we investigated the ECMA. The ECMA is a group of structures within the basal forebrain. The centromedial group is found in the dorsomedial portion of the BAC and consists of the central (CEA), medial, and the amygdaloid part of the bed nucleus of stria terminalis. The ECMA is a mediator of aversive behaviors including the expression of conditioned fear and is involved in the emotional processing of pain. To date, it is unknown how the ECMA mediates or modulates the descending inhibitory pain pathway and FCA. Neurons within the ECMA can be distinguished based on their neuropeptide-containing phenotype. In the CEA, neurons are almost exclusively GABAergic; however, neurons which contain the opioid peptide enkephalin (ENK) do not project outside of the ECMA (interneuronal) whereas neurons which contain corticotropin-releasing factor (CRF) project outside the ECMA. In these experiments, we combined Pavlovian fear-conditioning with the formalin test of persistent pain which resulted in four groups: control (non-fear conditioned, saline), acute pain (non-fear conditioned, formalin), conditioned fear (fear conditioned, saline) and FCA (fear conditioned, formalin). We demonstrate that expression of nociceptive behaviors are significantly reduced in formalin-treated mice which are re-exposed to a contextually-aversive environment compared to formalin-treated, unconditioned mice. Quadruple-immunostaining of serial brain sections throughout the ECMA with 1) ENK, 2) CRF, 3) cFos (a marker of neuronal activation), and 4) NeuN (a non-specific neuronal nuclear marker) revealed an increase in co-localization of cFos with CRF in the capsular part of the CEA in mice expressing FCA compared to pain alone. This suggests that a CEA CRF-containing neuronal population may be important in amygdala-mediated analgesia induced upon exposure to a threatening environment. These data enhance our knowledge of the role of the amygdala in facilitating FCA and they provide a viable target for the development of analgesics.

Title: Negative role of PLCb4 in descending analgesia gating

Authors: *J. KIM;
Ctr. For Cognition and Sociality/Ibs, Daejeon, Korea, Republic of

Abstract: Endogenous opioids generate analgesic signals in the periaqueductal gray (PAG). These signals are projected to and relayed by the rostral ventromedial medulla (RVM) to the dorsal horn of the spinal cord (SC), which is called descending analgesia circuit. It is known that PAG GABAnergic neurons in Cav3.1 mice showed impaired opioid-dependent analgesia in the absence of T currents and low-threshold burst spikes. Furthermore, Phospholipase c beta 4(PLCb4) knockout mice with increased bursting in TC neurons showed reduction of visceral pain responses. Howevere, the role of PLCb4 in the control of descending pain pathway is unknown. Here, we found that PLCb4 is highly expressed in NPYnergic neuron in PAG, but not in GAD67-positive neurons or PAG-RVM projecting neurons. Also, PLCb4(-/-) mice displayed enhancement of anti-nociceptive effect by morphine administration and swim stress-induced analgesia(SSIA). Moreover, mice with PAG-specific knockdown of PLCb4 reproduced the phenotype of PLCb4 knockout. These findings suggest that role of PLCb4 signaling in PAG is negative control of opioid-dependent analgesia gating in descending pain pathway.

Abstract: Background and aim: It has been previously demonstrated that exercise can modulate pain in humans, which justifies its application as a non-pharmacological clinical intervention in various pathological pain conditions. However, it is not known whether it can affect the activity of the endogenous analgesic circuits. The ascending nociceptive control is a novel spino-striato-rostral ventral medulla pain modulation circuit that produces heterosegmental pain-induced analgesia, i.e., noxious stimulus-induced antinociception (NSIA) mediated by endogenous opioids in the nucleus accumbens. Therefore, the aim of this study was to investigate whether the exercise modulates the activity of NSIA. Methods: Male C57Bl/6JUniB mice (20-28g) were used in this study and all experimental procedures were approved by the Ethics Committee in Animal Research at the UNICAMP. The mechanical nociceptive threshold was quantified by an electronic pressure-meter test (Von Frey). The animals had access to wheel activity for 28 days. At the 28th day, Carrageenan (100µg / paw) was subcutaneously injected (15µL/paw) in the hindpaw 3 hours before behavioural testing. Capsaicin (7.5µg/paw) was locally injected in the subcutaneous forepaw to induce NSIA and the mechanical nociceptive threshold was quantified in the carrageenan injected hindpaw 1, 15, 30, 45 and 60 min after the capsaicin injection.. Two-way ANOVA followed by Tukey test was used for statistical analysis ($P<0.05$). Rats per group = 5 to 6. Results: NSIA significantly reduced carrageenan-induced hyperalgesia. Surprisingly, the exercise reduced 67.22% of NSIA. Conclusion: These data demonstrated that long lasting voluntary exercise reduces the activity an endogenous analgesic circuit.

Title: Central neuronal circuit underlying odor-induced analgesia in mice

Authors: S. ISHIKAWA, R. YAMAGUCHI, S. TASHIRO, Y. KANMURA, K. KAJIYA, T. KUWAKI, *H. KASHIWADANI;
Kagoshima Univ., Kagoshima, Japan

Abstract: Recently we found that odor exposure of odorant-X, one of the terpenoids derived from plant extract, had significant analgesic effects in mice. The effects were not observed in anosmic model mice, indicating that the effects were triggered by olfactory input evoked by odorant-X exposure. Furthermore, orexin mutant mice did not show the effects, indicating that orexin neurons in the hypothalamus play a pivotal role for the effects. Because odorant-X exposure did not induce aversive behaviors or elevation of plasma corticosterone, one of the stress markers, odorant-X-induced analgesia is, most probably, different from stress-induced analgesia. To address the central neuronal circuits underlying odorant-X-induced analgesia, we first examined the localization of neuronal activity induced by odorant-X exposure using c-Fos immunohistochemistry. After 1 hour odorant-X exposure, mice were perfused with saline following 4% paraformaldehyde under deep anesthesia. Sections of 40 um thickness were made from the fixed brain samples and were stained with rabbit antiserum prepared against c-Fos. The immunoreactivity was visualized by Alexa 568-conjugated secondary antibody. Though various brain structures were activated by odorant-X exposure, c-Fos expressing neurons were substantially increased in olfactory cortices (anterior olfactory nucleus, anterior piriform cortex, cortical amygdaloid nucleus), association corticies (prelimbic cortex, lateral orbitofrontal cortex, cingulate cortex), amygdala (medial amygdaloid nucleus), septum (lateral septum), thalamus (centromedial thalamic nucleus), hypothalamus (lateral hypothalamus), periaqueductal gray (dorsolateral part, ventrolateral part), and pons (laterodorsal tegmental nucleus). The contribution of each brain structures to odorant-X-induced analgesia has yet to be elucidated, however, we will further discuss the central neuronal circuits underlying the analgesia by comparing the odorant-X-induced c-Fos expression in orexin deficient mice.

Title: The prediction of placebo analgesia : a bayesian approach

Authors: *Y. CHAE[1], W.-M. JUNG[2], Y.-S. LEE[2];
[2]AMSRC, [1]Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Background: From the perspective of predictive coding, brain is not passively waiting for external stimuli but is actively making inferences based on prior experiences. Bayesian formulation within the predictive coding framework can be applied to the prediction of placebo analgesia, a hypoalgesia induced by experience and expectations of pain. Objectives: The present study established an experimental placebo analgesia using two different levels of precision of prior experiences with cue conditioning paradigms. We applied Bayesian model and predicted the individual placebo responses based on pain behaviors during the conditioning period. Methods: We implemented a medical decision task which was a modified trust game. In the task, participants (n=24) received a high pain (512mN) by PINPRICK and made a decision of choosing a virtual treatment among two given options: taking medicine or being treated by a doctor. The decision to take the medicine was followed by moderate pain (256mN) to patients whereas the decision to be treated by the doctor was followed by moderate (256mN) or mild pain (64mN) by the chance of 50%. Different monetary value was linked to the choice of both medicine and doctor, which also balanced the biased pain intensity. Participants reported relative intensity of the reduced pain to the original pain prior to making the choice. The task was repeated 40 times as a conditioning procedure. After conditioning, same task was repeated 8 times as a test, but instead of moderate or mild pain, high pain was always given. We formulated a Bayesian model by fitting pain ratings during conditioning period given each cue as the prior probability, and by fitting pain ratings to each pain stimuli without prior knowledge about cue as the likelihood. Pain ratings in the test period were predicted by the posterior probability of the fitted Bayesian model using Markov chain Monte Carlo (MCMC) algorithm. Results: Participants reported significantly less pain when they chose doctor or medicine compared to control, in which placebo analgesia were successfully induced. Using Bayesian model, the predicted pain ratings to doctor or medicine cue showed significant correlations to the actual average of pain ratings in the test period. Conclusions: For the prediction of placebo analgesia, we applied the Bayesian formulation within the predictive coding framework utilizing differences in the magnitude and the precision of conditioned experience. The Bayesian model could benefit for the understanding of individual differences of placebo analgesia.

Title: Descending pain modulation in irritable bowel syndrome

Authors: *R. J. CHAKIATH[1,2,3], P. SIDDALL[4,3], J. KELLOW[5,3], P. WRIGLEY[1,2,3];
[1]Pain Mgmt. Res. Inst., Sydney, Australia; [2]The Kolling Inst., Sydney, Australia; [3]Sydney Med. Sch., Univ. of Sydney, Sydney, Australia; [4]Dept. of Pain Management, HammondCare,Greenwich Hosp., Sydney, Australia; [5]Dept. of Gastroenterology, Royal North Shore Hosp., Sydney, Australia

Abstract: Background. Descending neural modulatory circuits from the brain are able to inhibit or facilitate ascending nociceptive transmission (descending pain modulation, DPM). Changes in DPM profoundly influence pain perception. Neurophysiological measures of DPM have been developed however the clinical utility of these techniques remains to be determined. Recently, it has been suggested that results from these measures may contribute to the development of a person's *pain modulation profile* which range from pro- to anti-nociceptive. **Method.** With this in mind, we undertook a case-control study (age/gender matched) comparing DPM in participants with irritable bowel syndrome (IBS, n=19) and healthy controls (HC, n=19). Using a conditioned pain modulation (CPM) protocol we performed nociceptive spinal cord withdrawal (RIII) reflexes by applying an electrical test stimulus to the sural nerve (ankle) and muscle potentials were recorded (Synergy, Nicolet EDX, USA) from the biceps femoris muscle (upper leg). After baseline measurements, participants placed their left hand in a refrigerated bath (JeioTech RW-3025G, Korea) previously adjusted from 10^{o}C, to achieve a pain intensity 30-70/100. Reflex potential measurements were repeated at 2 and 5 minutes immersion and 2 minutes post immersion. The change in RIII reflex potential (AUC) and pain intensity scores (NRS101) from baseline, during the second minute of testing and post testing were calculated and grouped as reflecting either an inhibitory (change from baseline < 0) or facilitatory effect (change from baseline > 0) or no change (change = 0). Depression, anxiety and stress were also measured prior to testing using the Depression Anxiety and Stress Questionnaire (DASS-21). Independent sample t-tests were used to assess differences in depression, anxiety and stress. **Results.** People with IBS report greater anxiety, stress and depression when compared to HC ($p < 0.05$). There were no significant differences between groups during and post CPM in the proportion of participants with inhibitory or facilitatory effects using change in reflex potential (subjects classified as inhibitory during 5th minute of CPM: IBS = 10/19, HC = 15/19, Facilitatory: IBS = 9/19, HC = 4/19) or pain scores (subjects classified as inhibitory during 5th minute of CPM: IBS = 13/19, HC = 13/19, Facilitatory: IBS = 5/19, HC = 5/19, No change: IBS 1/19, HC = 1/19). **Conclusions.** These results show that while mood is altered in people with IBS, the responses to the DPM protocol in people with IBS were not different to HCs. These initial findings suggest that uniform changes in DPM do not occur in people with IBS which varies from inhibitory to facilitatory.

Title: The effect of cobalt chloride on lateral hypothalamic-induced pain modulation in male and female hyperalgesic rats

Authors: ***M. A. WAGNER**, J. E. HOLDEN;
Univ. of Michigan, Ann Arbor, MI

Abstract: We recently reported that tonically active alpha1-adrenoceptors contributed to centrally mediated hyperalgesia in the chronic constriction injury (CCI) model of neuropathic pain. The lateral hypothalamus (LH) is part of a descending system that modulates nociception in the spinal cord dorsal horn via a connection with the A7 cell group, which provides norepinephrine (NE) to the spinal cord dorsal horn in rat. To verify whether the source of tonically released NE is the A7 catecholamine cell group, we microinjected cobalt chloride (CoCl; a reversible blocker of synaptic transmission) into the A7 cell group and blocked antinociception induced by intrathecal (IT) application of the alpha-1 adrenoceptor antagonist, WB4101, in both male and female hyperalgesic rats. To determine the role of the LH in tonic activation of alpha1-adrenoceptors, we tested the effect of microinjecting CoCl into the LH on WB4101-induced antinociception. Male and female Sprague-Dawley rats (5-6 per group) received left sciatic nerve ligation via CCI surgery to model hyperalgesia. Fourteen days later, rats received IT infusion of either WB4101 (97 nmol) or normal saline for control. Left paw withdrawal latency (PWL) from a thermal stimulus was measured at 1, 3 and 5 min. After the 5 min measurement, CoCl (100 mM/0.5 μl) was microinjected into the left LH and PWL was measured every 5 min for 45 min. Male rats demonstrated significant antinociception for left PWL following IT administration of WB4101 (9.93 ± 0.91 vs. 5.35 ± 0.83 sec, WB4101 vs. saline, respectively) that was blocked by administration of CoCl in the LH. PWL returned to baseline levels within 10 min as compared to control rats. This was not the case for female rats. Left PWL in female rats receiving WB4101 remained significantly different ($p < 0.001$) from those receiving saline control after microinjection of CoCl in the LH throughout the 45 min of

testing. These findings are suggestive of bilateral hypothalamic innervation of the A7 cell group in females compared to males, and a difference in descending modulation based on sex.

Title: Dissecting the mechanism of substance P release in the rat rostral ventromedial medulla during inflammatory injury

Authors: *M. V. HAMITY[1], U. MADUKA[2], D. HAMMOND[1];
[1]Anesthesia, [2]Pharmacol., Univ. Iowa, Iowa City, IA

Abstract: It is accepted that substance P (SP) acts in the rostral ventromedial medulla (RVM) to facilitate pain under conditions of peripheral inflammatory nociception induced by ipl injection of complete Freund's adjuvant (CFA). The mechanism may entail an enhanced release of SP that is dependent on presynaptic N-methyl D-aspartate receptors (NMDARs). We therefore examined the release of SP from prisms of RVM tissue obtained from saline or CFA-treated rats. The RVM was dissected from the brainstem of rats that received an ipl injection of CFA or saline in one hindpaw four days earlier. The tissue was chopped into prisms that were incubated at 37 °C for one hr and superfused with artificial cerebrospinal fluid. Releasates were collected and analyzed for SP by enzyme immunoassay. Basal release of SP did not differ between saline and CFA-treated rats (0.007 ± 0.0007 and 0.007 ± 0.0005 pg/ml per mg protein, respectively). Release evoked by 50 mM K^+ also did not differ between saline (0.028 ± 0.003) and CFA-(0.033 ± 0.006) treated rats. As hypothesized, the addition of NMDA to the perfusate facilitated K^+-evoked SP release in both saline- (0.068 ± 0.007) and CFA- (0.072 ± 0.008) treated rats. However, contrary to expectations, the facilitation of SP release by NMDAR activation was not enhanced in CFA-treated rats. Substance P measured in releasates represents overflow from the synaptic cleft. Because peripheral inflammatory injury increases the expression of NK1R in the RVM, we considered the possibility that the upregulation of NK1R in CFA-treated rats served to

effectively internalize and sequester SP internally - making it less available for measurement. To test this, we repeated these experiments in the presence of aprepitant, a NK1R antagonist. The addition of 30 μM aprepitant significantly increased the amount of K^+-evoked release of SP in both treatment groups (0.047 ± 0.004 and 0.053 ± 0.005 pg/ml per mg protein) , but again the release of SP was not significantly greater in CFA-treated rats. Overall, our data support the hypothesis that presynaptic NMDAR can facilitate SP release in the RVM, but do not support the hypothesis that this is the mechanism by which excitatory inputs to pain facilitatory neurons in the RVM are facilitated. However, the finding that aprepitant significantly increased the amount of SP in releasates suggests that binding to and subsequent internalization with the NK1R is significant mechanism to remove SP from the synapse and extracellular environment. Title: Nicotinic receptor excitation of descending pain modulatory pathways

Authors: *I. C. UMANA[1], B. A. MILLER[2], V. T. WAN[3], C. A. DANIELE[4], D. S. MCGEHEE[4];
[1]Univ. of Chicago MSTP, Chicago, IL; [2]PREP Program, [4]Anesthesia and Critical Care, [3]Univ. of Chicago, Chicago, IL

Abstract: The α7 subtype of the nicotinic acetylcholine receptor (nAChR) may be an alternative target for analgesic drug development, as α7 selective agonists and positive allosteric modulators produce antinociception without evidence of adverse side effects. Interestingly, icv administration of α7 agonists decreases nociceptive behavior in chronic pain models, suggesting supraspinal sites of action of these drugs. A strong candidate site of action is the periaqueductal gray (PAG), which is part of the descending pain control pathway. The PAG integrates inputs from higher centers and sends projections to the rostral ventromedial medulla (RVM), which in turn projects to the spinal cord to modulate incoming nociceptive signaling. We recently found functional α7 nAChR expression in 63% of recorded vlPAG-RVM projection neurons. In

addition, somatic μ-opioid receptor (MOR) expression was rare in neurons containing nAChRs, suggesting segregation of these two receptor classes. Therefore, our working model is that activity of vlPAG α7-expressing (α7+) neurons suppresses ascending nociception and activity of MOR-expressing vlPAG neurons facilitates nociceptive signaling. We explored the modulation of excitatory and inhibitory drive to vlPAG-RVM projection neurons by presynaptic nAChRs. RVM-projecting vlPAG neurons were identified by *in vivo* injection of a fluorescent dye into the RVM. In neurons lacking somatic nAChRs (α7-), nicotine enhanced spontaneous inhibitory postsynaptic current (sIPSC) frequency (12/19 neurons), whereas in α7+ neurons, sIPSC frequency increase was less prevalent (7/24 neurons, Fisher's test $p<0.05$). Nicotine-induced enhancement in sIPSC frequency also occurred in the presence of methyllycaconitine, an α7 selective antagonist, suggesting contribution of non-α7 nAChRs. Finally, nicotine bath application increased miniature EPSC frequency in α7+ and α7- neurons. Thus, nicotine enhances excitatory, but not inhibitory drive to α7+ neurons that we propose are pain-inhibiting. Together, our data suggest that presynaptic non-α7 and somatic α7 nAChRs contribute to excitation of putative pain-inhibiting neurons in the vlPAG, which could be a supraspinal mechanism for α7-mediated analgesia. We used the formalin test to assay acute and chronic antinociceptive potential of vlPAG α7 nAChRs. Administration of the selective α7 agonist, PHA-543613, into the vlPAG substantially reduced Phase II nociceptive responses. This antinociception was completely blocked by intra-vlPAG administration of α-bungarotoxin, an α7 selective antagonist. Our findings demonstrate vlPAG α7 nAChR is a promising target for analgesic drug development.

Title: Anatomical plasticity in spinal terminals and functional release of oxytocin after peripheral nerve injury

Authors: *A. L. SEVERINO[1], C. A. ASCHENBRENNER[2], J. C. EISENACH[2];
[2]Anesthesiol., [1]Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Speed of recovery from pain following nerve injury varies across individuals, with some individuals having pain for many years. Recovery from pain involves many mechanisms, including increased inhibition or decreased sensitization. This study focuses on oxytocin (OT) induced inhibition after injury. Spinal OT fibers originating in the paraventricular nucleus of the hypothalamus terminate in the superficial laminae of the spinal dorsal horn (SDH) where OT excites inhibitory interneurons that modulate primary afferent activity to produce antinociception. Preliminary work suggests that the density of OT fibers in the SDH increases after sub-acute pain states, but whether this occurs after nerve injury has not be investigated. To test this, we performed partial L5 spinal nerve ligation (pSNL), and quantified OT immunoreactivity (IR) in spinal regions ipsilateral (IPSI) and contralateral (CONTRA) to nerve injury. We randomly assigned male, Sprague-Dawley rats at 7W age to pSNL surgery or not and quantitatively assessed spinal cord IR in animals at 9W and 19W (n=8/group). OT fiber density was greater in the IPSI lumbar SDH in the pSNL compared to normal groups ($p=0.012$), but not in the CONTRA SDH ($p=0.343$). This effect was regionally constrained to the lumbar region of the spinal cord. These data suggest an increased capacity for OT release in the lumbar spinal level, where afferents injured with pSNL terminate. We further hypothesized that since spinal OT IR is increased after injury, OT release might also be increased after injury, either tonically or when evoked by noxious stimulation. We performed spinal microdialysis in the IPSI lumbar SDH of male rats in the same 4 groups as the OT IR study above (n=8/group). Baseline OT concentration did not differ among groups, and peripheral noxious stimulation did not evoke spinal release of OT in any group ($p>0.05$). These data suggest that OT anatomical plasticity occurs after injury, but there is no significant increase in spontaneous or evoked OT release in the paradigm tested. Supported by R37-GM48085 from the NIH.

Title: Nabilone (CB1-agonist) reverses fibromyalgia (FM) symptomology. Therapeutic role of endocannabinoid system

Authors: *J. I. ROMERO[1], D. ROMERO-CANO[2];
[1]Hosp Gen Queretaro, Queretaro, Mexico; [2]Ophthalmology, Hosp Gen Mexico, Mexico, D.F., Mexico

Abstract: FM, a complex, diffused syndromatic bodily disarray and peripheral-central multi-domain nervous system disorder, cannot be narrowed down to a simple pathology. Multiples mechanisms for FM phenotype complex symptomology have been proposed: hyper ascending peripheral pain transmission, increased excitatory neurotransmitters, inflammatory cytokines in cerebral spinal fluid, dysfunctional descending modulation, central sensitization, oxidative stress, distinct anatomical cerebral alterations for pain and affective symptoms and early life stress or prolonged severe stress affects brain modulatory circuitry of pain and emotional in genetically susceptible individuals. Years of proposed drug guidelines to modulate different neurotransmitters system have not accomplished satisfactory clinical results. Endocannabinoid signaling system (ECBS) has recently been considered as a therapeutic alternative for FM, since it subserves a multiplicity of cellular and behavioral functions. FM broad symptomology seems to fit possible ECB dysfunctional disarray. Hypothesis: Nabilone, CB1-synthetic agonist, a therapeutic medical alternative will revert ECB hypo-dysfunctional state in FM patients, improving quality of life by increasing sleep time, reducing awakenings, pain intensity and anxiety. Methodology: 30 female patients ranging from 8 to 40 years of confirmed diagnosis by rheumatologist or internist were accepted under consent agreement to participate in a Nabilone open trail, for a period of 10 weeks, each patient paid for her own treatment. Rheumatologic and psychiatric treatments had already been suspended. Following scale were used to evaluate patients pre-trans and post: Fibromyalgia Impact Questionnaire (FIQ), Modified Athens scale to assess sleep and fragmented sleep pattern, VAS pain scale and Hamilton anxiety scale. Results: No-parametric statistical analysis have shown significant change ($P<0.05$) in all four main symptoms. Nabilone alone restores sleep by reducing FSP, quality of profound sleep, reduced pain intensity and anxiety, Sumary: Nabilone activated ECB signaling system reverting disarray of bodily, central and autonomous nervous system. However, ECB system alone does not bring about the cure, but does allow for control of symtoms and an improvement in que quality of life of each patient within 10 weeks and has continue to do so for over a year.

Title: Parabrachial input to pain-modulating circuit in acute and chronic pain

Authors: *Q. CHEN, M. HEINRICHER;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: An important factor in both normal and clinically significant pain is the intrinsic pain-modulating system that regulates nociceptive processing via projections from the brainstem to the dorsal horn. The output of this modulating system, the rostral ventromedial medulla (RVM), can facilitate or suppress nociceptive transmission at the dorsal horn by the respective action of two physiologically and pharmacologically distinct classes of neurons, “ON-cells” and “OFF-cells”. Both classes are known to respond to noxious inputs: ON-cells are activated, leading to a “burst” of activity associated with behavioral responses to noxious stimulation, whilst OFF-cell firing is suppressed, producing a “pause” in any ongoing activity. However, the pathway through which noxious inputs drive changes in RVM activity has not yet been defined. Anatomically, the RVM receives direct afferents from the parabrachial complex (PB), which is the major target of supraspinal projections from the superficial dorsal horn. The spinoparabrachial pathway is known to be crucial in behavioral hypersensitivity in chronic pain. The aim of this study was to test the hypothesis that noxious information is relayed to the pain-modulating neurons of the RVM via the PB in acute and persistent pain. Single-cell recording studies were performed in lightly anesthetized rats. ON-cells and OFF-cells were recorded in the RVM before and after block of the PB using local microinjection of muscimol. Spontaneous activity and responses to von Frey probes applied to the paw were recorded. The reflex-related ON-cell burst and OFF-cell pause were attenuated by inactivation of the PB. Spontaneous firing of both cell classes was also altered. Optogenetic manipulation of PB terminals in RVM demonstrated that this relay is at least in part direct. In animals subjected to persistent inflammation (CFA), PB block also attenuated ON- and OFF-cell responses to noxious stimuli. However, PB block did not eliminate the sensitization to innocuous stimuli. These data show that a substantial component of the relevant nociceptive drive to RVM pain-modulating neurons is relayed through the parabrachial complex. The differential effect of PB block in a persistent inflammatory pain state implies altered or additional input to the RVM in persistent pain. While the parabrachial nucleus is well known as an important relay for ascending nociceptive information, the connection with the RVM allows the spinoparabrachial pathway to access descending control systems as well.

Title: Periaqueductal grey EP3 receptor activity facilitates spinal nociception in arthritic secondary hyperalgesia

Authors: *R. DRAKE[1], L. J. LEITH[1], B. M. LUMB[1], L. F. DONALDSON[2];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Sch. of Life Sci. and Arthritis Res. UK Pain Ctr., Univ. of Nottingham, Nottingham, United Kingdom

Abstract: The midbrain periaqueductal grey (PAG), together with downstream nuclei within the medulla and brain stem, can affect pain experience by regulating the spinal processing of A- and/or C-nociceptor inputs and subsequent transmission of nociceptive information to the brain. The balance of descending inhibitory and/or facilitatory control of spinal nociceptive processing plays a major role in shaping the pain phenotype following tissue injury. For instance, sensitisation to noxious stimuli develops within undamaged tissue adjacent, and also distant to, the damaged site (secondary hyperalgesia) and spinal neuronal pools that serve this secondary domain are dominated by descending facilitatory controls that amplify spinal inputs from unsensitised peripheral nociceptors. Cyclooxygenase enzyme activity and/or prostaglandin E 2 signalling within the ventrolateral (vl) PAG is known to be pro-nociceptive in naïve and acutely inflamed animals but its role in more persistent inflammation or, specifically, its contribution to secondary hyperalgesia remains unknown. We have used a combined pharmacological and electrophysiological approach to determine the effects of prostaglandin EP3 receptor activity within the vlPAG on the spinal processing of A- and C-nociceptor inputs in naïve and arthritic rats, and its contribution to secondary hyperalgesia in arthritic animals. In naïve male Wistar rats blockade of COX enzyme activity or EP3 receptor activity increased thermal withdrawal thresholds in the awake animal. Additionally, in anaesthetised naïve animals, activation or inhibition of vlPAG EP3 receptors affected C-, but not A-, nociceptor evoked reflex withdrawal thresholds. Arthritic rats (Freund's complete adjuvant model) developed a mechanical and thermal secondary hyperalgesia of the hind-paw that was associated with a sensitisation of withdrawal thresholds to A-, but not C-, nociceptor activation. Notably, in arthritic animals the influence of EP3 receptor activity within the vlPAG extended to the spinal processing of A-nociceptor inputs and PAG EP3 receptor blockade increased withdrawal thresholds to A- and C-

nociceptor activation in the area of secondary hyperalgesia. Unexpectedly, vlPAG EP3 receptor blockade increase the firing threshold of spinal dorsal horn neurones to C-, but not A-, nociceptor activation in the area of secondary hyperalgesia. We conclude that in the naïve animal EP3 receptor activity in the vlPAG facilitates the spinal nociceptive processing of C-nociceptor inputs alone but affects the spinal processing of both A- and C-nociceptor inputs from an area of secondary hyperalgesia in the arthritic animal.

Title: Modulation of TRPV1 activity in spinal cord neurons presynaptic endings by paclitaxel is mediated by TLR4 activation

Authors: P. ADAMEK[1,2], P. MROZKOVA[1,2], *J. PALECEK[3];
[1]Inst. of Physiology, Czech Acad. of Sci., Prague, Czech Republic; [2]Fac. of Sci., Charles University, Czech Republic; [3]Inst. of Physiol., Prague, Czech Republic

Abstract: Paclitaxel is widely used in the clinical practice as chemotherapeutic, but the treatment is frequently accompanied with development of persistent painful peripheral neuropathy. In our study we tested hypothesis that these adverse effect could be at least partialy mediated due to activation of Toll Like (TLR4) and Transient Receptor Vanilloid 1 (TRPV1)

receptors at the spinal cord level. Whole-cell patch clamp recordings of miniature (mEPSC), spontaneous (sEPSC) and dorsal root stimulation evoked (eEPSC) excitatory postsynaptic currents were made from superficial dorsal horn neurons (Voltage-Clamp configuration at -70 mV) in acute spinal cord slices (300 μM) prepared from adult male mice C57BL/6 weighting 25 to 30 g and from male Wistar rats 21 days old. All the recordings were made in the presence of strychnine (5 μM) and bicuculline (10 μM), TTX (0.5 μM) application was used for mEPSC detection. Our data demonstrated that acute application of low concentration paclitaxel (50 nM) induced significant increase in the frequency of mEPSC. This effect was prevented by the TRPV1 antagonist SB366791 (10 μM) pretreatment. However, the paclitaxel application did not influence frequency or amplitude of the sEPSC and eEPSC. These results indicate direct modulation of presynaptic endings by paclitaxel. In other set of experiments we tested the effect of paclitaxel application on repeated capsaicin evoked response in superficial dorsal horn neurons recorded as mEPSC frequency. Under control conditions the mEPSC frequency of the second response to capsaicin (0.2 μM) was significantly smaller when compared with the first one (32,6 %). Acute application of paclitaxel before the second capsaicin application prevented the decrease of mEPSC frequency and was not different from the first response. This effect was prevented by coapplication of the paclitaxel with TLR4 antagonist LPS-RS (2 μg/ml). Our results demonstrate that functional interaction between TLR4 and TRPV1 receptors may play an important role in modulation of nociceptive synaptic transmission in spinal cord dorsal horn after paclitaxel treatment. Understanding these mechanisms is needed to improve treatment of the chemotherapy-induced neuropathic pain.

Title: The role of proinflammatory cytokines and TRPV1 receptors in paclitaxel induced peripheral neuropathy

Authors: *N. KALYNOVSKA[1,2], M. DIALLO[1], J. PALECEK[1];
[1]Inst. of Physiology, The Czech Acad. of Sci., Praha, Czech Republic; [2]Fac. of Sciences, Charles Univ., Prague, Czech Republic

Abstract: Chemotherapy-induced peripheral neuropathy often represents a dose-limiting negative side effect for the use of paclitaxel in clinical practice. However, the underlying mechanism of the disease remains still poorly understood. Accumulating evidence from animal models of peripheral neuropathy has implicated a number of peripheral and central proinflammatory processes to play an important role in the development of neuropathic pain. In our experiments we have focused on the function of TNFalpha, CCL2 and TRPV1 receptors in paclitaxel induced neuropathy. The model of peripheral neuropathy was established in adult male Wistar rats by i.p. injection of paclitaxel solution (5 x 2 mg/kg) on five alternate days. On days 10 and 21 after the first injection, lumbar dorsal root ganglia (DRGs) and spinal cord dorsal horn (SCDH) tissues were collected and further used for Western blot and RT PCR experiments. The acute effect of paclitaxel application was tested on spinal cord slices from 21 days old rats under *in vitro* conditions. Paclitaxel treatment significantly increased protein expression of TRPV1 receptors, glial cell marker GFAP, protein levels of TNFalpha and CCL2 in lumbar DRGs at day 10 and with exception of TNFalpha also at 21 days after the first injection of paclitaxel. In the spinal cord dorsal horn, paclitaxel induced TRPV1 overexpression only at day 10, but not at day 21. GFAP, TNFalpha and CCL2 increased levels were detected on day 21, but not on day 10. mRNA levels of TRPV1 and proinflammatory markers did not change significantly during both tested periods (days 10 and 21). We have used *in vitro* spinal cord slices to study molecular mechanisms of paclitaxel-induced cellular changes within the central nervous system. In the first experiments, c-Fos expression was evaluated in dorsal horn neurons after incubation with 100 nM paclitaxel for 60 min. The paclitaxel application induced a significant increase in c-Fos expression within the superficial area of spinal cord dorsal horn. This increased expression of c-Fos protein was significantly attenuated by preincubation of lumbar spinal cord slices with TRPV1 antagonists (SB 366791 and AMG 9810). Our data indicate an important role of TRPV1 receptors in the cellular mechanisms of paclitaxel-induced neuropathy and possible modulation of their function by proinflammatory cytokines.

Abstract: Peripheral neuropathy is dose-limiting in cancer chemotherapy with paclitaxel and can often induce persistent pain and discomfort in cancer survivors. The hypothesis tested was that chemotherapeutic agents produce these adverse effects at least in part by sensitizing transient receptor potential vanilloid subtype 1 (TRPV1) through Toll-like receptor 4 (TLR4) signaling. The data show that paclitaxel-induced behavioral hypersensitivity to mechanical stimuli is prevented and reversed by spinal administration of a TRPV1 antagonist (AMG9810). TLR4 is expressed in TRPV1-positive rat and human dorsal root ganglion (DRG) neurons. TRPV1 expression is increased in DRG neurons in paclitaxel-treated rats. Perfusion of paclitaxel or the archetypal TLR4 agonist lipopolysaccharide (LPS) directly activated rat DRG neurons and produces acute sensitization of TRPV1 via a TLR4-mediated mechanism. All these effects were prevented by co-administration with LPS-RS (TLR4 antagonist). Paclitaxel and LPS sensitize TRPV1 in HEK293 cells stably expressing TLR4 and transiently expressing TRPV1. Finally, paclitaxel directly activates and sensitizes TRPV1 responses in dissociated human DRG neurons. In summary, TLR4 was activated by paclitaxel and led to sensitization of TRPV1. This mechanism could contribute to paclitaxel-induced acute pain and chronic painful neuropathy.

Title: Increase of mast cells through TRPV1-expressing primary afferents are involved in oxaliplatin-induced mechanical allodynia in mice

Authors: *T. ANDOH, A. SAKAMOTO, Y. KURAISHI;
Univ. Toyama, Toyama, Japan

Abstract: The chemotherapeutic agent oxaliplatin induces peripheral neuropathy, as a dose-limited side effect. However, the mechanisms of oxaliplatin-induced peripheral neuropathy are still unclear. In this study, we demonstrated that cutaneous mast cell was involved in oxaliplatin-induced mechanical allodynia in mice. Male C57BL/6NCr mice were used, except for one series of experiments in which male mast-cell deficient mice (WBB6F1 W/Wv) and the normal littermates (WBB6F1+/+) were used. In addition, neonatal capsaicin-treated C57BL/6NCr mice were also used. A single intraperitoneal injection of oxaliplatin (3 mg/kg) or vehicle (5% glucose) was given in above mice. Mechanical allodynia was evaluated using a von Frey filament (0.69 mN). A single intraperitoneal injection of oxaliplatin elicited mechanical allodynia, which peaked on day 10 after the injection. Mast cell deficiency inhibited significantly and completely oxaliplatin-induced mechanical allodynia. Oxaliplatin-induced mechanical allodynia was significantly inhibited by serine protease inhibitor camostat mesilate and proteinase-activated receptor 2 antagonist FSSLY-NH2, but not H1 histamine receptor antagonist terfenadine. In the plantar skin of mice treated with oxaliplatin, the number of total mast cells was significantly increased. In neonatal capsaicin-treated adult mice, an intraperitoneal injection of oxaliplatin did not induce mechanical allodynia and increase the number of cutaneous mast cells. Neonatal capsaicin-treatment results in the deletion of TRPV1 expressing peripheral sensory neurons. Thus, it is suggested that TRPV1-expressing primary afferents are involved in the increase of cutaneous mast cells. In addition, serine proteases from mast cells may play an important role in oxaliplatin-induced mechanical allodynia.

Title: The transcription factor Sp1 regulates the expression of the Ca^{2+} channel α2δ-1 auxiliary subunit in neuropathic pain

Authors: ***K. GOMEZ**[1], M. PEREZ-RODRIGEZ[1], P. BARRAGAN-IGLESIAS[1], V. GRANADOS-SOTO[1,2], R. GONZALEZ-RAMIREZ[2,3], R. FELIX[3];

Abstract: High voltage-activated calcium (CaV) channels are a family of transmembrane proteins that form Ca2+-selective pores. These channels are oligomeric complexes of a CaVα1 ion-conducting subunit and CaVβ and CaVα2δ auxiliary subunits that open by depolarization of the plasma membrane, being essential regulators of the intracellular Ca2+ concentration. At the transcriptional level, the expression of the α2δ-1 subunit is regulated by the Sp1 transcription factor. The main role of this auxiliary subunit is to promote the trafficking of functional CaV channels to the plasma membrane and to modify the channel kinetics and its voltage-dependent properties. During peripheral nerve injury, an upregulation of the CaV α2δ-1 auxiliary subunit occurs in the dorsal root ganglia (DRG) ipsilateral to the nerve injury, which has been correlated with allodynia. In the present report, in order to investigate the possible involvement of the transcription factor Sp1 as a molecular determinant of the exacerbated expression of CaVα2δ-1 auxiliary subunit we examined the expression of α2δ-1 and Sp1 in the DRG using the L5/L6 spinal nerve ligation model in rats with or without intrathecal administration of mithramycin-A, a Sp1 inhibitor, and its correlation with tactile allodynia. Our data indicate that tight ligation of the L5/L6 spinal nerve results in a time-dependent α2δ-1 and Sp1 upregulation in the DRG that correlates with tactile allodynia. Mithramycin-A treatment of spinal nerve ligated animals, at doses that alleviate allodynia, markedly decreased the levels of Sp1 and prevented the elevation of α2δ-1 expression that normally occurs in neuropathic pain, in a dose-dependent manner. Thus, it is reasonable to hypothesize that Ca2+ currents may be increased in DRG neurons during

neuropathic pain development, and that this effect may be explained, at least in part, by an elevation of α2δ-1 expression as a result of an overexpression of Sp1 in sensory neurons. Title: Molecular mechanisms for the upregulation of $Ca_v3.2$ T-type calcium channels in the dorsal root ganglion of rats with spinal nerve injury-induced neuropathy: involvement of Egr-1 and USP5

Authors: *S. TOMITA, F. SEKIGUCHI, M. TSUBOTA, A. KAWABATA;
Kinki Univ. Sch. Pharm., Higashi-Osaka, Japan

Abstract: We have reported that the upregulation of $Ca_v3.2$ T-type calcium channels in the primary sensory nerves contributes to the development of neuropathic pain in rats with L5 spinal nerve cutting (L5SNC). It has been reported that expression of $Ca_v3.2$ is transcriptionally promoted by early growth response 1 (Egr-1) and suppressed by RE-1 silencing transcription factor (REST), and that $Ca_v3.2$ protein is protected by ubiquitine specific peptidase 5 (USP5), a deubiquitinating enzyme, from proteasomal degradation. We thus determined protein levels of Egr-1, REST and USP5, in parallel with $Ca_v3.2$, in the dorsal root ganglia (DRG) after L5SNC in the rats, and analyzed their possible involvement in the upregulation of $Ca_v3.2$ and development of neuropathic pain. After L5SNC, mechanical nociceptive threshold in the ipsilateral hindpaw, as assessed by the paw pressure test and von Frey test, significantly decreased on day 6 (early phase) and reached a bottom level on days 9-14 (persistent phase). The hyperalgesia/allodynia induced by L5SNC was suppressed by administration of RQ-00311651, a T-type calcium channel blocker. Protein levels of Egr-1 and $Ca_v3.2$ significantly increased in L4, but not L5 or L6, DRG on days 6 and 14 after L5SNC, although REST expression remained constant before and after L5SNC. USP5 was upregulated on day 14, but not day 6, in L4 DRG, while it was

upregulated on days 6 and 14 in L5 DRG. Knockdown of Egr-1 in the early phase with the antisense method inhibited the neuropathic hyperalgesia and upregulation of $Ca_v3.2$ in L4 DRG on days 8-9 after L5SNC. Knockdown of USP5 in the persistent phase abolished the neuropathic hyperalgesia and upregulation of $Ca_v3.2$ in L4 DRG on day 14 after L5SNC. These data suggest that, in the L4 DRG of rats after L5SNC, Egr-1 induces $Ca_v3.2$ upregulation and contributes to the development of neuropathy in the early phase, and USP5 plays a critical role in the maintenance of the upregulated $Ca_v3.2$ and neuropathic pain in the persistent phase.

Title: Complement 3a receptor mediates dorsal horn Ca^{2+} signaling evoked by the VGF peptide TLQP-21 in the setting of neuropathic pain

Authors: *S. DOOLEN[1], K. F. KITTO[2], C. A. FAIRBANKS[2,3,4], L. VULCHANOVA[2], B. K. TAYLOR[1];
[1]Dept. of Physiol., Univ. of Kentucky, Lexington, KY; [2]Dept. of Neurosci., [3]Dept. of Pharmaceutics, [4]Dept. of Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: VGF (non-acronymic) is granin-like neuropeptide precursor whose expression is upregulated in sensory and spinal cord neurons after peripheral nerve injury. Intrathecal administration of the VGF-derived peptide TLQP-21 produces hyperalgesia, while TLQP-21 immunoneutralization reduces behavioral signs of neuropathic pain. Recently, the complement 3a receptor (C3aR1) was identified as a receptor for TLQP-21. We have shown that TLQP-21 induced thermal hyperalgesia is dose-dependently reversed by co-administration with a C3aR1 antagonist, SB209157. Here, we tested the hypothesis that TLQP-21 contributes to neuropathic pain through the activation of C3aR1. We determined whether TLQP-21/C3aR1 activation increases Ca^{2+} signaling in dorsal horn, and whether these effects are potentiated by nerve injury.

Spared nerve injury was performed in adult mice, and mechanical hypersensitivity was confirmed 14 d later. Transverse lumbar slices (450 um; L3/L4) were bulk loaded with 10 uM fura-2 AM for ratiometric Ca^{2+} imaging, labeled with the astrocyte marker SR-101, and evaluated for TLQP-21-evoked Ca^{2+} signaling. Superfusion with TLQP-21 evoked Ca^{2+} signals in SR-101-negative lamina II profiles (presumably cells) from both sham and injured mice, suggesting that the TLQP-21 induced Ca^{2+} responses were evoked in either neurons or microglia, but not astrocytes. The majority (86.4%) of TLQP-21-evoked Ca^{2+} signals did not respond to glutamate, suggesting a non-neuronal (likely microglial) origin. Nerve injury significantly increased peak Ca^{2+} signals evoked by either 0.1 or 1.0 μM TLQP-21. This was significantly decreased in the presence of SB290157 (1 μM). These data support the hypothesis that TLQP-21 activation of C3aR1 in dorsal horn of spinal cord contributes to spinal neuroplasticity under conditions of neuropathic pain.

Title: AFA019 differentially inhibits T-type Ca^{2+} currents over Na+ and K+ currents in DRG neurons and mitigates neuropathic pain in mice

Authors: *B. ZOU[1], C. PASCUAL[1], C. LIEU[1], M. J. GUNARATNA[2], M. ZHANG[2], D. H. HUA[2], S. X. XIE[1];
[1]AfaSci Res. Lab., Redwood City, CA; [2]Dept. of Chem., Kansas State Univ., Manhattan, KS

Abstract: Overactivation of the T-type Cav3 Ca2+ channel (T-channel) is involved in development of seizures and neuropathic pain. Current pharmacotherapeutics do not treat neuropathic pain well. To discover a potent and selective T-channel inhibitor for the treatment of neuropathic pain, we took a rational drug design approach. A new series of 1,3,4-oxadiazole compounds was synthesized and evaluated. The versatility of the synthetic strategy was using two different substituents at C2 and C5 of the oxadiazole scaffold to generate new molecules. This involved coupling reactions of various acid halides with 5-substituted-2-amino-1,3,4-oxadiazoles, which were made from the ring closing sequence of acid chlorides with

thiosemicarbazide followed by 1,3-dibromo-5,5-dimethylhydantoin. AFA019 represents one of these chemicals producing potent inhibition of T-currents *in vitro* and analgesic efficacy against neuropathic pain in mice. Using voltage-clamp recordings of acutely isolated dorsal root ganglion (DRG) neurons from adult mice, we observed that AFA019 (1 μM) inhibited T-Ca2+ current by 50 ± 9.7% (n = 8). At the same concentration, AFA019 caused 16.5 ± 8.9% (n = 7) inhibition of voltage-gated Na+ currents, and 18.9 ± 11.8% (n = 4) inhibition of early transient K+ currents and 24.1 ± 14.6% (n = 4) inhibition of the delayed steady K+ currents. The effect on the T- currents was concentration-dependent with an IC50 of 0.93 μM. In contrast, the inhibitory effect of AFA019 on Na+ and K+ currents appears to be less concentration-dependent. At 30 μM the inhibition of AFA19 was around 20~30% on both Na+ and K+ currents. The selectivity against T-current over high-voltage-activated Ca2+ currents is under investigation. For comparison, we tested Z944 which is in clinical trials for treatment of neuropathic pain. Z944 inhibited T-currents in DRG neurons with an IC50 of 0.2 μM. However, it also potently inhibited Na+ currents with an IC50 of 0.51 μM. At 1 μM, Z944 also caused 45% inhibition of K+ currents. Administration of AFA019 (0.3 - 30 mg/kg, i.p. n = 8) significantly mitigated neuropathic pain in both spared nerve injury- and paclitaxel (Taxol, 4 mg/kg, i.p.)-induced chronic pain models in mice in a dose-dependent manner. AFA019 (30 mg/kg, i.p.) also significantly reduced seizures and fatality induced by either pentylenetetrazole (40 mg/kg, i.p.) or maximal electric shocks in mice. These results demonstrate that AFA019 could be a potentially effective therapeutic to treat both neuropathic pain and epilepsy.

Title: Interferon-gamma activates NMDA receptors in the dorsal horn of spinal cord

Authors: M. SONEKATSU[1], *W. TANIGUCHI[1], M. YAMANAKA[1], N. NISHIO[1], S. TSUTSUI[1], H. NISHI[1], H. HASHIZUME[1], T. NAKATSUKA[2], M. YOSHIDA[1];
[1]Dept. of Orthopaedic Surgery, Wakayama Med. Univ., Wakayama, Japan; [2]Pain research center, Kansai Univ. of Hlth. Sci., Osaka, Japan

Abstract: A pro-inflammatory cytokine, interferon-gamma (IFNγ), is upregulated in the dorsal horn after peripheral nerve injury, and it has been implicated as one cause of neuropathic pain. It was reported that intrathecal injections of IFNγ induce pain related behaviors in rats and mice, whereas IFNγ receptors knock-out mice does not respond. However, little is known about the roles of IFNγ in the spinal cord. To elucidate how the excitatory synaptic transmissions mediated by IFNγ in the spinal cord, we investigated the effects of IFNγ on synaptic transmission by using whole-cell patch-clamp recordings from substantia gelatinosa (SG) neurons. At first we investigated the action of IFNγ on AMPA (α-amino-3-hydroxy-5-methyl-4-Isoxazole-4-propionic acid) receptor-mediated currents in the voltage-clamp mode -70 mV. Bath application of IFNγ did not affected AMPA-induced current. While, NMDA (N-methyl-D-asparate)-receptor-mediated currents were significantly increased by the application of IFNγ in the voltage-clamp mode -50 mV. This IFNγ-induced facilitatory actions of NMDA current was inhibited by IFNγ receptor selective antagonist. In addition, minocycline, an inhibitor of microglia activation, also blocked the facilitatory effect of IFNγ on NMDA-induced currents. These results suggest that IFNγ binds own receptor and enhances the activity of NMDA but not AMPA receptors in the dorsal horn of spinal cord. It is also considered that this mechanism includes the microglia-neuron crosstalk. The activation of NMDA receptors in SG neurons by IFNγ may contribute the persistent neuropathic pain.

Title: Role of anion exchanger 3 in different models of chronic pain

Authors: *M. J. PÉREZ RODRÍGUEZ, K. GOMEZ, P. BARRAGAN-IGLESIAS, V. GRANADOS-SOTO;
Farmacobiologia, CINVESTAV Sede-Sur, Ciudad DE Mexico, Mexico

Abstract: Primary sensory neurons keep a high intracellular chloride concentration ([Cl−] in). In addition, these neurons show a depolarizing GABAA receptor conductance not only during the development but also in its mature state. The polarity and magnitude of these currents is determined primarily by [Cl-]i. In normal conditions This mechanism contributes to the development of primary afferent depolarization (PAD); therefore in the presynaptic inhibition. However, after tissue or nerve injury this phenomenon instead of inhibitory becomes excitatory, contributing to pain states. Thus, chloride plays an important role in pain processing. It is known that the anion exchanger 3 (AE3) is expressed in dorsal root ganglia (DRG) and also contributes to maintain [Cl-]i in the primary neurons. It has been shown that AE3 inhibitors produce acute antinociception in the formalin test while formalin injection increases AE3 expression. However, the role of the AE3 in chronic pain conditions is unknown. The purpose of this study was to determine the participation of AE3 in two different models of chronic pain. Neuropathic pain was induced by spared nerve injury (SNI) whereas chronic inflammatory pain was induced by intraplantar injection of complete Freund's adjuvant (CFA). Tactile allodynia and thermal hyperalgesia of the left hind paw (ipsilateral) and right hind paw (contralateral) were assessed at 0, 3, 7, 14 and 21 days after ligation or administration of CFA. Western blotting was used to determine AE3 protein expression in DRG. Axotomy and ligation of tibial and common peroneal nerves and intraplantar injection of CFA induced tactile allodynia and thermal hyperalgesia, which were maintained for 21 days. The AE3 protein expression was modulated differentially and time-dependent manner in DRG after SNI or CFA injection. An enhancement of AE3 protein expression in L4 and L5 DRG was observed at 7 and 14 days after SNI. On the other hand, AE3 protein expression in L4 DRG increased 14 days after CFA injection, while the increment in L5 and L6 occurred 7 days after injection. Inthrathecal pre-treatment (-10 min) with the chloride-bicarbonate anion exchanger inhibitor, 4,4´-diisothiocyanatostilbene-2,2-disulfonic acid (DIDS, 50 µg/10µl) partially prevented SNI- and CFA-induced nociception. These results suggest that chronic pain upregulates AE3 expression in DRG. Data also suggest that AE3 participates in the development and maintenance of chronic pain. Title: The role of SorLA, a sorting protein-related receptor, in neuropathic pain development

Authors: *F. FRATTINI[1,2], J. HU[1];
[1]Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Grad. Sch. of Neural & Behavioural Sciences/International Max Planck Res. School, Eberhard Karls Univ. Tübingen, Tuebingen, Germany

Abstract: Neuropathic pain is an intractable and frequent condition characterized by exaggerated response to painful stimuli (hyperalgesia) or normally innocuous stimuli (allodynia), and spontaneous pain. One of the mechanisms involved in the development of neuropathic pain is the loss of inhibition mediated by γ-aminobutyric acid (GABA) in the spinal cord after peripheral nerve injury. Altered intracellular chloride (Cl-) concentration regulated by brain-derived neurotrophic factor (BDNF) upon potassium chloride co-transporter 2 (KCC2) and sodium-potassium-chloride co-transporter 1 (NKCC1) plays an important role to promote neuropathic pain since it affects GABAA receptor reversal potential, thus leading to loss of inhibition or even a switch to excitation. But how BDNF regulates KCC2/NKCC1 remains unclear. SorLA (sorting protein-related receptor with A-type repeats), an intracellular trafficking receptor which is associated with Alzheimer disease, has been shown to regulate the phosphorylation of NKCC2 (the renal analog of NKCC transporters) in kidney, influencing Cl- intake and supporting the maintenance of renal function. Interestingly, BDNF has been reported to regulate SorLA expression in neurons. We therefore hypothesize that SorLA may be involved in the development of neuropathic pain while acting downstream of BDNF signaling pathway. We first detected a prominent expression of SorLA in the spinal cord and dorsal root ganglion neurons, indicating that this protein could have a function in somatosensory system. Furthermore, after sciatic nerve injury, animals lacking SorLA did not develop allodynia, the major cause of complaints among neuropathic pain patients. Similar observation was made after mimicking nerve injury pain through BDNF intrathecal injection, confirming that BDNF regulates pain behavior through SorLA. Taken together, our findings suggest that SorLA influences pain perception induced by mechanical stimulus after nerve injury and support the hypothesis that it acts downstream in the BDNF pain pathway to promote neuropathic pain. Further experiments will address whether SorLA influences KCC2/NKCC1 regulation in neuropathic pain. This study may unravel an innovative role for SorLA as a mediator between

BDNF and chloride regulation in neurons after injury and may have relevant clinical implications for patients suffering from neuropathic pain.

Title: Nerve injury promotes loss of nociceptive neuron-specific Gαi-interacting protein (Ginip) expression in neuropathic pain rat

Authors: *H. YU, Z. LIU, F. WANG, G. FISCHER, Q. H. HOGAN;
Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Gαi-interacting protein (Ginip) is a signal transduction molecule that expresses specifically in dorsal root ganglion (DRG) nociceptive neurons and plays a role in modulating metabotropic GABAb receptor (GBR)-mediated antinociception via interactions with Gαi. Genetic deletion of *Ginip* leads to impaired responsiveness to GBR agonist-mediated analgesia in mouse. However it has not been defined whether nerve injury changes Ginip expression. Here we showed that Ginip expresses in ~40% of total lumbar DRG neurons in normal adult rats and its immunoreactivity (IR) is distributed in ~80% of IB4+ (nonpeptidergic) and ~30% of CGRP+ (peptidergic) neurons. The Ginip+ central axonal fibers terminate in lamina II of spinal dorsal horn (DH). Ginip is expressed in DRG neurons immunopositive for GBR1, GBR2, Gαi(s), and Gαo; and its IR is also extensively colabeled with multiple nociceptive neuronal markers, including $Ca_V2.2$α1b, $Ca_V3.2$α1b, $Na_V1.7$, TRPV1, and Trek2. Importantly, peripheral nerve injury by L5 spinal nerve ligation (L5-SNL) significantly decreases the proportion of Ginip-positive neurons from 40±8.4% to 1.8±1.2% ($p<0.01$) and the total Ginip protein to 1.3%±0.04% of its basal level ($p<0.01$, n = 6 animals in each group, mean± SD) in the ipsilateral L5 DRGs. In contrast, no significant change in Ginip was found in adjacent non-injured L4 DRGs. These data support that Ginip is a marker predominant for nonpeptidergic small nociceptive neurons, and also point that nerve injury triggers loss of Ginip expression. Results also indicate that the signal transduction roles of Ginip may be diverse as it colabeled with various subgroups of nociceptive neurons. Future studies may investigate details of the signaling mechanism engaged by Ginip, as well as the pathophysiological significance of lost expression of Ginip in neuropathic pain.

Title: α9-nAChR: Novel analgesic target or crucial for mental health?

Authors: ***S. MOHAMMADI**, M. J. CHRISTIE;
The Univ. of Sydney, Sydney, Australia

Abstract: The α9-subunit of nicotinic acetylcholine receptors (α9-nAChR) has recently been identified as a novel analgesic target. However, the evidence for the involvement of this receptor in pain has been indirect and confounded. Peptides from marine cone snail venom, known as conotoxins, are highly selective for mammalian receptors and ion channels. These conotoxins are proving to be incredibly useful pharmacological tools for dissecting the specific roles of cellular proteins in the mammalian system. A number of conotoxins that are highly selective for α9-nAChRs have been identified and these have been shown to be effective analgesics in animal models of chronic pain. From these analgesic conotoxins, it has been inferred that the α9-nAChR is a valid target for analgesics. However, evidence has emerged that α9-nAChR-inhibition is not necessary or sufficient for the broad analgesic effects of these conotoxins, nor is it their primary mechanism of analgesia. Furthermore, α9-nAChRs are necessary for only one (mechanical hyperalgesia) of the many pain modalities that are affected by chronic pain. Behavioural testing of mice with germline α9-nAChR-deletion revealed a vital role of the α9-nAChR in coping mechanisms during acute and chronic stress conditions. This highlights, for the first time, potential side effect liabilities of α9-nAChR-inhibiting analgesics. α9-nAChR knockout (KO) mice demonstrated both behavioural and physiological aberrations in their stress-responses, and demonstrated a susceptibility to stress-induced anxiety and depression-like behaviour compared to their wildtype (WT) counterparts. Behaviourally, KO mice exhibited reduced stress-induced arousal in the forced swim test (FST) and the elevated plus maze (EPM), increased stress-induced anxiety-like behaviour on the EPM, and increased stress-induced depression-like behaviour in a sucrose preference test, compared with WT mice. Physiologically, KO mice exhibited dysregulation of the stress-hormone response, with muted corticosterone responses to

an acute stressor, but exaggerated corticosterone responses after persistent stress. Inhibition of the α9-nAChR is unlikely to offer broad analgesic relief to pain sufferers, and the present results suggest that such inhibition would cause detrimental side effects manifesting as dysregulation of the stress response.

Abstract: Calcium-activated chloride channels (CaCCs) activation produces a chloride efflux in primary sensory neurons that might facilitate their depolarization contributing to action potentials generation. Previous studies have suggested the participation of bestrophin-1 and anoctamin-1, members of the CaCCs family, in inflammatory pain models. However, their role in neuropathic pain is unclear. The aim of this investigation was to study the involvement of anoctamin-1 and bestrophin-1 in rats submitted to the L5/L6 spinal nerve ligation model. Intrathecal administration of non-selective CaCCs inhibitors 9-anthracenecarboxylic acid (9-AC, 10-300 microg), 5-nitro-2-(3-phenylpropylamino) benzoic acid (NPPB, 30-300 microg) and niflumic acid (NFA, 10-300 microg), but not vehicle, reduced in a dose-dependent manner established tactile allodynia. Moreover, intrathecal administration of selective CaCCs inhibitors (T16Ainh-A01 and CaCCinh-A01, 0.01-10 microg) diminished in a dose-dependent fashion tactile allodynia and thermal hyperalgesia. Both anoctamin-1 and bestrophin-1 mRNA and

protein were expressed at the dorsal spinal cord and dorsal root ganglia of naïve, sham and neuropathic rats. L5/L6 spinal nerve ligation increased mRNA and protein expression of anoctamin-1, but not bestrophin-1, at the dorsal spinal cord and dorsal root ganglia from day 1 to day 14 after nerve ligation. In addition, repeated administration of CaCCs inhibitors (T16Ainh-A01, CaCCinh-A01 and NFA) or antibodies anti-bestrophin-1 or anti-anoctamin-1 prevented spinal nerve ligation-induced rise in anoctamin-1 mRNA and protein expression. Although bestrophin-1 was not upregulated by spinal nerve ligation, we found that bestrophin-1 is expressed in non-peptidergic neurons at outer laminas of the dorsal horn. Spinal nerve ligation increased the compound action potential of C fibers while administration of selective CaCCs inhibitors (T16Ainh-A01 and CaCCinh-A01) attenuated such increase. Our results indicate that CaCCs are present in sites related to the nociceptive processing. Also, our data imply that CaCCs participate in the maintenance of neuropathic pain and therefore selective inhibitors may function as analgesics in nerve injury pain states. Title: Involvement of ROS-dependent PI3-kinase activation in leptin-induced enhancement of NMDA receptor-mediated tactile hyperalgesia in neuropathic rats

Authors: J. B. JUN[1,2], S. J. JUNG[1], H. A. KIM[1], *J. W. LEEM[1,2];

Abstract: Recent studies have shown that leptin (an adipocytokine) played an important role in influencing neuropathic pain. It was revealed that leptin enhanced NMDA-induced spinal neuronal excitation. We have previously displayed that upregulation of phosphatidylinositol

(3,4,5)-triphosphate (PIP3) levels via reactive oxygen species (ROS) in the dorsal horn was involved in tactile hyperalgesia seen in neuropathic rats. In the present study, we investigated whether leptin aggravated NMDA receptor-mediated neuropathic pain behavior and, if so, whether this leptin-induced effect was mediated through the ROS-PI3 kinase pathway. Tactile hyperalgesia of the hind paw, evaluated by measuring paw withdrawal threshold upon the application of von Frey hairs, was induced using naive rats either by lumbar 5 spinal nerve ligation (L5 SNL) or by intrathecal (i.t.) administration of leptin or glutamate. The L5 SNL-induced tactile hyperalgesia was attenuated by i.t. administration of leptin antagonist, NMDA antagonist MK-801, ROS scavenger alpha-phenyl-N-tert-butyl nitron (PBN), or PI3-kinase inhibitor LY294002. When intrathecally administered in naive rats, both leptin and glutamate induced tactile hyperalgesia. Leptin and glutamate administered together induced more severe tactile hyperalgesia than glutamate alone. Leptin-induced tactile hyperalgesia was attenuated by MK801. Both leptin-induced and glutamate-induced tactile hyperalgesia were attenuated by either ROS scavenger PBN or LY294002. The results suggested that leptin enhanced NMDA receptor-mediated tactile hyperalgesia, via the ROS-PI3K pathway, in the neuropathic state.

Title: Dorsal root ganglion transcriptome analysis following peripheral nerve injury in mice

Authors: ***S. WU**[1], B. M. LUTZ[2], L. LIANG[3], K. MO[3], Y.-J. CHANG[4], P. DU[4], A. Y. BEKKER[3], Y.-X. TAO[3];

Newark, NJ; [4]High Performance and Res. Computing, Office of Information Technology, New Jersey Med. School, Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Peripheral nerve injury leads to the changes in some gene expression in primary sensory neurons of dorsal root ganglia (DRG). These changes are believed to involve in neuropathic pain genesis. However, the alternation of whole transcriptomes in DRG following nerve injury is still unclear. Next generation RNA-seq is a highly sensitive method of analyzing differential expression of not only mRNAs but also non-coding RNAs and splice variants. The present study chose the eliminate mRNA poly-A selection with strand-specific and higher depth next generation sequencing to analyze whole transcriptomes in DRG following spinal nerve ligation (SNL). Our results showed that more than 50 million (M) mapped sequences in pairs with strand information were yielded in each group (51.87 M-56.12 M in sham vs. 51.08 M-57.99 M in SNL). Six days after SNL, expression levels of 11,164 out of total 38,925 identified genes in the injured DRG were significantly changed, including 3,278 transcriptional isoforms. The largest transcriptional changes were observed in protein-coding genes (91.5%) followed by non-coding RNAs. Within 944 differentially expressed non-coding RNAs, the markedly observed changes were seen in long interspersed non-coding RNAs followed by antisense RNAs, processed transcripts, and pseudogenes. We observed a notable proportion of reads aligning to intronic regions in both groups (44.0% in sham vs. 49.6% in SNL). Using quantitative real-time PCR, we validated that the levels of DNMT3a mRNA, DNMT1 mRNA and Gm26883 RNA (a non-coding RNA) were significantly up-regulated and that the amounts of Kcna2 mRNA, Oprm1 mRNA and 4732491K20Rik RNA (another non-coding RNA) were down-regulated following SNL. Our findings suggested that next generation RNA-seq can be used as a promising approach to analyze the changes of whole transcriptomes in DRG following nerve injury and to possibly identify new targets for prevention and treatment of neuropathic pain.

Abstract: We have recently demonstrated that following thoracic spinal cord injury (SCI) astrocyte activation spreads via gap junctions to the lumbar spinal cord and this rapid intercellular communication is critical to the induction of bilateral below-level neuropathic pain. The present study determined whether sigma-1 receptors (Sig-1Rs) are involved in astrocyte activation and whether they modulate the expression of the astrocyte-specific gap junction protein connexin 43 (Cx43) ultimately leading to SCI-induced below-level chronic neuropathic pain. SCI was performed by transverse hemisection of the right thoracic spinal cord between the $T_{11\text{-}12}$ vertebral segments in mice. Below-level mechanical allodynia and thermal hyperalgesia were evaluated bilaterally in the hindpaws of SCI mice. Immunohistochemistry and western blotting were performed to determine potential changes in connexin, glial fibrillary acidic protein (GFAP), and Sig-1R expression in the spinal cord. SCI significantly increased the expression of Sig-1Rs in astrocytes, but not in neurons or microglia, in the dorsal horn of lumbar enlargement spinal segments located below the level of injury and this increase peaked at the same time as SCI-induced mechanical allodynia. In addition, there was a bilateral, significant increase in the expression of GFAP and the astrocyte gap junction protein, connexin 43 (Cx43) in the spinal cord dorsal horn, which was significantly reduced by repeated injection of the Sig-1R antagonist, BD1047 in SCI mice. Conversely there were no changes in oligodendrocyte (Cx32) or neuronal (Cx36) gap junction protein expression after SCI. Administration of BD1047, the non-selective gap junction blocker (carbenoxolone), or the selective Cx43 blocker (Cx43 mimetic peptide ^{43}Gap26) significantly reduced SCI-induced bilateral below-level mechanical allodynia. Collectively these findings demonstrate that SCI-induced Sig-1R stimulation activates astrocytes and increases the expression of the astrocyte gap junction protein Cx43 in the lumbar regions of the spinal cord dorsal horn. This ultimately contributes to the induction of the bilateral below-

level chronic mechanical allodynia in SCI mice and raises the possibility of using Sig-1R antagonists to treat spinal injury-induced neuropathy.

Title: Phosphorylation of Ser-481 stabilizes the inactivated state of the Kv3.4 channel: hinting at a mechanism of SCI-induced neuropathic pain

Authors: *B. M. ZEMEL, M. COVARRUBIAS;
Thomas Jefferson Univ., Philadelphia, PA

Abstract: The voltage-gated K+ channel Kv3.4 undergoes protein kinase C (PKC)-dependent modulation of both fast inactivation and functional expression in dorsal root ganglion (DRG) nociceptors. Although the mechanism underlying elimination of fast inactivation upon phosphorylation of four N-terminal serines is well understood, the basis of the PKC-dependent downregulation of the Kv3.4 current is unknown. To tackle this problem, we are investigating: 1) the phosphorylation site(s) responsible for the downregulation; 2) the kinase(s) and phosphatase(s) involved; and 3) the mechanism of the downregulation. Here, we report that persistent PKC activation coupled with calcineurin (PP2B) inhibition induces downregulation of the Kv3.4 current in CHO cells and DRG neurons. This downregulation results from a negative shift in the steady-state inactivation curve, which indicates a relative stabilization of the

channel's inactivated state. Mutational analysis revealed that Ser-481 plays a major role in this modulation. Whereas S481A nearly eliminates the downregulation by PKC activation and PP2B inhibition, S481D mimics the negative shift of the steady-state inactivation curve in heteromeric channels. These results are mechanistically tantalizing because S481 is located at the channel's activation gate. Additionally, immunostaining and coimmunoprecipitations showed that PKC-ε and Kv3.4 co-localize and interact, suggesting that this PKC isoform might be responsible for the phosphorylation-dependent modulation of the Kv3.4 channel in DRG. Further supporting this possibility, PKC-ε is robustly expressed in DRG neurons. We propose that the Kv3.4 channel, PKC-ε and possibly PP2B coexist in a signaling complex expressed in DRG neurons. There, the Kv3.4 channel undergoes PKC/PP2B-dependent modulation to eliminate fast N-terminus-dependent inactivation (due to phosphorylation of four N-terminal serines) and enhance a novel inactivation mechanism (due to phosphorylation of Ser-481). Additional results suggest that these mechanisms could be implicated in peripheral pain sensitization induced by spinal cord injury (SCI).

Title: Upregulation of T-type calcium channels activated by toll like receptor 4 in primary sensory neurons in paclitaxel induced peripheral pain

Authors: *Y. LI[1], R. M. CASSIDY[2], A. K. KOSTURAKIS[3], D. S. HARRISON[4], P. M. DOUGHERTY[1];
[1]MD ANDERSON CANCER CENTER, Houston, TX; [2]The Univ. of Texas Hlth. Sci. Ctr., Houston, TX; [3]The Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX; [4]Duke Univ. Sch. of Med., Durham, NC

Abstract: Paclitaxel induced peripheral neuropathy is a common dose-limiting side effect in cancer chemotherapy and often persists in cancer survivors. Paclitaxel increases excitability of peripheral sensory neurons and produces these adverse effects at least in part by activation of low voltage activated calcium channels (T-type, Cav3.2) via toll-like receptor 4 (TLR4)

signaling. The data show that the percent of cells showing spontaneous action potentials and the mean frequencies of action potentials are significantly increased at day 7 and day 14 in the paclitaxel treatment group compared to vehicle controls. Analysis of action potential parameters indicated that the enhanced excitability was observed in small size DRG neurons in paclitaxel treated animals. Cav3.2 expression is increased in DRG and spinal cord in paclitaxel-treated rats, is localized to CGRP-positive, IB4-positive small DRG neurons and GFAP-positive spinal cord cells. Cav3.2 was also co-localized with TLR4 in DRG neurons and spinal cord astrocytes. Perfusion of LPS (TLR4 agonist) directly activated DRG neurons, while pretreatment with ML218 (specific T-type calcium channel blocker) significantly blocked this. Paclitaxel-induced behavioral hypersensitivity to mechanical stimuli is prevented but not reversed by spinal administration of ML218. In summary, paclitaxel treatment led to sensitization of Cav3.2 and blockade of TLR4 prevented this. This mechanism could contribute to paclitaxel-induced acute pain and chronic painful neuropathy.

Title: Roles of Acid-Sensing Ion Channels in neuropathic pain induced by experimental autoimmune encephalomyelitis

Authors: *I.-C. WANG[1,2], C.-H. LEE[2], S.-H. LIN[2], C.-Y. CHUNG[2], F. LIAO[2], C.-C. CHEN[2,3]; [1]Dept. of Life Science, Natl. Taiwan Univ., Taipei, Taiwan; [2]Inst. of BioMedical Sciences, Academia Sinica, Taipei, Taiwan; [3]Taiwan Mouse Clinic, Natl. Comprehensive Mouse Phenotyping and Drug Testing Center, Academia Sinica, Taipei 115, Taiwan, Taipei, Taiwan

Abstract: Neuropathic pain is one of the major symptoms in Multiple Sclerosis, but the underlying neurological mechanisms is still under debate. Since acidosis has been reported in multiple sclerosis, the Acid-sensing ion channels, which are involved in acid-induced neuropathic pain, may participate in the pain pathway. Therefore, we hypothesize that ASICs may play a role in pain development in MS. We utilize experimental autoimmune encephalomyelitis (EAE), a well-established MS rodent model, to evaluate clinical deficits, mechanical response and pathological alterations in four different ASIC subtypes knockout mice.

Both wild-type and knockout mice showed clinical deficits and mechanical hypersensitivity in the recovery phase of EAE. Also, pathological studies demonstrated that dorsal root ganglion (DRG) neurons are injured after EAE induction by co-staining with neuron injury marker, activating transcription factor 3 (ATF3). Further characterization of injured neurons showed that myelinated (neurofilament 200-positive) and non-peptidergic (isolectin B4-positive) neurons were the principal populations and that peptidergic neurons were excluded (calcitonin gene-related peptide-positive and substance P-positive neurons). These results suggested that peripheral nerve might participate in the nociceptive hypersensitivity in EAE. Moreover, analgesic drug application indicated that EAE-induced neuropathic pain is modulated by ASIC3 mediated anti-nociceptive pathway.

Title: Anti-nociceptive effects of botulinum toxin type A on trigeminal neuropathic pain in rats

Authors: *M. KIM[1], H. KIM[1], J. SON[1], J. JU[1], K. YANG[1], M. LEE[2], M. PARK[3], J. PARK[4], D. AHN[1];
[1]Sch. of Dent. KNU, Daegu, Korea, Republic of; [2]Dong-Eui university, Busan, Korea, Republic of; [3]Kyung-Woon university, Gumi, Korea, Republic of; [4]Sch. of Medicine, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: We investigated the anti-nociceptive effects of botulinum toxin type A (BoNT-A) in a rat model of trigeminal neuropathic pain produced by inferior alveolar nerve injury. Experiments were carried out in male Sprague-Dawley rats. The left mandibular second molar was extracted under anesthesia, followed by a miniature dental implant placement to induce injury to the inferior alveolar nerve. Mechanical allodynia was monitored after subcutaneous injection of 0.3, 1 or 3 U/kg BoNT-A into the vibrissa pad on postoperative day (POD) 3, 7 or 12. Subcutaneous

injections of 1 or 3 U/kg BoNT-A on POD 3 significantly attenuated mechanical allodynia although the 0.3 U/kg BoNT-A did not affect the air-puff threshold. A single injection of 3 U/kg BoNT-A produced prolonged anti-allodynic effects over the entire experimental period. Double treatments with 1 U/kg BoNT-A produced prolonged anti-allodynic effects compared with single treatments. Besides, treatment with BoNT-A on POD 7 and 12, when pain had already been established, also produced prolonged anti-allodynic effects. Treatment with BoNT-A did not affect up-regulated the number of activating transcription factor 3 (ATF3)-positive cells in a rat with inferior alveolar nerve injury. Although nerve injury increased the level of Nav1.6, 1.7, 1.8 in the trigeminal ganglion on POD 3, subcutaneous injection of BoNT-A produced down-regulated only Nav1.7 expression. These results suggest that subcutaneous injection of BoNT-A produced prolonged anti-nociception and this anti-nociception is mediated by the regulation of Nav1.7. In summary, our current results suggest that BoNT-A injections can be used to treat the trigeminal neuropathic pain associated with dental implant surgery. Although our results are encouraging in this regard, however, their general applicability is limited by the use of an animal model. Further clinical human studies involving large cohorts are needed to properly estimate the clinical efficacy of BoNT-A and its potential as new treatment for neuropathic pain.

Title: HIV-Associated pain and peripheral sensory neuropathy: the role of Wnt5a signaling

Authors: ***S. YUAN**, W. RU, M. DE CABO JAUME, S.-J. TANG;
Neurosci. and Cell Biol., Univ. of Texas Med. Br., Galveston, TX

Abstract: Peripheral sensory neuropathy is a major neurological complication in HIV infected patients. Pathological pain in HIV patients is intimately associated with the development of neuropathy. To study the mechanism of HIV-Associated sensory neuropathy (SN), we used a HIV-1 gp120 mouse model generated by intrathecal injection (i.t.) of gp120. Our recent work showed that the model with three i.t. gp120 injections (i.t. at 1, 3, 5 day, each time 100ng

gp120Bal) developed behavioral, cellular and molecular abnormalities that resembled the pathologies in the HIV patients who had pathological pain, including SN. At day 7 after the first i.t. injection, the density of PGP 9.5+ intraspinosum nerve fiber (ISNF; fibers located in the inner layer of the epidermis) began to decrease (control: 34.84 fibers/mm, model: 21.1 fibers/mm), although it was not statistically significant. At this time point, the PGP 9.5+ intragranulosum nerve fibers (IGNF, c-fibers reaching the out layer of the epidermis) were significantly reduced (control: 18.16 fibers/mm, model: 8.20 fibers/mm, $p<0.05$). At the end of the 3rd week, PGP 9.5+ ISNF density in the gp120 model further dropped to 9.53 fibers/mm, comparing with the 34.84 fibers/mm in the control ($p<0.0001$). Since our recent studies suggested a critical role of Wnt5a-JNK signaling pathway in HIV-Assocaited pain, we wanted to determine the potential contribution of Wnt5a signaling to gp120-induced SN. Repeated administration (i.t.) of a specific Wnt5a agonist foxy-5 (10μg/i.t., 3 times, every other day in the first week and collected tissue at the end of 3 week) caused the severe allodynia and epidermis denervation (ISNF: 10.96 fibers/mm). The effect of Foxy-5 was significantly attenuated by the administration of the JNK inhibitor, SP600125. To further test the role of endogenous Wnt5a, we generated condition knockout (CKO) of Wnt5a in neurons where Wnt5a was predominantly expressed. We found that the Wnt5a CKO diminished gp120-induced denervation in the epidermis. These dada collectively indicate the important role of Wnt5a signaling in gp120-caused SN.

Title: MeCP2 regulates gene expression in dorsal root ganglia after peripheral nerve injury

Authors: ***M. T. MANNERS**[1], A. ERTEL[2], Y. TIAN[1], K. MCCORMICK[2], Z. ZHOU[3], S. AJIT[1];
[1]Pharmacology/Physiology, Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Cancer Biol., Thomas Jefferson Univ., Philadelphia, PA; [3]Dept. of Genet., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Decreased pain perception is commonly reported in children with Rett syndrome (RTT). RTT is caused by mutations in methyl-CpG-binding protein 2 (MECP2), suggesting that normal MeCP2 function is important in modulating pain. Our objective is to investigate genes regulated by MeCP2 in the dorsal root ganglia (DRG), as well as microRNA (miRNA)-mediated regulation of MeCP2 in neuropathic pain. Our previous study showed that miRNAs predicted to target Mecp2 are downregulated in the DRG from a rodent model of neuropathic pain. We confirmed miRNA-mediated regulation of MeCP2 *in vitro* and MeCP2 upregulation in the DRG following nerve injury. MeCP2 regulates brain derived neurotrophic factor (BDNF) and repression of MeCP2 by miRNAs resulted in a concomitant decrease in Bdnf. Mecp2-null and MeCP2 T158A knockin mice have decreased Bdnf in DRG and MeCP2 T158A mice exhibited reduced mechanical sensitivity. Diminished pain sensitivity resulting from mutations in Mecp2 could be mediated by downregulation of Bdnf. Increased MeCP2 expression and binding can play a critical role in inducing gene expression changes in a pain state. We performed ChIP-seq using DRG from a spared nerve injury (SNI) model of neuropathic pain and a subset of loci with enriched MeCP2 binding including miR-126 and Ptger1 were further investigated. miR-126 expression decreased in SNI model while its target, Vegfa and Dnmt1 were upregulated. These data suggests that increased MeCP2 binding induced by neuropathic pain can lead to the repression of this miRNA. Conversely, prostaglandin E receptor 1 (Ptger1), a gene implicated in mediating pain, was increased in the SNI model and decreased in Mecp2-null mice, indicating MeCP2 may activate expression of Ptger1. Our studies using rodent models of pain and RTT can lead to a better understanding of the mechanistic basis of pain and thus to innovative approaches for its treatment.

Title: Effects of NR2B mediated signaling on neuropathic pain in a rat model of peripheral nerve injury

Authors: *Y. KIM[1], J. KIM[2], Y. YOON[1];
[1]Korea Univ., Col. Med., Seoul, Korea, Republic of; [2]Korea Univ., Col. Hlth. Sci., Seoul, Korea, Republic of

Abstract: N-methyl-D-aspartate receptor 2B (NR2B), one of the NMDAR subunits, is restrictively located in the sensory region of the central nervous system, especially, in the superficial lamina of the spinal cord. Besides, that has various phosphorylation sites in the c-terminal and interacts with postsynaptic density protein-95 (PSD-95), which is a scaffold protein located in the postsynaptic density. Thus, these signaling may be important to the mechanism of neuropathic pain. Therefore, this study was performed to find out the roles of NR2B mediated signaling pathway in the development and/or maintenance of neuropathic pain after peripheral nerve injury. Left side of the L5 spinal nerve was tightly ligated with 6/0 silk under isoflurane anesthesia in the male Sprague-Dawley (Crl: CD, 180-200 gram) rats. Quadrants of the L4 and L5 spinal cord were obtained from normal and SNL rats. The temporal expression of NR2B, NR2B Tyr1472, NR2B Ser1303, Ca++/calmodulin dependent complex II (CaMKII), Thr286 CaMKII, protein kinase C (PKC) and PSD-95 were quantified after SNL. In addition, RO 25-6981, autocamtide-2 related inhibitory peptide (AIP) or chelerythrine (CHE) were intrathecally injected in the early phase (1-4 days after SNL) and in the late phase (7-21 days after SNL) after nerve injury. The paw withdrawal threshold was assessed with series of von Frey filaments before and after drug injection. Co-immunoprecipitation (co-IP) was performed to analyze the interaction between Ser1303 and CaMKII, Ser1303 and PKC, and Ser1303 and PSD-95. NR2B and Thr286 CaMKII expression were more increased at the L5 spinal cord in the early phase than in the late phase after SNL. On the contrary to this, PKC expression was increased in the late phase. Phosphorylation of NR2B Ser1303 was increased from the early phase until the late phase. Moreover, Ro 25-6981 and AIP elevated paw withdrawal threshold more efficiently in the early phase than in the late phase, whereas CHE elevated that in the late phase. Interaction between Ser1303 and CaMKII was increased in the early phase, and interaction between Ser1303 and PKC was existed in the late phase. Interaction between Ser1303 and PSD-95 was gradually increased over time after injury. Above all, AIP and Ro 25-6981 reduced the interaction between Ser1303 and PSD-95, but CHE did not. Thus, our results suggested that NR2B mediated signal transduction pathway may be a possible connector from the developmental phase to the maintenance phase of neuropathic pain after peripheral nerve injury.

Title: Assessing properties of small cutaneous nerve fibers

Authors: *C. D. MORCH[1], K. HENNINGS[3], S. FRAHM[2], L. PETRINI[2], M. B. JENSEN[2], L. ARENDT-NIELSEN[2], O. K. ANDERSEN[2];

Abstract: Introduction: Peripheral neuropathy is a common pathology in e.g. diabetes and after chemotherapy. The integrity and membrane properties of large peripheral nerve fibers can be assessed by nerve conduction studies and the threshold tracking. Today, diagnostic methods for assessing changes in small fiber membrane properties are inadequate. Here we present a novel method for assessing the membrane properties of small and large cutaneous nerve fibers using perception threshold tracking. Methods: 20 healthy human subjects (9 females, mean age: 29.4 years) participated in the study (ethical approval: N-20120046). Small cutaneous nerve fibers were activated by a circular array of 16 small area electrodes (diameter = 0.2mm) and large cutaneous nerve fibers were activated by a surface electrode (20 x 15 mm). Perception thresholds were assessed by an adaptive staircase method. The strength duration time constant and rheobase were estimated by fitting the perception thresholds to rectangular constant current electrical pulses of 50µs, 100µs, 200µs, 400µs, 800µs, 2ms, 8ms, and 16ms to Weiss' law. The threshold electrotonus was assessed as the perception threshold reduction by depolarizing conditioning pulse at 10ms, 20ms, 40ms, and 80ms and hyperpolarizing conditioning pulse at 30ms and 80ms with an intensity of 20% of the perception threshold of a 1ms rectangular pulse. Results: The average time constant of the small fibers (1060µs ± 690µs) was significantly longer than the time constant of the large fibers (580µs ± 160µs; $p = 0.01$, paired t-test). The rheobase of the small fibers (0.070mA ± 0.041mA) was significantly lower than the rheobase of the large fibers (0.43mA ± 0.10mA; $p < 0.001$, paired t-test). The threshold electrotonus protocol showed no statistical difference between small and large fibers threshold reduction for depolarizing pulses and 30ms hyperpolarizing pulses. For the 80ms hyperpolarizing pulse, the threshold increase was higher for the small (61.2% ± 11.2%) than the large (27.1% ± 2.3%) cutaneous nerve fibers (RM ANOVA and Bonferroni, $p = 0.006$). Conclusion: This novel perception threshold tracking technique enables assessment of the membrane properties of small and large cutaneous nerve fibers based on automatic detection of perception thresholds. Different membrane properties observed may relate to different diameters, myelination, and distribution of ion channels. The method provides information about small fiber membrane properties and may be used for diagnosis of thin fiber neuropathy.

Title: GABAA α2 subunit in dorsal root ganglia plays an important role in the development and maintenance of neuropathic pain post-crush injury of the sciatic nerve in female rats

Authors: *A. L. OBRADOVIC[1], J. SCARPA, Jr.[2], H. P. OSURU[3], J. L. WEAVER[4], J.-Y. PARK[6], S. PATHIRATHNA[3], A. PETERKIN[3], Y. LIM[7], M. JAGODIC[3], S. M. TODOROVIC[5], V. JEVTOVIC-TODOROVIC[5];

Abstract: Objectives: The pathophysiology of neuropathic pain (NPP) after peripheral nerve injury remains unknown and it likely results from repetitive high frequency bursts of peripheral afferent activity, leading to long-lasting changes in synaptic plasticity in the spinal dorsal horn (DH). Although treatments that promote GABA activity in the DH provide partial relief of neuropathic symptoms, their beneficial properties are usually complicated by numerous side effects. We examined how *in vivo* silencing of the $GABA_A$ α_2 gene in dorsal root ganglion (DRG), known as a main peripheral sensory relay formation, controls development of NPP in rats. **Methods:** After crush injury to the right sciatic nerve of female rats, the α_2 $GABA_A$ antisense and mismatch oligodeoxynucleotides or NO-711 (a GABA uptake inhibitor) were applied to the L5 DRG. *In vivo* assessment of thermal and mechanical hyperalgesia was conducted prior to the injury and ensuing 10 days. *In vitro* quantification of α_2 $GABA_A$ protein and electrophysiology studies of $GABA_A$ currents were performed on acutely dissociated L5 DRG neurons at relevant time-points. **Results:** NPP post-crush injury of a sciatic nerve in adult female rats coincides with significant down-regulation of the α_2 subunit expression in the ipsilateral DRG (about 30%); this effect was not observed in sham operated animals. Selective down-regulation of α_2 expression by antisense oligodeoxynucleotides in DRGs significantly worsens mechanical and thermal hypersensitivity in crush-injured animals and also, causes development of profound hypersensitivity in sham animals. Conversely, up- regulation of endogenous GABA *via* blockade of its uptake by NO-711 in DRG alleviates NPP. We also found that prolonged NPP phenotype correlate with significant α_2 subunit protein down-regulation even at post-operative day (POD) 10, which suggests strong association between GABA function in DRG cells and the NPP phenotype. **Conclusions:** We demonstrate that peripheral nerve injury resulting in NPP is accompanied by a significant down-regulation of $GABA_A$ α_2 subunit in the ipsilateral DRG neurons. Further down-regulation of this subunit results in worsening of pain, while selective inhibition of GABA reuptake at DRG level alleviates thermal hyperalgesia. Also, we showed that at the later days of NPP progression (POD 10) pain phenotype is still associated with significant down-regulation of α_2 $GABA_A$ subunit.

Title: Role of CD4 in spinal cord chemokine responses in a murine model of neuropathic pain

Authors: *L. CAO[1], J. T. MALON[2];
[2]Biomed. Sci., [1]Univ. New England, Biddeford, ME

Abstract: Previously, using a murine model of neuropathic pain, spinal nerve L5 transection (L5Tx), we showed that there is a transient infiltration of CD4+ T lymphocytes into the lumbar spinal cord post-L5Tx and these cells are predominantly type I helper T cells that can promote pro-inflammatory responses within the spinal cord. Behavioral tests indicated that CD4+ T lymphocytes contribute to the maintenance phase of L5Tx-induced mechanical hypersensitivity. It is well-known that chemokines (such as CCL2) plays important role in the development of neuropathic pain. To further understand the role of CD4+ T lymphocytes in peripheral nerve injury-induced spinal cord chemokine response, we determined the levels of various chemokines in the lumbar spinal cord in both CD4 knockout (KO) and wild type mice post-L5Tx. A total of eight chemokines CXCL1 (KC), CCL1 (TCA-3), CCL2 (MCP-1), CCL3 (MIP-1 alpha), CCL5 (RANTES), CCL11 (Eotaxin), CCL17 (TARC), and CCL22 (MDC) were examined. CD4 KO mice displayed blunt responses in L5Tx-induced CCL2 and CCL5. This is consistent with our previous observation that significantly less spinal cord infiltrating cells were detected in CD4 KO mice post-L5Tx. Further, L5Tx-induced upregulation of phosphorylated p38 MAPK was not observed in CD4 KO mice, suggesting a role of CD4+ T lymphocytes in activation of p38 pathway. Altogether, our data indicate a contributing role of CD4+ T lymphocytes in L5Tx-induced chemokine responses and possibly upstream p38 MAPK pathways.

Title: VIP deficient mice exhibit reversible alterations in molecular and epigenetic determinants of cold and mechanical nociception

Authors: *T. L. MADUNA, P.-E. JUIF, N. P. UPPARI, N. PETIT DEMOULIERE, A. LACAUD, P. POISBEAU, V. LELIEVRE;
Inst. of Cell. and Integrative Neurosci., Strasbourg, France

Abstract: The vasoactive intestinal (neuro)peptide (VIP) is involved in a variety of functions including nervous system development and regeneration. Several studies have reported opposite effects of exogenous VIP on nociception depending on administration site. Here, we investigated the role of endogenous VIP in nociception using VIP knockout (VIP KO) mice. Compared to wild type (WT) and heterozygous (Hz) adults, VIP KO mice exhibited robust cold and tactile hyperalgesia whilst their sensitivity to heat remained unaffected, similar to human neuropathic symptoms. In VIP KO mice, *in vivo* electrophysiology revealed that the C-fiber activation of spinal neurons was triggered by non-noxious mechanical and electrical stimulations compared to WT. Intraperitoneal injection of VIP to deficient mice restored normal C-fiber thresholds and abrogated the pain symptoms for 3 days. This rescue is transduced by VIP receptor type 1 (VPAC1) that initiates rapid changes in gene expression regulation. We then screened for gene candidates classically altered under pain conditions. We showed that expression of specific thermo- and mechano-induced receptors as well as pain-related secreted factors were altered in VIP KO mice but restored following VIP treatment. Gene expression was associated with epigenetic changes including DNA methylation. These results highlight a novel role for VIP in nociceptive sensitivity in basal and pathological conditions. Its analgesic properties in neuropathic pain states warrants further evaluation in a translational context.

Title: Effects of alpha7 nicotinic acetylcholine receptor positive allosteric modulator on microglia BDNF expression following LPS-induced neuropathic pain in mice

Authors: *M. ABBAS, S. RAHMAN;
Pharmaceut. Sci., South Dakota State Univ., Brookings, SD

Abstract: Evidence suggests that neuro-immune activation plays a critical role in the pathophysiology and maintenance of neuropathic pain phenotypes involving central nervous system alpha7 nicotinic acetylcholine receptors (nAChRs). Here, we examined the effects of 3a,4,5,9b-Tetrahydro-4-(1-naphthalenyl)-3H-cyclopentan[c]quinoline-8-sulfonamide (TQS), an alpha7 nAChR positive allosteric modulator on microglia brain derived neurotropic factor (BDNF) expression following lipopolysaccharide (LPS)-induced neuropathic pain models in mice. Pretreatment of TQS (1 or 4 mg/kg, i.p.) reduced LPS-induced tactile allodynia and hyperalgesia. Furthermore, pretreatment of TQS (4 mg/kg) reduced (~60% of control, $p<0.05$) LPS-induced increased microglia BDNF expression in hippocampus. Taken together, these results suggest that TQS decreases LPS-induced neuropathic pain by modulating hippocampal microglia BDNF level. Therefore, microglia alpha7 nAChR positive allosteric modulator could be a potential drug candidate for neuropathic pain.

Title: PAP-I activates spinal microglia and induces nociceptive response in rats

Authors: *X. ZHANG, J. LI, H. LIU;
Inst. of Neuroscience, Chinese Acad. of Sci., Shanghai, China

Abstract: Objective Pancreatitis-associated proteins (PAPs) are a family of secretory proteins and their function is not studied in the sensory system. Previous studies revealed that in the rat chronic pain models with inflammation or nerve injury, PAP-I was dramatically upregulated in distinct types of dorsal root ganglion (DRG) neurons. These interesting findings suggest that PAP-I may contribute to the development of chronic pain. Methods The dorsal roots and sciatic nerves of anesthetized SD rats were ligated after surgical exposure. The nerve segments including the ligation points were dissected at 24 h for further analysis. P14 rat spinal cord was

isolated and disaggregated for cell culture. After 10-14 days, the flasks were gently shaken for microglia to detach and to be harvested from culture medium. We used Neuro Probe BW200L chambers for chemotaxis assay. Primary spinal microglia were seeded and cultured for 7 h before analysis. P3 SD rats were injected i.p. with AAV2/8. Behavior tests were done two months later. Results (1) PAP-I was upregulated and transported by distinct types of rat DRG neurons in the CFA-inflammation model and nerve injury model. (2) Rat recombinant PAP-I served as a chemoattractant and stimulating factor for primary spinal microglia *in vitro*. (3) PAP-I overexpression in DRG neurons induced a slight change of resting membrane potential but a significant increase in neuronal excitability. (4) PAP-I overexpression (intrathecal/intraplantar injection of recombinant PAP-I-myc-His; AAV expressing PAP-I-2A-EGFP) induced stronger responses to nociceptive stimulus. Conclusion PAP-I has a pro-nociceptive effect *in vitro* and *in vivo*. The PAP-I-induced attraction and activation of spinal microglia may play an important role in pathological pain.

Title: Dietary vitamin B6 differentially modulates cutaneous sensitivity, peripheral sensory axon morphology and spinal cord neurotransmitter content in diabetic and non-diabetic mice

Authors: *S. E. TAGUE[1], M. K. WINTER[1], N. ŞANLı[4], C. E. LUNTE[5], K. E. MCCARSON[2], P. G. SMITH[3];
[1]Kansas Intellectual and Developmental Disabilities Res. Ctr., [2]Pharmacology,Toxicology, and Therapeut., [3]Mol. and Integrative Physiol., Univ. Kansas Med. Ctr., Kansas City, KS; [4]Engin., Uşak Univ., Uşak University, Turkey; [5]Dept. of Chem., Univ. of Kansas, Lawrence, KS

Abstract: Vitamin B6 is a coenzyme that is vital for sensory nerves. Due to shifts in vitamin B6 metabolism, many diabetics become deficient in the active form of this coenzyme, pyridoxal 5'-phosphate. Deficiencies in vitamin B6 lead to paraesthesias, reductions in axon density, and decreased conduction velocity. Peripheral sensory neuropathy is also commonly associated with diabetes mellitus. Some diabetic patients experience a loss of sensation, while others have

painful symptoms, yet both may exhibit similar anatomical degeneration of epidermal nerves in the distal extremities. Vitamin B6 has been shown to have anti-nociceptive properties in diabetics; however, the mechanisms are not well defined. In this study diabetes was induced by injection of streptzotocin (STZ) in fasted A/J mice on two consecutive days (85mg/kg and 65mg/kg), while non-diabetic mice were injected with sodium citrate buffer vehicle. Mice were fed vitamin B6 deficient (0.1mg/kg pyridoxine HCL) or replete (35mg/kg pyridoxine HCL) diets. By the end of 5.5 weeks, vitamin B6 deficient nondiabetic mice exhibited reduced non-peptidergic GFRα2-immunoreactive epidermal innervation, which may account for the observed cutaneous mechanical insensitivity after 3 weeks. In contrast to non-diabetics, diabetic mice on a pyridoxine-deficient diet developed cutaneous mechanical hypersensitivity along with cutaneous neuropathy. The vitamin B6 replete diet was able to abrogate the diabetes induced hypersensitivity; however, dietary pyridoxine did not affect the loss of epidermal nerves in the footpad due to diabetes, suggesting that the positive effect of increased dietary vitamin B6 on pain-related behavior was due to central mechanisms. Spinal cord amino acid neurotransmitters were analyzed by HPLC and found to be influenced by both diabetes and dietary vitamin B6. Diabetic mice showed elevated spinal cord levels of glutamic acid, glycine, and GABA, but not taurine. Vitamin B6 deficiency decreased GABA levels in the spinal cord. In diabetic mice, vitamin B6 deficiency resulted in a lower ratio of the inhibitory neurotransmitter GABA compared to the excitatory neurotransmitter glutamic acid, which may diminish attenuation of afferent nociceptive signaling in diabetic neuropathy. In conclusion, vitamin B6 deficiency leads to insensate distal sensory neuropathy in non-diabetic animals, but in diabetics vitamin B6 deficiency increases painful symptoms of diabetic neuropathy, possibly by reducing the content of the inhibitory amino acid neurotransmitter GABA.

Title: Dorsal root ganglia proteome profile of early painful diabetic neuropathy in a rat model of type-i diabetes

Authors: *C. A. PARADA[1], M. C. P. ATHIE[2], A. S. VIEIRA[3], J. M. TEIXEIRA[2], E. V. DIAS[2], C. H. TAMBELI[2];

Abstract: Diabetic Peripheral Neuropathy (DPN) manifests in 50-60% of types I and II diabetic patients and is the major cause of limb amputation. Although electrophysiological and morphological aspects are well described, little is known about its development and progression, undermining effective therapies. Hyperglycemia and insulin signaling impairment are considered the triggering events of oxidative stress production observed in the dying nerves. Several hypotheses try to explain the phenomenon, but until now there are still many gaps in the pathogenesis and the plastic changes it generates. Significant advances in label-free quantitative proteomics by mass-spectrometer coupled to high-performance-liquid-chromatography have been made, allowing a robust and sensitive methodology for identification and quantitation of proteins that could help understand the molecular events observed in early DPN. In this study we show that proteomic changes in L4 and L5's Dorsal Root Ganglia (DRG) already take place after only two weeks of DPN in a rat model for type I diabetes (n=4). We used an LTQ-Velos Orbitrap mass spectrometer for DRG peptides injection, Mascot Search Engine and Scaffold 4 v. 4.4.3 software for protein identification and quantification. 1410 proteins were identified, 55 were differentially expressed between diabetic and control groups by T-test's $p<0,05$. Molecular function analysis grouped proteins involved in cellular transport (6), cell metabolism (9), mitochondrial activity (10), proliferation/cell growth (11), regeneration/degeneration (11) and antioxidant activity (7). Of those, only 3 remained significant after applying Hochberg-Benjamini Correction for multiple tests (1 down - Gstk1; and 2 up-regulated in diabetic group - Sirt2 and Ppp2r4). Gstk1 is a Glutathione S-Transferase protein member present in peroxisomes playing a role as an antioxidant. Sirt2 - Sirtuin 2 is a deacetylase commonly related to other neurodegenerative diseases, such as Alzheimer, believed to positively modulate myelination, microtubule stability but also to be activated by oxidative stress, triggering an autophagic cascade. Finally. Ppp2r4 or Protein phosphatase 2A is also related to neurodegenerative diseases and is a known tau protein phosphatase. This protein profile may reveal that an oxidative stress due to increase in metabolism is ongoing in DRG two weeks after mechanical sensitivity onset, altering protein expression to pathways that compensate stress and maintain cell homeostasis. A better comprehension of proteomic profile might help elucidate the first cellular alterations and how diabetic neuropathy develops and evolve.

Title: Nociceptin/orphanin FQ receptor antagonist JTC-801 inhibits spinal nitric oxide production and neuropathic pain in diabetic mice

Authors: *K. OHNO, H. SAKAMOTO, T. YASUNAGA, E. OKUDA-ASHITAKA;
Med. Engin., Osaka Inst. Of Technol., Osaka, Japan

Abstract: Diabetic neuropathy is the most common chronic complication of diabetes mellitus. The pathological mechanisms of diabetic neuropathy include peripheral nerve degeneration and neurological damage. Although it is well known that diabetic neuropathy affects peripheral nerves, the mechanisms of this disease in the central nervous system remain poorly understood. In the present study, we examined the role of spinal nitric oxide (NO) in diabetic mice and the effect of gabapencin and nociceptin/orphanin FQ receptor antagonist JTC-801 on diabetic neuropathic pain. Diabetes was induced in mice by an intraperitoneal injection of streptozotocin (STZ). The STZ-injected mice showed significant loss of body weight and developed mechanical allodynia at 1-3weeks measured by von Frey filaments. NO synthase (NOS) activity in mouse spinal cord was assayed by NADPH-diaphorase histochemistry using beta-NADPH and nitroblue tetrazolium. NADPH-diaphorase activity was significantly increased in the dorsal spinal cord of the STZ-injected mice at 3 weeks, although the expression of NOS mRNAs, inducible NOS (iNOS) and neuronal NOS (nNOS), were not changed by STZ injection. Furthermore, oral administration of gabapentin (30 μg/g), a widely used analgesic drug for neuropathic pain, inhibited the mechanical allodynia as well as the increase of NADPH-diaphorase activity in the spinal cords of the STZ-injected mice. In addition, the increased spinal NADPH-diaphorase activity of the STZ-injected mice was inhibited by the exposure of JTC-801 (100 nM) to spinal cord slice. Oral administration of JTC-801 (10 μg/g) significantly decreased in the mechanical allodynia and NADPH-diaphorase activity in the STZ-injected mice. These results indicate that increased spinal NOS activity, assayed by NADPH-diaphorase histochemistry, contributes to diabetic mechanical allodynia. Furthermore, nociception/orphanin FQ receptor antagonist may provide a novel effective treatment for diabetic neuropathic pain.

Title: Activation of ephrinB-EphB receptor signaling in rat spinal cord contributes to diabetic neuropathic pain

Authors: *X. T. DENG[1,2], M.-Z. WU[1,2], P.-C. MA[1,2], H. MA[1,2], B. ZHENG[3], P. ZHAO[3], X.-J. SONG[1,2,3,4];

Abstract: EphrinB-EphB receptor signal, which is critical cues in regulating cell shape, adhesion/repulsion, migration and positioning during developmental processes of the nervous systems, plays important roles in the development and maintenance of neuropathic pain after certain forms of severe stress such as peripheral nerve injury, bone cancer and morphine withdrawal. Chronic pain accompanied with diabetic neuropathy is a typical form of neuropathic pain in certain patients with diabetes. Diabetic neuropathic pain (DNP) possesses a major clinical challenge and its underlying mechanisms remain elusive. We hypothesized that DNP might share the similar neural mechanisms with other forms of neuropathic pain, thus the ephrinB-EphB receptor signal might play an important role in DNP. Here, we report that activation of ephrinB-EphB receptor signaling in the spinal cord contributes to DNP in adult Sprague-Dawley rats. DNP was induced by intraperitoneal injection of streptozotocin (STZ, 70 mg/kg body weight), which induced long-lasting mechanical allodynia in the animals in addition to the increased level of blood sugar. Western blotting analysis showed that phosphorylation of EphB1 receptor as well as the proinflammatory cytokines interleukin (IL)-1β and tumor necrosis factor (TNF)-α in the spinal cord were significantly increased in STZ-induced DNP. Intrathecal administration of a blocking reagent for EphB1 receptor, EphB1-Fc (5 μg), greatly suppressed STZ-induced increased expression of TNF-α and IL-1β as well as activation of astrocytes in spinal dorsal horn. A single dose of EphB1-Fc produced a transient inhibition of mechanical allodynia starting within 2 h and lasted for about 8 h; repetitive administration of EPhB1-Fc (5 μg, daily for 3 consecutive days) produced a stable, long-lasting analgesic effect in DNP rats. Our results demonstrate that activation of EphB1 receptor in the spinal cord is important for the maintenance

of DNP at least partly through glial cell activation and proinflammatory cytokine pathways; blocking EphB1 activation can greatly reduce DNP syndromes. This study suggests that EphB receptor may be a potential target for treating chronic pain after diabetic neuropathy.

Title: Development of diabetes-induced acidosis in the rat retina

Authors: A. V. DMITRIEV, D. HENDERSON, *R. A. LINSENMEIER;
Northwestern Univ., Evanston, IL

Abstract: VEGF is known to be regulated by acidosis in some tissues, but the role of pH in controlling VEGF in the adult retina is unknown. We hypothesized that the retina of diabetics would be unusually acidic due to increased glycolytic metabolism. Acute hyperglycemia markedly acidified the normal cat retina and in a small number of diabetic cats that were available for study, dysregulation of retinal pH accompanied capillary dropout, and acidosis was found in an animal with earlier background retinopathy. Acidosis, or responses to acidosis, may affect retinal functions in addition to VEGF regulation, and could be responsible for neural dysfunction independently. The purpose of this study was to determine the extent of acidosis at the early stages of diabetes in the rat retina. Double-barreled H^+-selective microelectrodes were used to measure profiles of H^+ across the central retina of dark-adapted intact Long-Evans rats. Profiles were measured in adult diabetic rats 1 to 6 months after intraperitoneal injection of streptozotocin and also in age-matched normal rats. In diabetics, blood glucose was at least 300 mg/dl during measurements made weekly prior to the H^+ recordings. The intraretinal electroretinogram (ERG) was evaluated to determine the retinal depth of the electrode and the condition of the retina. Respiration was adjusted to maintain normal arterial blood gas values for pH, PCO_2 and PO_2 in all animals. In both control and diabetic animals, the most acidic part of the retina was the outer nuclear layer. However, the retina of rats tested at very early stages of diabetes (1-1.5 month) was significantly more acidic than the retina of age-matched controls.

The increased acidity was observed in all layers of the retina, but the change in the outer retina was larger. H^+ profiles were more variable in diabetics than in controls, both within an animal and across animals. A substantial part of this variation was correlated with the degree of hyperglycemia. Interestingly, the acidity of diabetic rat retina was diminished at later stages (2 – 6 months) and sometimes diabetic retinae were even less acidic than in controls. Retinal acidosis begins to develop at an early stage of diabetes (1 month) in rats. The elevation of $[H^+]$ in the retina is expected because of increased glucose in the blood. The shape of H^+-profiles, which are generally uniform in healthy rat retinas, are more variable in diabetics, hinting at a disruption of retinal H^+ regulation due to a progressive abnormality in the retinal circulation and/or cellular pH regulatory processes.

Title: Neonatal streptozotocin-induced Type 2 diabetes mellitus: a model to study peripheral neuropathy

Authors: *P. BARRAGAN-IGLESIAS[1], V. OIDOR-CHAN[1], J. PINEDA-FARIAS[1], E. HONG[1], A. SANCHEZ-MENDOZA[2], V. GRANADOS-SOTO[1];

Abstract: The aim of this study was to characterize the neonatal streptozotocin-induced type 2 diabetes mellitus (n-STZ) as a model of peripheral neuropathy. Three-day-old male Wistar rats were injected with STZ (70 mg/kg, i.p.). Three weeks after n-STZ, rats were weaned and separated in individual cages to perform further behavioral and molecular experiments. A time course of weight, blood glucose, oral glucose tolerance test (OGTT), and insulin secretion was performed at 4, 8, 12 and 16 weeks after n-STZ. At the same time course, we evaluated the pancreatic beta cells damage and the impact in the number of Langerhans islets. Moreover, we also evaluated allodynia and molecular changes in sciatic and L4-L6 spinal nerves by using

western blot and immunofluorescence. n-STZ produced signs of type 2 diabetes including hyperglycemia; glucose intolerance and low secretion of insulin from 4 weeks post n-STZ. In addition, n-STZ also reduced the number of Langerhans islets and pancreatic beta cells. A partial recovery in the number of Langerhans islets and insulin secretion was observed only at 8 weeks post n-STZ. As sign of nerve damage, we observed a time-dependent overexpression of activating transcription factor 3 (ATF3) in L4-L6 dorsal root ganglions (DRGs); satellite glial cells surrounding DRGs, and sciatic nerve. Moreover, we observed overexpression of glial fibrillary acidic protein (GFAP) in satellite glial cells. Interestingly, these changes correlated with the presence of allodynia. The analgesic drugs tested at week 16 showed the following antiallodynic profile: Gabapentin (10-100 mg/kg, p.o.) > morphine (1-3 mg/kg, s.c.) > diclofenac (1-3 mg/kg, p.o.). On the other hand, the AMP-activated protein kinase (*AMPK*) *activator* metformin (200 mg/kg, p.o. during 15 days, starting at week 14) produced an antiallodynic efect in rats subjected to n-STZ. Results demonstrate that n-STZ produces signs of type 2 diabetes and peripheral neuropathy. This model could be used to study diabetic peripheral neuropathy in rats. PB-I, VHO-C and JBP-F are Conacyt fellows.

Title: Chemogenic silencing of Nav 1.8 nociceptors reverses neuropathic pain and hyper-excitability in Painful Diabetic Neuropathy (PDN)

Authors: *B. BHATTACHARYYA[1], N. JAYARAJ[1], D. REN[2], A. BELMADANI[2], R. J. MILLER[2], D. M. MENICHELLA[1];
[1]Dept. of Neurol., [2]Dept. of Pharmacol., Northwestern Univ., Chicago, IL

Abstract: Painful Diabetic Neuropathy (PDN) is a debilitating affliction present in 26% of diabetic patients with substantial impact on their quality of life. Despite this significant prevalence and impact the electrophysiological mechanisms underlying PDN are not well understood. Neuropathic pain is caused by sustained excitability in sensory neurons that reduces

the pain threshold. Extensive characterization of DRG neurons has revealed molecularly defined sub-populations of sensory neurons (Chiu and Woolf 2014, Usoskin et al., 2015), including Nav 1.8 nociceptors. The specific role of Nav1.8 nociceptors in PDN is unknown. Nav1.8::Cre, Ai9 (td tomato reporter) or Nav1.8::Cre, RC::PDi mice were generated to conditionally express hM4D DREADD receptors in this neuronal subset. Mice were given regular (RD) or high fat diet (HFD) for ten weeks, and then tested to determine glucose intolerance. Immunohistochemical staining was performed to confirm DREADD receptors expression in Nav 1.8 nociceptors. Mice were analyzed by pain behavioral tests and electrophysiological studies. We first studied the properties of these nociceptors in normal (RD) and diabetic (HFD) mice. Action potentials evoked from the Nav1.8 expressing neuronal population (Nav 1.8 cre/tomato) by using depolarizing current injections from a set holding membrane potentials (-50 mV) indicated that the subthreshold and threshold level for generating APs are lower in HFD DRGs vs RD DRGs (subthresold HFD 35 pA±5 and RD is 55 pA±8; n=5; threshold for AP in HFD is 80pA±10 and RD is 123± 12, n=5) indicative of diabetes induced hyperexcitability in these animals. We next generated mice in which hM4D receptors (Designer Receptor Activated by a Designer Drug, DREADD) were expressed exclusively in these DRG neurons. We confirmed that DREADD receptors are expressed in Nav 1.8 nociceptors in both IB4 positive and negative subtypes. Intraperitoneal injection of the drug clozapine-N-Oxide (CNO) signiifcantly reduced allodynia in the HFD model of type II diabetes. Furthermore, electrophysiological current clamp studies show that activation of DREADD receptors with CNO (2.5 mM) blocked action potential generation(n=4) in Nav 1.8 DREADD animals. On the contrary, CNO did not show any effect on Aps Nav1.8::Cre, Ai9 (tomato) nociceptors due to the absence of DREADD receptors in both HFD and RD DRGs. We demonstrated that diabetic mice display hyperexcitabilty in their Nav 1.8 nociceptors. Chemogenetic silencing of Nav 1.8 nociceptors reverses neuropathic pain and hyper-excitability in PDN, suggesting a critical role of Nav 1.8 nociceptive neurons hyperexcitability in the pathogenesis of neuropathic pain in diabetes.

Title: Tadalafil promotes recovery from peripheral neuropathy in type ii diabetic mice

Authors: *L. JIA[1], M. CHOPP[1,2], A. SZALAD[1], X. LU[1], Z. G. ZHANG[1], L. WANG[1];
[1]Neurol. Res., Henry Ford Hosp., Detroit, MI; [2]Dept. of Physics, Oakland Univ., Rochester, MI

Abstract: Background: We previously demonstrated that treatment of diabetic peripheral neuropathy with a potent phosphodiesterase 5 (PDE5) inhibitor, sildenafil, improved functional outcome in diabetic db/db mice. To further examine the effect of PDE5 inhibition on diabetic peripheral neuropathy, we investigated the effect of another potent PDE5 inhibitor, tadalafil, on diabetic peripheral neuropathy. Tadalafil is pharmacokinetically distinct from sildenafil and has a longer half-life than sildenafil. Methods and Results: Diabetic db/db mice at age 20 weeks (n=10) were treated with tadalafil (10 mg/kg/ every other day, p.o.) for 8 consecutive weeks, and db/db mice (n=10) at the same age treated with saline were used as a control group. We found that the tadalafil treatment significantly ($p<0.05$) increased motor and sensory conduction velocity by 22 % and 23% ($p<0.05$), respectively, compared to the saline treatment. Tadalafil markedly ($p<0.05$) improved sensory function by reducing the thermal latency measured by the plantar test (7±0.5 m/s vs. 11±1.2 m/s in saline) and by the tail flick test (5±0.3 m/s vs. 6±0.3 m/s in saline). Tadalafil treatment also significantly ($p<0.05$) increased local blood flow in the sciatic nerve (93±5 vs. 58±6% in saline) and increased the density of FITC-dextran perfused vessels (18±2 vs.11±1% in saline). Immunohistological analysis showed tadalafil substantially increased intra-epidermal nerve fibers density (16±1 vs.11±1/mm in saline, $p<0.05$) compared to saline treatment. To investigate the molecular mechanisms that mediate therapeutic effect of tadalafil on peripheral neuropathy, the effect of tadalafil on expression of nerve growth factor (NGF) was examined by Western blot. Tadalafil treatment significantly reversed the diabetic reduced NGF protein level (1.09±0.1 vs.0.7±0.2 in saline, $p<0.05$) in diabetic sciatic nerve. The tadalafil treatment did not significantly alter blood glucose levels, Ac1, triglyceride, and animal body weight compared to the saline treatment. Conclusion: Tadalafil improves regional blood flow in the sciatic nerve, which likely contributes to improved peripheral nerve function, and the amelioration of diabetic peripheral neuropathy.

Title: Selective chemokine receptor CXCR4 deletion in Nav 1.8 nociceptive neurons reverses neuropathic pain and small fiber neuropathy in diabetes

Authors: *N. D. JAYARAJ[1], B. J. BHATTACHARYYA[1], D. REN[2], A. BELMADANI[2], R. MILLER[2], D. M. MENICHELLA[1];
[1]Neurol., [2]Pharmacol., Northwestern Univ., Chicago, IL

Abstract: Painful Diabetic Neuropathy (PDN) is a debilitating affliction present in 26% of diabetic patients with substantial impact on their quality of life. Despite this significant prevalence and impact, current therapies for PDN are only partially effective. Moreover, the electrophysiological mechanisms underlying PDN are not well understood. Neuropathic pain is caused by sustained excitability in sensory neurons that reduces the pain threshold, so that pain is produced in the absence of appropriate stimuli. Sensory neurons display sustained and enhanced excitability in response to different molecules including chemokines. In particular, by pharmacological blockade with a CXCR4 antagonist, we have recently demonstrated the role of CXCR4/SDF-1 signaling in PDN (Menichella et. al. 2014). Nav1.8 cre::CXCR4 f/f and Nav 1.8 Cre::Ai9 /CXCR4 f/f were generated to conditionally knockout CXCR4 chemokine receptors in Nav 1.8 nociceptors. Mice were given regular or high fat diet (HFD) for ten weeks, and then tested to determine glucose intolerance. *In situ* hybridization was performed to confirm selective ablation of CXCR4 receptors in Nav 1.8 nociceptors. Mice were then analyzed by pain behavioral tests, electrophysiological studies and *in vitro* and *in vivo* calcium studies. We demonstrated that selective chemokine receptor CXCR4 deletion in Nav 1.8 nociceptive neurons reverses neuropathic pain in the HFD induced model of type II diabetes. Furthermore, electrophysiological studies on Nav 1.8 cre::CXCR4 f/f heterozygous HFD induced-diabetic DRG culture demonstrated that application of SDF-1 (20nM) not only depolarized DRG neurons (RMP; d-33.2±0.84 mV n=3) but also increased firing frequencies in response to current injection. On the contrary, SDF-1 application does not display any effects on Nav 1.8 cre::CXCR4 f/f homozygous HFD induced-diabetic DRG culture. Additionally, *in vitro* and *in vivo* calcium image studies revealed increased calcium influx in response to chemokine SDF-1 in Nav 1.8 nocicpetors in diabetes. Finally, we observed significant improvement of skin innervation in diabetic mice when chemokine receptor CXCR4 was selectively deleted in Nav

1.8 nociceptors. These observations establish CXCR4 chemokine signaling as a new candidate responsible for hyperexcitability and calcium influx in a distinct subpopulation of DRG neurons and will add to our understanding of how changes in the excitability and calcium influx of sensory neurons contribute to the progression of small fiber neuropathy in PDN, which is a critical barrier to progression for effective treatment of this currently intractable and widespread affliction.

Title: Possible involvement of opioid receptors in the antihyperalgesic and antiallodynic effect of celecoxib in diabetic rats

Authors: *I. E. JUAREZ-ROJOP, JR[1], P. E. MORALES-HERNÁNDEZ[1], M. ALPUIN-REYES[1], J. L. BLE-CASTILLO[1], H. AGUILAR-MARISCAL[1], T. RAMÓN-FRÍAS[1], C. TOVILLA-ZARATE[2], J. C. DIAZ-ZAGOYA[3], V. GRANADOS-SOTO[4];
[1]Univ. Juárez Autonoma De Tabasco, Villahermosa, Tabasco, Mexico; [2]UJAT. División Académica Multidisciplinaria de Comalcalco, Comalcalco, Tabasco, México, Mexico; [3]Facultad de Medicina, Univ. Nacional Autónoma de México., México, D.F., México, Mexico; [4]Neurobio. of Pain Laboratory, Dept. de Farmacobiología, Cinvestav, México, D.F., Mexico

Abstract: In this study we show the antihyperalgesic and antiallodynic effect of celecoxib in diabetic rats and the possible involvement of opioid receptors in the mechanism of action of celecoxib in these rats. We induced experimental diabetes using streptozotocin. To produce hyperalgesia in non-diabetic and diabetic rats, formalin (0.5%) was injected in the right hindpaw. von Frey filaments were used in order to determine the 50% withdrawal threshold in diabetic rats. Celecoxib (0.3-30 mg/kg) administered orally reduced formalin-induced nociceptive behavior during phase 2. Systemic administration of naltrexone (3 mg/kg) as pre-treatment (-10 min), prevented celecoxib-induced antihyperalgesia in formalin-treated diabetic rats. Additionally, naltrexone as well as the δ and κ opioid receptor antagonists naltrindole (3 mg/kg) and 5'-guanidino naltrindole (1 mg/kg), respectively, fully prevented celecoxib-induced antihyperalgesia (10 mg/kg) in formalin-treated non-diabetic and diabetic rats. Furthermore,

celecoxib (0.3-30 mg/kg) exhibited an antiallodynic effect in diabetic rats. Pre-treatment with naltrexone (3 mg/kg) also prevented the antiallodynic effect of celecoxib (0.3, 3 and 10 mg/kg). Interestingly, this dose of naltrexone only partially prevented the antiallodynic effect of celecoxib 30 mg/kg. Naltrexone and naltrindole (3 mg/kg), but not 5'-guanidino naltrindole (1 mg/kg), fully prevented the antiallodynic effect of celecoxib in diabetic rats. Our data suggest that celecoxib produces an antihyperalgesic and antiallodynic effect indiabetic rats. These effects may result from activation of μ, δ and κ opioid receptors for antinociception and μ and δ for antiallodynia. Thus, celecoxib could be useful to treat neuropathic pain in diabetic patients.

Title: Role of macrophage migration inhibitory factor in diabetic peripheral neuropathy

Authors: *S. NOH, K. YOON;
Med. Res. Institute, Kangbuk Samsung Hospit, Seoul, Korea, Republic of

Abstract: Diabetic peripheral neuropathy (DPN) is a common complication of diabetes mellitus which accompanied with distressful sensory symptoms, initially in the feet. With its dual proinflammatory and metabolic effects, macrophage migration inhibitory factor (MIF) has been recently suggested to be a logical target in the field of diabetes. In this study, we attempted to investigate the peripheral changes that elicit pain symptom in DPN rat model, and then we assessed the expression of MIF to the footpad skin. Also, we determined whether this MIF expression is correlated with the expressions of intraepidermal nerve fiber (IENF) and glyoxalseI (GLO1). Experimental DPN was made in male SD rats streptozotocin (STZ) injection. Body weights (BW) and blood glucose (BG) levels were checked. To compare the pain symptom between DPN and sham group, we weekly evaluated mechanical threshold and serially analyzed footpad thickness for 24 weeks. At the last day, all the footpads were excised and prepared for the following procedures; quantitative RT-PCR, western blot, and immunohistochemistry of MIF, IENF and GLO1 . As compared to sham group, DPN group significantly increased BG levels within one week after STZ injection, after BW decreased progressively, and occurred

hyperglycemia until the 24th week. Likewise, the DPN group also developed significantly lower mechanical threshold as early as 7-8 weeks after the induction of diabetes, at which time the footpad thickness became reduced. On the immunohistochemical staining, the DPN group markedly diminished the expressions of IENF and GLO1, while increased MIF on the footpad skin lesions. Similarly, mRNA and protein levels of IENF and GLO1 were significantly down-regulated as the levels of MIF up-regulated on the lesions of DPN group. As hyperglycemic state was continuously maintained until the 24th weeks, the differences between two groups grew prominent. These results demonstrated that MIF may play a role in the pathogenesis of DPN. To our knowledge, this is the first to investigate MIF expression on the DPN-like footpad skin lesions and its potential role in the correlation with IENF and GLO1. Taken together, it is suggested that MIF can be a therapeutic target to control DPN in footpad skin.

Title: PET-MRI of microglia and neuropathic pain after spinal cord injury

Authors: *C. LINNMAN;
Boston Children's Hosp., Waltham, MA

Abstract: Neuropathic pain is one of the most challenging medical problems following a spinal cord injury. It is personally devastating to a degree that it can exceed the impact of other SCI consequences. Neuropathic pain is also difficult to treat successfully, and it significantly impacts rehabilitative efforts, mood and life satisfaction. Animal studies indicate that microglia, the resident macrophages of the CNS, are overexpressed in SCI-induced neuropathic pain. A first step in translating these findings to clinical applications is to establish the role of microglia in human neuropathic pain after SCI. This study presents data on microglial expression in the human brain in SCI with and without neuropathic pain investigated using simultaneous PET-

MRI and the radioligand 11C-PBR28, a highly selective microglial marker. Preliminary analysis suggests: i) Microglial expression may be elevated in the anterior cingulate (most evident in severe neuropathic pain). ii) Resting state networks (independent component analysis) are more clearly defined in the healthy control subjects that in patients, suggesting potential disruption of both "default" and motor networks in SCI patients, potentially co-localized with neuroinflamamtion. These findings suggest that active microglia, as imaged by 11C-PBR28 PET, may be a key component in neuropathic pain in SCI. Microglia may be an attractive pharmacological target for novel analgesics, and the PET-MR imaging methods developed here may provide new objective endpoints for monitoring treatment success.

Sch., Boston, MA; [6]Behavioral Neuroscience, Sch. of Med., Oregon Hlth. and Sci. Univ., Portland, OR; [7]Anesthesia and Critical Care, Beth Israel Deaconess Med. Center, Harvard Med. Sch., Boston, MA

Abstract: Migraine is about twice as common in females as in males. Whereas pre-pubertal boys and girls have the same prevalence, with puberty, the prevalence in girls becomes around 3 times greater. However, the underlying mechanisms remain poorly understood. Using magnetic resonance imaging (MRI) we evaluated 28 children with migraine (14 girls and 14 boys) and 28 sex- and age-matched healthy controls to determine differences in brain structure and function

between: (a) girls and boys with migraine, and (b) girls and boys with migraine during early- and midpuberty (ie., 10-11 years vs 14-16 years) compared to matched healthy controls. Cortical thickness preprocessing and analysis steps were performed using FreeSurfer. Cortical thickness analysis was performed using a mask that included the primary sensory cortex (S1), primary motor cortex (M1), insula, Precuneus (PCu), dorsolateral prefrontal cortex (dlPFC), frontal pole (FP), and temporal pole (TP). Results were corrected for multiple comparisons based on Monte Carlo permutations with 5,000 iterations using AlphaSim. Subcortical gray matter (GM) volume analysis was performed with voxel-based morphometry (VBM) using FSL-VBM. VBM was performed using a mask that included thalamus, caudate, putamen, pallidum, hippocampus, amygdala, nucleus accumbens, periaqueductal gray (PAG), and hypothalamus. Results were corrected for multiple comparisons using Monte Carlo simulations with an image-wide threshold of $p < 0.01$. Finally, seed-based resting-state functional connectivity (rsFC) was performed using FEAT in FSL. A data-driven approach was used to perform rsFC. Thus, we performed rsFC from the left and right amygdala, as well as from the right PCu. Results were corrected for multiple comparisons using cluster-correction with $z > 2.3$ and $P < 0.05$. Compared to boys, girls had more GM in the S1, SMA, PCu, basal ganglia, and amygdala, as well as greater PCu functional resting state connectivity to the thalamus, amygdala and basal ganglia, and greater amygdala functional resting state connectivity to the thalamus, cingulate, and SMA. Moreover, in migraine girls, midpuberty was related to more GM in the S1, amygdala, and caudate compared to midpuberty migraine boys and matched healthy controls. This is the first study showing sex and developmental differences in pediatric migraineurs in brain regions associated with sensory, motor, and affective functions, providing insight into the neural mechanisms underlying distinct migraine sex-phenotypes. Title: Changes in pain-related brain activity following a mindfulness meditation intervention in chronic migraine are associated with reduced anxiety

Authors: *V. A. MATHUR[1,2], S. A. B. BURROWES[1], M. L. KEASER[1], S. A. KHAN[1], M. GOYAL[3], D. A. SEMINOWICZ[1];
[1]Dept. of Neural & Pain Sci., Univ. of Maryland, Baltimore, MD; [2]Psychology, Texas A&M Univ., College Station, TX; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Patients with chronic migraine experience frequent and ongoing periods of severe and disabling headache. Migraine is also associated with altered brain response to pain. Prior research suggests that brief meditation can acutely reduce migraine pain and improve related health outcomes among patients, as well as modulate laboratory pain-related brain response among healthy controls. The aim of the current study was to determine the effect of meditation on pain-related brain networks in chronic migraine, and the relationship between brain changes and improved clinical outcomes. Patients were scanned using fMRI before and after a one-time 10-day intensive Vipassana meditation retreat, as well as at 6- and 12-month follow up visits. At each visit, patients completed two fMRI runs (Siemens 3T Tim-Trio, TR=2.5s, resolution = 1.8x1.8x4mm) where they received heat stimuli (three intensity levels, two painful) on the left forearm within a block design. Patients also completed self-report assessments of average past month migraine pain intensity, pain catastrophizing, and mood states. Twenty patients with chronic migraine (16f, 41.8 ± 2.7 y/o) participated in the study, though not all participants completed all time points. Linear mixed models were used to examine changes in brain response and clinical outcomes after the meditation intervention (two time points) and lasting effects at follow up visits (omnibus model, all four time points). A significant reduction was found in migraine pain intensity (p=.05) and anxious mood (p=.006) after the intervention. These effects persisted in the omnibus models (migraine pain p=.01, anxiety p=.05). Omnibus models also revealed a marginal overall reduction in pain catastrophizing (p=.07). No changes were found in other mood states, including depression. To assess pain-related brain responses, parameter estimates were extracted from five clusters of interest defined based on response to heat pain at BL (p_{FWE}<.05). Omnibus models revealed significant reduction in pain-related activation in the right anterior insula (INS, p=.05), and marginal reductions in the right posterior INS (p=.06) and thalamus (p=.06). Pain-related reductions in these three regions was significantly correlated with reductions in anxious mood state (RaINS p<.001, RpINS p=.01, thalamus p=.007), but not with migraine pain intensity or pain catastrophizing. Our findings suggest that a one-time intensive meditation intervention may have long lasting effects on migraine pain, anxiety, and pain-related

brain networks. These results also suggest that meditation's effects on pain may be mediated by reductions in anxiety.

Title: Hypothalamic functional connectivity in ongoing pain in healthy subjects and spontaneous pain in burning mouth syndrome patients

Authors: *J. S. PAYANO SOSA[1], T. J. MEEKER[2], S. A. KHAN[3], T. F. MEILLER[4], D. SEMINOWICZ[2];
[1]Neurosci. Program, Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Neural and Pain Sci., [4]Oncology and Diagnos. Sci., [3]Univ. of Maryland Sch. of Dent., Baltimore, MD

Abstract: Burning mouth syndrome (BMS) is a chronic pain syndrome characterized by burning in the superficial oral mucosa. About 12-18% percent of postmenopausal women experience a type of BMS. While the mechanisms of BMS are unclear, several lines of evidence implicate dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis. Because the hypothalamus is known to link the endocrine and nervous systems and is involved in thermoregulation and circadian rhythm, we examined hypothalamus connectivity as a potential target for understanding BMS symptoms. We investigated resting-state fMRI functional connectivity in a homogeneous sample of 9 female (age range 40-61) peri- or post-menopausal BMS Type I patients and 9 matched healthy control subjects. Patients underwent two scanning sessions on the same day: in the morning when the burning is typically absent or minimal, and in the afternoon when the burning is usually most intense. To control for changes in functional connectivity that could be attributed to ongoing pain not specific to BMS, we included 14 healthy male and female controls (age range 23 to 61), with resting-state scans during pain-free and ongoing pain conditions. Ongoing pain was induced by applying capsaicin cream on the leg and placing a warm thermode on the site of application during the entire time of the scan. We used Conn Toolbox and SPM12 to assess seed-to-voxel connectivity with four seed regions, bilateral medial

(MH) and lateral (LH) hypothalamus. Here we focus on the connectivity of the right MH. We hypothesized that compared to healthy controls, BMS patients have increased connectivity of the MH to regions involved in thermoregulation, pain processing, and emotional circuitry. Patients had increased functional connectivity between MH and the stria terminalis, ventral striatum, midbrain, anterior (aMCC) and posterior (pMCC) midcingulate cortex, posterior insula, and orbitofrontal cortex in the afternoon scans when compared to healthy controls. The increased connectivity in the majority of these regions was explained by the presence of ongoing pain in BMS patients (i.e. determined by BMS morning vs. afternoon). In the ongoing pain healthy control group, increased aMCC overlapping with that in the BMS analyses was related to ongoing pain. We therefore showed abnormal connectivity of the MH in BMS, which was mostly explained by the presence of ongoing pain. The MH-aMCC connectivity in particular appears to be related to ongoing pain, even in the absence of a disease state.

Title: Brush allodynia susceptibility is related to baseline heat pain sensitivity, regional blood flow differences, and sensitization-induced heat allodynia and mechanical hyperalgesia

Authors: A.-C. SCHMID[1,2,3], T. J. MEEKER[1,4,3], S. ZHU[5], D. A. SEMINOWICZ[1,4,3], S. G. DORSEY[6,4,3], *J. D. GREENSPAN[1,4];

Sch., Baltimore, MD; [2]Neurosurg., Johns Hopkins Sch. of Med., Baltimore, MD; [3]Ctr. to Advance Chronic Pain Res., [4]Program in Neurosci., Univ. of Maryland, Baltimore, MD; [5]Orgnizational Systems and Adult Hlth., [6]Pain and Translational Symptom Sci., Univ. of Maryland Sch. of Nursing, Baltimore, MD

Abstract: Introduction: Brush allodynia (BA) often, but variably occurs in many chronic neuropathic pain conditions. It is not known what factors determine allodynic development in any given individual, or to what extent BA is related to hyperalgesia expression. The goal of this study was to determine 1) whether baseline pain sensitivity can predict BA susceptibility, and 2)

the extent to which a sensitizing provocation engages separate mechanisms for hyperalgesia and allodynia. Methods: 29 healthy participants (15f) between 20-43 years (27.2±7.1) were evaluated before and after exposure to a sensitizing capsaicin-heat pain model (C-HP). The model consisted of topical application of 10% capsaicin cream, accompanied by a heat stimulus for 35 minutes provoking a moderate level of pain. Sensory testing included Heat Pain Thresholds (HPT), and Mechanical Pain Ratings (MPR) of sharp probes (512mN, 256mN, 128mN, 64mN). Further we assessed BA at multiple time points after C-HP exposure. Following these sensory test sessions, a subset of subjects (N=15) participated in a replicate arterial spin label (ASL) session. Results: Half of the participants (15) developed BA within 1 hr of capsaicin-heat exposure. The BA group had a significantly lower HPT both pre- (X^2=-2.532, p=0.011) and post C-HP exposure (Z=-2.706, p=0.007); both groups had significantly reduced HPT post C-HP exposure. Additionally, mechanically evoked hyperalgesia (based on MPR) was significantly greater for the BA group post C-HP exposure, at all forces tested: 512mN (Z=-2.010, p=0.044), 256mN (Z=-2.468, p=0.014), 128mN (Z=-2.706, p=0.012), 64mN (Z=-2.171, p=0.030). This group difference in MPR was seen at all time points tested, but the HPT difference was only seen at the first post C-HP time point. The ASL results revealed that the allodynic group showed greater CBF in anterior mid-cingulate cortex (aMCC) than the non-allodynic group post C-HP. This CBF result was not related to group differences in the pain intensity evoked by C-HP exposure. Discussion: In this preliminary analysis we show that sensitization-induced brush allodynia is related to greater baseline heat pain sensitivity. Further, BA is associated with greater heat allodynia and mechanical hyperalgesia, although the time courses of these two phenomena are distinctly different, implying separate underlying mechanisms at work. Finally, the group difference in CBF suggests a particular role for aMCC in the development of BA.

Title: Superior colliculus: A role in migraine?

Authors: *D. SEMINOWICZ[1], H. JOHANI[1], S. YOO[1], R. MASRI[1], R. L. QUITON[2]; [1]Dept of Neural & Pain Sci., Univ. of Maryland, Baltimore, Baltimore, MD; [2]Univ. of Maryland, Baltimore County, Catonsville, MD

Abstract: The superior colliculus (SC) may play an important role in the pathophysiology of migraine headaches, and abnormal processing in SC may explain key features of migraine attacks such as photophobia, phonophobia and cutaneous allodynia. The intermediate and deep layers of the SC contain neurons that integrate multiple modalities of inputs (visual, auditory, and somatosensory) and project to brain areas that are abnormally active in migraineurs including PAG, medial thalamus, and PFC. Approximately 70% of inputs to deep and intermediate SC neurons arise from trigeminal afferents, many of which are activated by noxious stimuli. We aimed to show evidence of SC involvement in migraine headache onset and maintenance in humans and rodent models. We examined pain-related activity in the SC and controlled for activity in the neighboring periaqueductal gray (PAG) in 17 patients with chronic migraine and 20 matched healthy controls. Pain was evoked with a thermal stimulus on the left forearm at one of two painful heat levels with an innocuous warm stimulus as control. We also tested for abnormal functional connectivity between SC and brain structures involved in pain processing and sensory function. In rodent studies, we tested if noxious stimulation of meningeal afferents is associated with the expression of the immediate early gene, c-Fos (a marker of neuronal activation), in the SC. Heat pain consistently activated SC in patients, but not controls. PAG activity was elevated in patients compared to controls, but this was true even during nonpainful stimulation. Thus, patients had consistently higher SC activity compared to controls when controlling for PAG activity, especially on the left side. During resting state, patients had increased SC connectivity to primary sensory cortices and areas involved in nociceptive processing. In rats, noxious chemical stimulation of meningeal afferents resulted in a significant expression of c-Fos in the SC compared to controls. These results support our prediction of a role for SC in migraine. Ongoing work will test this role more specifically by comparing interictal and migraine attack states in a within-patient design and using rodent fMRI studies.

Title: Does anti-NGF reverse symptoms of chronic neuropathic pain?

Authors: ***J. T. SILVA**[1,2], B. EVANGELISTA[1], D. SEMINOWICZ[2], M. CHACUR[1];
[1]Anat., Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Univ. of Maryland Sch. of Dent., Baltimore, MD

Abstract: Introduction: Nerve growth factor (NGF) has been widely studied by the scientific community for its pro-nociceptive role in chronic pain conditions, and it is characterized as a chemical mediator responsible for the induction and maintenance of these pathologies. Chronic neuropathic pain is characterized by spontaneous burning pain accompanied by allodynia and hyperalgesia. Anti-NGF drugs have been used to reduce these symptoms in cancer pain, irritable bowel pain and osteoarthritis in both animals and human models. However, in chronic neuropathic pain its multiple actions are not fully understood.Methods: Male Wistar rats (200-220g, 2 months old) underwent induction of neuropathic pain by chronic constriction injury of the sciatic nerve (CCI). Control groups included sham-operated animals (Sham), which underwent the same incision, but without nerve ligation, and Naive animals, which underwent no surgical procedures. We performed Western blot to detect NGF in the sensory ganglia (DRG L4-6) of CCI, Sham and Naive animals. In addition, anti-NGF was injected (1 and 3ug, ipl.) in the hindpaw 14 days after surgery and a dose-response curve was performed. Sensory testing included mechanical nociceptive thresholds, thermal hyperalgesia and cold allodynia.Results: We observed an increase in NGF synthesis in the CCI group compared with the control groups. The CCI animals demonstrated a reduction of the nociceptive threshold and increased thermal hyperalgesia and cold allodynia compared to control groups. After pharmacological treatment with anti-NGF (CCI + anti-NGF), we observed a reduction of hyperalgesia and allodynia in these animals.Conclusions: Our results suggest that NGF is an important factor in the induction and maintenance of neuropathic pain, since increased NGF levels were observed in the DRG after injury. We also demonstrated the relevance of this mediator as a therapeutic target, since anti-NGF was able to reverse the often difficult to treat symptoms of this pathology. Studies for the characterization of anti-NGF as well as magnetic resonance imaging are underway to further elucidate these findings.

Title: Functional alterations in resting state connectivity in rat pups following postnatal morphine exposure

Authors: D. BAJIC, M. M. CRAIG, D. BORSOOK, *L. BECERRA;
P.A.I.N. Group, Boston Children's Hosp., Waltham, MA

Abstract: Our previous preliminary work described spontaneous, intrinsic brain activity in the absence of any stimulation as system-wide, resting state networks in the developing rat brain under light inhalational anesthesia. Whether patterns of resting state activity are affected by prolonged morphine administration in a developing rat model is unknown. Therefore, we used functional MRI and independent component analysis to map patterns of resting-state activity in 2-week old rat pups following either morphine or saline twice-daily injections for two weeks since postnatal day 1 (N=12/group). A total of 11 networks were identified, 6 of which displayed significant differences in connectivity between treatment groups. Morphine treated rats showed increased connectivity in the Default Mode Network, Basal Ganglia-Hypothalamic Network, Sensory (Exteroceptive) Network, Interoceptive Network, Auditory network, and Hippocampal Network. In contrast, morphine treated rats showed decreased connectivity in three of these networks: Basal Ganglia-Hypothalamic Network, Sensory (Exteroceptive) Network, and Auditory Network. Presented results suggest that resting-state networks driven by spontaneous BOLD signal fluctuations under light anesthesia are not only present in the developing rat brain at 2 weeks of age, but are also affected by prolonged morphine administration.

Title: Resting state networks in the infant rat brain under light isoflurane anesthesia

Authors: *D. BAJIC, M. M. CRAIG, D. BORSOOK, L. BECERRA;
Dept Anesthesiol., Boston Children's Hosp., Boston, MA

Abstract: Resting state functional magnetic resonance imaging (fMRI) measures fluctuations in blood oxygenation level-dependent (BOLD) signal in the absence of stimuli and has become a powerful tool for mapping large scale brain networks in humans and animal models. Several fMRI studies have been conducted in anesthetized and awake adult rats, reporting an apparent similarity between the identified patterns of activity at the systems levels. The consistency of these resting-state networks, however, has not yet been evaluated and quantified in the developing rat brain. In this study, we used independent component analysis (ICA) to identify brain networks in lightly anesthetized 2-week old infant rats (N=11). An adult rat brain template from our lab (Becerra et al. Neuroimage 2011) was used for registration, comparison, and identification of infant rat group ICA results. The analysis identified 6 out of 7 template networks to be present in the infant rat. These include: Default mode network, Basal Ganglia-Hypothalamic, Basal Ganglia-Thalamic-Hippocampal, Autonomic, Sensory (Exteroceptive), as well as Interoceptive network. Some of these networks consisted of more than one component. Furthermore, infant rat networks appear underdeveloped, showing reduced connectivity with subcortical structures in comparison to the adult templates. ICA also revealed 5 additional components that did not correlate with our templates and include the following networks: Basal Ganglia, Hippocampal, Thalamic-Ventral Midbrain, Thalamic-Periqueductal Gray, as well as the Brainstem network. In summary, we demonstrate that (1) fMRI can be applied to study the functional connectivity of the infant rat brain at 2-weeks of age, and (2) that detected slow fluctuations in the BOLD signal correspond to functionally relevant resting-state networks.

Title: FDG-PET imaging bone pain- and morphine analgesia- related brain changes in the mice

Authors: ***W.-H. CHU**[1], W.-Y. LIN[1,2], W.-Z. SUN[2], C.-T. YEN[1];
[1]Life Sci., Natl. Taiwan Univ., Taipei City, Taiwan; [2]Anesthesiol., Natl. Taiwan Univ. Hosp., Taipei City, Taiwan

Abstract: Metastatic cancer-induced bone pain (CIBP) is one of the most devastated symptoms throughout end-stage life. Bone metastasis is associated with unbearable pain, both in rest and during movement, which would lead to eventual disability and miserable quality of life. Morphine is the standard drug of choice in CIBP. However, the question whether morphine relieves CIBP through modulating neuropathic and nociceptive pain components is not well elucidated. In this study, we investigated morphine-induced effect on CIBP mice brain by 18F-fluorodeoxyglucose (FDG) positron emission tomography-computed tomography (PET/CT). We injected 4T1 mouse breast cancer cells into left femur bone marrow cavity of the BALB/c mice. Mice in control group were injected with phosphate buffered saline. Neuropathic pain behaviors, i.e. von Frey filaments and cold acetone, were measured on the day before surgery, Day 7, Day 10 and Day 14 after the surgery. Morphine doses (10, 15, 30 mg/kg, i.p.) were treated on Day 16 after the surgery. Behaviorally, 15 mg/kg morphine was sufficient to relieve mechanical and cold allodynia of the CIBP mice between 30 to 90 minutes post-treatment. In the PET imaging study, each mouse was scanned 3 times: before bone surgery, Day 14, and Day 16 after the surgery at 30 min after the 15 mg/kg morphine treatment. We found that glucose metabolic activity significantly increased in contralateral insula and bilateral primary somatosensory cortex (S1), primary motor cortex (M1), secondary motor cortex (M2), and hypothalamus; while decreased in anterior cingulate cortex (ACC), nucleus accumbens (NAc), striatum, ventral posterior nucleus (VP), periaqueductal gray (PAG) in CIBP, as compared to pre-surgery condition. In particular, morphine reversed the brain metabolic activity of bilateral M1, M2, ACC, PAG, contralateral insular cortex, S1, and VP; increased habenular nucleus (Hb) and interpeduncular nucleus (IPN) activity. Our data suggest that several brain regions are involved in the cancer-induced bone pain, and morphine analgesia may be produced by reversing most changes of the CIBP mice brain.

Title: Aberrant processing of pain in autism spectrum disorder: FMRI evidence for immediate suppression of pain networks in ASD

Authors: *M. D. FAILLA[1], E. J. MOANA-FILHO[2], G. K. ESSICK[3], C. J. CASCIO[1]; [1]Psychiatry, Vanderbilt Univ., Nashville, TN; [2]Sch. of Dent., Univ. of Minnesota, Minneapolis, MN; [3]Sch. of Dent., Univ. of North Carolina, Chapel Hill, NC

Abstract: Individuals with autism spectrum disorders (ASD) exhibit aberrant behavioral responses to noxious stimulation compared to neurotypical controls, yet little is known regarding mechanisms of sensory processing in ASD. Thus, we investigated neural patterns of pain processing in ASD by applying a noxious heat stimulus (49°C) to the right calf during functional MRI. Subjects included 17 adults with ASD and 16 neurotypical controls. ADOS and ADI-R were administered to confirm ASD diagnosis and to estimate symptom severity. Sensory processing in daily life was assessed with the Sensory Profile Questionnaire. Blood oxygenation level-dependent (BOLD) signal in response to noxious heat was assessed with a whole brain and region of interest (ROI) approach. ROIs related to pain processing were selected based on previous literature: 5 mm spheres were created surrounding the peak voxel within the left primary somatosensory cortex (SI), left secondary somatosensory cortex (SII), and the left insular cortex in the control group. Mean activation was calculated for all voxels within the ROI. There were no differences in calf heat pain thresholds between the two groups ($p=0.551$). In whole brain analysis, individuals with ASD had hypoactivation in response to noxious heat, with controls exhibiting greater activation in cerebellum, thalamus, left putamen, left insula, and left premotor cortex compared to those with ASD. In ROI analysis, the ASD group had significantly less mean activation in the left SI ($p=0.047$), SII ($p=0.004$) and insula ($p=0.002$) ROIs. Additionally, BOLD response time series also differed between groups. The time course of BOLD responses in controls exhibited sustained activation during stimulus presentation, yet individuals with ASD had an early peak followed by an immediate undershoot. This pattern was consistent within left SI, left SII, and left insula ROIs. Left insula mean activation during noxious heat correlated with calf heat pain threshold ($r=0.39$, $p=0.04$) across groups. Mean activation in S1 correlated with restricted and repetitive behaviors (RRB) as measured on the ADOS ($r=-0.54$, $p=0.04$). A negative correlation between SI activation and RRB fits with

hypotheses that RRB may be a compensatory behavior for sensory hypo-responsiveness in ASD. Importantly, activation patterns of an immediate peak followed by possible active suppression in areas involved in pain processing may indicate suppression of pain networks immediately following onset of a painful stimulus in ASD. Future studies are needed to characterize pain processing in ASD, including neural networks for pain and general sensory salience, as they relate to behavioral symptoms.

Title: Autonomic pain responses during an empathic and non-empathic context: a study of heart rate variability

Authors: C. FAUCHON[1], I. FAILLENOT[1], F. CHOUCHOU[1], C. BORG[2], A.-M. PERRIN[3], *R. PEYRON[4,1];
[1]NeuroPain - Central Integration of Pain in Humans Lyon Neurosci. Res. Ctr. - Inserm U1028 - CNRS UMR 5292, Lyon & Saint-Etienne, France; [2]Univ. Lyon 2, Lab. EMC (EA3082), 69676 Bron, Lyon & Saint-Etienne, France; [3]Pain Center, CHU, F- 42055 Saint-Etienne, France, saint-Etienne, France; [4]Hosp. Nord, Saint-Etienne Cedex 2, France

Abstract: The autonomic nervous system (ANS) reacts to nociceptive stimulation and also to emotional events, which produce electroencephalographic (EEG) activation and concomitant changes of physiologic parameters under autonomic control such as RR intervals (RR). Empathy has been widely studied as a physiological phenomenon, and it's intuitively acceptable that other people can have a significant impact on one's pain. However, the mirror situation of how I receive empathic feedback from others and how I modulate the pain I am confronted to is still unexplored. Here we studied whether empathy or non-empathy of an observer can modulate subjective pain ratings, ANS responses to pain and whether one of the autonomic arms

(sympathetic/ parasympathetic) predominates. To this aim, we built experimental scenarios in which volunteers could hear comments from the observers on their ongoing pain made of hot stimulations delivered on the left hand via a heat thermode. Professional actors were recorded while playing roles of experimenters observing a subject. Some of them were empathic while others were non-empathic. Subjects received 90 stimulations at a constant temperature. They were asked to score their pain with a continuous online rating from 0 to 100 (VAS). We assessed ANS reactivity to nociceptive stimulation during the entire experiment through heart rate variability monitoring and correlated the results with the presence of empathic or non-empathic allegations. Autonomic parameters (LF, HF and LF/HF ratio) were obtained by spectral analysis. The experiment was conducted in 30 volunteers. We found that pain ratings was significantly attenuated (-12%) during empathic as compared to non-empathic conditions and this was also significant individually in 16/26 (61,5%) volunteers. Nociceptive-induced RR decrease was present whatever the conditions, mainly related to a sympathetic reactivity, which was significantly more important in non-empathic as compared to the empathic condition. In addition, RR was significantly decreased during non-empathic dialogues as compared to a baseline condition (=absence of pain and audio stimuli). To conclude, these results showed that for a constant painful stimulation, empathic and non-empathic contexts can influence significantly both pain ratings (VAS) and autonomic cardiac reactivity (RR and ratio LF/HF). Future investigations will help to clarify the neural nature of these pain modulations and their relationship with autonomic cardiac reactivity.

Title: Intrinsic functional connectivity of the periaqueductal gray (PAG) is related to fibromyalgia clinical symptoms

Authors: *M.-A. COULOMBE[1], K. ST. LAWRENCE[2,3], D. E. MOULIN[3], P. MORLEY-FORSTER[3], M. SHOKOUHI[2,3], W. R. NIELSON[2,3], Y. BUREAU[2,3], K. D. DAVIS[1,4]; [1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Lawson Hlth. Res. Inst., London, ON, Canada; [3]Western Univ., London, ON, Canada; [4]Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction: Fibromyalgia syndrome (FMS) is characterized by chronic widespread pain, muscle tenderness, and distressful symptoms such as fatigue, sleep disturbances, anxiety and depression. Previous studies have found deficient endogenous pain modulation in FMS and suggested that this is linked to clinical symptoms. The periaqueductal gray (PAG) is a central node of the descending pain modulation pathway. In addition to its implication in pain and analgesia, this region is also involved in emotional and behavioral aversive responses (anxiety, fear, defensive reaction). In this study of FMS, we investigated 1) resting state functional connectivity (FC) of the PAG, 2) the relationship between PAG FC and FMS clinical symptoms, and 3) how FC of the default mode and salience networks (DMN, SN) relates to FMS clinical symptoms. Methods: Resting state 3T fMRI scans were acquired from 23 female FMS patients and 16 age- and sex- matched healthy controls (HC) after obtaining informed consent. FMS symptoms were assessed using the brief pain inventory (BPI), fibromyalgia impact questionnaire (FIQ), hospital anxiety and depression Scale (HADS), and pain catastrophizing scale (PCS). Seed-to-voxels analyses were performed using FMRIB's FEAT higher level cluster analysis ($z > 2.3$, $p > 0.05$). FC of PAG, DMN and SN were analysed in relation to clinical symptoms. Results: 1) Compared to healthy controls, the FMS group had greater PAG FC with the left lingual gyrus and left hippocampus, but decreased PAG FC with regions associated with motor and executive function as well as the SN and DMN (premotor and prefrontal cortex, temporoparietal junction, posterior cingulate cortex). 2) PAG FC in the FMS group with the PMC and dlPFC was negatively correlated with FIQ scores, and PAG FC with the PFC was correlated with the magnification subscale of the PCS. 3) Intra-network FC of the DMN and SN in the FMS group was similar with only subtle differences compared to healthy controls. 4) FMS subjects had disrupted FC between medial PFC and PMC. This decreased FC was negatively correlated with the global distress and anxiety components of the HADS. Conclusion: Patients with FMS exhibit significant disruptions in PAG FC, particularly with brain regions implicated in distress, threat-induced negative affect, self-awareness and saliency. These abnormalities were correlated with emotional and behavioral symptoms. This study thus implicates the PAG in FMS symptomatology.

Title: Influence of medication value on the nocebo effect and its mechanism assessed by cortico-spinal imaging

Authors: *A. TINNERMANN[1], S. GEUTER[2], C. SPRENGER[1], J. FINSTERBUSCH[1], C. BÜCHEL[1];
[1]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Inst. of Cognitive Sci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Background and aims The nocebo effect in pain research is characterized by an increase in pain perception after the administration of an inert treatment. In this study, we investigated the influence of a medication's price (cheap vs. expensive) on the magnitude of the nocebo response and the underlying modulation of the cortico-spinal pain network. Methods 52 subjects (25 females) underwent a heat pain stimulation protocol using a thermode on the left volar forearm while BOLD responses in the brain and spinal cord were recorded using functional MRI. The nocebo treatment was introduced as a medical cream that increases pain sensitivity as a negative side effect and was compared to a control cream. Subjects were randomly assigned to one of two groups, one receiving the cheap medical cream whereas the other group was tested with the expensive cream. One day before scanning and directly before scanning, subjects underwent a conditioning procedure which simulated the higher pain sensitivity (i.e. side effects of the cream) through a higher temperature. In the fMRI test phase, subjects received 36 identical heat stimuli (18 control/18 nocebo) with a duration of 20 seconds each and individual pain ratings were recorded after every trial. Additionally, physiological noise (pulse, respiration) was recorded during scanning. Results Pain ratings in the nocebo condition were significantly higher ($t = 3.11$, $p<0.01$) compared to the control condition. The interaction between the cheap and the expensive nocebo cream was significant ($t = -2.6$, $p<0.05$), indicating that the nocebo effect was increased in the expensive condition whereas in the cheap condition, the nocebo effect was mostly absent. Neural correlates of the nocebo effect were found in the left insula, the striatum and bilateral hippocampus. The comparison of the expensive and the cheap nocebo group revealed increased activations in the left insula, left anterior cingulate cortex and bilateral hippocampus. Conclusions This study shows that medication value modulates brain activity in the pain network. More specifically, an expensive medication can increase pain perception and lead to a greater nocebo effect in humans. These results indicate that an expensive medication elicits stronger side effects than a cheap medication.

Title: Identifying chronic pain biomarkers using EEG informed fMRI analysis on sickle cell disease patients during wakeful rest

Authors: ***M. CASE**[1], C. H. ZHANG[1], Y. DATTA[1], S. C. NELSON[2], K. GUPTA[1], B. HE[1]; [1]Univ. of Minnesota, Minneapolis, MN; [2]Children's Hosp. and Clinics of Minnesota, Minneapolis, MN

Abstract: Sickle cell disease (SCD) is the most common inherited disorder characterized by sickling of red blood cells (RBCs) under low oxygen, leading to impaired oxygenation, organ damage and pain. As compared to other pain conditions, sickle pain is unique because it can start in infancy and continue to increase throughout life, and can be accompanied by frequent episodes of acute pain due to vasoocclusive crises caused by occlusion of venules by sickled RBCs. Pain treatment remains challenging because of the use of opioids as most common therapy. Patients often remain under-treated due to the fear of opioid addiction, partly due to the lack of an objective pain measurement system. Therefore, an unbiased imaging method to quantify pain is needed to help treat pain in SCD and other disorders. The goal of this study is to discover chronic pain biomarkers using non-invasive imaging methods. Eight SCD patients and five healthy controls were recruited and all subjects gave written informed consent. All experimental methods were approved by the IRB of the University of Minnesota. Functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) were simultaneously recorded while the subjects were in a wakeful resting state. EEG informed fMRI (EEG-fMRI) analysis using spontaneous power fluctuations and microstates was performed. A general linear model was used to calculate statistical activation maps from the EEG-fMRI analysis. Both power and microstate methods reflected that the healthy controls had default mode network (DMN) activity. DMN is active during the lack of a task and is one of the main resting state networks of

the brain. The alpha band was negatively correlated with DMN activity in healthy controls. SCD patients had reduced DMN activity compared to healthy controls; this was observed in both power and microstate results ($p<0.001$, uncorrected). The best activation of DMN negatively correlated with beta band for SCD patients. The results of this study suggest that DMN activity is a candidate for being a chronic pain biomarker and that EEG analysis can reflect DMN activity. An objective pain quantification method will be valuable for treating chronic pain objectively to maximize treatment outcomes and developing new analgesics. This work was supported in part by NIH grant U01-HL117664 and NSF IGERT grant DGE-1069104.

Title: Abnormalities in brainstem descending inhibitory structures could explain the deficient conditioned pain modulation commonly observed in fibromyalgia patients

Authors: *D. E. HARPER[1], E. ICHESCO[1], J. P. HAMPSON[1], D. J. CLAUW[1], T. SCHMIDT-WILCKE[2], R. E. HARRIS[1], S. E. HARTE[1];
[1]Chronic Pain & Fatigue Res. Ctr., Univ. of Michigan, Ann Arbor, MI; [2]Neurosci., Ruhr Univ. Bochum, Bochum, Germany

Abstract: Fibromyalgia (FM) is a chronic widespread pain disorder characterized by muscle tenderness, fatigue, poor sleep, and mood disturbance. Quantitative sensory testing has also identified deficient conditioned pain modulation (CPM) in this population. The present study used a combination of behavioral CPM testing with noxious pressure stimulation, voxel based morphometry (VBM), and resting state seed based functional connectivity (fcMRI) to identify structural and functional differences associated with CPM between FM patients (n=14) and age- and sex-matched healthy controls (HC, n=15). We performed a whole-brain VBM analysis using diffeomorphic anatomical registration through exponentiated lie algebra (DARTEL), and resting

state connectivity analysis with the functional connectivity toolbox (v13; nitric.org/projects/conn), both in Statistical Parametric Mapping 8. Neuroimaging results were deemed significant at FWE p<.05 cluster-level corrected derived from a voxel-level threshold of p<.001. We observed significantly less gray matter volume in the periaqueductal gray (PAG) of FM patients [p<.001; small volume corrected] as compared to controls. This region was then used as a seed to determine whether the groups displayed different resting state fcMRI between this region and the rest of the brain. The degree of connectivity between the PAG seed and more caudal areas of the brainstem, including the locus coeruleus, was found to be significantly correlated with CPM magnitude in HCs [r=-.892, p=.007 FWE], with greater connectivity being related to more efficient CPM. In contrast, there was no significant relationship between PAG connectivity and CPM in FM patients, who as a group had significantly deficient CPM compared to controls [t(24)=-2.21,p=.037]. In summary, these results add to the growing literature on CPM deficiencies in FM, and they suggest that potential reasons for this abnormal endogenous pain modulation might be decreased gray matter volume in the antinociceptive PAG and altered connectivity of this structure to other descending pain modulatory regions.

Title: Decoding pain from multimodal sensory stimuli in EEG

Authors: J. M. LANCASTER[1], H. MANO[2,1,3], D. CALLAN[2], *B. SEYMOUR[3,2,1];
[1]Advanced Telecommunications Res. Inst. Intl. (ATR), Kyoto, Japan; [2]Ctr. for Information and Neural Networks, Natl. Inst. for Information and Communications Technol. (NICT), Osaka, Japan; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Across neuroscience research, clinical diagnostics, and engineering applications in pain characterization and treatment, there is a desire for an objective measure of pain experience and detection when it occurs. This detector should be reliable across subjects in real-world settings using easily accessible, non-invasive data sources. We present a simple yet robust paradigm for decoding pain using neural and physiological data including electroencephalography (EEG), pulse, and skin conductance (GSR) measurements. The present study uses multivariate classification to distinguish painful events from non-painful multimodal sensory stimuli. In our experiment, pain was induced by cold stimulation which became noxious with prolonged exposure. Due to the long, ramp-and-hold nature of the stimulus, along with individual variability in sensitivity to pain, we suspected a lack of common time-locked events across participants. However, this format more closely resembles the experience of tonic pain conditions requiring intervention, which could be facilitated by the response of a decoding system. To classify the pain response and detect relevant data attributes, we employed a sparse logistic regression (SLR) machine learning protocol with automatic feature selection. EEG and physiological data is preprocessed and decomposed using independent component analysis (ICA). SLR is iterated using different high-performing feature vectors, including time series data in independent component space and power-frequency representations for each of the characteristic EEG activity bands. Classification performance exceeded 85% accuracy and selected between 5 and 15 features. These techniques allow us to address basic science questions by indicating which data characteristics most reliably identify pain events. Refining this approach will lead to the ability to objectively decode, detect, and quantify pain experience, as well as giving insight to important temporal, spectral, and spatial EEG events and physiological indicators of pain states. Success of a classifier protocol using these parameters should lead to the creation of a closed-loop system for decoding and intervention which can be applied in engineering and medical contexts.

Title: Fluctuations of pelvic pain intensity in men with urologic chronic pelvic pain syndrome (UCPPS) are modulated with successful treatment

Authors: *M. A. FARMER[1], D. DAVIS[2], A. J. SCHAEFFER[3], A. APKARIAN[4];
[1]Physiol., [2]Feinberg Sch. of Med., [3]Feinberg Sch. of Medicine, Dept. of Urology, [4]Feinberg Sch. of Medicine, Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The pain experience of men with urologic chronic pelvic pain syndrome (UCPPS) remains poorly characterized. Whereas UCPPS severity has traditionally been assessed with a numeric rating scale, recent investigations have revealed that pelvic pain may manifest in one or more locations, each of which exhibit unique qualitative, spatial, and temporal qualities during basal conditions and periods of exacerbated pain (pain "flares"). As part of an ongoing double-blind randomized controlled trial to evaluate the impact of d-Cycloserine versus placebo on male pelvic pain, men were asked to rate their pelvic pain three times per day using a custom-developed smartphone application. The objectives of this report were to a) evaluate the spatial, qualitative, and time-varying properties of male pelvic pain prior to treatment; b) determine the impact of treatment response on pain properties; and c) investigate the interactions between pain intensity, urinary symptom severity, and mood over time. Men diagnosed with chronic prostatitis/CPPS and/or interstitial cystitis/bladder pain syndrome with moderate (>4/10) baseline pain intensity who met inclusion/exclusion criteria were consented and enrolled. Subject-wise daily pain intensity ratings (0-10 NRS) were extracted from the 3 week run-in period to characterize temporal variability and compared to rating vectors at 2, 3, and 4 months. Participants who exhibited a reduction > 20% from mean baseline intensity were classified as "treatment responders" and may include men taking d-Cycloserine or placebo (blind not broken during ongoing trial). Results indicate that men were > 90% compliant in providing three daily ratings; most men reported pain ≥ 2 locations, including testicles, perineum, urethra, bladder, prostate, anus, pelvic floor muscle, and nonspecific diffuse pelvic pain. At baseline, men bifurcated into two groups based on temporal properties of pain: a) a high pain variability group (with short periods of low or no pain) and b) a low pain variability group (stable mean pain intensity, pain always present). Following treatment these groups were conserved, yet treatment responders exhibited significant reduction in pain variability. Furthermore, pain reduction in treatment responders was evident across multiple sites of pain. These findings constitute the first longitudinal characterization of male pelvic pain intensity and establish that temporal variability

is a critical (and infrequently assessed) property of pelvic pain that is impacted by successful treatment of UCPPS. Future analyses will determine whether d-Cycloserine or placebo treatments differentially impact pain fluctuations.

Title: Non-invasive exploration of neurovascular coupling following acute noxious stimulation in the human term neonate

Authors: ***M. VERRIOTIS**[1], L. FABRIZI[1], A. LEE[1], S. LEDWIDGE[1], J. MEEK[2], M. FITZGERALD[1];
[1]Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom; [2]Elizabeth Garrett Anderson Obstetric Wing, Univ. Col. London Hosp., London, United Kingdom

Abstract: Aim: To explore the coupling between nociceptive electrophysiological and haemodynamic responses in the human infant brain. Background: Previous electroencephalography (EEG) studies [1] have demonstrated a specific pattern of cortical activity in term infants following noxious heel lance, and previous near-infrared spectroscopy (NIRS) studies [2] have shown a clear increase in total haemoglobin concentration following this stimulus. Here we have explored the relationship between these haemodynamic and electrophysiological responses using combined EEG and NIRS recordings in term neonates. Methods: Participants were 17 healthy term-born infants (8 females) studied at 0-13 days of age. Informed written parental consent was obtained prior to each study. The noxious stimulus was a clinically required routine heel lance. Brain activity was recorded with EEG electrodes placed according to the international 10:20 system and with a single NIRS emitter-detector pair centred over the primary somatosensory cortex (at C1 or C2, whichever was contralateral to the stimulation site). Ethical approval for this study was given by the UCLH ethics committee.

Results: It was possible to record artefact-free NIRS and EEG traces in most infants. Significant increases in oxyhaemoglobin concentration ([HbO2]) were observed in response to heel lance. EEG responses measured concurrently at the vertex (Cz) consisted of two waveforms, corresponding to the early sensory waveform and the later nociceptive specific waveform identified in previous work [1]. Of the 14 trials where both recordings were available, the EEG nociceptive specific waveform and NIRS HbO2 response were coupled in 9 cases (n=6, present in both; n=3 not present in both). In these trials there was a significant positive correlation between NIRS and EEG responses. By contrast, the EEG non-nociceptive specific waveform was coupled with the NIRS HbO2 response in only 5 of the 14 trials. Conclusion: Increases in oxyhaemoglobin concentration in the contralateral somatosensory cortex were more likely to be coupled with the nociceptive specific than with the non-nociceptive specific component of the electrophysiological response to tissue-breaking heel lances in term neonates. Title: Hippocampal volume is associated with placebo propensity in a blinded randomized clinical trial with chronic low back pain patients

Authors: *S. E. BERGER, E. VACHON-PRESSEAU, D. A. DAVIS, K. B. ZOSZAK, T. J. SCHNITZER, A. V. APKARIAN;
Dept. of Physiol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: The placebo effect describes an improvement in symptoms caused by receiving an inert treatment disguised as an active treatment. It is a phenomenon rooted in underlying and identifiable neurobiology while simultaneously affected by psychological and social factors, and

it has been observed across a variety of systems, treatments, and conditions, including pain. The bulk of studies on placebo analgesia have been conducted in healthy, pain-free participants over a short period of time with acute stimuli. Thus, whether the placebo response differs in chronic pain populations and the extent to which is it repeatable and predictable remains unknown. The present research is part of a longitudinal trial investigating placebo propensity in individuals with chronic low back pain (CBP). The study lasted 8 weeks and had 6 visits, 4 with functional and structural magnetic resonance imaging. After a 2-week baseline monitoring period, participants were scanned and randomized into either a no-treatment (n=4) or treatment (placebo, n=20) group. There were two 14 day treatment sessions, each followed by a 1-week washout period to assess reliability and length of response. Behavioral measurements via questionnaires were collected at each visit, and pain and mood were monitored twice daily on a VAS scale using a smart phone app provided to participants for the study duration. Placebo response was defined as a 20% decrease in pain from baseline for at least 1 of the 2 treatment periods; using this criteria, n = 11 were classified as non-responders and n = 9 as responders. Responders experienced a decrease in reported pain ($p<0.001$) and a corresponding increase in reported mood ($p<0.05$) compared to non-responders, whose ratings were indistinguishable from those in no-treatment. Intriguingly, responders demonstrated a recall bias, remembering greater pain intensity than was reflected in their daily pain ratings ($p<0.05$), a finding not seen in non-responders. Subcortical structures were segmented for all participants at scan 1 (pre-treatment) and hippocampal volume was compared between groups; responders had a smaller left hippocampus than non-responders ($p =0.056$), with an AUC = 0.76. These initial results indicate that placebo response can be captured behaviorally in CBP and that hippocampal volume may be associated with propensity to respond to placebo in this patient population. This study is still active and expected to be completed by October 2015; thus by the conference, our sample size will greatly increase (no treatment, n = 20; treatment, n = 44) and additional analyses and results will be reported.

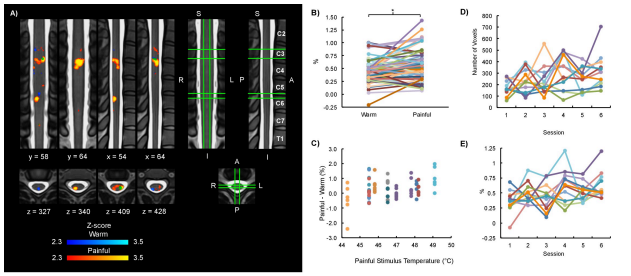
Title: Functional magnetic resonance imaging of the spinal cord during thermal stimulation

Authors: *K. A. WEBER, Y. CHEN, X. WANG, T. KAHNT, T. B. PARRISH;
Northwestern Univ., Chicago, IL

Abstract: Introduction Recent advancements have increased the potential use of fMRI to study neural processing in the spinal cord (SC). The purpose of this study was to expand on earlier work and demonstrate the feasibility of using fMRI to detect SC activity during thermal stimulation. Methods Twelve subjects were recruited. The cervical SC was imaged with a T2*-weighted sequence using ZOOMit selective field-of-view imaging on a 3T Siemens Prisma scanner (TR=2500 ms, TE=30 ms, resolution 1x1x3 mm^3) during thermal stimulation. For each session, 10 warm (43°C) and 10 painful (temperature producing 65/100 pain) 7.5 s thermal stimuli were applied to the right ventral forearm over 400 s, and each subject completed 6 sessions. The images were preprocessed, and statistical parametric maps were generated with the task vectors as explanatory variables and physiological noise vectors as covariates of no interest.[1,2] A fixed effects analysis was performed to generate average subject level activity maps. Spatial normalization was performed,[3] and average group activity maps were generated in a mixed-effects analysis. Results The extent of the activity exceeded that of a control analysis. Significant group activity was present for both the warm and painful stimuli (A). The signal change was greater for the painful stimulus than the warm stimulus and correlated to the painful stimulus temperature (B-C). The number of active voxels and signal change increased across the sessions for the painful stimulus, possibly due to sensitization (D-E). A trial-wise multi-voxel pattern analysis successfully classified the warm and painful stimuli based on activity patterns in the entire SC ($p<0.05$) and at the C3 level ($p<0.01$). Conclusions Both stimuli resulted in activity at the group and single-subject level. The activity was anatomically specific, and the signal change was proportional to the stimulus temperature. Moreover, SC fMRI may even have utility in studying phenomena such as sensitization. 1. Woolrich, MW. NeuroImage 14, 1370-1386, 2001 2. Brooks, JC. NeuroImage 39, 680-692, 2008 3. Cohen-Adad, J. OHBM 2014



A) Group average activity maps resulting from the warm (blue-light blue) and painful (red-yellow) thermal stimuli are shown. For the warm stimulus, the activity was more localized to the posterior hemicord, while the painful stimulus resulted in activity that extended across the anterior and posterior hemicords. The average activity maps were thresholded at a Z-score>2.3, which corresponds to a p<0.01 (uncorrected). The location of the sagittal, coronal, and axial slices on the standard spinal cord template with the corresponding vertebrae labeled is shown. B) The average signal change at the intersection of the subject level average activity maps for the warm and painful stimuli was calculated for each session. The percent signal change±1 standard deviation for the warm and painful stimuli was 0.44%±0.22% and 0.55%±0.29%, respectively. The painful stimulus resulted in a significantly greater signal change than the warm stimulus (paired two-tailed t-test, $t_5>0.001$). C) The signal change for the painful stimulus when baseline corrected for the warm stimulus signal change was significantly correlated to the painful stimulus temperature (Spearman's Rho=0.625, p<0.05). D-E) The total number of active voxels for each subject and the average signal change of the active voxels across the six sessions is shown for the painful stimulus. The number of active voxels and the average signal change significantly increased across the sessions for the painful stimulus, while no increase was present for the warm stimulus (repeated measures ANOVA, $p<0.01$ and $p<0.05$ for D and E, respectively). The increase in the number of active voxels and the average signal change may be due to peripheral or central sensitization from the repeated painful stimuli.

Title: Decreased functional brain connectivity during itch compared to pain

Authors: *R. RINGLER[1], M. RANK[2], V. VIEROW[2], K. DETMAR[3], R. LOOSE[3], C. FORSTER[2];
[1]Univ. of Technol. Amberg-Weiden, Weiden, Germany; [2]Inst. of Physiol., Univ. of Erlangen-Nuremberg, Erlangen, Germany; [3]Dept. of Radiology, Clin. Ctr. of Nuremberg, Nuremberg, Germany

Abstract: Histamine is well known as the prototypical itch mediator. If a smaller number of primary afferents fibers are activated by histamine stimuli the sensation is described as itch whereas activation of larger populations of afferent fibers activates the pain system. The aim of this study was to identify the cerebral networks with the help of functional imaging (fMRI). Since we expected a quite similar network during itch and pain stimuli the functional connectivity's within these networks were explored and compared. 18 healthy subjects were included in the study. They participated on two separated psychophysical pre-examination where pain and itch rating were recorded. Itch was applied by iontophoresis of histamine into the skin of the volar forearm. The recording started when the itch intensity passes 30% of the visual analogue scale (VAS, 0: no itch; 30: desire to scratch; 100: maximal conceivable itch). For pain the skin of the forearm was pretreated by topical application of capsaicin (0,05% for 30 minutes). Then two heat stimuli each 3 min with 5 minute break in between were applied to this site. This lead to a thermal hyperalgesia and heat pain could be induced by temperatures of less than 50 degree Celsius. The individual intensity was 1 degree above the pain threshold. Recording started when the pain passes 30% of the VAS. In two fMRI session itch and pain was assessed using a classical connectivity fMRI-design with EPI sequences on a 1.5 T Siemens Espree. The first run was without stimuli to detect the subject default mode network. During the second fMRI sequence the stimulus (itch or pain) was applied. The itching or painful sensation lasted during the whole fMRI. No earlier than 2 weeks the experiment was repeated with the other stimulus. Predefined anatomical regions (ROI) were used and the mean MRI time courses in these regions were extracted for each subject. These signals were z-transformed and Pearson's correlation coefficients (r) were calculated between the ROI for the periods baseline (B), itch (I) or pain (P) respectively. Nearly all connectivity values were higher during (P) than during (I). The highest r

values were found between S1 and S2 (BA 40) on both hemispheres (r>0.8, p0.6, p<0.00) between the areas insular cortex, anterior cingular cortex, amygdala for the painful stimuli. These findings support the “special contrast theory of itch” which assumes that itch could be induced by a focal but selective activation of a view sparsely distributed neurons innervating the skin. In contrast to that pain activates a larger population of skin afferents leading to a higher activity also in the CNS which facilitate synchronous activity between the affected brain regions.

Title: Individual differences in temporal summation of pain reflect pro- and anti-nociceptive brain structure and function

Authors: *J. CHENG[1,2], N. ERPELDING[1], A. KUCYI[1,2], D. D. DESOUZA[1,2], K. D. DAVIS[1,3,2];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Inst. of Med. Sci., [3]Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada

Abstract: Introduction: Temporal summation of pain (TSP) is the perception of increasing pain evoked by repetitive noxious stimuli, and is highly variable between individuals. Individuals with facilitated pain processing and/or reduced pain-modulatory capabilities are characterized as pro-nociceptive, whereas individuals with reduced pain processing and/or facilitated pain-modulatory capacity are considered anti-nociceptive. Here, we tested the hypothesis that pro-nociceptive individuals have enhanced TSP compared to anti-nociceptive individuals, marked by facilitated ascending nociceptive processing and/or reduced capacity for descending pain modulation. **Methods**: 80 healthy subjects were tested with a TSP protocol as follows: 10 consecutive thermal stimuli were delivered to the left volar forearm at 0.5Hz, to a target temperature of 48°C at 10°C/s from a 32°C base. During each interstimulus interval (40°C) subjects rated pain from 0-100 (0 = no pain, 100 = worst pain imaginable). Subjects also underwent 3T imaging to collect a high resolution structural scan and a 5-min resting state fMRI

scan to measure functional connectivity (FC). Ascending nociceptive FC was determined between seeds in the right sensory thalamus and Brodmann Area 3a (thal-BA 3a), and correlated against TSP (significance: $P < 0.05$). In the descending pain-modulation system, a seed-to-voxel analysis (FSL's FEAT) with TSP as a regressor was performed between a seed in the RVM and a mask including the subgenual ACC (sgACC) (FWE-corrected $Z > 2.3$, cluster-based $P < 0.05$). **Results:** There were large inter-individual differences in TSP responses (% change from first to peak pain rating). Individual subject TSP was positively correlated with their thal-BA 3a FC, and with cortical thickness in the right insula and medial prefrontal cortex. In contrast, individual subject TSP was negatively correlated with RVM-sgACC FC. When subjects were grouped as pro- or anti-nociceptive based on whether they had greater thal-BA 3a or RVM-sgACC FC respectively, pro-nociceptive subjects showed greater TSP responses compared to anti-nociceptive individuals. Furthermore, TSP was positively correlated with the imbalance towards ascending nociceptive processing. **Conclusions:** We found that TSP in individual subjects reflects the balance of FC of their ascending nociceptive and descending pain-modulation pathways, with pro-nociceptive subjects demonstrating greater TSP than anti-nociceptive individuals. These findings provide insight into brain mechanisms that mediate central sensitization and a framework to examine chronic pain conditions.

Title: Interactions between pain and motor processing in the human brain

Authors: M. POSTORINO, E. S. MAY, M. M. NICKEL, L. TIEMANN, *M. PLONER; TU Muenchen, Munich, Germany

Abstract: Pain is mostly conceptualized as a perceptual phenomenon. However, in order to be adaptive, pain not only includes a perceptual component but essentially depends on motor responses to avoid injury and promote recovery. The brain mechanisms of this motor component of pain are largely unknown yet. Here, we investigated how the preparation of an adaptive motor response functionally interacts with pain processing in the human brain. 20 healthy human subjects participated in an experiment, where thermal stimuli of increasing intensity were applied to the hand. Subjects were able to stop the painful stimulation by an adaptive motor response, i.e. by pressing a button. Button presses without pain, and pain without button presses served as control conditions. During the experiment, brain activity was recorded by using EEG. To test for the specificity of our results, a comparable control experiment with non-painful thermal stimuli was performed. The adaptive motor response was associated with reduced amplitude of the preparatory readiness potential as compared to a similar button press, which did not serve any protective function. Likewise, the adaptive motor response was associated with a weaker preparatory suppression of beta oscillations (14-30 Hz) over frontal premotor areas than the non-protective button press. Our results show that protective motor responses are associated with less preparatory brain activity than phenomenologically similar, but non-protective motor acts. This relative lack of voluntary motor preparation directly before an adaptive motor response indicates that motor preparation occurs involuntarily and continuously during pain. The results further suggest that motor preparation represents an inherent part of pain processing in the human brain.

Title: A Magnetoencephalography study of multi-modal processing of pain anticipation in primary sensory cortices

Authors: *R. GOPALAKRISHNAN[1], R. C. BURGESS[2], A. G. MACHADO[1];
[1]Ctr. for Neurolog. Restoration, [2]Epilepsy Ctr., Cleveland Clin., Cleveland, OH

Abstract: Pain anticipation plays a critical role in pain chronification and results in disability due to pain avoidance. It is important to understand how different sensory modalities (auditory, visual or tactile) may influence pain anticipation, as different strategies could be applied to mitigate anticipatory phenomena and chronification. In this study, using a countdown paradigm, we evaluated with magnetoencephalography, the neural networks associated with pain anticipation elicited by different sensory modalities in normal volunteers. Testing was performed with 10 adult healthy controls seated upright in a 306 channel MEG array (Elekta AB). Conditioning stimulus were presented using visual, tactile and auditory modalities which uniquely signaled the imminent arrival of an unconditioned stimulus that was painful (PS), non-painful (NPS) or absence of stimulus (NOS). The paradigm consisted of 15 blocks of 63 pseudo-randomized trials consisting of conditions from all three modalities. Each trial had 1s of baseline, 2s of pre-stimulus anticipatory countdown and 5s post-stimulus period. The data were pre-processed to remove artifacts, trials parsed and band-pass filtered to 1-100 Hz. Trials were averaged to compute evoked activity. Min-norm source estimation was performed on a tessellated cortex extracted from MRI that was anatomically parcellated to ROIs. The average time series from ROIs was subjected to a wavelet analysis. Statistics was performed using cluster based permutation analysis to compare PS vs. NOS and PS vs. NPS within each modality. Time-frequency analysis was focused on beta (12 - 30 Hz) and gamma (30 - 90 Hz) bands because of their association with cognitive functions and related sensorimotor transformations during pain anticipation. Our results showed that the visual modality evoked significant gamma band oscillations during PS in V1 indicative of independent processing of contextual meaning of the cue after interacting with associative areas. Both tactile and auditory modalities engaged the associative areas during PS, however they did not present independent cue processing capabilities. Visual and tactile modalities evoked anticipation early in the countdown, whereas auditory cortex displayed delayed processing. Interestingly, cross-modal activation was also evident and strong when visual and tactile cues signaled upcoming pain. Dorsolateral prefrontal cortex and mid-cingulate cortex showed significant activity during PS regardless of modality. Our results show the highest degree of higher-order processing is modulated by context (pain) rather than content (modality) and rests within the associative limbic regions.

Title: Detection of brain glial activation in chronic pain using [11C]PBR28 positron emission tomography imaging: occipital cortex as a pseudo-reference region

Authors: *D. S. ALBRECHT[1], S. SHCHERBININ[2], A. J. SCHWARZ[2], D. B. CHONDE[1], O. AKEJU[1], C. CATANA[1], R. R. EDWARDS[3], D. IZQUIERDO-GARCIA[1], R.-R. JI[4], A. D. WASAN[5], N. R. ZURCHER[1], B. R. ROSEN[1], V. NAPADOW[1], V. N. BARTH[2], J. M. HOOKER[1], M. L. LOGGIA[1];

Abstract: Using [[11]C]PBR28 PET, our group recently provided novel evidence that patients with chronic low back pain (cLBP) exhibit elevated brain levels of the translocator protein (TSPO) (Loggia et al., Brain 2015). As TSPO is upregulated in activated microglia and reactive astrocytes, this observation supports a role for activated glial cells in human pain conditions. For more widespread use of TSPO neuroimaging, it is preferable to work with simpler, and in some cases, more reliable SUVR analyses in lieu of traditional plasma kinetic analyses. In our previous analyses, we obtained standardized uptake value ratio (SUVR) values by normalizing SUV to whole brain. This method accounted for global signal differences across subjects, such as those introduced by the Ala147Thr *TSPO* polymorphism, which affects binding affinity. However, whole-brain normalization may reduce sensitivity to detect extended areas of signal increase throughout the brain. Thus, we evaluated pseudo-reference regions for SUVR. Nine cLBP patients and 9 age, sex, and *TSPO* genotype-matched controls were included in these analyses.

Integrated PET/MRI scanning began with IV injection of 11.1 ± 0.6 mCi [^{11}C]PBR28, and continued for 90 minutes. MPRAGE MRI scans were acquired for attenuation correction. 60-90 minute SUV images were reconstructed for each subject. SUV images were transformed to MNI space, spatially smoothed, and divided by average SUV from one of three pre-defined pseudo-reference regions: whole-brain, occipital lobe, and cerebellum, to create SUVR data. Region of interest (ROI) analyses and ROC curves characterized the ability of each pseudo-reference region to discriminate groups. In addition, voxelwise group analyses were performed to generate test statistic maps corresponding to these three regions. Occipital-normalized ROI SUVRs demonstrated the greatest ability to detect between-group differences, followed by whole-brain and cerebellum, respectively. The ROC curve was optimal for the occipital lobe normalization with AUROC=0.98, 0.89, and 0.77 for occipital lobe, whole brain, and cerebellum, respectively. In voxel-wise analyses, the use of occipital lobe as a pseudo-reference region confirmed the initial whole-brain results, and identified several additional regions of glial activation in cLBP patients, including bilateral posterior insulae, anterior cingulate cortex, and striatum. In our current sample, compared to whole-brain normalized SUVR analyses, the occipital lobe appears to be a viable pseudo-reference region for quantification of [^{11}C]PBR28 SUVR, and led to detection of glial activation in additional areas implicated in pain.

Title: Prestimulus EEG markers of subjective pain perception

Authors: ***P. TAESLER**, M. ROSE;
Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: The perception of pain is strongly influenced by cognitive processes such as, for example, expectations toward the efficacy of pain medication . Such processes have been shown to significantly modulate the analgesic effects of opiates through a descending pain modulatory network. A possible correlate for this effect could be present in neural pre-stimulus activity. We utilized state of the art psychophysical methods to contrast pain perception with non-painful sensations at the threshold level without changes in stimulus intensity in an EEG paradigm. This way, the observed fluctuations in intensity ratings could directly be linked to oscillatory activity in the pre-stimulus time range. We observed strong differences at the contralateral Insula in theta-band (4-7Hz) co-varying with subjective pain perception, as well as more pronounced lateralization in fronto-lateral connectivity (theta band). A decrease in fronto-parietal connectivity for painful sensations was located in the low gamma band (39-42 Hz). These findings can help in developing an understanding of subjective pain sensitivity - a quantity closely related to effects such as placebo/nocebo and a potential modulator of drug efficacy.

Title: BOLD fMRI and it's predictive value for pain treatment success in inflammatory diseases

Authors: ***A. HESS**[1], J. RECH[2], R. ATREYA[3], A. DOERFLER[4], M. NEURATH[3], G. SCHETT[2];
[1]I. F. Pharmacol & Toxicol, Erlangen, Germany; [2]Dept. of Intrnl. Med. 3, [3]Dept. of Intrnl. Med. 1, [4]Div. of Neuroradiology, Univ. of Erlangen-Nuremberg, Erlangen, Germany

Abstract: Pain is the key symptom in patients with inflammatory diseases like rheumatoid arthritis (RA) or Morbus Crohn (MC). It is well known, that TNF-alpha is the primary molecule in these pathological processes. However the role of TNF-alpha for the pain perception remains unclear. Therefore, we hypothesized that the hypernociception due to chronic TNF

overexpression leads to an altered pain processing in the brain which should be true for different inflammatory diseases depending on TNF-alpha. Consequently we investigated patients suffering RA as well as from MC using standard BOLD fMRI and disease specific painful stimuli. For both diseases after treatment with an anti-TNF drug (Infliximab) a reduction of the hypernociception, i.e. reduced activated brain volume, in brain areas activated by the painful stimulation was found. For RA and MC this happened as fast as 24 h after the first drug application which is weeks before any established clinical score indicates an improvement. Most interestingly was the finding that by our fMRI approach we were able to retrospectively differentiate between therapy responders and non-responders, again for both diseases. In order to further validate, if this predictive value of fMRI for indicating treatment success was limited to the anti-TNF tested so far (Infliximab) we investigated the anti-TNF Certolizumab pegol in RA patients. Likewise for Certolizumab fMRI was able to demonstrate a fast but long lasting reduction of pain induced activity in the brain of the patients. Further graph theoretical connectivity analysis data showed rewiring within the pain matrix under chronic pain conditions i.e. tight clustering of brain activity in thalamus and periaqueductal grey. Neutralization TNF by antibodies rapidly reversed this hypernociception. This was reflected by an overall decrease of the functional activity in the brain pain matrix and by dissociation of the tight clustering. These dynamic changes in the brain happened long before anti-inflammatory effects were evident. Our results suggest profound functional changes of nociceptive brain activity in inflammatory diseases like RA or MC, which normalizes upon hTNF blockade very fast and strongly contributes to the well-being of the patients.

Title: Changes in pain processing in the spinal cord and brainstem after traumatic spinal cord injury characterized by means of functional MRI

Authors: ***P. W. STROMAN**[1], H. S. KHAN[1], D. CADOTTE[2,3], R. L. BOSMA[1], A. COTOI[1], R. LEUNG[1], M. G. FEHLINGS[2,3];

[1]Ctr. for Neurosci Studies, Queen's Univ., Kingston, ON, Canada; [2]Dept. of Surgery, Div. of Neurosurg., Toronto Western Hosp., Toronto, ON, Canada; [3]Krembil Neurosci. Ctr., Toronto Western Hospital, Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Traumatic spinal cord injury (SCI) has a number of devastating consequences including high prevalence of chronic pain. The causes of pain vary depending on the injury, and are difficult to diagnose and treat. A better understanding of pain mechanisms after SCI is expected to lead to better diagnostic capabilities and improved treatments. The purpose of this study was to use functional magnetic resonance imaging (fMRI) to characterize responses in the brainstem and spinal cord to the same heat stimulus in a group of people who have previously had a traumatic spinal cord injury (SCI), in order to further our understanding of post-injury pain conditions. Functional MRI of the brainstem and spinal cord was carried out at 3 tesla and was used to determine the neuronal activity evoked by a series of repeated brief heat pulses at 49 °C applied to the right hand. A group of 16 participants was studied with a range of cervical and upper thoracic injuries, and participants provided ratings of the pain perceived from the thermal stimulation. Blood oxygenation-level dependent (BOLD) responses were detected with a General Linear Model (GLM) and effective connectivity was examined with Structural Equation Modeling (SEM). The pain perceived varied widely across participants from 0 to 52, out of 100, with a mean value of 25 ± 16, compared to a mean rating of 42 ± 18 in healthy participants. Functional MRI results were also observed to be highly variable in terms of location and magnitude of responses. However, the results were observed to vary in relation to the perceived pain and the level/severity of injuries, particularly in terms of hypothalamus connectivity with other regions, and descending modulation via the PAG-RVM-cord pathway. The results appear to provide sensitive indicators of each individual's pain response. We conclude that the results of this study demonstrate mechanisms of altered pain processing in the 16 participants that were studied. The ability to characterize changes in pain processing in individuals with SCI represents a significant technological advance.

Abstract: Background and aims: Placebo response is identified to be mainly driven by central nervous system mechanisms, and it is thus reasonable to expect that specific brain states or traits can predispose individuals to respond to placebo treatment. Resting state functional magnetic resonance imaging (rs-fMRI) may provide such brain markers for placebo propensity. However, in a clinical context, no functional brain properties have yet been recognized that are able to identify and predict placebo responses. Methods: We studied placebo related brain functional connectivity (FC) in 2 separate clinical trials using rs-fMRI in knee osteoarthritis (OA) patients. Study 1 was used to identify brain circuits for placebo propensity, and study 2 to validate outcomes. Study 1 was a single blinded trial, where 17 OA patients underwent rs-fMRI before receiving placebo treatment for two weeks. Study 2 was a double-blinded trial, where 39 OA patients underwent rs-fMRI and then received either placebo or duloxetine for 3 months. Results: We prospectively defined an analgesic response as a 20% or greater decrease in pain. In both studies, approximately half of participants displayed placebo analgesia, exhibiting about 50% decrease in OA pain on average. The extent of right middle frontal gyrus (r-MFG) FC with the rest of the brain differentiated placebo responders and non-responders and predicted magnitude of placebo analgesia, and this area preferentially connected to anterior insula and periaqueductal gray. The density of FC of r-MFG discriminated placebo responders from non-responders in study 2 with an AUC of 0,92 (95% confidence interval, 0.78 to 1.1), but did not discriminate duloxetine responders from non-responders, implying that the latter response is not fully a placebo effect. Conclusion: This study suggests that propensity of placebo response to a treatment is embedded in functional properties of patients and represents a unique brain characteristic that may be a useful biomarker in targeted treatment approaches. Additionally, with functional brain properties, we were able to dissociate placebo response from a drug response of equal magnitude that was indistinguishable with behavioral outcome.

Title: Structural plasticity in primary somatosensory/motor cortex in carpal tunnel syndrome is improved following acupuncture

Authors: *H. KIM[1,2], Y. MAEDA[1], N. KETTNER[3], J. LEE[1], J. KIM[1], S. CINA[1], C. MALATESTA[4], J. GERBER[1], C. MCMANUS[4], P. MEZZACAPPA[1], R. ONG-SUTHERLAND[5], A. LIBBY[1], L. R. MORSE[4], K. PARK[1], J. AUDETTE[6], V. NAPADOW[1]; [1]A.A. Hosp., medford, MA; [5]Boston Alternative Hlth., Boston, MA; [6]Dept. of Pain Medicine, Harvard Vanguard Med. Associates, Boston, MA

Abstract: We have previously demonstrated maladaptive structural and functional neuroplasticity in primary sensorimotor (S1/M1) cortices for carpal tunnel syndrome (CTS). Previous clinical studies have suggested that acupuncture may improve both subjective and objective (nerve conduction latency) outcomes for CTS patients, the mechanisms are unknown. We investigated gray matter volume (GMV) changes following acupuncture in bihemispheric S1/M1 areas consistent with the cortical representations of median nerve innervated digits. White matter (WM) microstructural changes in the tracts between these regions were also investigated. We enrolled 60 CTS patients and 34 controls. CTS patients were randomized to a 2-month course of either local (n=21), distal (n=18), or sham (n=21) acupuncture. T1-weighted MPRAGE structural brain images were used to quantify GMV for S1/M1 ROIs defined by fMRI evaluation of brain response to vibrotactile stimulation for median nerve innervated digits from the more affected hand. ROIs were defined from contralesional S1 activation and ipsilesional S1/M1 deactivation clusters. DTI was performed to assess mean FA and MD in WM tracts obtained from probabilistic tractography. Clinical evaluation included nerve conduction studies and symptom/functional scales from the Boston CTS Questionnaire (BCTSQ). All acupuncture

interventions significantly improved symptom and function BCTSQ scales (P<0.05). As no differences were noted between local and distal acupuncture, these groups were combined into a single "verum" acupuncture group. Verum acupuncture improved nerve conduction latency more significantly than sham (P=0.04). At baseline, contralesional S1 GMV was reduced in CTS (P=0.01), consistent with our previous studies. GMV was also increased in ipsilesional M1 (P=0.03). Verum acupuncture reduced ipsilesional M1 volume more than sham (P=0.02). At baseline, mean diffusivity in WM tracts connecting contralesional S1 to ipsilesional M1 were reduced in CTS (P<0.05). Verum acupuncture increased mean FA in these tracts than sham acupuncture (P=0.03). Verum acupuncture improved both subjective (symptoms) and objective (peripheral nerve conduction) outcomes in CTS, which provided greater somatosensory afference compared to sham acupuncture, also improved structural brain plasticity in ipsilesional M1, and altered white matter microstructure in tracts connecting this region with contralesional S1. As GMV in the latter region was not altered immediately following acupuncture, future studies should explore longer-term changes and linkages with clinical outcomes.

Title: Evidence of alterations to cerebral-midbrain-spinal mechanisms of pain control in Fibromyalgia

Authors: *R. BOSMA[1], E. AMELI MOJARAD[1], L. LEUNG[1], C. PUKALL[1], R. STAUD[2], P. STROMAN[1];
[1]Queen's Univ., Kingston, ON, Canada; [2]Univ. of Florida, Gainesville, FL

Abstract: Fibromyalgia syndrome (FM) is a prevalent debilitating chronic pain condition, which afflicts primarily females. Although the etiology of this disease is not completely understood, FM pain is believed to be due to enhanced pain sensitivity maintained by central mechanisms. Central pain amplification can be evaluated by assessment of the temporal summation of second pain (TSSP). Here we use a TSSP paradigm and functional MRI (fMRI) to build upon previous brain fMRI studies and investigate the expected site of central sensitization in the spinal cord, and modulation from brainstem regions. Functional MRI of the brain, brainstem, and spinal cord, of pain-free female adults (NC) (N = 15) and FM patients (N = 14) was conducted while TSSP (0.33 Hz) and Control (0.17 Hz) heat pain paradigms were applied to the right hand. The stimulus intensity was adjusted to each participant's heat pain sensitivity. Data were analyzed by means of a General Linear Model and Structural Equation Modeling. As predicted, all participants demonstrated significant behavioral summation of pain in the TSSP condition. In FM patients compared to NC, fMRI responses to sensitivity calibrated pain stimuli identified similar brain activity; however, there were multiple areas in the brainstem (RVM and PAG) and spinal cord (DH) that showed greater activity. Altered effective connectivity differences between descending control regions was also detected in the FM group. Finally, increased after-sensations and enhanced dorsal horn activity was demonstrated upon cessation of the heat pain stimuli. In conclusion, our results suggest that the descending control mechanisms are altered in fibromyalgia and provide strong evidence for the involvement of central neural mechanisms in modulating fibromyalgia pain.

Title: Trigeminal sensory nucleus connectivity is modulated by respiratory-gated auricular vagus nerve stimulation in migraine patients

Authors: *R. G. GARCIA[1,2], R. LIN[3], J. LEE[3], H. JUNG[3], J. KIM[3], M. LOGGIA[3,4], A. D. WASAN[5], R. EDWARDS[4], N. HADJIKHANI[3], V. NAPADOW[3,4];

Abstract: Objective Migraine is a primary brain dysfunction associated with increased sensitization of the trigeminal pain pathway. Respiratory-gated auricular vagal afferent nerve stimulation (RAVANS), an optimized version of transcutaneous vagus nerve stimulation, involves electrical stimulation at specific points of the respiratory cycle. While RAVANS has demonstrated improved outcomes in chronic pain patients, its mechanisms of action are unknown. Our aim was to use functional MRI (fMRI) to evaluate brain response to RAVANS and potential modulation of functional connectivity between trigeminal sensory nuclei (sp5) and the cortex in migraine patients. Methods Sixteen subjects with episodic migraine (interictal) and 16 age-matched healthy controls were randomized to receive RAVANS or sham stimulation during a 6 minute fMRI scan, with cross-over stimulation following 30 minutes. Electrodes were placed in vagal-innervated ear regions. RAVANS stimulation at 30Hz (0.5s duration) and gated to exhalation was delivered with current intensity set to achieve moderate (but not painful) sensation. FMRI was performed at 3T (TR/TE=2.5s/30ms, 43 slices, voxel size=2.6x2.6x2.6mm). Functional connectivity was computed using seed-based connectivity analysis for a nucleus tractus solitarius/sp5 ROI defined based on the peak activation voxel (-8,-38,-42 in MNI coordinates) from a permutation-based analysis contrasting RAVANS and sham stimulation. All group-level brain maps were cluster corrected for multiple comparisons ($Z>2.3$, cluster-size threshold=$p<0.05$). Repeated-measures ANOVA models were used for post-hoc ROIs, significant at $p<0.05$. Results During RAVANS, NTS/Sp5 connectivity was found to a network of brain regions, including anterior insula, putamen, midbrain, and thalamus. A significant INTERVENTION effect (RAVANS > sham) was found for NTS/Sp5 connectivity to left (peak voxel: -30,18,-6 in MNI coordinates; $F=27.51$, $p<0.001$) and right anterior insula (peak voxel: 44,12,-6 in MNI coordinates; $F=11.98$, $p<0.01$), and putamen (peak voxel: -30,0,2 in MNI coordinates; $F=9.32$, $p<0.01$). Significant INTERVENTION by GROUP interactions were found for left anterior insula ($F=4.52$, $p=0.04$) and putamen ($F=4.6$, $p=0.04$), with post-hoc analyses showing a significant increase in connectivity in migraine patients but not in controls. Conclusion RAVANS effectively activates NTS/Sp5 in the ipsilateral pontomedullary region of the brainstem. Regulation of NTS/Sp5 connectivity to known pain-modulatory brain regions may constitute an underlying mechanism supporting previously reported analgesic effects of RAVANS therapy.

Title: Pain specific encoding of temporal dynamics of aversive stimuli in the ventral striatum

Authors: *S. GEUTER, E. A. REYNOLDS LOSIN, T. D. WAGER;
Univ. of Colorado Boulder, Boulder, CO

Abstract: The nucleus accumbens and putamen have been shown to encode appetitive events and appetitive prediction errors (more reward than expected) in numerous studies. Recent studies in animals and humans suggest that the striatum may also respond to painful stimuli and aversive prediction errors (more aversive outcome than expected), though human findings have been inconsistent. Several functional magnetic resonance imaging (fMRI) studies in humans and animals have revealed phasic responses in the nucleus accumbens to pain onset and offset, but the sign of these responses (activation vs. deactivation) varies across studies. Activation to pain onset could be related to motivational properties of pain, and activation to offset could be related to the rewarding aspects of pain relief. Here, we investigated phasic responses to aversive stimuli (thermal pain and aversive sounds) in the basal ganglia and their functional significance in a large fMRI data set (N=60). Participants experienced painful heat and aversive sounds of varying durations and intensities. We observed phasic positive responses to pain onset in the putamen and caudate nucleus. Caudate nucleus also responded to cues that signaled upcoming painful stimulation. At stimulus offset, caudate, putamen and nucleus accumbens showed deactivation; we found no activity increases related to pain relief in the basal ganglia. These activity changes were strongly predictive of pain intensity ratings in a cross-validated multivariate regression analysis across individuals. Deactivation to pain offset in the basal ganglia explained 25% of the variance in pain ratings. To test for the functional significance of these bi-phasic responses, we regressed BOLD activity against the temporal derivative of ongoing pain. We found that caudate, putamen, and accumbens encoded the change in perceived pain and that these regions overlapped with the regions showing the bi-phasic responses. Importantly, accumbens and ventral caudate responses were specific for pain as the relationship was significantly stronger for changes in pain compared to aversive sounds. The positive responses to pain onset together with increased activity during periods of increasing pain and decreased activity with ongoing relief suggest that

the ventral striatum not only encodes the motivational significance of appetitive stimuli, but also the motivational demands imposed by pain and relief of pain along a single, bipolar dimension.

Title: Cognitive behavioral therapy changes pain-evoked activity and intrinsic connectivity of the default mode network

Authors: A. KUCYI[1,2], T. V. SALOMONS[1,3], *K. D. DAVIS[1,4];
[1]Toronto Western Res. Inst., Univ. Hlth. Network, Toronto, ON, Canada; [2]Dept. of Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA; [3]Sch. of Psychology and Clin. Language Sci., Univ. of Reading, Reading, United Kingdom; [4]Dept of Surgery and Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada

Abstract: **Introduction:** We recently demonstrated that cognitive training modifies pain unpleasantness and secondary hyperalgesia (Salomons et al, 2014). A key question is how such training alters neural pain responses and network connectivity. We examined how cognitive behavioral therapy (CBT) impacts painful stimulus-evoked neural activity and changes intrinsic brain-network organization. **Methods:** Healthy subjects were assigned to a CBT (n=17) or inert treatment (Control) (n=13) group and underwent 8 experimental sessions of treatment and painful thermal stimuli. Before and after treatment, participants were scanned at 3T during painful stimulation (percept-matched) and at rest. Painful stimulus-evoked activity was analyzed both within- and between-groups. Data were preprocessed with FSL and Matlab as done previously (Kucyi et al, 2013). A region in right ventrolateral prefrontal cortex (R vlPFC) of the executive control network, that displayed group differences in pain responses was selected as a seed region for resting state functional connectivity analyses. Resting state and stimulus-evoked activity were examined using FSL, with significance set at family-wise error corrected (whole brain, $Z>2.3$, $p<0.05$). **Results:** In the Control group, repeated painful stimulation over time attenuated normal default mode network (DMN) deactivation during pain. This effect was

blocked by CBT, accompanied by a relative decrease in painful stimulation-evoked R vlPFC activation. Greater maintenance of DMN deactivation in the CBT group was associated with greater reduction in pain intensity and unpleasantness. Finally, the CBT group showed enhanced intrinsic functional connectivity between the executive control (based on a seed in the R vlPFC) and default mode medial prefrontal cortex) networks over time, compared to the Control group. **Conclusion:** This work highlights that the neural representation of pain is dynamic, in line with the concept of a "dynamic pain connectome" (Kucyi and Davis, 2015). Specifically, we show that cognitive training can impact behaviourally-relevant reorganization of neural responses to painful stimuli and intrinsic network communication. These findings point to the potential utility of cognitive training in pain therapy and also reveal a mechanism underlying its effect based on altering DMN activity and connectivity with the executive control network.

Title: Neural and behavioral correlates to pain perception in nerve growth factor beta (NGFB) mutation carriers

Authors: *I. PERINI[1], M. TAVAKOLI[2], A. MARSHALL[3], J. MINDE[4], I. MORRISON[1]; [1]Dept. of Clin. and Exptl. Medicine, IKE, Linkoping, Sweden; [2]Ctr. for Endocrinol. & Diabetes, Inst. of Human Development, Univ. of Manchester;, MAnchester, United Kingdom; [3]Greater Manchester Neurosci. Centre, Salford Royal Hosp. NHS Trust, Stott Lane, Salford M6 8HD, Manchester, United Kingdom; [4]Dept. of Orthopaedics, Gällivare Hospital, Gällivare, Sweden, Gällivare, Sweden

Abstract: Implementing an adequate behavioral response to a noxious event is a crucial component of pain perception. Central mechanisms are important in forecasting whether a nociceptive input mediate a real threat for tissue damage. However, what happens when the nociceptive input is not efficient? We investigated a population of carriers of a rare mutation affecting the nerve growth factor beta (NGFB) gene, which causes a loss of unmyelinated C afferents. The carriers show different levels of impaired pain sensitivity although their thresholds

don’t differ from controls. To characterize the components of the carriers’ pain experience we designed a study that involved cerebral, psychophysical and peripheral measurements. At the brain level we investigated functional brain correlates to an action-based task that involved thermal stimulation as in Perini et al. 2013. This design allowed modeling of voluntary motor responses and painful stimulation separately. Using signal detection theory we calculated their sensitivity to the behavioral task (d'), that is their ability to distinguish painful from non-painful stimulations. At the behavioral level we looked at the carriers’ pain evaluation via the administration of the Situational Pain Questionnaire (SPQ) and their motivation to react to acute pain using a design in which they continuously rated their urgency to move away from a painful stimulation. To characterize the peripheral loss we carried out a quantification of the fiber density using corneal confocal microscopy (CCM), a non-invasive method that reliably detects and quantifies C-fibre loss in neuropathy. Carriers showed lower sensitivity to the task (d') and rated their urgency to move significantly lower than controls. Right AI and right inferior frontal gyrus were positively correlated to the carriers' sensitivity to the task (d') suggesting an involvement of those areas in discriminating painful versus non-painful stimulation. The mid cingulate cortex (MCC) was activated for both painful stimulation and motor response (button press) confirming previous finding on the action-related role of MCC during pain. In addition it was positively correlated to the urgency to react to painful stimulation during the response interval. Finally peripheral C-afferent loss correlated negatively with pain intensity evaluation, revealed by SPQ scores. In this study we show that NGFB mutation carriers have a lower ability to evaluate and react to pain that correlates to the extent of the loss of nociceptors. We show that the right AI has a role in the discrimination between different stimulation qualities, whereas the cingulate has a more action-related role during pain.

Title: Intrinsic functional connectivity predicts task evoked responses and pain modulation in an experimental model of placebo analgesia

Authors: *J. A. HASHMI[1,2], R. YU[3], S. KHAN[3], R. L. GOLLUB[3], J. KONG[3];
[1]Harvard Med. Sch., Belmont, MA; [2]MGH, Boston, MA; [3]Harvard Med. School, MGH, Boston, MA

Abstract: Introduction: Placebo analgesia is a type of pain modulation mediated by the brain where pain intensity is reduced due to positive expectations engendered by the procedure of undergoing treatment. Several brain imaging studies have clearly shown task related activation during experimental pain modulation suggesting a role of the brain in placebo analgesia. We have shown that placebo analgesia can be predicted by mean local efficiency and clustering in resting state networks measured with functional MRI before treatment (Hashmi et al., 2013). Why local connectivity parameters predict placebo analgesia is not clear. Since greater network clustering represents higher number of local connections and more efficient information transfer within a network, we hypothesized that the regions that show a predictive relation between clustering and pain modulation are components of a local network that plays an important role in processing pain modulation. Methods: We investigated the relation between resting state network architecture and task related responses in an experimental placebo paradigm. Healthy subjects (n=43) were given two types of visual text cues that created expectancies for incoming heat pain stimuli. Cues that read either “high pain” or “low pain” preceded high or low intensity stimuli after which the subjects rated pain intensity. In some epochs, the engendered expectancies were tested by presenting high intensity stimuli after cues that induced expectations of low pain (placebo epochs) (Kong et al., 2013). We used Graph theory to identify connectivity patterns in resting state scans and BOLD signal dynamics in network nodes to observe activation patterns in task related scans. Networks were constructed at 5 different thresholds from a 131 ROI parcellation. Results: Network efficiency of regions in six medial prefrontal regions measured in resting state scans predicted the placebo analgesia induced during subsequently measured placebo task ($p<0.05$). The nodes that showed significant cue, pain, rating and placebo analgesia related activations (FDR corrected) showed 75% overlap with regions that were members of local networks of regions identified in the resting state scan. Conclusions: Here we show that greater clustering in resting state architecture predicts individual variability in placebo analgesia. The regions that most prominently show this affect are components of a local network that plays an important role in pain modulation. Thus, we confirm our previous findings and suggest a putative mechanism that explains the predictive relation between local functional connectivity and placebo analgesia.

Title: The indirect pathway of nucleus accumbens shell amplifies tactile allodynia in rodent pain model

Authors: *W. REN, M. V. CENTENO, D. J. SURMEIER, M. MARTINA, A. V. APKARIAN; Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The forebrain limbic circuitry has long been hypothesized to play a critical role in the representation of pain, and the medial shell of the nucleus accumbens (msNAc) is a key node in this circuitry. msNAc has two parallel, opposing networks charged with affective evaluation of salient events. The direct pathway, which is linked to reward and positive affect, is anchored by spiny projection neurons (dSPNs) whose activity is enhanced by dopamine (DA) acting at D1 DA receptors. The indirect pathway, which is linked to aversion and negative affect, is anchored by spiny projection neurons (iSPNs) whose activity is suppressed by DA acting at D2 DA receptors. To investigate how these two networks respond to chronic pain, the electrophysiological adaptations in msNAc neurons were examined in a rodent peripheral nerve injury (spared nerve injury, SNI) model of chronic pain. Five days after the SNI (or sham) surgery, mice were tested for tactile allodynia and sacrificed to obtain msNAc brain slices for patch clamp recording. In iSPNs from SNI mice, the intrinsic excitability assessed by intrasomatic current injection was significantly increased both ipsilateral and contralateral to the nerve injury; moreover, rheobase current and first spike latency decreased, whereas input resistance increased. In contrast, early-SNI had no effect on neighboring dSPNs. To determine whether the cell type-specific adaptations in the nucleus accumbens have a causal correlation with neuropathic pain behavior, msNAc iSPNs were activated *in vivo* using a chemogenetic approach. Adora2-Cre mice had bilaterally stereotaxic msNAc injections of adenoassociated virus carrying Cre-dependent PSAML141F,Y115F-5HT3 HC/green fluorescent protein expression construct. In brain slices from infected mice, the PSAM ligand - PSEM89S - induced a reversible depolarization of iSPNs that led to increased spiking. 3 days post SNI surgery, treatment of PSAM expressing SNI mice with an intraperitoneal injection of PSEM89S (30 mg/kg) rapidly led to an exacerbation of tactile allodynia. The PSEM-induced decrease in tactile threshold was repeated and more significant at Day 5 post SNI surgery. However, PSEM89S had no effect on tactile threshold in sham animals. Our data suggested that SNI-induced adaptation of msNAc iSPNs drive descending segmental pathways that enhance the reactivity of segmental circuitry controlling withdrawal reflexes.

Title: Generalized placebo improvement of both pain and pleasure evoked by specific suggestions of therapeutic benefit

Authors: *D.-M. ELLINGSEN[1,2], S. LEKNES[2], C. TRISCOLI[3], H. OLAUSSON[4], J. WESSBERG[3];
[1]Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hospital, Harvard Med. Sc, Charlestown, MA; [2]Dept. of Psychology, Univ. of Oslo, Oslo, Norway; [3]Inst. of Neurosci. and Physiol., Univ. of Gothenburg, Gothenburg, Sweden; [4]Dept. of Clin. and Exptl. Med., Linköping Univ., Linköping University, Sweden

Abstract: Although placebo effects are often assumed to arise from symptom-specific expectations of therapeutic benefit, the evidence for such explicit expectations as a defining factor is inconsistent. An emerging view, however, is that placebo effects (e.g. analgesia) builds on a more generic process of reward prediction, whereby the importance, and in turn the experience, of pain, is modified by the inferred predictive (positive or negative) value of available contextual cues. We recently showed that placebo improvement of pain (analgesia) and pleasure (hyperhedonia) employ a similar modulatory circuit. Here, we investigated whether modality-specific expectations, like “reduced pain” or “increased pleasure”, are necessary for placebo analgesia or hyperhedonia, respectively, or whether these effects can be induced by expecting “something good” more generally. In a crossover design, 47 healthy volunteers self-administered a saline nasal spray suggested to either (1) reduce pain (ANA group) or (2) enhance touch pleasantness (HYP group). To strengthen participants’ expectations of treatment benefit, they were, immediately before intranasal treatment, shown one out of two brief video documentaries that summarized scientific findings supporting either treatment-induced improvement of pain (ANA) or touch pleasantness (HYP). Next, they rated (un)pleasantness (Visual analogue scale -5 - 5) and sensory intensity of moderate heat pain and gentle stroking touch. After placebo treatment (PL), relative to a control condition without treatment (CO), both

groups reported reduced pain unpleasantness (ANA: PL: -1.56 ± 0.6 (mean ± SD); CO: -2.37 ± 0.9; HYP: PL: -1.5 ± 1.3; CO: -2.04 ± 1.2) and increased touch pleasantness (ANA: PL: 2.61 ± 1.3; CO: 2.21 ± 0.9; HYP: PL: 2.1 ± 1.4; CO: 1.79 ± 1.6). This was mirrored by placebo-induced improvement of sensory intensity, whereby pain intensity was reduced and touch intensity was increased, in both groups. Both trait optimism (LOT-R) and resting heart rate variability (HRV-HF), collected before the placebo manipulation, correlated positively with expectations of therapeutic benefit. However, neither placebo analgesia nor hyperhedonia were reliably associated with explicit expectations of improvement of pain or pleasure. The results indicate that modality-specific expectations are not necessary for beneficial placebo effects, but that these can be evoked by non-specific expectations of therapeutic improvement. This is consistent with a view of placebo responses as a generalized mechanism of reward prediction, by which a placebo-induced "affective state" affects both positive and negative hedonic feelings.

Title: Changes in pain and cold sensitivity over time after peripheral nerve injury relate to pain catastrophizing and insula gray matter

Authors: *R. GOSWAMI[1], D. J. ANASTAKIS[2,3], J. KATZ[4,3,5], K. D. DAVIS[1,3];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Toronto Western Hosp., Toronto, ON, Canada; [3]Univ. of Toronto, Toronto, ON, Canada; [4]York Univ., Toronto, ON, Canada; [5]Toronto Gen. Hosp., Toronto, ON, Canada

Abstract: Introduction: We do not know precisely why pain develops and becomes chronic after peripheral nerve injury (PNI), but it is likely due to a constellation of biological and psychological factors. We previously reported that a year after PNI, there are brain abnormalities linked to sensory deficits (Taylor et al., Brain 2009) and increased pain castastrophizing in patients who developed chronic pain (Davis et al., Neuroscientist 2011; Taylor et al., Pain 2010).

Here we conducted a longitudinal study to test the hypotheses that 1) high pain catastrophizing at the time of injury and repair is associated with pain and cold sensitivity during a 1 year recovery period, and 2) gray matter changes in the insula (a region implicated in pain and thermal sensation) reflect the course of injury and improvements over time. Methods: Ten patients with accidental or work-related transections of the median and/or ulnar nerve (2 F/ 8 M; 37 ± 15 yr), and primary surgical nerve repair within 3 days, and age/sex matched healthy controls provided informed consent. Testing including quantitative sensory testing, pain and personality questionnaires [MPQ, painDetect, Pain Catastrophizing Scale (PCS)]. and 3T MRI (Freesurfer cortical thickness analysis of the insula) at ~3 weeks after surgical nerve repair (Time 1) and again ~1 year later for 6 of the 10 patients (Time 2). Results: Overall, pain intensity and painDetect neuropathic pain scores were correlated with PCS, including the subscales of rumination, helplessness and magnification. Additionally, at time 1: 1) affected digits were insensate with an inability to detect thermal and pain stimuli, 2) pain present in the affected digits in all but 1 patient, and 3) cortical thinning of the right insula. The time 2 assessment showed: 1) partial recovery of sensorimotor function, 2) average pain in 5 of 6 patients followed from Time 1, 3) chronic pain was related to the Time 1 pain-PCS relationship, 4) cold sensitivity, 5) pain catastrophizing scores correlated with cold pain sensitivity, and 6) a reversal of the insula cortical thinning to control levels. Conclusion: This study provides evidence for the interplay between personality, sensory function and pain in patients following traumatic PNI and repair. The association between catastrophizing and pain suggests that a focus on affective or negative components of pain could render patients vulnerable to chronic pain. The common experience of cold sensitivity and the change in insula thickness may represent changes in the lamina 1-VMpo-insula thermosensory pathway implicated in cold and pain sensation, or the neural representation of sensorimotor awareness.

Ctr., Pittsburgh, PA

Abstract: While substantial evidence has established that microglia and astrocytes play a key role in the establishment and maintenance of persistent pain in animal models, the role of glial cells in human pain disorders remains unknown. Here we present the results of two studies providing evidence of glial activation in the brain and spinal cord of patients with chronic low back pain (cLBP). In the first study, 9 cLBP patients and 9 healthy controls received integrated brain PET/MR scans with [11C]PBR28, a recently-developed radioligand that binds to activated microglia and reactive astrocytes. The scanned participants were identified from a larger pool of subjects (n=44) so that each patient was matched to a healthy control for sex (5 M, 4 F in both groups), age (mean ± SD: cLBP = 48.8 ± 12.3, controls = 49.9 ± 12.7; p=0.37) and the Ala147Thr polymorphism in the TSPO gene (7 Ala/Ala, 2 Ala/Thr in both groups), which predicts binding affinity for [11C]PBR28 (Owen DR et al., J Cereb Blood Flow Metab 2012). [11C]PBR28 Standardized Uptake Values (SUVs) were computed from data collected 60-90 minutes post-injection and normalized to whole brain (SUVRs). Whole-brain nonparametric voxelwise analyses revealed that SUVRs were significantly higher in patients than controls in thalamus, the putative sensorimotor representations of the lumbar spine (in the central sulcus) and the leg (in the paracentral lobule). In a second, ongoing study, six chronic sciatica patients (2F; 48 ± 8 y.o.), and 4 healthy controls (3F; 40 ± 18 y.o.), were recruited for a spinal [11C]PBR28 scan. SUVs were computed from data collected 90-110 minutes post-injection. As all patients had L4/L5 and/or L5/S1 pathology, target ROIs were drawn on the lower lumbar/upper sacral spinal cord segments, which are situated at the T11-T12 vertebral levels. Results from preliminary (not genotype-corrected) nonparametric analyses on both SUVs and SUVs normalized by T12 vertebral signal (SUVR) suggest that patients with sciatica have higher spinal [11C]PBR28 signal compared to healthy control subjects (p=0.057 and 0.033, one-tailed, respectively). Together, these studies provide evidence for glial activation in the central nervous system of chronic pain patients. Given our emerging understanding of the importance of

activated glia in clinical pain management, the present findings offer far-reaching clinical implications that may serve to guide future studies on the pathophysiology and management of a variety of persistent pain conditions.

Title: Repeated verum but not placebo acupuncture normalizes connectivity in brain regions dysregulated in chronic pain

Authors: *N. EGOROVA, R. L. GOLLUB, J. KONG;
Massachusetts Gen. Hosp. / Harvard Med. Sch., Charlestown, MA

Abstract: Acupuncture, an ancient East Asian therapy, is aimed at rectifying the imbalance within the body caused by disease. Studies evaluating the efficacy of acupuncture with neuroimaging tend to concentrate on brain regions within the pain matrix, associated with acute pain. We, however, focused on the effect of repeated acupuncture treatment specifically on brain regions known to support functions dysregulated in chronic pain disorders. Transition to chronic pain is associated with increased attention to pain, emotional rumination, nociceptive memory

and avoidance learning, resulting in brain connectivity changes, specifically affecting the periaqueductal gray (PAG), medial frontal cortex (MFC) and bilateral hippocampus (Hpc). We investigated the relationship between chronic knee osteoarthritis symptoms measured with Knee injury and Osteoarthritis Outcome Score (KOOS) pain and sport subscales, and resting state connectivity between the PAG-MFC and PAG-Hpc in a group of 30 patients at baseline and after 6 sessions of either verum (n=20) or sham (n=10) acupuncture treatment. We found that the PAG-MFC and PAG-Hpc connectivity in patients with chronic pain correlates with baseline clinical severity scores - higher PAG-Hpc $r(30)=0.40$, $p=0.033$ (2-tailed) and lower PAG-MFC $r(30)=0.43$, $p=0.021$ (2-tailed) connectivity are associated with increased pain during regular and increased physical activity (pain and sport scores respectively). Repeated verum acupuncture produced a significant positive effect on sport (Mean=18.4, SE=5.7, $F(1,27)=4.252$, $p=0.049$) and pain (Mean=12.1, SE=3.0, $F(1,28)=5.596$, $p=0.025$) clinical outcomes compared to sham. Furthermore, we show that verum acupuncture-induced improvement in KOOS scores (compared to sham) is related to the modulation of PAG-MFC and PAG-Hpc connectivity. Specifically, following verum acupuncture PAG-Hpc connectivity is decreased ($p=0.002$), while baseline PAG-MFC connectivity is maintained. Following sham acupuncture PAG-MFC connectivity is decreased ($p=0.016$) with no changes to the PAG-Hpc connectivity. This study shows that repeated verum acupuncture might act by restoring the balance in the connectivity of the key pain brain regions, altering pain-related attention and memory.

Title: Contribution of layer 2/3 neurons to sensory adaptation in mouse somatosensory cortex

Authors: *M. ADIBI[1], E. KHERADPEZHOUH[1], L. R. FENLON[2], R. SUAREZ[2], L. J. RICHARDS[2,3], E. ARABZADEH[1];
[1]Eccles Inst. of Neurosci., Australian Natl. Univ., Acton, Australia; [2]Queensland Brain Institute, The Univ. of Queensland, Brisbane, Australia; [3]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: Exposure of cortical neurons to sustained sensory stimulation results in changes in their response function: a phenomenon known as sensory adaptation. Sensory adaptation in the primary somatosensory cortex is predominantly attributed to the depression of the thalamocortical synapses. However, the contribution of other intra-cortical circuits to adaptation is not well characterized. Here, we investigated the contribution of sustained activation of L2/3 neurons to adaptation in deeper cortical neurons located in deeper layers . We used the well-characterized mouse whisker-barrel system. To activate L2/3 neurons, channelrhodopsin-2 was expressed selectively in L2/3 by *in utero* electroporation at embryonic day 15.5. We juxtacellularly recorded single cell activity in the primary somatosensory cortex of urethane-anaesthetised mice (n=30) while applying mechanical stimuli of varying amplitudes (0-256 μm) to the vibrissae under two states: non-adapted and adapted. In the adapted state, 200ms optogenetic stimulation (454 nm light, 16 lm/W) of L2/3 preceded each vibrissal stimulation, while there was no optogenetic stimulation in the non-adapted state. In total, 240 neurons were recorded from granular and infra-granular layers. Histological reconstruction of labelled neurons (n=49) indicated that 38.8, 28.6, 26.5 and 4.1% of neurons were located in L4, 5a, 5b and 6, respectively. Optogenetic stimulation increased the average spiking rate of 56% of neurons, and decreased that of 32%. Overall, across all neurons, optogenetic stimulation elicited an average response rate of 6.33 spike/s, 2.06 times higher than the average spontaneous activity. This level of activation was 18% greater than the average neuronal response to the highest vibrissal stimulus (5.37 spike/s to 256 μm stimulus). We performed a linear regression analysis of the average neuronal response functions to vibrissal stimulation between adapted and non-adapted states. This revealed that sustained optogenetic stimulation of L2/3 neurons resulted in an attenuation of the response function by a factor of 0.92 with a 5.9% (0.18 spike/s) decrease in the average background activity. In contrast to a sustained vibrissal stimulation that produced prominent adaptation (rightward shift in neuronal response function), sustained optogenetic activation of L2/3 neurons caused minimal adaptation in downstream neurons.

Title: Representation of egomotion in rat trident whisker cortex

Authors: *E. CHOREV, P. PRESTON FERRER, M. BRECHT;
BCCN, Berlin, Germany

Abstract: The submandibular trident whiskers, a set of three whiskers on the rat's chin, exhibit biomechanics that are consistent with speed sensing1. Moreover, these whiskers are in contact with the environment in particular contexts: exploring novel environments and while foraging for food in darkness, both instances which require probing ones location in the environment. These observations led to the hypothesis that the trident whiskers are used for monitoring egomotion. To test this hypothesis we identified the cortical area representing the medial trident whisker in the right hemisphere S1 area. This area differs in its anatomical connectivity pattern from facial whiskers, innervating both the spinal vestibular nucleus and the posterior parietal cortex, both areas involved in egomotion processing2, 3. Two thirds of units in the trident area showed speed tuning, a larger portion than the one fifth of speed tuned cells found in non-trident somatosensory areas. When electrically stimulating the trident area we were able to affect the locomotion speed of the animal. Stimulating non-trident areas was less efficient in driving such behavioral changes. These results show that the trident cortex activity represents aspects of egomotion and that this information is used to control locomotive behavior. 1.Thé, L., Wallace, M. L., Chen, C. Title: The somatosensory input to the brain during active sensation in awake behaving mice

Authors: *D. CAMPAGNER[1], M. H. EVANS[1], M. R. BALE[1,2], A. ERSKINE[1,3], R. S. PETERSEN[1];
[1]Fac. of Life Sci., The Univ. of Manchester, Manchester, United Kingdom; [2]Inst. de Neurociencias de Alicante UMH-CSIC, Alicante, Spain; [3]Natl. Inst. for Med. Res. (NIMR), London, United Kingdom

Abstract: Sensation is an active process where animals use motor control of their sense organs - eyes, fingers or whiskers - to inform their brains about the external world[1]. In any sensory system, it is fundamental to establish which sensory signals are transduced. Although it is well-understood how first order neurons respond to passive stimulation of sense organs under anaesthesia[2], it is not known whether these properties generalise to the awake, actively sensing state. We recorded the activity of single, well-isolated trigeminal primary afferents from awake, head-fixed mice (see the method described in [3]) as they explored a metal pole with their whiskers and, simultaneously, measured both kinematics (whisker position) and mechanics (forces on the whiskers) with high speed videography (1000 frames/s, total 1.5M frames). In each frame, we extracted key sensory parameters (whisker angle, whisker curvature, whisker-object contact) using a semi-automatic, custom tracking algorithm ('*WhiskerMan*')[,4,5,6]. We used Generalised Linear Models[2,7] to correlate kinematic/mechanic variables with neural activity. Consistent with theoretical predictions[5], we found that the best predictor of primary afferent activity during active sensation is the rotational force due to whisker bending ('bending moment')[6]. In contrast, the kinematic predictor (whisker position), known to predict activity well under passive conditions[2], performed poorly. We found that the relationship between kinematic and mechanical

variables is much richer in the awake, active sensing state compared to the passive state and that this difference can reconcile the apparent discrepancy in signalling between states. Our results identify a major somatosensory input to the brain in the awake, active sensing state and provide a framework for somatosensory encoding that unifies observations under active and passive conditions. 1. Title: Vibrotactile intensity coding by cortical neurons from the hindpaw representation in the rat SI cortex

Authors: *B. GUCLU;
Bogazici Univ., Istanbul, Turkey

Abstract: Our previous work suggested that high-frequency vibrotactile intensity information is poorly encoded by individual neurons from the hindpaw representation in the rat SI cortex (Güçlü, 2013; *Soc. Neurosci. Abstr.* 39, program no: 72.16). To quantify this in detail, extracellular spike data from 24 neurons of 7 anesthetized Wistar albino rats were analyzed based on several measures: average firing rate, vector strength of the spike phases, mutual information, and information rate. After classification of single units, a stimulator probe (d = 1.9 mm) was placed on the center of each receptive field in the glabrous skin. Sinusoidal mechanical displacements (duration: 0.5 s, rise/fall times: 50 ms) were applied at 5, 40 and 250 Hz with various amplitudes (0.1 μm - 270 μm; 10 trials for each amplitude). The neurons mostly responded at the onset of the stimulus at 40 and 250 Hz. Average firing rate and vector strength were calculated for the spikes occurring within the entire duration (including rise/fall times) of

the stimulus (*rd*, *vd*) and the 0.1-s onset period (*ro*, *vo*). At 40 Hz, *rd* and *ro* were significantly correlated with stimulus amplitude only in 15 and 18 neurons respectively (avg. r = 0.76 and 0.79). Similar results were obtained at 250 Hz for *rd* and *ro* (14 and 10 neurons sig. correlated with avg. r = 0.77 and 0.81). Correlation was higher at 5 Hz (18 and 20 neurons sig. correlated with avg. r = 0.85 and 0.87). However, in all cases the change in the average firing rate was low as the stimulus amplitude increased. Nonlinear regression for power law did not necessarily yield better results. Vector strength (*vd*, *vo*) was only correlated with amplitude in a few neurons, but it was especially high in the onset period at 5 Hz. Mutual information was calculated by 3×3 and 4×3 stimulus-response matrices by using shuffle correction. Information rate was found as a function of time by neglecting associations between bins, and analyses were repeated at successive bin sizes (2.9, 5.8, 11.6, 29, 58, 116, 290, 580 ms). Due to the high variability, mutual information between stimulus and response was very low (< 1 bit) at all frequencies. Information rate peaked approximately 30-60 ms after the stimulus onset, which accounts for the latencies in the somatosensory pathway and the rise time of the stimulus. Therefore, the results show that single neurons in the hindpaw representation mostly act as onset detectors especially for high-frequency vibrotactile stimuli. Intensity information is probably represented in a population of activated neurons.

Title: Subthreshold optogenetic modulation changes the representation of sensory stimuli by layer 6 corticothalamic neurons and disrupts neocortical processing of sensory change

Authors: *J. VOIGTS[1], C. A. DEISTER[2], C. I. MOORE[2];
[1]MIT, Cambridge, MA; [2]Brown Univ., Providence, RI

Abstract: Neocortex learns predictive models of sensory input and detects and represents novel stimuli differently from expected or repeated stimuli. How this detection of stimulus deviations

is implemented in the layered neocortical circuitry however, and how the novelty of a stimulus can be represented independently of the stimulus content is currently not understood. Here, using single-neuron recordings across neocortical layers and calcium imaging in awake mice, we find that layer 2/3 neurons encode heterogeneous, history dependent change signals, in contrast to layer 4 and 6 neurons that represent stimuli faithfully. Using calcium imaging in layer 6, we find that instead of selectively reacting to stimulus changes, layer 6 cells represent stimuli faithfully, similar to neurons in the main cortical input layer 4. This finding can explain why layer 2/3 neurons, which are driven by layer 4 and suppressed by layer 6 can represent stimulus changes without being constrained to represent the content of the most recent stimulus. Weak optogenetic stimulation of layer 6 disrupts the heterogeneous change encoding in layer 2/3 neurons, causing them to linearly represent current stimuli, without changing overall firing rates. Using simultaneous bidirectional optogenetic manipulation and 2-photon imaging in L6 corticothalamic neurons, we find that weak de- or hyperpolarization of these neurons does not change their overall baseline or vibrissa-stimulus evoked firing rates, but heterogeneously made neurons stimulus driven that were not without stimulation, or suppressed stimulus responses in otherwise driven neurons. The receptive fields of individual neurons were also changed, with optogenetic depolarization generally removing the neural representation of small changes in stimulus amplitude, while hyperpolarization preferentially made the L6 neuron firing rates reflect stimulus amplitude changes more faithfully. These findings suggest a central role in feature-independent change detection by normalization of neural responses to previous or expected stimuli through layer 6 mediated inhibition.

Title: Air-Track: a novel physical and virtual environment for sensorimotor behavior

Authors: *M. N. ABDELHAMID[1,2], H. ORABY[2], R. SACHDEV[2], Y. WINTER[2], M. LARKUM[2];
[1]Berlin Sch. of Mind and Brain, [2]Neurocure Cluster of Excellence, Dept. of Biol., Humboldt Univ. of Berlin, Berlin, Germany

Abstract: Natural behaviour occurs in multiple sensory and motor modalities. These multimodal behavioural interactions are embodied in the various iterations of the head-fixed rodent stepping on a treadmill or walking on an air ball while navigating a virtual reality, or discriminating between somatosensory stimuli. A goal of these new developments is to elicit natural behaviour by mimicking a quasinatural environment and to study the effect of locomotion on cortical responses at the cellular level. Here we have developed an "Air-Track" where head-fixed mice navigate a physical environment - an environment rich in visual, auditory and somatosensory cues. The environment has walls in the shape of a small plus maze, and surfaces for the animal to discriminate with its forepaws or whiskers or both. The Air-Track system combines a virtual reality - the animal is moving an Air-Track, but is not physically moving itself - and a physical reality, where movement by the mouse positions physical discriminanda that mouse uses in making decisions. In a two alternative forced choice task, the animal moves the Air-Track back and forth and rotates the maze from lane to lane, performing contextual behaviour. We are developing methods for tracking feet and whiskers, while monitoring the neocortical physiologic response in S1 and M1 forepaw and vibrissal cortex. This compact, light weight, low cost, and open source method for studying complex decision making is amenable to both head-fixed, and freely moving mice, and can be used with more complicated radial mazes, Y-mazes or with gap crossing paradigms using different modalities. With Air-Track, we come closest to providing a physical environment for eliciting the natural behaviour of mice in closed spaces.

Title: Area S1 and S2 mapping of vibrotactile stimulation using microECoG electrodes

Authors: *J. C. TANNER[1], T. HEARN[2], S. HELMS TILLERY[3];
[1]SBHSE, Arizona State Univ., Tempe, AZ; [2]SBHSE, ASU, Tempe, AZ; [3]ASU, SBHSE, AZ

Abstract: A dire prosthetic need remains in providing natural and discernible tactile feedback. Mapping the differences in cortical response to mechanical stimuli versus electrical nerve stimuli

is the first step in rectifying the differences. Our goal is to observe both responses and obtain a methodology for stimulating the peripheral nerve in a manner that elicits neural responses mimicking physical stimuli. The secondary goal is to observe any potential adaptation or reorganization of the peripheral stimulation response towards the natural response. A 64 channel 8x8 microECoG array was surgically placed over S1 and S2 on the surface of the right anterior parietal cortex in an anesthetized Rhesus macaque, NHP-M. A pneumatic mechanical stimulator was designed and built in order to provide specific frequencies of punctate stimulation that does not cause electrical noise interference with neurophysiological recording equipment. Using vibrotactile stimulation, specific locations on the NHP's dorsal and palmar left hand were stimulated. All channels were recorded using Tucker Davis Technology equipment and software at a sampling rate or 4000 Hz, with a bandpass filter of 2-1000 Hz and a notch filter at 60Hz. Preliminary principal component analysis was performed on two sessions' data to determine if individual digital stimulation could be decoded and there is substantial success. Experiments are undergoing and we plan on having a much more detailed response map from multiple NHP subjects.

Title: Whisker-based encoding of grating stimuli in head-fixed mice

Authors: ***B. R. ISETT**[1], D. E. FELDMAN[2];
[1]Helen Wills Neurosci. Inst., [2]Mol. & Cell Biol., Univ. of California Berkeley, Berkeley, CA

Abstract: Rodents use facial vibrissae to gather tactile information about their environment, including location, texture, and shape of nearby objects. While whisker sensory coding of location and texture are well studied, how the whisker system encodes shape is poorly understood. We studied how whiskers encode the spatial frequency of tactile gratings in head-fixed mice performing grating-smooth discrimination during a virtual foraging task. Mice ran on

a rotary treadmill while a smooth wall moved past, carrying either grating stimuli (raised ridges of 2, 4, 8 or 10 mm spatial period) or smooth stimuli (the curved wall alone), randomly interleaved. Stimulus movement was yoked to the mouse's locomotion, thus allowing for naturalistic stimulus presentation and self-initiated trials. Animals learned to lick for a water reward when a grating was present, and to suppress licking for smooth stimuli in a Go/No-Go design. 50% of mice learned to discriminate grating from smooth with 80-90% accuracy after ~3 weeks of training (d' = 1.5-1.7, n= 3 mice). All gratings were equally discriminated from smooth. To ask whether grating features are sensed similarly to texture, we examined high-acceleration whisker micromotion events (slip-sticks), which occur as a whisker skitters across a surface, and whose frequency and magnitude have been proposed to encode texture. We tracked 2 whiskers with high-speed imaging and found that average slip-stick rate and amplitude were higher on grating stimuli than smooth surfaces. Meanwhile, mean whisker velocity lowered, which is likely due to a reduction in whisking amplitude during grating contact. Despite these findings, linear classification of stimulus identity using slip-stick frequency, amplitude, or mean whisker speed substantially underperformed the observed mouse detection rates. This indicates that these features alone are not sufficient to explain behavioral performance. We next asked whether slip-sticks could encode grating period. Calculating whisker position along the stimulus surface for each slip-stick, we found that many slip-sticks were spatially aligned with ridge edges, and therefore the mean spatial interval between slip-sticks matched the spatial frequency of the underlying stimulus. We are currently recording spikes in primary somatosensory cortex (S1) to learn how grating period is represented in S1 spike patterns. We hypothesize that grating representations are transformed across cortical layers in S1, and that different neurons may exhibit different spatiotemporal receptive field properties analogous to those observed in primate area 3b when embossed letters and dots are scrolled over the fingertips.

Title: Affective social touch: Electrophysiological correlates of “ticklishness” in juvenile rats

Authors: *S. ISHIYAMA, M. BRECHT;
Bernstein Ctr. For Computat. Neurosci. Berlin, Humbold-Universität zu Berlin, Berlin, Germany

Abstract: The phenemenon of “ticklishness” has fascinated humans for more than two millennia. In rats much like in humans, heterospecific play and “tickling” body contacts induce vocalizations. Theses 50 kHz ultrasonic vocalizations (USVs) indicate positive emotions or “laughter” in these animals (Panksepp & Burgdorf, 1999). However, the neurophysiological correlates of ticklishness are poorly understood. We aimed to study ticklish “laughter” as well as its somatosensory neural correlates in rats. Male juvenile rats were implanted with an eight-tetrode microdrive in the trunk region of the primary somatosensory cortex. Rats received tickling and gentle touch stimulation by experimenter’s hand on the dorsal/ventral trunk and the tail, or experimenter’s hand was placed in the test box so that the rats chased the hand to initiate play. Bouts of 50 kHz USVs were emitted especially during tickling on the ventral trunk and chasing hand. Electrophysiological recordings revealed various neural response patterns to ‘tickling’ and gentle touch. Some cortical units increased the firing rate during ‘tickling’, while others were suppressed. Most interestingly, some tickling-activated cells also responded strongly when the rat chased the experimenter’s hand, even though this experimental condition did not involve physical interaction or direct tactile stimulation. Our data point to an involvement of somatosensory cortical responses in ‘tickling’ and play related behaviors.

Title: Two-photon calcium imaging depicts population encoding of vibrotactile information within excitatory and inhibitory networks of the limb associated mouse somatosensory cortex

Authors: *M. V. BANDET[1,2], I. R. WINSHIP[1,2,3];
[1]Neurosci. and Mental Hlth. Inst., [2]Neurochemical Res. Unit, [3]Psychiatry, Univ. of Alberta, Edmonton, AB, Canada

Abstract: To distinguish between varying somatosensory stimuli, the somatosensory cortex should process dissimilar stimuli with different patterns of neuronal activation. Intrinsic optical signal (IOS) imaging reveals activation in the mouse somatosensory cortex in response to limb stimulation and allows functional segregation of cortical regions activated by the contralateral hindlimb (cHL) and contralateral forelimb (cFL). IOS imaging and electrophysiological recordings of small numbers of single cells have been used in the past to demonstrate "tuning" of cortical regions and of individual cells within the somatosensory cortex of monkeys to different modalities of cutaneous stimulation. However, a large scale population based examination of somatosensory tuning to complex somatosensory stimuli has never been reported within the limb associated somatosensory cortex of rodents. Further, the differential role of excitatory and inhibitory neuronal responses to the processing of somatosensory information has never been elucidated. Here we used *in vivo* two-photon Ca2+ imaging after IOS to measure HL and FL somatosensory neuron responsiveness and response dynamics of populations as large as 250 neurons per optical section. We show that individual neurons within the somatosensory cortex can be precisely tuned to particular frequencies of vibrotactile limb fluctuation or broadly tuned to multiple frequencies of fluctuation, thereby forming a population code for sensory processing. We further demonstrate that higher frequency vibrotactile fluctuation of the limbs results in a larger percentage of neuron populations responding and with greater neuronal response strength. These population codes may result from preferential activation of different subsets of cutaneous and musculoskeletal receptors that respond to particular stimuli features and encode a sensory percept of somatosensory information needed for fine adjustment of motor control during limb movement. Here we also expressed an AAV for GcAMP6S under a neuron specific promoter and an AAV for tdTomato selectively in parvalbumin positive (PV+) inhibitory interneurons under CRE dependent control in PV-CRE mice. We demonstrate that long duration high frequency limb fluctuation results in increased PV+ cell activity within the somatosensory cortex as a potential means to actively inhibit prolonged responses of non-PV+ cortical neurons. As PV+ cell dysfunction is thought to be a contributor to sensory abnormalities in disorders such as schizophrenia and stroke, these results will be highly useful as a comparison for cell population specific changes in activity in these disorders.

Title: Stimulus feature coding by trigeminal ganglion neurons during natural whisking against an object

Authors: *K. S. SEVERSON, D. XU, D. H. O'CONNOR;
Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The rodent whisker system is a common model for sensorimotor processing, yet the stimulus features encoded by primary afferent neurons during active sensing remain poorly understood. To fill this gap, we aimed to explain variance in spiking of mouse trigeminal ganglion (Tg) neurons in terms of the forces and moments exerted during natural whisking against an object. We recorded 29 Tg single units, 15 rapidly adapting (RA) and 14 slowly adapting (SA), while simultaneously capturing high-speed video of whiskers (>1500 minutes at 500 frames/s) as head-fixed mice actively whisked in air and against a thin pole. Single unit spike rates ranged from 0.6 spikes/s to 47 spikes/s over the entire recording session, with instantaneous rates often surpassing 1000 spikes/s. Using measurements of whisker curvature, we calculated axial force, lateral force, and moment exerted on the follicle at each time point. Analysis to relate these quasistatic force/moment components to contact-evoked spiking is currently ongoing.

Title: Decoding acupuncture point specificity using multi-voxel pattern analysis

Authors: *W. JUNG, Y. CHAE;
AMSRC / Kyunghee Univ., Seoul, Korea, Republic of

Abstract: Objectives: Despite a number of previous fMRI studies, strong and consistent evidence supporting the neural representations of acupoint specificity have not been introduced. The present study applied multi-voxel pattern analysis (MVPA) and investigated the predictive capacity of fMRI data for decoding the neural representations of two different acupoints. **Methods:** Fourteen participants received acupuncture needles at both PC6 (median nerve) and HT7 (ulnar nerve) acupoints on their left hand. Twenty manual stimulations were randomly given at one of two acupoints. Using Freesurfer Desikan-Killiany Atlas, we defined region of interest (ROI) masks in individual brain. After constraining trial-wise data in anatomical ROIs, the prepared images were preprocessed by standardization of the parameter estimates within each voxel and by Euclidean normalization of image within each trial. We trained and tested a Gaussian Naive Bayes classifier on trial-wise fMRI data for discriminating accuracy in each ROI. **Results:** Our analysis showed a rank order of brain regions: activity in the primary somatosensory cortex and primary motor cortex yielded the most accurate trial-by-trial discrimination between acupuncture stimulations at PC6 and HT7. **Conclusions:** The present study demonstrated that distributed spatial patterns of brain activations encode two different acupoints. Our findings suggest that characteristics of acupoint specificity could be revealed with the application of MVPA approach.

Title: High stimulus-related information in inhibitory fast-spiking interneurons of the adult rat barrel cortex *in vivo*

Authors: *V. REYES-PUERTA, S. KIM, J.-J. SUN, B. IMBROSCI, W. KILB, H. J. LUHMANN;
Inst. of Physiology, Univ. Mainz, Mainz, Germany

Abstract: A major goal in current neuroscience is to understand how sensory information is represented and processed in the central nervous system. In this respect, the manner in which populations of inhibitory (INH) and excitatory (EXC) neocortical neurons collectively encode stimulus-related information is a fundamental, yet still unresolved question. In the present study we address this question by simultaneously recording with 128-channel multi-electrode arrays the activity of cell ensembles (of up to 74 neurons) upon sensory stimulation in the anesthetized adult rat barrel cortex *in vivo*. The recorded cells were distributed along all cortical layers of 3-4 neighboring columns, and further classified as fast-spiking (presumed INH) and putative pyramidal EXC neurons according to their distinct extracellular spike waveforms. Using two different whisker stimulus modalities (location and frequency) we estimated the stimulus encoding performance of identified neurons by means of mutual information and linear classifiers. These analyses revealed that in granular and infra-granular layers individual INH neurons discriminate better between restricted sets of stimuli (containing ≤6 stimulus classes) than EXC neurons. In addition, assemblies containing all INH cell provided as much information about such stimuli as comparable large ensembles including the ~20% most informative EXC neurons, however, presenting a lower amount of information redundancy. Moreover, the information provided by the remaining ~80% least informative EXC neurons was majorly redundant to that conveyed by the most informative ones, advocating for a sparse stimulus encoding scheme employed by EXC cortical neurons. Our results were consistent when applying both linear discriminant analysis classifiers and theoretical information measurements, thus indicating that a rather similar amount of information might be represented by the total population of EXC neurons as compared to that represented by INH neurons, however with a higher degree of redundancy. Taken together, these data suggest that a consortium of INH neurons dominates the information content about sensory stimuli within the neocortical network, thereby efficiently shaping the processing of incoming sensory information. This conclusion extends our view on the role of the INH system to orchestrate cortical activity.

Title: Functional dynamics of heterogenous interneuron and pyramidal cell subnetworks over multiple time scales

Authors: *C. A. DEISTER, K. SALEHI, A. TRIEDMAN, C. I. MOORE;
Neurosci., Brown Univ., Providence, RI

Abstract: Dynamic sensory processing in neocortex relies on interactions between populations of pyramidal cells and interneurons. The general activity of pyramidal cells and key interneuron subtypes, such as parvalbumin-positive (PV+) and somatostatin-containing (SOM) neurons, has been studied across cortical sensory areas and is reasonably understood. However, there is remarkable heterogeneity (both functional and genetic) within each of these well-described cell classes whose behavioral relevance is largely unknown. We studied the activity of PV+, SOM and pyramidal cells in layers 2/3 and 5a within the vibrissal region of mouse primary somatosensory cortex (barrel cortex) over multiple days using two-photon calcium imaging, before and after animals learned to report the detection of weak tactile stimuli. Using the genetically encoded calcium indicators GCaMP6f and 6s along with an array of cre-driver and bac-transgenic lines, we imaged the activity of each interneuron population alone or in combination with pyramidal cells. For each cell class there are distinct alterations in the trial-to-trial reliability of sensory-evoked responses for 'threshold-level' stimuli, with the overall trend being a stable increase. Of note, many SOM neurons showed very large increases in reliability, with most appearing unresponsive before training and ultimately many showing even higher reliability than PV+ and pyramidal cells. We also examined the degree of trial-to-trial correlation between the evoked-responses of cells within each class, and across classes, during detection. For PV+ and pyramidal cells these correlations were relatively weak in trained and untrained animals, but small subgroups of cells showed strong correlations that were highly indicative of successful perception. In contrast, we found negligible correlations among SOM cells in untrained animals, but once animals were trained, SOM cells showed high correlations with each other. Further, highly informative pyramidal neurons showed large, and significant, positive and negative correlations with SOM neurons. Overall, our data support the notion that interneurons form distinct and functionally heterogeneous subnetworks with pyramidal cells to help represent weak or ambiguous sensory information, and potentially use that representation to better inform action. Ongoing studies are aimed at characterizing these dynamics with competing representations by using an active tactile discrimination task.

Title: Temperature representation in the *Drosophila* brain

Authors: *M. GALLIO[1], D. D. FRANK[1], G. C. JOUANDET[1], P. J. KEARNEY[1], L. J. MACPHERSON[2];
[1]Neurobio., Northwestern Univ., Evanston, IL; [2]Departments of Biochem. and Mol. Biophysics, Columbia Univ., New York, NY

Abstract: In *Drosophila*, rapid temperature changes are detected at the periphery by dedicated receptors forming a simple sensory map for hot and cold in the brain. However, flies show a host of complex innate and learned responses to temperature, indicating that they are able to extract a range of information from this simple input. Our work aims at defining the anatomical and physiological repertoire for temperature representation in the *Drosophila* brain. Here, we use a photolabeling strategy to trace the connections that relay peripheral thermosensory information to higher brain centers, and show that they largely converge onto three target regions: the Mushroom Body, Lateral Horn (well-known centers for sensory processing) and the Posterior Lateral Protocerebrum, a region we now define as a major site of thermosensory representation. Then, using *in vivo* calcium imaging, we describe the thermosensory projection neurons selectively activated by hot or cold stimuli. Fast-adapting neurons display transient “ON” and “OFF” responses and track rapid temperature shifts remarkably well, while slow-adapting cell responses better reflect the magnitude of simple thermal changes. Unexpectedly, we also find a population of 'broadly-tuned' cells that respond to both heating and cooling, and show that they are required for normal behavioral avoidance of both hot and cold in a simple 2-choice temperature preference assay. Taken together, our results uncover a coordinated ensemble of neural responses to temperature in the fly brain, demonstrate that a broadly tuned thermal-line contributes to rapid avoidance behavior, and illustrate how stimulus quality, temporal structure, and intensity can be extracted from a simple glomerular map at a single synaptic station.

Title: Choice- and stimulus-related activity mapped across layer 2/3 of mouse s1 and s2

Authors: *S. E. KWON, H. YANG, G. MINAMISAWA, D. H. O'CONNOR;
Neurosci., Brain Sci. Inst. / Johns Hopkins Univ., Baltimore, MD

Abstract: During perceptual decisions, the activity of single sensory cortex neurons and behavioral choices often co-vary, even when the stimulus is identical. “Choice probability” (CP) is the probability with which an ideal observer can predict the choice of the animal based on a single-trial neuronal response. CP is frequently studied because it links neuronal activity and perception. CP is often higher for neurons with greater stimulus sensitivity. Intuitively, this is consistent with more informative neurons contributing more to perceptual decisions. However, theoretical studies suggest a key role for inter-neuronal “noise” correlation (Rsc) in determining CP. The exact relationship between CP, neuronal sensitivity, and Rsc is unclear. Also unknown are how CP is mapped at cellular resolution across multiple sensory cortex areas, and to what degree choice is predicted by population activity patterns unobservable when recording from one or a few neurons at a time. We trained mice to detect weak deflections of a single whisker. Using cellular resolution 2-photon calcium imaging during the task, we measured activity across hundreds of L2/3 neurons in whisker areas of primary (S1) or secondary (S2) somatosensory cortex (S1: 4 mice; S2: 4 mice). Ideal observer analysis quantified how well each neuron discriminated stimulus presence/absence (“Stimulus probability”, SP) and the choice of the mouse. SP is a measure of neuronal sensitivity to our stimulus. We also quantified Rsc among neuron pairs. The fraction of neurons with significantly above-chance SP was greater in S1 than S2 (S1: 47%, S2: 30% of responsive neurons). S1 neurons also had higher SP (S1 median: 0.57; S2: 0.53, $p<0.001$, K-S test). Thus, stimulus representation was somewhat stronger in S1. In contrast, S2 and S1 neurons predicted choice similarly (S1 median CP: 0.56, S2: 0.55, $p=0.065$, K-S test). Mean Rsc with other responsive neurons was higher for neurons in S2 vs S1 (0.17 vs 0.09; $p<0.001$, Wilcoxon rank sum test). Partial correlations revealed that CP depended

separately on a neuron's stimulus sensitivity and its mean Rsc. We used a machine learning algorithm to decode the stimulus and choice from populations of hundreds of S1 or S2 neurons. S1 populations yielded better decoding of the stimulus (S1: 93 ± 3% correct; S2: 75 ± 4%; mean ± SEM across mice). Mouse performance (78 ± 1%) was similar to that of the S2 decoder. Decoding of choice was similar in the two areas (S1: 75 ± 4%; S2: 77± 2%). Could widespread choice- and stimulus-related activity reflect direct S1<->S2 communication? We imaged S1->S2 axons (2 mice), and S2->S1 axons (4 mice), and found stimulus- and choice-related activity propagating bidirectionally.

Title: TMS over V5/hMT+ disrupts tactile direction discrimination

Authors: ***T. AMEMIYA**[1,2], B. BECK[2], H. GOMI[1], P. HAGGARD[2];
[1]NTT Communication Sci. Labs., Kanagawa, Japan; [2]Univ. Col. London, London, United Kingdom

Abstract: Several human imaging studies have found that visual motion area V5/human medial temporal complex (hMT+) responds to tactile motion. A multivariate pattern analysis found specific patterns of activity in V5/hMT+ corresponding to leftward and rightward tactile directions. Some studies have also reported activations in the primary somatosensory cortex (SI) and posterior parietal cortex (PPC) during tactile motion, but they have not established a causal involvement of these areas in tactile direction processing. Here, we created an ecological tactile motion stimulus by varying the direction of a single object moving across the fingertip. We disrupted activity in SI, PPC (Brodmann's areas 7/40) and V5/hMT+ using online double-pulse transcranial magnetic stimulation (TMS) while participants judged tactile motion direction. TMS over both SI and V5/hMT+, but not over PPC, reduced tactile direction discrimination. Our results demonstrate, for the first time, that V5/hMT+ plays a causal role in tactile direction processing, extending previous studies that found directionally sensitive patterns of activity in

V5/hMT+. Further, our findings are consistent with a serial model of cortical tactile processing, in which processing by higher-order perceptual areas depends upon the quality of input received from SI. By contrast, our results do not provide clear evidence that the PPC is causally involved in discriminating tactile direction. This suggests that the pathway for tactile motion processing is not routed through inferior regions of the PPC.

Title: Locus coeruleus activity patterns modulate coding properties of the ventral posteromedial nucleus in the thalamus of the rat vibrissae pathway

Authors: *C. RODENKIRCH, Y. LIU, Q. WANG;
Columbia Univ. Dept. of Biomed. Engin, New York, NY

Abstract: The locus coeruleus (LC) is the sole source of norepinephrine (NE) to the forebrain. The varying firing patterns of the LC have a large effect on behavioral state, with certain patterns shown to be associated with optimal performance in sensory-initiated behavioral tasks. However, how LC activity modulates neural coding in the early stage of the sensory pathways remains poorly understood. We recorded single-unit activity in the ventral posteromedial (VPM) nucleus of the thalamus, an early stage of the rat's vibrissae pathway, in pentobarbital-anesthetized rats. During each recording, varying microstimulation patterns (Tonic 1, 2, and 5 Hz as well as Phasic) were delivered to the LC. For these varied patterns, the feature selectivity of each recorded neuron was then estimated using spike-trigged reverse correlation analysis. Our preliminary data showed that stimulation of the LC resulted in a moderately decreased firing rate for neurons in the VPM. More interestingly, we found that LC stimulation caused a dramatic reduction in the occurrence of bursting activity within the VPM while concurrently causing an increase in the temporal precision of events in the peristimulus time histogram. Feature selectivity of the VPM neurons was not significantly altered by LC stimulation. However, on average, spikes were found to encode significantly more information about the feature during LC stimulation. Taken together, these results suggest that LC activity modulates the coding properties of neurons in the early stage of sensory pathways.

Title: Context-dependent information decoding of sensory-evoked responses in the rat vibrissa pathway

Authors: *H. J. ZHENG[1], C. WAIBLINGER[1], B. J. HE[2], G. STANLEY[1];
[1]Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. & Emory Univ., Atlanta, GA; [2]Natl. Inst. of Neurolog. Disorders and Stroke, Natl. Inst. of Hlth., Bethesda, MD

Abstract: A fundamental pursuit of neuroscience is to understand how external stimuli are encoded in the brain and how the information about the stimuli is extracted to form sensory perception. A confounding problem in sensory coding is that the representation of the same stimulus in the primary sensory cortex is highly variable. This variability arises at least partially from the internal state of the brain, which is spontaneously dynamic, and can also be influenced by bottom-up mechanisms such as sensory adaptation and top-down mechanisms related to level of arousal, attention, etc. We hypothesize that the internal state of the cortex can be at least partially extracted from the spontaneous activity and provide the context under which the stimulus is encoded. Therefore, given access to the spontaneous activity, an ideal observer can reduce the uncertainty about the stimulus despite the variable cortical response. In order to uncover the interaction between spontaneous and sensory-evoked activity, we recorded the cortical activity simultaneously with a genetically-encoded voltage indicator (ArcLight) and local field potential (LFP) in the same cortical column of rat barrel cortex in response to a single, punctate whisker deflection. We find that the frequency content in the pre-stimulus spontaneous activity predicts the magnitude and the variability of the stimulus-evoked response. In trials where the pre-stimulus spontaneous activity exhibits less low frequency fluctuation (quantified with a frequency ratio, which is the ratio of total power in 0-5 Hz band to the total power in 0-50

Hz), a whisker stimulus evokes a smaller but less variable thus more easily discriminable response. We find that sensory adaptation, where repetitive whisker stimulation (10 Hz deflection) attenuates the cortical response over hundreds of milliseconds, changes the frequency content in the spontaneous activity in a dynamic manner. Adaptation shifts low frequency trials into a higher-frequency regime and vice versa, suggesting that sensory adaptation may serve to stabilize the frequency content in the cortex and may have dynamic effects on the detection and discrimination of the stimulus depending on the initial state of the cortex.

Title: Altered sensory processing following cortical spreading depression in awake mice

Authors: ***P. D. PARKER**[1,2], J. J. THERIOT[1], J. M. MENDEZ[1], K. BRENNAN[1];
[1]Dept. of Neurol., [2]Interdepartmental Program in Neurosci., Univ. of Utah, Salt Lake City, UT

Abstract: Migraine is a pervasive neurological disorder affecting 12% of the population. For many individuals, the disorder exceeds the hallmark headache and includes maladaptive distortions of sensory perception and motor function. Cortical spreading depression (CSD), the physiological correlate of many of these distortions, has the capability of inducing plasticity in neural networks that might underlie the sensory features of individual migraine attacks, and of chronic migraine. To better understand the effects of CSD on sensory processing, we used 2-photon microscopy to characterize neural response patterns in awake mice to whisker stimulations prior to and after CSD. This includes both wild type mice and knock-in mice carrying the genetic mutation for familial hemiplegic migraine, type 2 (FHM2). CSD entails a major shift in the ionic environment in the extracellular space, including dramatic increases in the concentrations of extracellular potassium and neurotransmitters, such as glutamate. Intracellularly, cytosolic Ca^{2+} levels remain elevated in neurons for several minutes and neurons

remain depolarized for 3-5 minutes after the passing of the wave. A subset of neurons within the barrel cortex showed a potentiated response to trains of whisker stimulations after CSD. More interestingly, additional subsets of neurons showed a depressed response following CSD, as well as alterations in the timing of responses to whisker stimulation. This provides evidence that CSD induces complex changes in neural network processing and provides potential network level mechanisms that underlie the changes in sensory perception seen in migraine.

Title: Establishing the link between single afferent firing and perception across the foot sole

Authors: *N. STRZALKOWSKI, R. MILDREN, L. BENT;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Introduction: Four classes of cutaneous afferents (FAI, FAII, SAI, SAII) mediate tactile sensibility across the soles of the feet. Each class is sensitive to unique features of tactile stimuli, and may provide different functional cues to aid in the control of posture and gait. Monofilament (light touch) testing is a common clinical and research tool used to determine perceptual and afferent firing thresholds. Previous work in the hand found light touch perceptual thresholds to most closely couple with the firing threshold of FAI afferents. FAI afferent thresholds were consistent across the hand and similar to perceptual threshold in the fingers, however perceptual thresholds were found to be elevated in the palm [1]. The purpose of the present study was to establish the link between afferent firing and perceptual thresholds across the foot sole, and to investigate the influence of skin hardness on these measures. Methods: Microneurography was used to identify and record from 102 foot sole cutaneous afferents in 21 subjects (12 male, 20-27 yrs). Once identified, afferent monofilament firing thresholds (minimum force to evoke an action potential) were measured. Monofilament perceptual thresholds (minimal force to evoke a percept) were also recorded and compared to afferent firing thresholds. Skin hardness was measured at each receptive field using a hand held durometer

(arbitrary units; au). Results: FAI and FAII afferents had significantly lower firing thresholds than SAI and SAII afferents. Perceptual thresholds were not found to be different from FAI or FAII afferent firing threshold but were significantly lower than the firing thresholds of SAI and SAII afferents. Both perceptual threshold and FAI afferent threshold were significantly lower in the arch compared to the heel, forefoot and toe regions. Positive correlations were found between both FAI ($r=0.357$, $p<0.018$) and FAII ($r=0.758$, $p=0.007$) firing threshold and receptive field hardness. Perceptual threshold was also found to correlate with receptive field hardness ($r=0.433$, $p<0.0001$). Conclusions: Across the foot sole, the firing of FA afferents appears to mediate monofilament perceptual threshold, while SAI and SAII afferents do not contribute. Receptive field hardness was shown to influence FAI and FAII firing thresholds, and is thought to help explain observed afferent firing and perceptual threshold differences across the foot sole. Establishing the link between foot sole afferent firing and perceptual threshold is necessary to fully understand the contributions of cutaneous afferent classes to perception and motor control. Title: Mechanisms of illusory continuous force sensation induced by asymmetric vibration - A computational approach to sensory processing -

Authors: ***H. GOMI**, T. AMEMIYA, S. TAKAMUKU, S. ITO;
NTT Communication Sci. Labs, Kanagawa, Japan

Abstract: Force sensation is one of the important information in various interactions with environments. Several recent attempts have succeeded to elicit illusory perception of tangential continuous force only by applying asymmetric vibration without any application of continuous force (e.g, Amemiya et al. 2004; Tappeiner et al. 2009; Amemiya & Gomi 2014), but its perception mechanism is not yet well understood. The present study, therefore, focuses on the following questions. How do we perceive an illusory force while temporal mean force is physically zero? Which mechanoreceptor contributes in yielding this illusory sensation? To examine these questions, we have developed a sensory processing model which can fit the illusory force perception performance obtained from a psychophysical experiment. In the

experiment, subjects (n = 10) pinched a small hexahedron object (19 g) in which a linear actuator was embedded, so as to apply the vibration in tangential direction at the skin contact. We used 50 patterns of vibration stimuli (6 sec with sign reversal twice) generated by bipolar rectangular driving patterns. The subjects answered the perceived force direction (2-alternative) of the last phase of each stimulus (100 trials in random order). The selection probability of perceived force direction for each vibration stimulus, which corresponds to the force direction clarity, was greatly varied by the stimulus patterns. To find dominant factors in characterizing the force-direction clarity, we introduced a model which calculates temporal average of detected sensory signal over a threshold. Then, we tested position, velocity, acceleration, and interaction force patterns during the application of vibration stimuli as candidates of the dominant sensory signal for the direction perception. As a result, selection probability function of the force directions for all the stimulus patterns was successfully modeled (correlation coefficient: 0.83) by the interaction force signal. The force threshold obtained by the fitting optimization was 10 mN, which is comparable to the threshold of the slowly adapting type II (SA II) mechanoreceptor measured previously (Johansson et al. 1980). These results suggest that SAII signal strongly contributes to induce the illusory continuous-force perception caused by asymmetric vibration. This implication is consistent to the functional role of the SA II expected in the previous studies, and therefore the model would bridge the gap between the tactile sensory processing and force perception.

Title: Closed-loop optogenetic stimulation reveals primary somatosensory cortex participation in whisk timing

Authors: ***J. B. SCHROEDER**, V. J. MARIANO, G. I. TELIAN, J. T. RITT;
Boston Univ., Boston, MA

Abstract: Active sensing incorporates closed-loop behavioral selection of information during sensory acquisition. The rodent whisker tactile system provides an ideal platform for studying these processes. We examined coordinated head and whisker motions of unconstrained mice performing tactile search for a randomly located reward, and found that mice select from a diverse range of available active sensing strategies, based at least in part on the behavioral context of whisker contacts. In particular, mice selectively employed a strategy we term contact maintenance, where whisking is modulated to counteract head motion and sustain repeated contacts, but only when doing so is likely to be useful for obtaining reward. The context dependent selection of sensing strategies, along with the observation of whisker repositioning prior to head motion, suggests the possibility of higher level control, beyond simple reflexive mechanisms. In order to further investigate a possible role for primary somatosensory cortex (SI) in whisk-by-whisk motion, we delivered optogenetic feedback to SI, time locked to whisking estimated through facial electromyography. We found that stimulation regularized whisking (increasing overall periodicity), and shifted whisking frequency, changes that emulate behaviors of rodents actively contacting objects. We found different effects for stimulation on protractions versus retractions, possibly encoding that contact is more likely during forward motion of the whiskers, and downstream areas may show greater sensitivity to SI activity during protractions. Additionally, stimulation induced small, short latency motions similar to those in a previous study (Matyas, et al., Science, 2010) in head fixed animals, except that we induced protractions rather than retractions. These findings support a role for sensory cortex in driving whisk-by-whisk motor outputs, but suggest a coupling that depends on behavioral context. Elucidating any role for sensory cortex in motor outputs is important to understanding active sensing, and may provide novel insights to guide the design of sensory neuroprostheses that exploit active sensing context.

Title: Sensory substitution in amputees: intraneural versus transcutaneous nerve stimulation for the bidirectional control of prostheses

Authors: *F. M. PETRINI[1], E. D'ANNA[1], S. RASPOPOVIC[1,2], S. MICERA[1,2];
[1]EPFL, LAUSANNE, Switzerland; [2]The BioRobotics Inst., Scuola Superiore Sant'Anna, Pisa, Italy

Abstract: Sensory feedback is essential for sophisticated and effortless hand control. Appropriate sensations from the periphery and their interaction with the external world are essential for correct agency and ownership of the hand. Sensory feedback in amputees can be conveyed both by direct neural stimulation (DNS) via implantable devices or by means of superficial transcutaneous electrical nerve stimulation (TENS). In this work, we systematically compared DNS and TENS, both in open (only electrical stimulation) and in closed-loop (i.e., stimulation integrated in a bidirectional prosthesis). The same transradial amputee was stimulated with TIME electrodes implanted in the median and ulnar nerves (DNS) and with TENS during two different sessions of experiments providing monopolar and multi-polar electrical stimulation. We showed that intraneural single channel stimulation elicits close-to-natural touch sensations over discrete areas of the phantom hand, while TENS provides a fuzzy paresthesia. For the first time, we studied the effects of multipolar stimulation, which evoked, in some cases, linear combinations and, in others, non-linear summation of the sensations resulting from mono-polar stimulation. Unexpectedly, in the latter condition, the resulting perceived area was completely different from those related to the mono-polar sensations. Finally, the performance of the control of the force exerted by the prosthesis, during bidirectional prosthesis control was evaluated when TENS feedback was used, and compared to the results reported with intraneural stimulation. We showed that similar performance can be achieved with the two approaches. Overall, these results establish clear guidelines regarding the use of non-invasive and invasive solutions for sensory feedback restitution in the next generation of prosthetic devices.

Title: The role of extracellular calcium concentration ($[Ca^{2+}]_e$) on methylmercury (MeHg)-induced toxicity in mouse dorsal root ganglia (DRG) primary cultures

Authors: *E. FORMILLER[1], H. HANNON[2], W. D. ATCHISON[3];
[1]Neurosci. Progam, [2]Comparative Med. & Integrative Biol., [3]Pharmacol. & Toxicology, Michigan State Univ., East Lansing, MI

Abstract: MeHg is a neurotoxicant that alters normal nervous system function in distinct neuronal populations. One of the first symptoms of MeHg poisoning is sensory neuropathy, corresponding to dysfunction and degeneration of DRG. Previous studies have shown that MeHg poisoning causes a biphasic increase in $[Ca^{2+}]_i$, with phase 1 attributed to the release of Ca^{2+} from intracellular stores and phase 2 due, in part, to the influx of Ca^{2+}_e; these perturbations in $[Ca^{2+}]_i$ contribute to MeHg-induced cytotoxicity. To examine the extent to which Ca^{2+}_e contributes to decreased viability in MeHg toxicity of DRG, we exposed primary mouse DRG to MeHg in the presence and absence of Ca^{2+}_e. DRG (T11-L6) were isolated from 4-6 week-old C57BL/6J mice, enzymatically and mechanically dissociated, and plated as heterogeneous cultures for experiments; experiments were carried out within 24 hours of isolation to prevent dedifferentiation of neuronal subtypes. Cells were exposed to 200 nM, 500 nM, 1μM, or 2 μM MeHg in Hepes Buffered Saline (HBS) for 30 minutes, and viability was assessed at either 1 hr or 4 hrs following MeHg exposure using a commercial cell viability assay. For experiments carried out in the absence of Ca^{2+}_e, Ca^{2+} was excluded from the HBS and EGTA was added to chelate trace amounts of Ca^{2+}. Viability of DRG was reduced 1 hr following exposure only at high [MeHg], as compared to controls. In contrast, all [MeHg] reduced DRG viability at 4 hrs post-exposure. Loss of DRG viability was both [MeHg]- and time-dependent in standard HBS. With the removal of Ca^{2+}_e, [MeHg]-dependence remained at only high [MeHg] and time-dependence was lost; viability remained significantly reduced at high [MeHg] 1 hr post-exposure. However, viability at 4 hrs was reduced only at 2 μM MeHg. Removal of Ca^{2+}_e increased DRG viability at intermediate [MeHg] 4 hrs post-exposure. In summary, reduction of DRG viability occured at high [MeHg] at 1 hr post-exposure in a Ca^{2+}_e-independent manner. In contrast, the loss of DRG viability at 4 hrs post-exposure is measureable at all [MeHg] and is Ca^{2+}_e-dependent. These results show that decreased DRG viability due to Ca^{2+}_e only occurs at later time points, and there may be another mechanism that is contributing to reduced DRG viability at earlier time points. Title: The modulatory effects of caffeine on the intrinsic properties of spinal lateral motoneurons

Authors: *M. S. RIVERA OLIVER[1], Y. ALVAREZ-BAGNAROL[2], M. DIAZ-RIOS[3]; [1]Univ. of Puerto Rico-Institute of Neurobio., San Juan, PR; [2]Anat. and neurobiology, Inst. of Neurobio., San Juan, Puerto Rico; [3]Anat. and Neurobio., Inst. of neurobiology, San juan, Puerto Rico

Abstract: Caffeine is the most consumed psychoactive drug worldwide. It produces similar behavioral effects as other classical psychostimulants, such as cocaine and amphetamines, mainly increasing motor activation, arousal, and reinforcing effects related to neural reward systems. Caffeine is known to be a non-selective adenosine receptor antagonist (A1/A2a mainly). Most of the studies assessing the effects of caffeine and/or adenosine receptor agonists and antagonists on locomotor behavior have been performed on freely behaving rodents using systemic administration of these drugs that can activate multiple neural pathways making extremely difficult to study specific mechanisms of action. We propose to elucidate the cellular mechanisms by which caffeine modulates the intrinsic membrane properties of spinal lateral motoneurons, which are an essential component of the lumbar neural network producing hindlimb locomotion in mammals, through bath perfusion onto spinal cord slices, which have significant components of the spinal network controlling locomotion. Recent data from our laboratory from extracellular recordings on spinal lumbar nerves in the presence of serotonin (5-HT), NMDA and dopamine (DA), which are known to elicit a fictive locomotor pattern, shows that caffeine modulates motor activity by enhancing the bursting properties of motoneurons (Acevedo et al. 2015). Thus, we studied the neuromodulatory effects of caffeine and other adenosine receptor antagonists on the intrinsic properties of spinal lateral motoneurons using pharmacological blockade and perforated patch clamp recordings. The application of 5-HT and NMDA, in the presence of synaptic blockers of inhibitory neurotransmission depolarized the membrane potential of most motoneurons reversibly. The addition of caffeine (50μM), in the

presence of 5-HT and NMDA, significantly depolarized the membrane potential (~10-15mV), hyperpolarized the action potential (AP) threshold and decreased the AP after-hyperpolarization (AHP) in 70% of the recorded lateral motoneurons. In 17% of the recorded lateral motoneurons caffeine showed an inhibitory effect by increasing the AHP and no effect in the AP threshold. Finally, in 13% of the recorded lateral motoneurons tha application of caffeine did not produce any significant effects on any of the parameters measured. The excitatory effects produced by caffeine on most of the lateral motoneurons suggest that they could be a primary target for the neuromodulatory effects of caffeine in the lumbar region of the spinal cord.

Title: Supraspinal changes following human spinal cord injury contribute to altered neural activation strategies during dynamic contractions

Authors: *H. E. KIM[1], L. M. ROGERS[2], D. M. CORCOS[3], T. G. HORNBY[4];
[1]Grad. Program in Neurosci., Univ. of Illinois At Chicago, Chicago, IL; [2]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [3]Physical Therapy and Human Movement Sci., Northwestern Univ., CHICAGO, IL; [4]Physical Therapy, Univ. of Illinois, CHICAGO, IL

Abstract: *Introduction:* Recent data suggest subjects with incomplete spinal cord injury (SCI) generate greater central drive of both the knee extensors and plantarflexors during lengthening maximal voluntary contractions (MVCs) than during isometric or shortening MVCs. Several lines of evidence link these unexpected gains in central drive during lengthening contractions to spinal mechanisms, including increased Ia excitation of agonists. The degree to which supraspinal changes following SCI may contribute to unique activation strategies during dynamic contractions is still unknown. The current study's aims were to investigate cortical and corticospinal contributions to specific control of dynamic contractions following SCI. *Methods:* Single-pulse transcranial magnetic stimulation (TMS) was used to probe modulation of peak-to-

peak motor evoked potential (MEP) amplitudes and cortical silent period (CSP) durations during lengthening and shortening contractions of the tibialis anterior in 8 SCI and 8 healthy control subjects. *Results:* Active motor thresholds during low-level contractions (10-30% MVC) were higher in SCI than controls (46.5 ± 10.5% vs 31.4 ± 14.6% of maximum stimulator output; $p < 0.05$). SCI subjects demonstrated smaller MEPs (normalized to maximal M-waves) than controls during submaximal (75% MVC) lengthening (0.41 ± 0.24 vs 0.66 ± .21 for SCI and controls, respectively; $p < 0.05$) and shortening contractions (0.36 ± .20 vs 0.64 ± 0.16; $p < 0.01$). Contraction type-dependent differences in modulation of MEPs were not detected within either group. However, there was a trend for larger lengthening than shortening MEPs in the SCI group ($p = 0.07$). SCI subjects demonstrated similar CSP durations during lengthening and shortening submaximal contractions (140 ± 29 and 152 ± 34 ms for lengthening and shortening, respectively; $p > 0.05$). Consistent with previous literature, however, controls demonstrated shorter CSPs during lengthening than shortening contractions (187 ± 79 vs 210 ± 85 ms; $p < 0.05$), indicating decreased intracortical inhibition during lengthening. Similar comparisons of CSPs were observed during MVCs. *Conclusion:* Overall, corticospinal excitability was decreased in SCI subjects compared to controls, most likely due to impaired transmission between pyramidal and spinal neurons. Differences in modulation of CSPs across contraction types between SCI and controls also suggest specific cortical changes post-chronic SCI. In the context of recent findings, the current study suggests changes at spinal and supraspinal levels following SCI alter the neural activation strategies used to control dynamic contractions.

Title: Galvanic vestibular stimulation is available to induce long-term potentiation of indirect cortico-motoneuronal excitation in a relaxed arm muscle in humans

Authors: *S. SUZUKI[1], T. NAKAJIMA[1], S. IRIE[1], Y. MASUGI[2], T. KOMIYAMA[3], Y. OHKI[1];
[1]Kyorin Univ. Sch. of Med., Tokyo, Japan; [2]Univ. of Tokyo, Tokyo, Japan; [3]Chiba Univ., Chiba, Japan

Abstract: We previously reported that repetitive combined stimulation (RCS) of pyramidal tracts and peripheral nerve can induce long-term potentiation (LTP) of indirect cortico-motoneuronal (C-M) excitation, which could be mediated by cervical propriospinal neurons (PNs) in humans. However, this procedure has a limitation for clinical application, since the LTP could be induced only when the target muscle was voluntarily contracted. We hypothesized that vestibular stimulation, which is known to activate cervical interneurons in animals, can be substituted for voluntary contraction to induce LTP in the indirect C-M excitation. Healthy volunteers, who all gave written informed consent, were seated with recording surface electromyogram of the right biceps brachii (BB). For RCS, transcranial magnetic stimulation (TMS) to the contralateral motor cortex (arm area) was delivered, in conjunction with electrical stimulation of the right ulnar nerve, at 0.2 Hz for 10 min (120 pairs). Interstimulus interval was set at 10 ms (TMS behind), which gave converging inputs in upper cervical segments. During RCS, BB was usually kept relaxed, and bilateral bipolar galvanic vestibular stimulation (GVS) was sometimes delivered. Four types of the interventions were conducted in separate sessions; (1) RCS alone, (2) RCS with cathodal GVS (right electrode cathode), (3) RCS with anodal GVS, and (4) RCS with weak voluntary contraction of BB. To evaluate effects of the interventions, motor-evoked potentials (MEPs) induced by TMS were obtained from BB. After the intervention with RCS alone, MEPs in BB were significantly suppressed, and this suppression lasted for ~60 min. In contrast, RCS with cathodal or anodal GVS induced LTP in MEP, which was very similar to that after RCS with BB contraction. The potentiation was not observed in the initial part of MEP. The spatial facilitation effect induced by the combined stimulation was significantly enhanced after RCS with GVS intervention. Our observations suggest that RCS with GVS could efficiently induce LTP in the indirect C-M excitation, which may be mediated by cervical PNs, even without voluntary contraction.

Title: Effects of sensorimotor rhythm modulation on the flexor carpi radialis H-reflex

Authors: *A. K. THOMPSON[1], H. CARRUTH[2], R. HAYWOOD[2], N. J. HILL[3], W. A. SARNACKI[4], D. MCFARLAND[4];
[1]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [2]Univ. of Glasgow, Glasgow, United Kingdom; [3]Burke Med. Res. Inst., White Plains, NY; [4]Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr., Albany, NY

Abstract: Over the past several decades of non-invasive brain-computer interface (BCI) research, it has become apparent that people can learn to control sensorimotor rhythms (SMR) of the electroencephalogram through a series of training sessions; people can voluntarily modulate SMR amplitudes in the mu (8-12 Hz) and/or beta (18-26 Hz) frequency bands over the sensorimotor cortex (Electroencephalogr Clin Neurophysiol 1991:78: 252-259; 1994:90: 444-449). Such BCI-based training of SMR might help to improve motor function recovery in people with CNS disorders by guiding activity-dependent brain plasticity (Lancet Neurol 2008;7:1032-1043). Since activity-dependent brain plasticity is thought to guide spinal cord plasticity in motor skill learning (Neuroscientist 2010;16:532-549), it is possible that BCI-based SMR training could affect spinal reflex excitability. If so, it could provide a potential therapy for people with CNS disorders affecting motor control. To test this hypothesis, we are currently investigating the effects of SMR (mu-rhythm) modulation on the H-reflex of the flexor carpi radialis (FCR) muscle. To date, 4 adult subjects with no known neurological conditions and 2 subjects with chronic incomplete spinal cord injury (SCI) have been studied. Subjects are trained using a BCI-based cursor control task to increase (SMR-up) and decrease (SMR-down) the mu-rhythm amplitude over the right hand/arm area (i.e., at/around the C3 or CP3 electrode locations over the left hemisphere). Once fully trained to control the SMR amplitude over >10 training sessions, subjects then perform the same SMR cursor task while the H-reflex is elicited in the right FCR muscle using electrical median nerve stimulation. H-reflex trials occur during SMR-up trials, SMR-down, or in-between SMR trials at random intervals. So far, in all four healthy subjects, the H-reflex was significantly larger during SMR-up trials, and smaller during SMR-down trials, as compared with the in-between trials. In one of the two subjects with SCI, the results were similar to those in healthy subjects, whereas in the other subject with SCI there was no clear

difference in the H-reflex between SMR-up and -down trials. Interestingly, in both subjects with SCI, spastic EMG activity in the FCR (i.e., clonus and spontaneous low-frequency firing) progressively decreased during the cursor task. The results to date suggest that SMR control training can influence spinal reflex excitability. They also support the possibility that SMR training may be developed as a therapeutic technique to aid motor control recovery in people with spinal cord injury or other central nervous system disorders.

Title: Innocuous flexion reflex shows windup, mediated partly by L-type calcium channels

Authors: K. P. JOHNSON, S. M. TRAN, E. A. SIEGRIST, M. S. ELSON, *A. BERKOWITZ; Dept. of Biol., Univ. Oklahoma, Norman, OK

Abstract: Windup is a form of multisecond temporal summation in which identical stimuli, delivered seconds apart, trigger increasingly strong neuronal responses. Windup is correlated with activation of a class of sensory neurons (C fibers) that have unmyelinated, slow-conducting axons. Most, but not all, such sensory neurons are nociceptive. Windup of spinal cord dorsal horn neurons and of leg withdrawal reflex (flexion reflex) has generally been linked to nociceptive processing. In these neurons, L-type calcium channels have been suggested to play an important role in the production of windup. We attempted to evoke windup using innocuous stimuli and examined the role of L-type calcium channels in producing windup *in vivo*, using the

L-type Ca2+ channel antagonist, nifedipine. We evoked flexion reflex *in vivo* in spinal cord-transected and immobilized red-eared turtles (Trachemys scripta elegans), using taps to the dorsal hind leg foot with a von Frey filament or electrical stimulation of the foot skin. The hip flexor nerve was recorded during flexion reflex and the flexion reflex response integrated amplitude was used for analysis. We found that we could consistently evoke windup using innocuous (4-g) mechanical or weak electrical stimuli. Application of 100 μM nifedipine to the spinal cord significantly reduced the amplitude of a single flexion reflex (evoked with a 10-g von Frey filament or stronger electrical pulses) and also significantly reduced windup of innocuous flexion reflex evoked by weak mechanical and electrical stimuli. We have shown that innocuous flexion reflex exhibits windup, using both mechanical and electrical stimulation of the foot skin, and that L-type calcium channels contribute to this windup, as they have previously been shown to do for noxious stimulation. Our findings suggest that multisecond temporal summation mechanisms may contribute to normal sensory processing of both noxious and innocuous stimuli. Title: Characteristics of the soleus h-reflex in middle-age people

Authors: *L. MCCANE[1], A. K. THOMPSON[2], Y. MAKIHARA[3], W. B. HAUG[1], J. R. WOLPAW[1,4];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYS Dep. Hlth., Albany, NY; [2]Med. Univ. of South Carolina, Charleston, SC; [3]RehabCare, Denver, CO; [4]Dept. of Neurol., Stratton VA Med. Ctr., Albany, NY

Abstract: Many studies have examined changes in the soleus H-reflex with age. Most have focused on H-reflex differences between young and old subject groups; characterization of H-reflexes in middle-aged (i.e., ~40-60 year-old) people is generally lacking. CNS damage commonly occurs in this age group; the current average age at which spinal cord injury occurs is 42 (www.mscisc.uab.edu), and up to 10% of strokes may occur in individuals under age 45. Thus, knowledge of H-reflexes in this group may contribute to development and/or evaluation of therapeutic methodologies. Thus, we are studying the soleus H-reflex in healthy, neurologically normal middle-age adults. To date, we have studied 14 middle-aged healthy adults (7 women and 7 men, mean age 45.9±7.5 SD, range 35-57). The soleus H-reflex/M-wave recruitment curve is obtained while the subject stands and maintains a defined level of EMG activity (typically natural standing level) (Thompson, et al., J Neurosci 2009:29:5784-5792). H-reflex and M-wave are measured at ~10 different intensities (range 0.75-7mA) from below H-reflex threshold to just above maximum M-wave (Mmax). Four trials are averaged at each intensity to determine the recruitment curve, the maximum H-reflex (Hmax), and the maximum M-wave (Mmax) (measured peak-to-peak). The results in the 14 subjects to date are: mean(±SD) Mmax 6.31(±2.5) mV; and mean(±SD) Hmax 3.20(±1.84) mV (similar to those during standing for a middle-age group in another recent study (mean age 56.4 years; mean Mmax 7.79 mV; mean Hmax 3.75mV) (Raffalt, et al., Muscle&Nerve 2015:51:419-425)). While the mean values are similar to those in previous aging studies (e.g., Kido et al., Can J Physiol Pharmacol 2004:82:238-248), Mmax and Hmax vary widely (i.e., Mmax range: 1.60-10.1 mV; Hmax range: 0.44-6.5 mV), resulting in a wide range of Hmax/Mmax ratios (0.12-0.87; mean±SD:0.50±0.20) with no significant dependence on age (Pearson's r = -0.02). These results indicate high variability in spinal reflex excitability in normal middle-aged subjects; this may result from differences in physical activity, life-style, and aging. They further suggest that studies using the H-reflex to investigate spinal plasticity in the normal and the damaged CNS should take such variability into consideration in protocol development and in data evaluation. Indeed, differences in baseline reflex values may correlate with differences in responses to specific therapeutic interventions, and thus may help to guide the design of individual treatment protocols.

Title: Effect of split-belt walking on cortical and spinal excitability

Authors: *T. M. KESAR[1,2], M. R. BORICH[2], M. SABATIER[2];
[1]Physical Therapy, 1441 Clifton Rd NE, Room 205, Atlanta, GA; [2]Rehabil. Med., Emory Univ., Atlanta, GA

Abstract: Split-belt walking is a well-studied locomotor adaptation paradigm that has been tested in children, young and elderly adults, as well as patients with stroke and Parkinson's disease. Split-belt walking involves treadmill walking with one belt going twice as fast as the other. Asymmetric stepping practice during split-belt walking may challenge the neural circuitry beyond existing gait interventions through error-based motor adaptation. In a recent study, a single session of split-belt walking was shown to enhance cortical excitability of lower extremity muscles, suggesting that split-belt walking may have potential as a rehabilitation paradigm to up-regulate the corticomotor pathways. However, whether split-belt walking modulates spinal excitability is unknown. The aim of this study was to evaluate changes in cortical excitability (measured using transcranial magnetic stimulation (TMS)) and spinal excitability (measured using H-reflexes) of the soleus muscle in response to a single session of split-belt gait training compared to a control walking task (regular or tied-belt treadmill walking). Thirteen able-bodied individuals (3 males and 10 females, ages 24-31) participated in 2 test sessions. During each session, measurements of cortical and spinal excitability were obtained before and after 20 minutes of split-belt treadmill walking or regular walking (tied-belts). EMG data were recorded from the Soleus muscle of the right leg (fast leg during split-belt walking). The primary measure of cortical excitability was the peak to peak amplitude of motor evoked potential in response to TMS delivered to the soleus hotspot at 125% active motor threshold. The primary measure of spinal excitability was the ratio of the maximum H-reflex and peak M-wave (H-max/M-max ratio) obtained via peripheral electrical stimulation of the tibial nerve. Our preliminary results to date show a trend toward decreased cortical excitability ($p=.07$) and significant reduction in H-max/M-max ratio ($p=.04$) of the soleus muscle following a single-session of split-belt walking. To our knowledge, our study is the first demonstration of changes in spinal excitability after a single-session of split-belt walking. The depression in spinal excitability observed after a single-session of split-belt walking may be reflective of the recalibration of neural pathways controlling locomotion and increase in segmental (local) and descending (supraspinal) inhibitory influences on the spinal segmental reflex circuitry. Ongoing studies are investigating the mechanisms and clinical implications of the modulation of corticospinal circuitry induced by split-belt walking.

Title: *In vivo* intraspinal neurochemical monitoring for characterization of underlying mechanisms of stimulation-evoked motor responses following spinal cord injury

Authors: *A. A. MENDEZ[1], E. NICOLAI[2], P. J. GRAHN[3], J. K. TREVATHAN[3], K. E. BENNET[2,4], S.-Y. CHANG[2], J. L. LUJAN[2,5], K. H. LEE[2,5];

Abstract: Introduction: Intraspinal microstimulation (ISMS) has been used to evoke motor responses following spinal cord injury. However, functional recovery remains far from optimal. In order to optimize stimulation-evoked limb movement, it is paramount to understand the neurochemical interactions associated with stimulation-evoked motor responses. To date, neurochemical monitoring within the spinal cord has focused on analysis of neurotransmitter presence using *in vitro* or off-line *in vivo* techniques (e.g., microdialysis). In this study, we demonstrate the feasibility of fast scan cyclic voltammetry (FSCV) to measure real-time stimulation-evoked and spontaneous (stimulation-OFF) neurotransmitter dynamics in the spinal cord of anesthetized, spinalized rodents. Methods: Rodents underwent a bilateral laminectomy to expose the lumbar enlargement (L1-L5) of the spinal cord. A stimulating electrode was implanted into the ventral horn at the L2 vertebral level to evoke hind limb extension. Additionally, a carbon fiber microelectrode was implanted within the ipsilateral ventral horn and approximately 5mm caudal to the stimulating electrode. ISMS required to evoke hind limb extension was applied for 2s, followed by 30s of rest, for up to 15 minutes. This ISMS ON phase was followed by a stimulation OFF phase for 10 minutes. After completing the described stimulation sequence, the carbon fiber microelectrode was repositioned within the ventral horn to detect additional neurochemical responses. Neurochemical monitoring was performed using FSCV for the duration of the experiment. Results: Neurochemical responses detected during both the ON and OFF-stimulation phases demonstrated seemingly random spontaneous release of electroactive analytes with characteristics similar to adenosine, as indicated by two current oxidation peaks at 1.4 and 1 V. In addition, neurochemical activity during the ON-stimulation phase demonstrated electrically evoked chemical changes that have yet to be identified.

Conclusions: These preliminary results, although inconclusive for specific analytes involved in ISMS evoked movement, demonstrate the feasibility of detecting real time *in vivo* spinal neurochemical events during stimulation-evoked restoration of movement. Thus, further electrochemical and pharmacological work is required to characterize neurochemical dynamics underlying stimulation-evoked restoration of movement.

Title: Preservation of reflex pathways following muscle adaptations accompanying tendon transfer

Authors: ***H. MAAS**[1], M. A. LYLE[2], E. KAJTAZ[2], T. R. NICHOLS[2];
[1]VU Univ., Amsterdam, Netherlands; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Tendon transfer surgery has been used to improve motor function in patients with weak or paralyzed muscles. In some cases function does not adequately recover. We asked whether this failure is due to increased myofascial force transmission from the transferred muscle or due to failure of neural circuits to adapt to the altered function of the transferred muscle. We transferred distal tendons of the plantaris muscle (PLANT) using the Pulvertaft Method to the severed distal tendons of tibialis anterior muscle (TA) in eight cats. In half of the animals TA was partly (approx. 50%) resected and in the other half TA and extensor digitorum longus (EDL) were denervated during the transfer surgery. Following a four-month survival period, we investigated the strength and distribution of inhibitory force feedback among muscles of the hindlimb as well as the anatomy of PLANT and TA. The organization of force dependent

feedback was not distinguishable from the distribution observed in the contralateral limb and in control animals. Preservation of normal feedback organization was observed despite the substantial atrophy of PLANT in the four cases where the transferred tendon had ruptured. Substantial alterations were observed, however, in the connective tissue elements associated with the donor and recipient muscles. In cases with partial resection of TA, the muscle regenerated, including a new tendon that joined the transferred tendon near its original insertion. The regenerated TA also provided strong reciprocal inhibition to the gastrocnemius muscle as observed in control animals. In addition, we found strong connective tissue linkages between PLANT and the calcaneous. We concluded that the response to the agonist-to-antagonist tendon transfer was to restore previous mechanical connections of the muscles. Despite a variety of tendon and muscle adaptations, no evidence of alterations in neural circuits was observed.

Title: Changes in Ia EPSPs and effective synaptic currents in hindlimb motoneurons following incomplete spinal cord injury

Authors: V. V. TURKIN, D. O'NEILL, *T. M. HAMM;
Div. Neurobio., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: What adaptations occur in spinal cord motor networks following incomplete spinal cord injury (SCI)? Do synaptic projections from muscle proprioceptors to motoneurons increase in strength following injury, compensating for loss of descending drive? To answer this question, we have compared Ia postsynaptic potentials and effective synaptic currents (I_N; Heckman and Binder, 1988) in gastrocnemius-soleus (GS) motoneurons of rats with chronic SCI and sham-operated controls. Female Long-Evans rats received a mild-moderate (170 kdyne) impact injury at thoracic vertebra 9 or a sham surgery. Terminal experiments were performed 8-10 weeks following injury/surgery after recovery of locomotor performance had reached a plateau. Tonic

Ia EPSPs were produced by vibration of the GS muscle at 200 Hz. In sham-operated controls, Ia EPSP amplitude increased with input resistance ($r = 0.74$, $p = 0.005$); I_N was not correlated with input resistance in the small sample used in this analysis ($N = 12$). The amplitudes of tonic Ia EPSPs and I_Ns recorded in low-input resistance motoneurons of SCI animals were more variable than those recorded in sham animals ($F = 6.27$, $p = 0.03$; $F = 5.65$, $p = 0.04$, respectively) and included larger values of Ia EPSPs and I_Ns than observed in the sham-operated animals. Mean Ia EPSPs and I_Ns tended to be larger at comparable values of R_N in SCI than in sham-operated animals, although these trends did not reach statistical significance ($p = 0.07$, $p = 0.11$, respectively). Too few cells were recorded in large R_N-cells of SCI animals to assess the size-related distribution of Ia synaptic inputs. These preliminary results suggest that Ia postsynaptic currents and their associated postsynaptic potentials increase in large, low-input resistance motoneurons following moderate spinal cord injuries associated with substantial recovery of locomotor function.

Title: Expression of C9ORF72 repeat expansions in mice causes behavioral impairments mimicking c9FTD/ALS clinical features

Authors: ***J. CHEW**[1,2], K. JANSEN-WEST[2], T. GENDRON[2], M. PRUDENCIO[2], C. W. LEE[2], Y.-J. ZHANG[2], M. CASTANEDES-CASEY[2], A. KURTI[2], M. YUE[2], L. ROUSSEAU[2], M. M.

Abstract: The C9ORF72 hexanucleotide repeat expansion (GGGGCC) is the major genetic cause underlying both amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Extensive efforts to study the pathogenic mechanisms associated with "c9FTD/ALS" have been hindered by a lack of animal models recapitulating key disease features. Here, we report the development and characterization of a novel model in which mice express an expanded repeat expansion ((G4C2)66) or non-expanded repeat ((G4C2)2) as control via somatic brain transgenesis mediated by adeno-associated virus (AAV). After 2 and 6 months of age following intracerebroventricular (ICV) injection on post-natal day 0, mice were subjected to a battery of behavioral and motor performance tests. Two months old (G4C2)66-mice did not exhibit any significant behavioral abnormalities compared to control (G4C2)2-mice, however, behavioral and motor deficits were detected in the 6 month cohort expressing expanded repeats. In addition, 6 months old (G4C2)66-mice exhibited decreased brain weight compare to controls suggestive of brain atrophy while this feature was not observed between mice of younger cohorts. Consequently, brains and spinal cord of 2 months and 6 months old mice will be evaluated for key c9FTD/ALS pathological features including the accumulation of RNA foci, repeat-associated non-ATG (RAN) translated polypeptides, phosphoTDP-43 inclusions and neuronal loss to further examine whether the neuropathological burden will correlate with behavioral deficits. In summary, these data suggest that the expression of expanded repeats in the murine CNS induces progressive behavioral abnormalities mimicking c9FTD/ALS clinical phenotypes and that further characterization of this model will be a useful tool in elucidating the pathogenic role of expanded repeat expression in c9ALS/FTD.

Abstract: Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease. A common model of ALS, the SOD1 mouse, presents with prominent hindlimb deficits beginning at postnatal day (P)90. To improve early diagnosis and understanding of disease progression, this study measured activity in hindlimb muscles during treadmill running over 8 weeks leading up to overt symptom onset, postnatal days (P) 55-100. Chronic electromyogram (EMG) electrodes were implanted into vastus lateralis (VL), biceps femoris posterior (BFP), lateral gastrocnemius (LG), and tibialis anterior (TA). Results were assessed using linear mixed models to account for numerous variables and repeated measures. Effects of the SOD1 mutation were mainly observed in three parameters: burst peak amplitude, mean intermuscular phase, and burst shape (skew). Peak amplitude is larger in BFP in mutant mice, while burst peaks in TA and LG increased in combination with other factors (mutation interacts with both treadmill incline (TA and LG), and age (LG)). Phase and skew are related parameters that indicate changes in the timing of muscle activation during locomotor behavior. In SOD1 mice, BFP and LG advanced in phase and skew shifted toward the early portion of the burst, while both parameters shifted in SOD1 VL in combination with treadmill incline. TA was relatively unaffected, suggesting extensors are better suited for detecting early disease-related changes. Future investigations should pursue exploiting these parameters in humans for early diagnosis of ALS, as well as revealing the underlying mechanistic changes in the neural control of muscle activation during disease progression.

Title: Connecting genes to pathways and networks in an effort to reveal the basis of selective motor neuron vulnerability

Authors: *P. KURU, P. H. OZDINLER;
Neurol., Northwestern Univ. Sch. of Med., Chicago, IL

Abstract: Even though motor neurons undergo progressive degeneration in motor neuron diseases, they differ by the motor neuron pools that display primary vulnerability. For example in ALS, different from hereditary spastic paraplegia (HSP) or primary lateral sclerosis (PLS) and spinal muscular atrophy (SMA), both the cortical and the spinal motor neurons are affected. To date numerous genetic mutations are identified as “causative” for ALS, SMA and HSP/PLS. We hypothesize that if a mutated gene causes a disease, then its protein product must be extremely important for the function and health of the motor neurons that show primary vulnerability. This may explain why some mutations lead to upper and some lead to lower motor neuron death. The goal of this study is to investigate the link between genes, proteins, and networks in an effort to understand the cellular and molecular basis of selective vulnerability in motor neuron diseases. In order to identify the networks and cellular pathways that are affected we focus on the binding partners of the proteins that are encoded by the mutated genes. We first generated an extensive data set for binding partners of proteins, whose mutated versions were reported to “cause” ALS, HSP, PLS and SMA. We performed systems analysis to reveal how these proteins interact,, which canonical pathways they are mainly involved in, and which cellular networks are critically important. We then identified common and unique pathways and networks in motor neuron diseases. Our preliminary studies reveal that underlying cellular events for upper and lower motor neuron vulnerability are distinct, and there are novel interaction domains for upper and lower motor neurons. However, common events, such as glucocorticoid receptor signaling occurs in all motor neuron diseases, which suggests the involvement of immune reaction, especially towards end-stage. This systems level analysis, using mutations that cause diseases in which upper and lower motor neurons are primarily affected will shed light onto common and unique mechanisms that are responsible for their degeneration. Our findings have the potential to reveal key signaling pathways responsible for selective neuronal vulnerability, and it will also define new targets for drug discovery efforts.

Title: CHCHD10 gene mutation causes ALS with complex mechanisms

Authors: *J. YAN[1], K. B. AHMETI[2], N. A. SIDDIQUE[2], E. B. RYAN[2], T. J. LUKAS[2], L. M. KINSLEY[2], Y. SHI[2], Y. YANG[2], N. MILLER[2], N. J. CORBETT[3], D. NICHOLSON[3], Y. MA[2], H.-X. DENG[2], T. SIDDIQUE[2];
[1]NORTHWESTERN UNIVERSITY, Chicago, IL; [2]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [3]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal large motor neuron degenerative disorder. Using whole exome sequencing and linkage analysis, we found R15L mutation of CHCHD10 gene in a large FALS pedigree, then 4 more FALS out of 308 FALS families by Sanger sequencing, but not in 84 SALS with disease duration equal to or more than 5 years. R15L was not present in 1480 controls we sequenced. The five CHCHD10 R15L families had a total of 55 ALS patients, 16 obligate carriers. Onset of site were available from 22 ALS patients, 4 had lower extremities onset, 1 had trunk onset, and 17 had upper extremities onset, none had bulbar onset. Age of onset were recorded in 23 ALS patients, the average was at 55 years. 34.8% of the 23 Affected developed ALS in their 50's, 21.7% in 60's, 13% in 40's, 17.4% in 30's.The average of disease duration of 14 deceased ALS was 81.2 months .9 affected are still living. Muscle biopsy of a male R15L ALS patient had two typical ragged red fibers and two myofibers with rimmed vacuoles which were stained for NADH-TR. Confocal microscopy showed both wild type and R15L CHCHD10 mutant were expressed diffusely in the cytoplasm as well as the extended neuronal processes and mostly colocalized with mitochondria. Immunohistochemistry

showed remarkable, tangle like CHCHD10 immunoreactive protein aggregates in the cytoplasm and neuritis of spinal cord motor neurons. EM of R15L skin fibroblast showed swollen mitochondria body, broken cristae, homogeneous matrix and multivesicular bodies and vacuoles . R15L fibroblast genomic DNA showed multiple additional bands in Southern Blotting comparing to controls. R15L fibroblast mitochondria DNA copy number by real-time PCR was significantly less than those of controls. The mitochondria movement was analyzed in 137 mitochondria of 9 motor neurons expressing wild type CHCHD10 and 180 mitochondria of 12 motor neurons expressing R15L CHCHD10. The backward moving frequency of R15L mitochondria was significant less. R15L fibroblast Mitochondria oxygen consumption rate (OCR) by Seahorse XFe Analyzer was 296.3 ± 24 compared to 534.0 ± 21.90 in controls. Complex IV and V activity were significantly decreased in R51L fibroblast. It is suggested that CHCHD10 mutation causes ALS with very complex mechanism involving mitochondria. (Yan and Ahmeti made equal contribution to the work)

Title: Mutant profilin1 toxicity in the transgenic mouse model for ALS

Authors: *M. KIAEI[1], A. BASNAKIAN[2], M. COZART[2];
[1]Neurobiology/Dev Sci., [2]Pharmacology/toxicology, Univ. of Arkansas for Med. Sci., Little Rock, AR

Abstract: The mechanism of neuronal degeneration and muscle atrophy in amyotrophic lateral sclerosis (ALS) is poorly understood. Current animal models have been helpful in defining disease development and identifying pathways and molecules potentially involved. This suggests

more models are needed to increase our understanding of molecular mechanisms responsible for motor neuron death. Recent discoveries of new genes linked to ALS will likely lead to new disease models and therapeutic targets. There are currently seven mutations in the profilin1 (PFN1) gene linked to fALS1-3. This argues that mutation in PFN1 causes ALS in humans. However, the mechanism of mutant profilin-1 toxicity and ALS pathogenesis remains unknown. To explore this relationship we have developed mouse models overexpressing mutant and wild-type (WT) human profilin1 (hPFN1) driven by mouse prion promoter. We chose the glycine to valine mutation at residue 118 (G118V) for our mutant hPFN1 mouse. These hPFN1G118V mice faithfully recapitulate ALS phenotype. We have now generated mice overexpressing WT human profilin1 (hPFN1WT). We found proteinopathy and multiple other abnormalities in our hPFN1G118V model while hPFN1WT mice are as viable and healthy as nontransgenic littermates. Here we report that lumbar spinal cords of symptomatic hPFN1G118V mice demonstrate a reduced F/G-actin ratio relative to WT mice, suggesting mutant profilin-1 may dysregulate actin polymerization. DNase I, which is another G-actin-binding protein and the most active apoptotic endonuclease, translocated to the nucleus in the hPFN1G118V mice. This DNase I redistribution in spinal cords correlated with the increase of nuclear DNA fragmentation measured using TUNEL assay indicating elevated cell death. We show mutant profilin-1 exists in the insoluble fractions of total spinal cord homogenates of PFN1G118V mice and most of proteins in the insoluble fraction are ubiquitinated. This confirms *in vitro* data published by Landers and colleagues and further suggests that aggregation of mutant profilin1 may contribute to neurotoxicity in ALS. In conclusion, we have developed two novel mouse models to investigate the role of mutant profilin-1 in ALS. In characterizing these models we have found multiple ALS-like pathologies in the hPFN1G118V mice while hPFN1WT mice show no pathology as expected. Title: New evidence for the role of dna repair defects in motor neuron diseases

Authors: *M. L. HEGDE;
Houston Methodist, Houston, TX

Abstract: Accumulation of genome damage including oxidized bases, single- and double-strand breaks, in affected brain cells has been linked to Motor neuron diseases including ALS whose underlying cause(s) are not completely understood. The transactive response DNA-binding protein-43 **(TDP-43),** is an hnRNP family protein whose intracellular aggregation has been etiologically implicated in Amyotrophic Lateral Sclerosis (ALS), a motor neuron degenerative disease affecting two per 100,000 people worldwide, and about 40% of other neurodegenerative diseases including Alzheimer's (AD) and Parkinson's disease (PD). Primarily involved in RNA processing, TDP-43 and related protein FUS also bind to DNA, but its DNA binding functions have not been investigated. While hereditary mutations in TDP-43/FUS have been linked to ALS, the molecular mechanism(s) of its pathology contributing to neuronal death are still unclear. *The unique feature of TDP-43 pathogenesis in ALS is its nuclear clearance and simultaneous cytoplasmic aggregation in affected motor/cortical neurons.* Furthermore, significant accumulation of genomic damage is observed in TDP-43-linked diseases and previous studies identified a key DNA repair protein 'Ku' in TDP-43 immunocomplex from human cells, raising the possibility of TDP-43's involvement in DNA damage repair, which led us to investigate this. We demonstrate that (1) TDP-43 stably interacts with DSBR proteins in neuroblastoma SH-SY5Y cells, which was enhanced after treatment with DSB-inducing radiation/bleomycin. (2) TDP-43 is recruited to the DSB sites neuronal cells, and (3) TDP-43's overall as well as nucleus-specific depletion markedly increased accumulation of DSBs in SH-SY5Y as well as motor neurons differentiated from hNSCs cells and sensitized the cells to radiation. (4) TDP-43 controls the recruitment of DSB repair protein 53BP1 at DSB sites and thus regulates non-homologous end joining pathway of DSB repair in neurons. These results are consistent with the dramatic accumulation of unrepaired DSBs in postmortem brains of ALS-affected human patients and a distinct nuclear clearance of TDP-43 in these affected neurons. Our more recent studies show that FUS, unlike TDP-43 is required for single strand break repair in neurons via activation Ligase III protein. In summary these results reveal that TDP-43 and FUS are critical components of genome damage response in the neurons whose loss of function(s) causing DNA repair deficiency is a key etiological factor in ALS and possibly other neurodegenerative diseases. Title: Identification of therapeutic targets for cytoskeletal defects in ALS

Authors: *A. JAVAHERIAN[1], P. GOYAL[1], M. ANDO[1,2], E. DANIELSON[2], C. FALLINI[2], J. LANDERS[2], S. FINKBEINER[1];

Abstract: The pathogenesis of ALS and the mechanisms that lead to selective motor neuron degeneration are still unknown. This lack of knowledge hinders the development of an effective therapy to prevent or stop progression of the disease. Identification of ALS causative genes has helped to identify potential pathogenic pathways involved in the development of familial and sporadic ALS that can be targeted for therapeutic intervention. We recently identified mutations in two cytoskeletal genes, the actin binding protein profilin 1 (PFN1) and the microtubule subunit α-tubulin 4A (TUBA4A) as causative for familial ALS. These observations suggest that alterations affecting the cytoskeleton architecture, dynamics, and function are important in ALS pathogenesis. Our central hypothesis is that alterations to cytoskeleton structure and dynamics disrupt essential cellular functions, such as synaptic plasticity, vesicle recycling, axonal transport, and neuronal plasticity, which are necessary for the maintenance of motor neurons. We have developed novel primary neuron cellular models of ALS based on TUBA4A and PFN1 mutations using a custom-built automated longitudinal imaging platform. We apply these cellular models to screen a subset of the druggable genome siRNA library focused on cytoskeletal genes and genes that have direct interactions with known ALS-linked cytoskeletal genes. Screening this RNAi library allows us to identify genes that play a role in the cytoskeleton pathway and act as disease modifiers. Cytoskeletal regulation represents a good candidate for therapeutic intervention, as it plays an essential role in a variety of cellular processes including axonal transport and neuronal plasticity.

Title: Tdp-43 suppression of non-conserved cryptic exons is compromised in amyotrophic lateral sclerosis and frontotemporal dementia

Authors: *J. LING, O. PLETNIKOVA, J. TRONCOSO, P. WONG;
Johns Hopkins Univ., Baltimore, MD

Abstract: Cytoplasmic aggregation of TDP-43, accompanied by its nuclear clearance, is a key common pathological hallmark of amyotrophic lateral sclerosis and frontotemporal dementia (ALS-FTD). However, a limited understanding of this RNA-binding protein (RBP) impedes the clarification of pathogenic mechanisms underlying TDP-43 proteinopathy. In contrast to RBPs that regulate splicing of conserved exons, we report here that TDP-43 suppresses the splicing of non-conserved cryptic exons. When TDP-43 is depleted from the cell, these cryptic exons are spliced into mRNAs, often disrupting their translation and promoting nonsense-mediated decay. Moreover, enforced repression of cryptic exons prevents cell death in TDP-43 knockout cells. Importantly, our work demonstrates that suppression of cryptic exons is impaired in brains of ALS-FTD, suggesting that this splicing defect underlies TDP-43 proteinopathy. TDP-43 may be the first member of a class of RBPs that serve to maintain the integrity of introns. Thus, our discovery not only has mechanistic and therapeutic implications for ALS-FTD and other human diseases that share TDP-43 pathology, but also reveals more fundamental principles regarding RNA splicing and the evolution of exon-intron structure.

Title: Identification of CDC7 mediated pathways regulating TDP-43 phosphorylation in simple models of ALS and FTLD-TDP

Authors: ***N. LIACHKO**[1,2], J. KUSHLEIKA[1], T. BIRD[1,2], B. KRAEMER[1,2];
[1]GRECC, VA Puget Sound Hlth. Care Syst., Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration with TDP-43 inclusions (FTLD-TDP) are severe progressive neurodegenerative diseases characterized by lesions containing aggregated, hyperphosphorylated TDP-43. To study the cellular, molecular, and genetic underpinnings of TDP-43 mediated neurotoxicity in tractable model systems, we have developed *C. elegans* and mammalian cell culture models of TDP-43 proteinopathy. Expression of familial ALS-mutant TDP-43 in all *C. elegans* neurons causes severe motor dysfunction, and recapitulates some characteristic features of ALS and FTLD-TDP including decreased lifespan, neuronal degeneration, hyperphosphorylation and ubiquitination of TDP-43, and accumulation of detergent insoluble aggregates. We have shown that in *C. elegans*, phosphorylation of TDP-43 at serine residues 409/410 (S409/410) drives mutant TDP-43 toxicity. Using these models, we found the kinase CDC7 directly phosphorylates TDP-43 at S409/410. To identify genes upstream of CDC7 controlling TDP-43 phosphorylation, we have assembled and screened an RNA interference (RNAi) library targeting known CDC7 interacting, regulating and pathways genes. This library includes genes involved in cell cycle regulation, DNA damage response and repair, and chromatin maintenance. 85 candidate genes were

individually tested for modification of TDP-43 dependent behavioural phenotypes, and for changes in the phosphorylation status of TDP-43 by immunoblot. From this primary screen we have confirmed 4 genes that suppress TDP-43 phenotypes. Additional work on these genes will provide mechanistic insight into the environmental and cellular triggers of TDP-43 phosphorylation, and provide potential novel avenues for therapeutic interventions into TDP-43 proteinopathies such as ALS and FTLD-TDP.

Title: Chitotriosidase, a putative biomarker augments neuroinflammation in sporadic amyotrophic lateral sclerosis

Authors: ***T. R. RAJU**[1], A. M. VARGHESE[2], M. GHOSH[2], P. S. MISHRA[2], K. VIJAYALAKSHMI[2], P. A. ALLADI[2], T. N. SATHYAPRABHA[2], A. NALINI[3];
[2]Neurophysiol., [3]Neurol., [1]Natl. Inst. Mentl Hlth. Neurosci, Bangalore, India

Abstract: Profuse increase (~20 fold; n=70) in the levels of Chitotriosidase (CHIT-1) in the cerebrospinal fluid (CSF) of patients with sporadic Amyotrophic Lateral Sclerosis (SALS; ALS-CSF) marks it a biomarker status. Additionally, CHIT-1 was found to be biologically active in view of the up-regulated enzyme activity (~16 fold; n=73). Expression of CHIT-1 specifically by microglia suggests a definitive role for the enzyme in the disease pathogenesis. The current study is aimed at investigating the effect of the recombinant CHIT-1 protein on spinal motor neurons and glial cells. Intrathecal administration of CHIT-1 (50, 100 and 200pg) to rat neonates resulted in microgliosis and astrogliosis in both white and grey matter of the spinal cord similar to what was seen following ALS-CSF administration. Qualitative observations revealed presence of several amoeboid microglial cells around the central canal. Several GFAP immunopositive astroglia bearing long processes were also seen around the central canal following CHIT-1 administration. CHIT-1 also induced loss of Choline Acetyl Transferase (ChAT) positive

neurons, similar to ALS-CSF at a dose of 500pg. Further, exposure of astroglial as well as the microglial cultures to ALS-CSF for 48hours resulted in a significant up-regulation of pro-inflammatory markers like IL-6, TNF-α, PGE-2 and COX-2, while the trophic factors namely, VEGF and GDNF were down regulated. These findings suggest that CHIT-1 in ALS-CSF induces microglial and astroglial activation accompanied by enhanced expression of inflammatory markers, resulting in neuroinflammation, which accentuates degeneration of motor neurons. In view of an initial surge of CHIT-1 activity which gradually decreases with progression of disease and its multifold increase observed in the definite ALS cases, it could be a potential target for therapeutic intervention at the early stages of the disease.

Title: Untangling the dendritic network degeneration of upper and lower motor neurons in amyotrophic lateral sclerosis

Authors: ***M. J. FOGARTY**[1], E. W. H. MU[1], N. A. LAVIDIS[1], P. G. NOAKES[1,2], M. C. BELLINGHAM[1];
[1]Sch. of Biomed. Sci., Univ. of Queensland, Brisbane, Australia; [2]Queensland Brain Inst., Brisbane, Australia

Abstract: The progressive death of both upper and lower motor neuron (MN) populations in the brain and spinal cord is pathognomic for amyotrophic lateral sclerosis (ALS). Although evidence from animal and clinical studies suggest that elevation of excitatory synaptic inputs onto upper and lower MNs occurs prior to neuron loss, the timing and structural correlates of this degenerative pathology remains unclear. We examined pre-symptomatic (postnatal [P] day 25-35) , disease onset (P60-70) and mid-disease (P100-120) heterozygote hSOD1G93A(SOD1) and wild type (WT) control mice using Golgi-Cox impregnation to visualise the dendritic arbors of upper or lower MNs (10 animals per age/genotype). Golgi-impregnated neuronal arbors were

traced in Neurolucida using a 63x oil (1.4NA) objective on a Zeiss Axioplan 2 microscope with an automated stage. All analyses were two-way ANOVAs with Bonferroni post-tests and $p<0.05$ determined significant results. Spine densities were calculated as spines per 100 μm. We report significant dendritic degeneration and spine loss of layer V pyramidal neurons in the motor cortex from SOD1 mice at pre-symptomatic ages (31% reduction in dendritic length and a 51% decrease in spine density) and lumbar MNs by mid-disease (71% decrease in dendritic length, and 29% decrease in spine density). By contrast, increases in neuronal arborisation and increased spine density of lumbar MNs occurred at pre-symptomatic ages in SOD1 mice (dendritic arbors increased by 26% and spine density increased by 21%). Our results suggest that prior to degeneration, the lower MN network is perturbed structurally, as illustrated by excessive arborisation and increased spine density. Concomitant with excessive lower MN arborisation, motor cortex layer V pyramidal neurons exhibited a regressive morphologic phenotype. By mid-disease, lower lumbar MNs also developed similar regressive degenerative characteristics. Thus, our findings correlate with recent clinical studies, where functional and network disturbances were seen in the cortex before overt lower motor symptoms. Our results pose two intriguing quandaries in the interpretation of our lower MN data. Firstly, are pre-symptomatic changes in lower MNs an adaptive or pathogenic response? Secondly, as the timing of regressive dendritic degeneration differs between upper and lower MNs, is the mechanism driving these changes similar or disparate in these neurons?

Title: Hydrogen sulphide: a double edged glial factor endogenously overproduced in Amyotrophic Lateral Sclerosis that enhances motor neuron death

Authors: *P. LONGONE[1], A. SPALLONI[1], V. GRECO[1], E. GUATTEO[1], A. DAVOLI[2], G. RICCIARDO RIZZO[2], A. URBANI[2,1], N. B. MERCURI[2,1];
[1]Fondazione Santa Lucia, Rome, Italy; [2]Univ. of Tor Vergata, Rome, Italy

Abstract: Hydrogen sulphide (H2S) is now considered, with nitric oxide and carbon monoxide, the third gaseous neurotransmitter. H2S can be generated both through enzymatic and non-

enzymatic ways. Enzymatically H2S is produced via the action of three enzymes cystathionine-beta synthase (CBS), cystathionine-gamma lyase (CSE) and 3-mercaptopyruvate sulphur transferase (3-MST). In the brain the main enzyme responsible for the production of H2S is CBS. H2S is a double-edged sword. Although the majority of the studies, looking at its role in brain function, have described neuromodulatory and neuroprotectant actions, when it reaches levels in the high microM to milliM concentrations, it turns to a poisonous agent. In a study performed in Amyotrophic Lateral Sclerosis (ALS) sporadic patients and in a familial ALS (fALS) mouse model, the classical SOD1G93A mouse, we have found toxic liquoral levels of H2S in the patients, higher H2S content in the brain tissues of the fALS mouse, and in the media from SOD1G93A primary spinal cord cultures (Davoli et al., AON 2015). In the same work we have described an increased toxicity of H2S toward motor neurons (compared to GABAergic neurons) and an increased Ca2+ concentration in spinal cord neurons following H2S treatment. We have also determined that glial cells release H2S. Here we describe its effects on the motor neurons demeanor at low (neuroprotective) and high (neurotoxic) concentrations. Moreover, we propose H2S as a modulator of the glial resting state and one of the possible mediators of the non-cell autonomous degeneration described in ALS.

Title: Dysfunction of Rab1-dependent ER-golgi transport is a common pathogenic mechanism in ALS

Authors: ***J. ATKIN**[1,2], M. HALLORAN[1], V. SUNDARAMOORTHY[1], J. SULTANA[1], K. SOUTHAM[3], A. KING[3], K. SOO[2,3];

[1]Biomed. Sci., Macquarie Univ., Sydney, Australia; [2]La Trobe Inst. for Mol. Sci., Melbourne, Australia; [3]Univ. of Tasmania, Hobart, Australia

Abstract: Several diverse proteins are linked genetically or pathologically to neurodegeneration in amyotrophic lateral sclerosis (ALS) including SOD1, TDP-43 and FUS, but currently, no common pathogenic mechanism has been described. Using a variety of cellular and biochemical techniques, we demonstrate that ALS-associated mutant forms of each protein inhibit protein transport between the endoplasmic reticulum (ER) and Golgi apparatus in neuronal cells. ER-Golgi transport was also inhibited in embryonic cortical and motor neurons obtained from a widely used animal disease model (SOD1G93A mice), validating this mechanism as an early event in motor neurons of mice. Each protein inhibited transport by distinct mechanisms, but each of these processes was dependent on Rab1. Mutant TDP-43 and mutant FUS both inhibited the incorporation of secretory protein cargo into COPII vesicles as they bud from the ER. We detected TDP-43 on the cytoplasmic face of the ER membrane whereas FUS was present within the ER. In contrast, mutant SOD1 destabilised microtubules and was not present within the ER. Furthermore, over-expression of Rab1 restored ER-Golgi transport and rescued inclusion formation, ER stress and apoptosis triggered by ALS-associated mutant SOD1. Rab1 also formed inclusions in motor neurons of spinal cords from sporadic ALS patients. Hence, these results describe a central and novel pathogenic mechanism shared by mutant TDP-43, mutant FUS, and mutant SOD1. These data thus implicate inhibition of Rab1-mediated ER-Golgi transport as a possible novel therapeutic target in ALS.

Title: Roles of osteopontin and matrix metalloproteinase-9 in the subtype-selective motor neuron vulnerability in ALS

Authors: Y. MORISAKI[1], A. TSUBOTA[1], M. WATANABE[1], Y. MORIWAKI[1], K. YAMANAKA[2], *H. MISAWA[1];
[1]Keio Univ. Fac Pharm, Tokyo, Japan; [2]Neurosci Pathol, Res. Inst. Env Med. Nagoya Univ., Nagoya, Japan

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by the progressive death of α-motor neurons (MNs) and consequent skeletal muscle denervation. α-MNs are classified into three subtypes: FF (fast-twitch-fatigable), FR (fast-twitch fatigue-resistant), and S (slow-twitch fatigue-resistant) MNs. In ALS, it is generally accepted that FF MNs are more vulnerable than FR and S MNs; the reason for this selective vulnerability remains enigmatic. In order to elucidate the mechanism of the subtype-specific neurodegeneration, we focused on two proteins: osteopontin (OPN) and matrix metalloproteinase-9 (MMP-9). OPN was originally discovered as a bone matrix protein, but later recognized as a multifunctional protein involved in tissue inflammation and remodeling. We have previously reported that OPN is selectively expressed in α-MNs. Kaplan et al. (Neuron, 81, 333-348, 2014) recently reported that MMP-9 is a marker for FF MNs and selectively conditions them to be vulnerable to mutant SOD1-induced toxicity. Other studies showed that OPN regulates the transcription and activation of MMP-9. In the spinal cord of wild type (WT) mice, we found that OPN and MMP-9 were expressed in different MNs; OPN was selectively expressed in FR and S MNs. In the spinal cord of ALS model mice (SOD1G93A-Tg), we observed that OPN-positive granules were accumulated in the extracellular matrix as the disease progressed. Around the period of disease onset, we detected OPN-MMP-9 double positive MNs, which were barely observed in WT mice. In the double positive MNs, increased ER stress and αvβ3 integrin (an OPN receptor) expression were observed. Furthermore, the analysis of neuromuscular junction revealed that double positive MNs are ‘remodeled’ MNs as a consequence of functional compensation after denervation of FF MNs. The OPN-induced expression of MMP-9 through αvβ3 integrin was also observed in mouse neuroblastoma cells stably expressing choline acetyltransferase cDNA (Neuro-2a-ChAT cells). From these results, we hypothesize as follows: MMP-9 positive MNs (FF MNs) first undergo denervation from their targeting muscle fibers and then OPN positive MNs (FR or S MNs) compensate for the denervated muscle endplate by sprouting and innervation. Such remodeled (FR or S) MNs obtain FF-like characteristics by expressing MMP-9, and gain selective vulnerability to the mutant SOD1-linked cellular stresses through OPN-αvβ3 integrin axis by an autocrine or paracrine manner. Collectively the present results suggest that OPN and MMP-9 are involved in the mechanism of the subtype-selective neurodegeneration in the mouse model of ALS.

Title: C9ORF72 knockout mice show amyotrophic lateral sclerosis-like motor abnormalities

Authors: *B. IKIZ, S. D. CROLL, V. LAI, N. STAHL, A. J. MURPHY, L. E. MACDONALD, M. L. LACROIX-FRALISH;
Neurosci., Regeneron Pharmaceuticals, Inc, Tarrytown, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is the most frequent adult-onset paralytic disorder, characterized by the loss of upper and/or lower motor neurons. GGGGCC hexanucleotide repeat expansions in the non-coding region of C9ORF72 are the most common mutations found in familial, as well as sporadic, ALS cases. However, the mechanism through which these mutations cause the disease, whether through a loss- or gain-of-function of toxicity, is not known. To test whether the genetic silencing of C9ORF72 would result in any ALS-like motor behavioral abnormalities, we have generated C9orf72 knockout mice by replacing the entire coding sequence of the mouse homolog (3110043O21Rik) with a LacZ reporter. We studied the motor behaviors of these mice using rotorod, open field and CatWalk assays up to 60 weeks of age. We also examined the mice for neurological deficits throughout this period. We observed that only 40% of C9orf72 knockout mice survived past 60 weeks of age and that they stopped gaining body weight beginning at 36 weeks of age. While rotorod tests did not show any significant changes due to C9orf72 deletion, these mice started showing significant hind limb paresis, motor impairment, decreased mobility and gait abnormalities at around 40 weeks of age. We have found that the genetic silencing of C9orf72 results in multiple motor and neurological abnormalities in the mouse similar to those found in human motor neuron diseases. These findings suggest that loss-of-function mutations in C9ORF72 warrant further examination as they may play a role in the development and progression of motor neuron diseases in patients.

Title: Lumbar spinal cord neuroprotective microglia and fractalkine are increased with disease progression in canine degenerative myelopathy, a model for amyotrophic lateral sclerosis

Authors: *C. SIBIGTROTH, M. JONES, V. GARCIA, E. VILLALÓN, J. COATES, M. GARCIA;
Univ. of Missouri, Columbia, MO

Abstract: Canine degenerative myelopathy (DM) is an adult-onset neurodegenerative disorder. Mutations in the superoxide dismutase 1 gene (*SOD1*) are causal for disease, similar to some forms of amyotrophic lateral sclerosis (ALS). SOD1-mutant microglia have a central role in ALS progression. Their behavior is dynamic and is characterized by neuroprotective (M2) or neurotoxic (M1) phenotypes. The mechanism(s) underlying microglial phenotype determination within ALS is not known. Fractalkine, a neuronally produced chemokine, has been shown to suppress *SOD1* mutant microglial-mediated neurotoxicity. Thus, it is a possible contributor to microglial phenotype determination. Progressive microglial accumulation has been documented in DM-affected dogs. My goal was to define the phenotype of microglia within close proximity to lumbar ventral horn motor neurons in DM-affected dogs and to correlate this with fractalkine expression. Preliminary data indicate a progressive increase in total number of M2 microglia closely associated with lumbar motor neurons in DM-affected dogs compared to age-matched controls without an increase in the number of M1 microglia. Additionally, lumbar spinal cord fractalkine levels increase with disease progression, correlating with increased M2 microglia.

Taken together, these data suggest that M2, but not M1, microglia are progressively recruited to motor neurons during disease progression.

Title: Role of CDNF in SOD1-G93A mouse model of amyotrophic lateral sclerosis

Authors: ***F. DE LORENZO**[1], M. H. VOUTILAINEN[1], E. MONTONEN[1], A. SAUKKONEN[1], M. AIRAVAARA[1], R. K. TUOMINEN[2], D. LINDHOLM[3], M. SAARMA[1]; [1]Inst. of Biotech., [2]Div. of Pharmacol. and Pharmacotherapy, [3]Inst. of Biomedicine, Univ. of Helsinki, Helsinki, Finland

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by the progressive degeneration of motor neurons (MN) in the ventral horn of the spinal cord, brainstem and motor cortex, which leads eventually to paralysis and muscular atrophy in the affected individuals. Patients usually die within 3-5 years of symptom onset and death is caused, in most cases, by the paralysis of respiratory muscles. Neither cure nor effective therapy is currently available. Several neurotrophic factors (NTFs) promote the survival of MNs *in vitro* and *in vivo*, thus being possible drug candidates for ALS. Among them, novel cerebral dopamine neurotrophic factor (CDNF) seems particularly promising, since it is highly expressed in muscle tissues, spreads better than other NTFs in the brain and rescues only degenerating neurons. Furthermore, CDNF is crucially involved in the regulation of the ER stress, which plays an important role in the pathophysiology of ALS. Here we show that intraventricular injection of human recombinant CDNF can significantly postpone appearance of clinical symptoms, improve motor coordination and increase lifespan in SOD1-G93A mouse model of ALS. CDNF treatment can prevent the death of MNs compared to controls and CDNF also preserves neuromuscular junctions (NMJs) in the studied gastrocnemius muscle. As mentioned above, ER stress is an

important pathway to cell death in sporadic ALS patients and in ALS rodent models. We found the upregulation of the mRNA level of unfolded protein response (UPR) genes GRP78, Xbp1, PERK, ATF6 and CHOP in SOD1-G93A model, whereas their levels were reduced in CDNF-treated animals. Therefore our results strongly suggest that CDNF has a protective effect in SOD1-G93A mouse model of ALS, promoting the survival of MNs and the preservation of NMJs. The decrease in UPR genes mRNA level after CDNF treatment also suggests the intriguing possibility that CDNF might rescue MNs by regulating the ER stress response.

Title: Mature oligodendroglia is not a contributor to amyotrophic lateral sclerosis

Authors: *Y. LI[1], D. BERGLES[2], J. D. ROTHSTEIN[2];
[1]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Amyotrophic lateral sclerosis is a fatal disease characterized by the death of upper and lower motor neurons. The etiology of the disease is largely unknown, although certain genes, such as superoxide dismutase 1 (SOD1), TDP43, FUS and C9orf72, have been found to be linked to disease development. Previous studies, by using a mutant SOD1 transgenic mouse model, showed that injury to motor neurons is the primary determinant of disease onset, while astroglial and microglial cells affect disease progression. Recently to determine the role of oligodendrocyte lineage in ALS pathogenesis, we genetically deleted mutant SOD1 in

oligodendrocyte progenitors and found disease onset was dramatically delayed. In addition, we found that gray matter oligodendrocytes degenerate not only in a SOD1 mouse model but also in both familial and sporadic ALS patient central nervous system motor areas. These findings together strongly suggest that oligodendrocyte lineage is a critical player in ALS pathogenesis. However, given that, in the OPC mutant SOD1 deletion study, the immature oligodendrocytes and mature oligodendrocytes generated from those OPCs did not have the mutant sod1 gene, it raised the question as to what is the role of mature/myelinating oligodendrocytes or immature/differentiating oligodendrocytes alone in ALS pathogenesis. Therefore, to further exam the role of mature/myelinating oligodendrocytes in ALS, we used a similar strategy to genetically delete mutant SOD1 selectively in mature myelinating oligodendrocytes. Surprisingly, we did not see any effects on disease onset, early disease and animal survival. In addition, no differences in gliosis were found. Together, this study showed that the mature oligodendrocyte is not a contributor to ALS pathogenesis and suggested immature oligodendrocytes are probably involved in the disease onset and development.

Title: Understanding the basis of CSMN vulnerability and degeneration using a proteomics approach

Authors: ***J. KLESSNER**[1], P. THOMAS[2,3], S. SANCHEZ[1], B. GENÇ[1], J. JARA[1], R. DAVIS[2], P. GOTTLIEB[2], N. KELLEHER[2,3], P. OZDINLER[1,3,4];

Abstract: Ubiquitin carboxy-terminal hydrolase L1 (UCHL1) is a deubiquitinase that plays a critical role in maintaining free ubiquitin levels in neurons. Patients with mutations in their UCHL1 gene develop motor function defects, paralysis, and upper motor neuron defects. Mice that lack all UCHL1 function (UCHL1nm3419, UCHL1-/-) display motor neuron defects and

profound corticospinal motor neuron (CSMN) degeneration characterized by increased ER-stress, vacuolated apical dendrites, and spine loss. These findings show the importance of UCHL1 for CSMN health. Here, we used a bottom-up proteomics approach coupled with UCHL1-immunoprecipitation to reveal the proteins that interact with UCHL1. We then investigated if these interactions were specific to neurons in the motor cortex by including neurons in the spinal cord and trigeminal ganglia (TG). Our initial findings suggest that UCHL1 binds to and interacts with different proteins in the motor cortex, spinal cord, and TG, and this may in part explain why in its absence CSMN display the most prominent cell loss and neuronal vulnerability. CSMN vulnerability is a key component of disease pathology in a number of motor neuron diseases, such as primary lateral sclerosis, hereditary spastic paraplegia, and amyotrophic lateral sclerosis. Understanding the underlying causes of their vulnerability using a proteomics approach will have significant impact on revealing key cellular and molecular pathways responsible for their degeneration.

Title: Isoform specific antibodies reveal distinct subcellular localizations of c9orf72 in amyotrophic lateral sclerosis

Authors: ***S. XIAO**[1], L. MACNAIR[2], P. MCGOLDRICK[2], P. MCKEEVER[2], J. MCLEAN[2], M. ZHANG[2], J. KEITH[3], L. ZINMAN[3], E. ROGAEVA[2], J. ROBERTSON[2];

Abstract: Objective: A noncoding hexanucleotide repeat expansion in *C9orf72* is the most common cause of amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). It has been reported that the repeat expansion causes a downregulation of *C9orf72* transcripts, suggesting that haploinsufficiency may contribute to disease pathogenesis. Two protein isoforms are generated from three alternatively spliced transcripts of *C9orf72*; a long

form (C9-L) and a short form (C9-S) and their function(s) are largely unknown due to lack of specific antibodies. **Methods:** To investigate C9orf72 protein properties, we developed novel antibodies that recognize either C9-L or C9-S. Multiple techniques including western blot, immunohistochemistry and co-immunoprecipitation were used to determine the expression levels and subcellular localizations of C9-L and C9-S. **Results:** Investigation of expression of C9-L and C9-S demonstrated distinct biochemical profiles, region-specific changes and distinct subcellular localizations in ALS tissues. In particular, C9-L antibody exhibited a diffuse cytoplasmic staining in neurons, and labeled large speckles in cerebellar Purkinje cells. In contrast, C9-S antibody gave very specific labeling of the nuclear membrane in healthy neurons, with apparent re-localization to the plasma membrane of diseased motor neurons in ALS. Co-immunoprecipitation experiments revealed an interaction of the C9-isoforms with both Importin 1 and Ran-GTPase, components of the nuclear pore complex. **Interpretation:** Using these antibodies, we have shown that C9orf72 may be involved in nucleocytoplasmic shuttling and this may have relevance to pathophysiology of ALS/FTLD. Our antibodies have provided improved detection of C9orf72 protein isoforms, which will help elucidate its physiological function and role in ALS/FTLD.

Title: Phosphorylated tau at threonine 175 and its role in ALS with frontotemporal degeneration

Authors: J. GOPAUL[1], A. MOSZCZYNSKI[2], P. MCCUNN[2], S. SCHMID[1], R. BARTHA[2], *M. J. STRONG[3];
[1]Anat. & Cell Biol., [2]Robarts Res. Inst., Western Univ., London, ON, Canada; [3]London Hlth. Sci. Ctr. - UH, London, ON, Canada

Abstract: Introduction: The majority of patients with amyotrophic lateral sclerosis (ALS) also have frontotemporal degeneration of the brain that can lead to severe personality and behavioural

dysfunctions. In ALS patients with frontotemporal degeneration, pathological tau aggregates are found in different brain regions. These tau proteins are aberrantly phosphorylated at Threonine residue 175 (p-Thr175-tau). **Hypothesis:** Our hypothesis is that the frontotemporal syndromes associated with ALS are a result of aberrant tau protein phosphorylation at Threonine residue 175. **Materials and Methods:** Rats are undergoing bilateral stereotactic hippocampal inoculations with one of four inoculums: a phosphorylated tau mimic (Thr175Asp-tau), a tau phosphorylation inhibitor (Thr175Ala-tau), wild-type human tau, or rAAV9-GFP (control). The specific aim is to characterize the behavioural effects of expressing Thr175Asp-tau *in vivo*, which is expected to lead to tau protein abnormalities in the brains of injected rats. Rats are undergoing behavioural testing (Morris Water Maze and Locomotor testing), as well as MRI neuroimaging at 1 month, 3 months, and 6 months post-injections. This will indicate changes in brain anatomy and determine if any cognitive deficits are observed. Groups of rats are to be euthanized at different time points to analyze pathology at a tissue level. There are 8 groups of 10 rats in this project. **Results:** Currently, 40 rats with hippocampal inoculations have undergone behavioural testing for the 1 and 3-month post-surgery time points. They have performed the Morris Water Maze (MWM) as well as Locomotor box testing. MWM data indicates that all groups of rats show normal cognitive abilities given this spatial learning task. In other words, there are no observed behavioural differences between the rats administered different tau constructs. The Locomotor data also displays normal motor activity and levels of anxiety in the rats. Behavioural experimentation is still to be carried out for the 6-month time-point. **Summary and Discussion:** Currently, there is neither a cure nor treatment for ALS or frontotemporal degeneration. People diagnosed with ALS die within 3-5 years, and the pathology is only enhanced by the associated dysfunction of the brain. This project investigates the mechanism behind frontotemporal degeneration associated with ALS. The effects of tau protein phosphorylated at Threonine residue 175 are being examined by inoculation of the Thr175Asp-tau construct in rat hippocampus. Understanding this mechanism offers potential for the development of a rational pharmacotherapy of ALS with frontotemporal degeneration.

Title: A screen for novel G4C2 hexanucleotide repeat expansions at ALS and FTD-associated loci

Authors: *F. HE[1], C. FIGUEROA-ROMERO[1], D. ZHANG[2], E. L. FELDMAN[1], P. K. TODD[1]; [1]Dept. of Neurol., Univ. of Michigan, Ann Arbor, MI; [2]Natl. Ctr. for Biotech. Information, NIH, Bethesda, MD

Abstract: Amyotrophic lateral sclerosis (ALS) is a common untreatable neurodegenerative disease affecting both upper and lower motor neurons. A dominantly inherited hexanucleotide GGGGCC repeat expansion in the first intron of C9ORF72 was recently identified as the most prevalent known cause of familial and sporadic ALS and frontotemporal dementia (FTD). In normal individuals, this repeat is usually quite short (2 repeats in a majority of the population) but it becomes dramatically unstable after expansion to 30 or more repeats. We hypothesized that other genes harboring short GGGGCC repeats could also induce ALS/FTD phenotypes. However, thousands of these types of repeat exist within the genome, making screening for such loci challenging. To overcome this, we took a candidate gene based approach, selecting 25 GGGGCC repeat containing candidate genes that reside within 2 Mb of either known ALS loci or SNPs associated with ALS identified by GWAS studies. Gene specific primers were designed, and the GGGGCC repeat numbers were determined by repeat primed PCR followed by fragment analysis. In a sample of 200 of ALS cases and 138 of controls, we found that these candidate gene showed very narrow variation in repeat number, and none of them were expanded to a predicted pathogenic range (>30 times). In comparison, we identified 25 of C9orf72 repeat expansion cases in this same cohort. We conclude that expansion of GGGGCC repeats in C9ORF72 as the cause of ALS is exceptional and that similar repeat expansions at other ALS associated loci are unlikely to be common contributors to disease.

Title: The expression and secretion of the co-chaperone STI1 in astrocytes from SOD1G93A ALS mouse model

Authors: *G. P. OLIVEIRA, T. G. SANTOS, V. R. MARTINS;
A.C.Camargo Cancer Ctr., Sao Paulo, Brazil

Abstract: Amyotrophic Lateral Sclerosis (ALS) is an adult-onset and fast progressive neurodegenerative disease caused by motor neuron loss, leading to muscle paralysis and death within two to five years of symptoms onset. About 20% of familial forms of ALS are linked to dominant mutations in the Cu/Zn superoxide dismutase gene (SOD1). Toxic signals from non-neuronal cells, mainly astrocytes and microglia, have been proposed to contribute to motor neuron death in ALS. Mutant SOD1 (mSOD1) is known to be prone to aggregation and a number of heat shock proteins have been found at mSOD1 aggregates in rodent models of ALS. In addition, the level of chaperones is decreased in the spinal cord of these mice. The co-chaperone STI1 (stress inducible protein 1) binds to Hsp70 and Hsp90 in a complex responsible for the correct folding of client proteins. STI1 could be actively secreted and, in extracellular milieu, interacts specifically with prion protein (PrPC). This interaction modulates several functions such as protection against cell death and neuritogenesis in hippocampal neurons. Herein, STI1 levels were evaluated in primary cultures of astrocytes derived from wild-type and transgenic SOD1G93A mice as well as in the conditioned medium of astrocytes submitted to 48 hours of serum deprivation. The levels of STI1 were 20% lower in SOD1G93A astrocytes when compared to wild-type cells. Otherwise, when cells were cultured for 48 hours in serum free medium, STI1 levels were increased to about 20% in SOD1G93A when compared to the wild-type controls at the same conditions. Furthermore, the secretion of STI1 by SOD1G93A astrocytes in serum deprived conditions were two-fold higher than in wild-type cells. It was hypothesized by others that astrocytes activate secretory pathways in order to eliminate mSOD1 and possibly other misfolded proteins that may cause intracellular toxicity. Furthermore, it was described that Hsp70 has a stronger affinity to mSOD1 than to the wild-type form. It remain to be determined if the increased levels of soluble STI1 detected in SOD1G93A astrocyte conditioned medium can be related to its sequestering in a complex with mSOD1/Hsp70, and also, if this might implicate in the impairment of its activity as a neuroprotective molecule.

Title: Endothelin-1 induces degeneration of motor neurons: a possible pharmacological target for amyotrophic lateral sclerosis

Authors: S. D'ANTONI[1], E. RANNO[1], M. SPATUZZA[1], P. LA ROCCA[1,2], *M. CATANIA[1,3]; [1]Inst. of Neurolog. Sciences, Natl. Res. Council (CNR), Catania, Italy; [2]Univ. of Catania, Catania, Italy; [3]IRCSS Oasi Maria SS, Troina (EN), Italy

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease characterized by progressive loss of motor neurons (MNs) and astrogliosis. Factors secreted by activated astrocytes might contribute to MN degeneration. We have found that endothelin-1 (ET-1), a peptide strongly up-regulated in reactive astrocytes under pathological conditions, is abundantly expressed in reactive astrocytes in the spinal cord of SOD-1 G93A mice and ALS patients and exerts a toxic effect on cultured MNs through activation of astrocytic ET receptors (Ranno et al., Neurobiol Dis. 2014; 65:160-71). In this study, we investigated the mechanisms underlying ET-1 toxicity, focusing on cell survival pathways, such as phosphatidylinositide 3-kinase (PI3K) and JAK-STAT pathways, and/or inflammatory processes. To this aim, mixed spinal cord cultures were treated with ET-1 (100 nM for 48 h) with/without LPS (40 ng/ml) or inhibitors of PI3K (LY294002, 50 uM) and JAK-STAT (AG-490, 50mM). The number of surviving MNs was assessed after treatments by direct counting SMI32-positive neurons. We observed that the inhibition of PI3K pathway or JAK-STAT pathway caused MN death, as expected; however, exposure to ET-1 in the presence of LY294002 did not result in a further increase of MN death whereas a treatment with AG-490 in the presence of ET-1 increased the toxic effect of the peptide. We also observed that LPS induced MN death, but its effect was not additive with that of ET-1. Our results suggest that ET-1 may cause neuronal death by a mechanism that involves the PI3K pathway. An inflammatory component may account for the ET-1 toxicity, but this requires further investigation. Considering the toxic effect that ET-1 exerts on MNs, we can assume that the modulation of ET-1 mediated mechanisms might be envisaged as a new therapeutic approach for ALS.

London, Inst. of Psychiatry, De Crespigny Park, London SE5 8AF, United Kingdom

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a devastating neurodegenerative disease that remains largely untreatable and incurable due to our incomplete understanding of the key pathogenic mechanisms that underlie motor neuron (MN) loss in the disease. Through the use of induced pluripotent stem cells (iPSCs), we can now study the consequences of ALS-related mutation(s) in functional disease-relevant human cell types. This can be done at a range of time points, including those prior to overt pathology, in order to understand early causative events in ALS and hopefully reveal novel therapeutic targets. In this study, we report the use of human induced pluripotent stem cell (iPSC)-derived MNs and astrocytes to study the pathophysiology of ALS. Using whole-cell patch-clamp recording techniques we have recently shown that patient iPSC-derived MNs harbouring C9ORF72 or TARDBP mutations, display an initial hyperexcitability followed by progressive loss of action potential output due to a decrease in voltage-activated sodium and potassium currents which occurs in the absence of changes in cell viability (Devlin et al., 2015, Nat Commun, 6:5999). Given evidence supporting non-cell autonomous disease mechanisms in ALS, we are currently studying whether interactions between neurons and astrocytes are involved in the pathophysiological phenotype we have recently revealed. Data to date indicate that patient iPSC-derived astrocytes induce

pathophysiological changes in control human iPSC-derived MNs. These changes are similar to those we have revealed in patient iPSC-derived MNs and include progressive loss of action potential output, due to decreases in voltage-gate sodium and potassium currents, but no indication of early hyperexcitability. We have also observed a reduction in synaptic input to control iPSC-derived MNs co-cultured with patient iPSC-derived astrocytes. We are currently investigating if such non-cell autonomous disease mechanisms are common across patient iPSC-derived astrocytes harbouring C9ORF72 and TARDBP mutations and whether they rely on direct astrocyte-MN interactions. Overall, our data implicate MN dysfunction, potentially due to non-cell autonomous disease mechanisms, as an early contributor to downstream degenerative pathways that ultimately lead to MN loss in ALS.

Title: Depletion of TDP-43 induces mitochondrial fragmentation

Authors: ***G. ITO**[1], A. KOYAMA[2], A. SHIGA[1], S. HIROKAWA[1], Y. TOYOSHIMA[1], A. KAKITA[1], M. NISHIZAWA[1], O. ONODERA[3];

Abstract: Background Mitochondria are movable organelles and build up a large network called mitochondrial dynamics by its fusion and fission. Mitochondrial dysfunction has been reported as a molecular pathogenesis of neurodegenerative diseases including Amyotrophic lateral sclerosis (ALS). Abnormal mitochondrial morphology and fragmentation have been detected in motor neuron with ALS (Sasaki et al., 2007). However, the molecular background for these findings are still obscure. Dislocation of nuclear protein TDP-43 to cytoplasm and form inclusions is a pathological hallmark of ALS. Thus, a loss of function of TDP-43 is thought to be a key process for the molecular pathogenesis of ALS. Here, we investigated whether a loss of TDP-43 affects mitochondrial morphology. Method and Result We found that the depletion of TDP-43 by siRNA induced mitochondrial fragmentation in HEK293T cells. By Western

Blotting, we investigated the amounts of mitochondrial dynamics related proteins: DRP1, FIS1, OPA1, MFN2. Among them, OPA1 regulate the fusion of mitochondrial inner membrane and its 87 kDa protein significantly increased under the depletion of TDP-43. OPA1 has eight-variation of mRNA splicing variants, and each of them undergoes protein cleavage finally produces five peptides. We investigated the amounts of each splicing variant by qPCR and found that variant 8, which produces 87 kDa peptide, increased. Finally, we found overexpression of OPA1 variant 8 resulted in the mitochondrial fragmentation and increased expression of OPA1 87 kDa. Conclusion The depletion of TDP-43 induced mitochondrial fragmentation and increased the OPA1 splicing variant 8, which produces OPA1 87 kDa peptide. Mitochondrial fusion is regulated by OPA1 mRNA splicing, and OPA1 variant 8 doesn't have an ability of mitochondrial fusion (Song Z et al., 2007). The perturbation of OPA1 splicing variants induced by TDP-43 depletion may associate with the mitochondrial fragmentation.

Abstract: Sporadic amyotrophic lateral sclerosis (SALS) accounts for 90% of all cases of ALS. Etiology of SALS is largely unknown and it is not well studied in African Americans. SALS is hypothesized to be a complex disorder in which disease is modulated by variations in multiple genetic loci interacting with each other and perhaps environmental factors. We have shown that the ubiquitin proteasome system (UPS) may be directly involved in the pathology of ALS. Cbl proteins negatively regulate receptor and nonreceptor tyrosine kinases by functioning as ubiquitin protein ligases that mediate the ubiquitination of activated tyrosine kinases. Therefore, mutations in cbl-c gene may affect degradation of tyrosine kinases in motor neurons, thus leading to motor neuron diseases. In this study we investigated association of SALS in African-Americans to a coding region cytosine duplication (dupC) mutation in CBLC. This variation has very low frequency in people of European descent, but common in Africans. It leads to frame-shift and premature stop codon. We analyzed dupC variant in a case-control cohort of 356 African-Americans for association with SALS. DNA samples extracted from whole blood from our own collection and others obtained from Coriell Cell Repositories were screened using four primers PCR reaction for the presence of dupC mutation in cbl-c. We investigated the association between sporadic ALS and the mutation using $\chi 2$ analyses. We found no significant difference between polymorphism frequency in the disease samples as compared to controls ($p=0.34$). Additional studies are underway to further investigate the association between SALS and the presence of additional polymorphism in cbl-c.

Title: Building an ipsc-derived astrocyte-motor neuron co-culture model to study non-cell autonomous toxicity in cases of fused in sarcoma (fus)-linked amyotrophic lateral sclerosis

Authors: *K. MCAVOY, K. KRISHNAMURTHY, S. SHAMAMANDRI MARKANDAIAH, D. TROTTI, P. PASINELLI;
Thomas Jefferson Univ., Philadelphia, PA

Abstract: It is well established that astrocytes contribute to motor neuron degeneration and disease progression in Amyotrophic Lateral Sclerosis (ALS), an incurable neurodegenerative disease. Mutations in fused in sarcoma/translocated in liposarcoma (FUS/TLS, FUS) account for approximately 5% of familial (fALS) cases and FUS-positive pathological inclusions have been identified in sporadic ALS (sALS) cases. We have identified a pro-inflammatory phenotype in primary rodent astrocytes expressing human ALS-linked FUS mutations. Furthermore, astrocytes expressing mutations in FUS damage and kill co-cultured primary motor neurons and this toxicity is at least partially mediated by the cytokine tumor necrosis factor alpha (TNFα) triggering increased motor neuron susceptibility to excitotoxic damage. The aim of the current study is to validate and extend these findings from primary rodent cultures using a patient-derived induced pluripotent stem cell model (IPSC). IPSCs were fully differentiated into astrocytes expressing glutamate transporters EAAT1 and EAAT2 and well as other astrocytic markers S100β and GFAP. Their effect on the health of motor neurons was examined. This work was supported by NINDS-RO1 NS051488 and the Farber Family Foundation.

Title: Activated inflammation and glial response in the skeletal muscle of a rat model of familial amyotrophic lateral sclerosis (ALS)

Authors: J. VAN DYKE, I. SMIT-OISTAD, D. KRAKORA, C. MACRANDER, M. MEYER, *M. SUZUKI;
Dept. of Comparative Biosci. and The Stem Cell and Regenerative Ctr., Univ. Wisconsin-Madison, Madison, WI

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease characterized by progressive motor dysfunction and loss of large motor neurons in the spinal cord and brain stem. While much research has focused on mechanisms of motor neuron cell death in the spinal cord, degenerative processes in skeletal muscle and neuromuscular junctions (NMJs) are also observed early in disease development. Relatively little is known about the role inflammation and glial responses in skeletal muscle at or near NMJs, and how these responses affect motor neuron survival or motor dysfunction in ALS. In this study, we evaluate inflammatory and glial responses in the skeletal muscle near NMJs in the limb muscle of familial ALS rat model (SOD1-G93A transgenic rats) as the disease progresses. Muscle samples were collected from pre-symptomatic, symptomatic, and endpoint stage animals and immunostained for inflammation markers (CD11b and CD68). The expression of these inflammatory markers increased significantly in the skeletal muscle during the symptomatic and end-stage SOD1-G93A rats. Interleukin 1 alpha (IL-1α) and tumor necrosis factor alpha (TNF-α) expression was measured in SOD1-G93A rat muscle homogenates. Both IL-1α and TNF-α were elevated in homogenates from symptomatic and end-stage rats. We next determined whether active glial responses occur in the muscle of SOD1-G93A rats near intramuscular axons and NMJs. Interestingly, strong expressions of glial fibrillary acidic protein (GFAP) and nestin, were observed in the areas adjacent to NMJs. The expression of these markers has been linked with the dissociation of NMJs and the activation of perisynaptic (terminal) Schwann cells. Together, these data suggest a significant increase in inflammation within the muscle tissue of ALS rats and that this increase occurs near degenerating NMJs. Understanding the inflammatory responses at the NMJ is important when investigating suitable cellular and molecular targets for treating ALS and other neuromuscular diseases.

Title: β-Sitosterol β-D-glucoside causes Parkinsonism in rats but ALS-like behaviours and motor neuron pathology in mice

Authors: *J. M. VAN KAMPEN[1], D. G. KAY[1], P. A. HOWSON[2], J. M. BROTCHIE[2], D. C. BARANOWSKI[1], C. A. SHAW[3], H. A. ROBERTSON[1];
[1]Neurodyn Inc., Charlottetown, PE, Canada; [2]Atuka, Toronto, ON, Canada; [3]Opthalmology and Visual Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Evidence suggests that amyotrophic lateral sclerosis-parkinsonism dementia complex of the Western Pacific (ALS-PDD) is caused at least in part by toxic sterols such as β-sitosterol β-D-glucoside (BSSG), which is present in cycad nuts. Rats fed chronically with cycad seed extracts or with BSSG progressively develop many if not all the symptoms of Parkinson's disease, including premotor olfactory deficits, neuroinflammation, motor deficits, aggregation of phospho-α-synuclein and cognitive decline. Some evidence suggests that mice and rats respond differently to cycad phytosterols. In contrast to rats, when mice were fed BSSG, motor behaviours suggested motor neuron deficits; similar results had previously been observed following feeding of cycad extract. Mice (CD1) were fed (1mg BSSG/mouse/day, 5 days/wk) daily for 15 weeks. At 28 and 35 weeks, there are significant locomotor deficits. BSSG administration significantly shortened stride length and significantly widened rear stance at week 28 and these deficits increased in magnitude by week 35. BSSG did not alter open field, rotarod, wire hang or splay reflex. JNX1001, a neurotrophic enhancer, improved motor behaviours in BSSG treated mice. Neuropathological changes were assessed by Nissl, ChAT, ILB4 and 3-NT staining. Total neuron loss in dorsal horn was approximately 50% and ChAT+ neurons are reduced by 60%. BSSG treatment led to a 66% increase in IL4+ cells in dorsal horn and a significant (140%) increase in 3-nitrotyrosine labeling. Locomotor deficits and histopathological changes in dorsal horn were all prevented by daily oral administration of JNX1001 (1 and 10 mg/kg/day in 0.5% HPMC containing 0.2% Tween 80). Currently, we have no adequate explanation for the difference in outcome between mice and rats. On a weight basis, the mice received a much higher dose of BSSG. It is however interesting that the human condition (ALS-PDD) also appears to exhibit a broad range of outcomes. BSSG treatment of mice may provide a progressive alternative to genetic models for ALS.

Title: MTHFSD and DDX58 are novel RNA-binding proteins abnormally regulated in ALS

Authors: *L. MACNAIR[1], S. XIAO[2], D. MILETIC[2], M. GHANI[2], E. ROGAEVA[2], J. KEITH[3], L. ZINMAN[3], J. ROBERTSON[2];

Abstract: INTRODUCTION: Tar DNA-Binding Protein 43 (TDP-43) is an RNA-binding protein normally localized to the nucleus of cells, where it elicits function related to RNA metabolism such as transcriptional regulation and splicing. In Amyotrophic Lateral Sclerosis (ALS), TDP-43 is mislocalized from the nucleus to the cytoplasm of diseased motor neurons, forming ubiquitinated inclusions. Although mutations in the gene encoding TDP-43, *TARDBP*, are found in ALS, these are rare. However, TDP-43 pathology is common to over 95% of ALS cases, suggesting that abnormalities of TDP-43 play an active role in disease pathogenesis. HYPOTHESIS: Since there is a loss of TDP-43 from the nucleus of affected motor neurons in ALS this will lead to a change in mRNA expression, and identifying these changes will uncover molecular pathways that underpin motor neuron degeneration. METHODS AND RESULTS: Translating ribosome affinity purification (TRAP) was coupled with microarray analysis to identify changes in mRNAs being actively translated in spinal cord motor neurons of pre-symptomatic and symptomatic TDP-43^{A315T} mice when compared to age-matched non-transgenic (NTg) littermates. The translational profile for pre-symptomatic TDP-43^{A315T} mice was not significant, however the translational profile of symptomatic TDP-43^{A315T} mice revealed an overrepresentation of genes involved in RNA metabolic process, immune response, and regulation of cell cycle. Of the 28 differentially expressed genes, 7 had a $\geq$ 2-fold change; 4

correlated with microarray results as validated by immunofluorescence labeling of motor neurons in TDP-43^{A315T} mice, and 2 were confirmed by immunohistochemistry in ALS cases. Both of these identified genes, DEAD Asp-Glu-Ala-Asp box polypeptide 58 (*DDX58*) and methenyltetrahydrofolate synthetase domain containing protein (*MTHFSD*) are RNA-binding proteins that are directly regulated by TDP-43. CONCLUSIONS: Translational profiling of a TDP-43 transgenic mouse model identified gene ontologies related to ALS pathogenesis. More importantly, this method identified 2 genes, *DDX58* and *MTHFSD* that were differentially expressed in spinal cords of ALS patients. TDP-43 bound to both of these transcripts. This discovery-based approach has, for the first time, revealed translational changes in motor neurons of a TDP-43 mouse model, which correlate with changes in ALS patients, providing greater insight into how TDP-43 abnormalities contribute to ALS pathogenesis.

Title: Dominant-negative effect" mechanism in OPTNE478G-linked amyotrophic lateral sclerosis

Authors: Y. SHI[1], F. FECTO[1], T. SIDDIQUE[1], *H.-X. DENG[2];
[1]northwestern university, chicago, IL; [2]Davee Dept. of Neurol. and Clin. Neurosciences, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Mutations in the gene encoding optineurin (OPTN) cause amyotrophic lateral sclerosis (ALS) in both autosomal recessive and autosomal dominant fashions, an uncommon phenomenon in genetic diseases. A convergent mechanism to explain this phenomenon is lacking. In this study, we analyzed a well-established autosomal dominant ALS mutant,

OPTNE478G. We show that wild-type OPTN (OPTNWt), but not OPTNE478G, is recruited to the autophagosomes. Intriguingly, the OPTNE478G prevents OPTNWt from being recruited to the autophagosomes. These data, therefore, indicate that the OPTNE478G acts in a "dominant-negative effect" mechanism in the OPTNE478G-mediated dominant ALS. Our data also suggest that loss of functional OPTN is the convergent pathway leading to the disease in both OPTN-linked recessive and dominant ALS. Because OPTN primarily localizes to autophagosomes and is an autophagy receptor, our data also suggest that autophagic dysfunction is the key molecular event in OPTN-linked ALS. OPTN-linked dominant ALS appears to be the first neurodegenerative disorder showing a "dominant-negative effect' in its pathogenesis.

Title: Motor neurons are impaired in Prune2 gene deficient mice

Authors: M. ITOH, E. NISHIDA, S. ISLAM, S. LI, M. OSAWA, D. LEE, H. CHEN, M. UEDA, M.-X. WANG, M. HAYAKAWA, G. IKENO, K. ICHIHASHI, K. OKAMOTO, J. TSUTSUMI, *T. NAKAGAWA;
Gifu Univ. Grad Sch. of Med., Gifu, Japan

Abstract: Motor neurons were degenerated in the Prune homolog 2 (*Drosophila*) (*Prune2*) gene deficient mice generated by CRISPR/Cas9 system. PRUNE2 is one of Bcl-2/adenovirus E1B 19 kDa-interacting proteins (BNIPs), which plays critical roles in several cellular processes such as cellular transformation, apoptosis, neuronal differentiation, and synaptic function, mediated by the BNIP2 and Cdc42GAP homology (BCH) domain. *Prune2* and its isoforms—*C9orf65*, BCH motif-containing molecule at the carboxyl terminal region 1 (*BMCC1*), and BNIP2 Extra Long (*BNIPXL*)—have been shown to be a susceptibility gene for Alzheimer's disease, a biomarker for leiomyosarcomas, a proapoptotic protein in neuronal cells, and an antagonist of cellular transformation, respectively. And also the prostate cancer antigen 3 (*Pca3*) gene is a marker of prostate cancer, which is localized within the *Prune2* gene and is transcribed by responsiveness to androgen in the opposite orientation. *Prune2* mRNA is predominantly expressed in the neurons of the cranial nerve motor nuclei and the motor neurons of the spinal cord (Li et. al., *Neurosci. letters*, 503, 208-214, 2011; sfn 33.07, 2011). However, function and distribution of

PRUNE2 protein are largely unknown. We generated *Prune2* gene deficient mice (*Prune2*$^{Ex16-/-}$) by CRISPR/Cas9 system, which deleted exon16. The levels of *Prune2* mRNA in the spinal cord of *Prune2*$^{Ex16-/-}$ were significantly decreased. Microscopical analysis indicated that motor neurons in the spinal cord were not stained by anti-PRUNE2 antibody. By electron microscopy, we observed that morphology of mitochondria in motor neurons was changed, suggesting that PRUNE2 may play a crucial role of maintenance of motor neurons.

Title: Mechanisms of synaptic dysfunction of C9ORF72 neurons *in vitro* and *in vivo*

Authors: *I. LORENZINI[1,2,3], T. O'DONNELL[2,3], E. L. DALEY[2,3], X. TANG[2,3], I. VARELA[2], S. VIDENSKY[2,3], J. CHEW[4], L. PETRUCELLI[4], R. SATTLER[2,3];

Abstract: The most common genetic mutation in sporadic and familial ALS is found in the non-coding region of C9orf72 gene. An abnormal expansion of the hexanucleotide repeat GGGGCC (G4C2) is present in this region causing up to 10% of sporadic and up to 40% of the familial ALS as well as up to 10% of familial FTD. Our laboratory used induced pluripotent stem cells (iPSCs) as a valuable research approach to study C9ORF72 (C9) disease pathogenesis. It is known that iPSCs differentiated neurons (iPSNs) carrying the C9 mutation present intranuclear repeat RNA foci, changes in neuronal excitability, increased susceptibility to cellular stressors, including excitatory amino acid glutamate and RNA interacting proteins sequestered to the G4C2 repeat. Based on these previous studies, we hypothesize that the G4C2 repeat expansion can sequester proteins critical for synapse function. To test this hypothesis, we performed structural and functional analysis of spinal and cortical iPSNs (ALS and FTD patients). The cells were analyzed for dendritic morphology and expression of synaptic protein markers. Confocal microscopy and 3D image analysis revealed that spinal C9ORF72 iPSNs show altered dendritic tree morphology as well as aberrant spine morphology. Specifically, we discovered an overall decrease in spine density as well as a decreased ratio of mature mushroom-shaped spines to immature stubby spines per dendritic length in C9ORF72 iPSNs when compared to control iPSNs. We further determined that the expression pattern of the synaptic protein synapsin-1 is altered in aged C9ORF72 spinal cord iPSNs when compare to control. To confirm synaptic alterations *in vivo*, we injected AAV9 viral construct overexpressing G4C2 repeats of different lengths into wild-type and Thy-1 eGFP mice . In conclusion, our data suggest that synaptic dysfunction plays a role in C9ORF72 pathogenesis and may explain the changes in neuronal excitability, the increased susceptibility to cellular stressors as well as cognitive impairment, as observed in C9ORF72 FTD patients and ALS patients.

Title: TDP-43 regulates expression of Ulk1/Atg1 and autophagy

Authors: *K. MATSUKAWA, R. IHARA, T. MATSUMOTO, M. MIURA, T. CHIHARA, T. WAKABAYASHI, T. HASHIMOTO, T. IWATSUBO;
The Univ. of Tokyo, Bunkyo-Ku, Tokyo, Japan

Abstract: TDP-43 is an RNA-binding protein that was identified as a proteinaceous constituent of ubiquitin-positive inclusions that characterize the neuropathology of frontotemporal lobar degeneration (FTLD) and amyotrophic lateral sclerosis (ALS). Mutations in TDP-43 gene are found in familial ALS, supporting the causative roles of TDP-43 in neurodegeneration. We previously reported that transgenic *Drosophila* melanogaster (tg flies) overexpressing human TDP-43 showed a progressive retinal degeneration, whereas those expressing TDP-43 lacking the RNA recognition motif 1 (RRM1) did not exhibit any degenerative phenotypes, proposing the RNA-binding dependent neuronal toxicity of TDP-43. To investigate into the molecular mechanism whereby TDP-43 causes neuronal death, we utilized a microarray-based gene expression analysis and identified Atg1 (Autophagy-specific gene 1), a *Drosophila* homologue of human ULK1, as one of the genes whose expression is upregulated in the retina of TDP-43 tg flies. Quantitative RT-PCR revealed that the expression level of Atg1 in the retina of TDP-43 tg flies was increased by ~4.7 fold compared with that in lacZ tg flies, whereas the level was not changed in the TDP-43 ΔRRM1 tg flies. RNA-immunoprecipitation assay showed an interaction of TDP-43 with Atg1 mRNA in the retina of TDP-43 tg flies. To determine whether Atg1 is involved in the TDP-43-induced neuronal toxicity, we crossed TDP-43 tg flies with Atg1 RNAi line, and found that the suppression of Atg1 expression in the retina of TDP-43 tg flies mitigated the retinal degeneration. We also crossed TDP-43 tg flies with RNAi lines of other autophagy-related genes, i.e., Atg3, 6 or 13, and found a significant mitigation of the retinal degeneration induced by TDP-43. Moreover, we revealed an increase in phosphatidylethanolamine-conjugated form of GFP-Atg8a, suggesting the autophagic activation in the retina of TDP-43 tg flies. These data suggest that overexpression of TDP-43 in the *Drosophila* retina causes neurodegeneration through an excessive autophagic activation by an increase in Atg1 expression. To examine whether TDP-43 regulates the expression of ULK1 in mammalian cells, we silenced the expression of endogenous TDP-43 in Neuro-2a cells by siRNA. Silencing of TDP-43 decreased the expression of ULK1 by ~60%, and suppressed autophagy, suggesting that TDP-43 is involved in autophagy through regulating ULK1 expression in mammalian cells. Taken together, we propose that TDP-43 may play a role in autophagy through ULK1/Atg1, and that excessive autophagy induced by overexpression of TDP-43 may contribute to the neurodegeneration in *Drosophila*.

Abstract: Over 30% of patients with amyotrophic lateral sclerosis (ALS) exhibit cognitive deficits indicative of frontotemporal dementia (FTD), suggesting a common pathogenesis for both diseases. Consistent with this hypothesis, neuronal and glial inclusions rich in TDP43, an essential RNA-binding protein, are found in the majority of those with ALS and FTD, and mutations in TDP43 and a related RNA-binding protein, FUS, cause familial ALS and FTD. TDP43 and FUS affect the splicing of thousands of transcripts, in some cases triggering nonsense-mediated mRNA decay (NMD), a highly-conserved RNA degradation pathway. Here, we take advantage of a faithful primary neuronal model of ALS and FTD to investigate and characterize the role of hUPF1, an RNA helicase and master regulator of NMD, in these

disorders. We show that hUPF1 significantly protects mammalian neurons from both TDP43- and FUS-related toxicity. Expression of hUPF2, another essential component of NMD, also improves survival, while inhibiting NMD prevents rescue by hUPF1, suggesting that hUPF1 acts through NMD to enhance survival. These studies emphasize the importance of RNA metabolism in ALS and FTD, and identify a novel and potentially effective therapeutic strategy for these disorders.

Title: Neuron-glial interaction in pathogenesis of sporadic amyotrophic lateral sclerosis (als): inflammation mediated neurotoxicity

Authors: *P. S. MISHRA[1], D. K. DHULL[4], K. VIJAYALAKSHMI[2], T. N. SATHYAPRABHA[2], A. NALINI[3], P. A. ALLADI[2], T. R. RAJU[2];
[2]Neurophysiol., [3]Neurol., [1]Natl. Inst. of Mental Hlth. and Neuroscien, Bangalore, India; [4]UGC-Center of Advanced Study (UGC-CAS), Panjab Univ., Chandigarh, India

Abstract: The intricate glial-neuron interplay in neurodegeneration remains ambiguous. Investigations on Sporadic Amyotrophic Lateral Sclerosis (SALS) models from our laboratory reported reactive astrogliosis along with neurodegeneration. Further, proteomic analysis of cerebrospinal fluid of ALS patients (ALS-CSF) revealed up-regulation of glial proteins, viz. chitotriosidase-1 and osteopontin, the mediators of neuroinflammation. Thereby, investigating glial responses in ALS becomes physiologically and therapeutically relevant. Briefly, pure astroglial and microglial cultures derived from Wistar rats (P3) were propagated in DMEM+10% FBS alone or exposed to 10%v/v ALS-CSF and CSF from patients suffering from non-neurodegenerative diseases (NALS-CSF), respectively for 48 hrs. Parameters studied included

assay for glutamate levels and reactive oxygen species (ROS) levels; expression patterns of iNOS, PGE2, and COX-2 using confocal microscopy, m-RNA expression and/or ELISA. MTT assay was performed on NSC-34 cells to study the effect of the conditioned media from glial cultures exposed to ALS-CSF. We found significant up regulation of inflammatory markers like PGE-2 and COX-2 in both astroglial and microglial cultures exposed to ALS-CSF. A phase contrast study, revealed microglial activation in the form of predominantly amoeboid phenotype over ramified ones in cultures exposed to ALS-CSF. Simultaneously, the ROS and glutamate levels were also elevated. The conditioned media from glial cultures exposed to ALS-CSF induced death in NSC-34 motor neuron cell line, suggesting a degenerative effect of the glial inflammatory profiles on motor neurons. We propose accentuated neuroinflammation and excitotoxity mediated by glia as the major events in the disease pathogenesis. Further investigating the synergism of glial-neuronal interactions can lead to better understanding of the disease, and possible therapeutic targets.

Title: *In vitro* analysis of axolotl spinal cord in terms of regeneration

Authors: *E. KUBAT OKTEM, B. POLAT, C. B. AKAGUNDUZ, G. OZTURK; Regenerative and Restorative Med. Res. Ctr. (REMER), Istanbul Medipol Univ., Istanbul, Turkey

Abstract: Mammals have a limited central nervous system (CNS) regeneration capacity in contrast to the salamander *A. mexicanum* (Axolotl), which has continuing axon and cell differentiation throughout life. The aim of this study is to investigate the regenerative capacity of freshly isolated and injured axolotl spinal cord *in vitro* which would shed light to mammalian regeneration research. A complete spinal cord cut was executed at lumbosacral level of the spinal column of young adult wild type axolotls. Response to injury effect was tested between three groups as; uninjured control spinal cord cells, spinal cord cells plated on 7^{th} day post-injury (DPI7) and spinal cord cells plated on 14^{th} day post-injury (DPI14). The cells were dissociated and cultured around 300 cells / mm^2 to either laminin or fibronectin coated petri dishes. Cell

cultures were kept at 18 °C and 5% CO_2. After 24 h in culture, propidium iodide was added for viability assesment. The same coordinates were examined and recorded with dedicated software for 10 days *in vitro*. Immunofluorescence staining was performed with antibodies against neural, glial and stem cell markers and imaged with laser scanning confocal microscope. Survival percentage, spheroid percentage (SP), total sphere number, total neurite growth and average neurite growth were the investigated parameters. Control survival percentage was best wheraas DPI7 was worst for both coating agents and laminin coating induced survival to a higher extent than fibronectin coating for every day *in vitro* (laminin (%): control=91, DPI7=87, DPI14=90; fibronectin (%): control=88, DPI7=79, DPI14=81). Spheroid percentage and sphere number of DPI 7 was higher than the two groups for all days *in vitro* regardless of the coating effect (SP for laminin (%): control=48, DPI7=54, DPI14=34; for fibronectin (%): control=23, DPI7=45, DPI14=19). Injury had a negative effect on neurite outgrowth and delayed outgrowth onset. ICC studies also confirmed the existence of proliferating cells, neurons and glia. This work is the only axolotl mix sc culture study to our knowledge. Results with high survival rate for uninjured control group, even for over three weeks *in vitro* without additional serum or factors, indicate an intrinsic regeneration capacity. The injury model also worked but the time window assigned for healing was not sufficient. Although high spheroid percentage and low survival observed at DPI7 implies an acute phase in healing; further studies of groups with more post injury days will be executed in order to measure the boosting phase of the injury healing.

Title: The relation between alpha motor neuron excitability and discharge rate depends on the membrane noise level

Authors: *U. YAVUZ[1], F. NEGRO[2], O. SEBIK[3], C. FRÖMMEL[1], K. S. TÜRKER[3], D. FARINA[2];

Neurorehabilitation Engineering,, Univ. Med. Ctr. Göttingen, Göttingen, Germany; [3]Sch. of Med., Koç Univ., Istanbul, Turkey

Abstract: Simulation and experimental studies have individually shown that the amplitude (probability) of the reflex response of motor neurons (MNs) to composite excitatory post synaptic potentials is dependent on the background discharge frequency and the membrane noise. In the present study, we hypothesized that the discharge frequency and the membrane noise may be the factors that determine the reflex response regime of a MN population activated at a given force level. For this purpose, the mono-synaptic H-reflex and the bi-synaptic reciprocal inhibition of a relatively large population of motor units were recorded from the tibialis anterior muscle of 12 subjects (6 for excitation and 6 for inhibition) at 10% and 20% of maximum voluntary contraction using high density EMG electrodes. During the task, the subjects received electrical stimulation of tibial and peroneal nerves in different sessions. The hypothesis was additionally tested using a model of 100 MNs for a specific case as the membrane resistance of MNs changed gradually while the afferent input received was kept constant. The reflex amplitudes were measured using the cumulative sum of peri-stimulus frequencygram. For both simulated and experimentally recorded MNs, the correlation between the reflex amplitude and the pre-stimulus mean discharge rate were estimated. A significant positive correlation was found between the discharge rate and the reflex amplitude for 10 subjects at 10% MVC (4 in excitation: $p<0.05$; 6 for inhibition: $p< 0.05$) and for 8 subjects at 20% MVC (3 in excitation: $p<0.05$; 5 for inhibition: $p< 0.05$). Moreover the correlation coefficients (r) decreased with decreasing coefficient of variation for the inter-spike-intervals ($p < 0.05$), that was used as a measure of membrane noise. The simulations supported the experimental results. The results suggest that the MNs that fire with higher frequency in a population activated at moderate contraction forces have higher responses to inhibitor or excitatory postsynaptic potentials. However this is dependent on the membrane noise.

Title: Is the synaptic input common to the whole motor neuron pool?

Authors: *F. NEGRO, S. MUCELI, M. CASTRONOVO, D. FARINA;
Univ. Med. Ctr. Göttingen, Goettingen, Germany

Abstract: During sustained contractions, motor neurons receive both common and independent synaptic inputs from presynaptic neurons and supraspinal centers. The common synaptic inputs generate a certain degree of correlation between the membrane potentials of the motor neurons that result in a significant level of synchronization between their spike trains [1]. Several studies have showed this phenomenon and quantified the amount of synchronization using different indexes [2]. Due to technical limitations, most of the studies have focused on the estimation of synchronization from pairs of motor neuron spike trains and not from larger populations. For this reason, it has not been proven experimentally if all motor neurons in a pool share a source of common input. Since the motor neurons discharge at relatively low rates, there is also a theoretical constraint in the identification of common inputs at high frequencies since the sample rate is too small [3,4]. For these reasons, we tested the existence of a shared synaptic input across relatively large motor neuron populations recorded from the tibialis anterior (TA) muscle. The presence of higher order correlations was tested using a novel approach based on the comparison between the binned superimposition of multiple spike trains (composite spike train, CST) and its shuffled version. The method was validated using simulated motor neuron spike trains and then applied to experimental recordings. For the experimental part, two subjects performed three isometric contractions of the TA muscle at 10, 20 and 30 % MVC for 30 s. Intramuscular EMG signals were recorded using two novel thin film electrodes with 16 contact points and decomposed manually with an advanced algorithm [5]. This technique provided the possibility to extract a relatively large population of motor neuron spike trains. A total of 231 (38 ± 20 per subject and contraction) motor unit spike trains were recorded. Using the proposed method, we detected a correlation degree greater than 9 (i.e., the maximum tested correlation degree) in all the recorded contractions. These results strongly point out that the synaptic input received by the motor neuron pool in the tibialis anterior muscle is common across the full motor neuron population in humans. Title: The motor neuron pool as a linear system

Authors: *J. L. DIDERIKSEN[1], F. NEGRO[2], D. FARINA[2];
[1]Ctr. for Sensory-Motor Interaction, Aalborg Univ., Aalborg Ost, Denmark; [2]Univ. Med. Ctr. Göttingen, Göttingen, Germany

Abstract: Most voluntary movements occur as a result of a coordinated central drive to the spinal motor neurons whose activation triggers muscle contractions and thus movement. This drive is believed to be determined by internal forward models. These models need to be flexible to allow adaptation to changes in the requirement for the movement, such as different inertial loads [1]. We hypothesize that such flexibility is most easily achieved with a linear system. However, the nervous system at the spinal level consists of several non-linear elements, including the motor neurons [2] and sensory neurons that provide a non-linear sampling of their inputs [3]. In this study, we characterized the linearity of the motor neuron pool using a novel computational model. In the model, two populations of motor neurons received synaptic input from descending drive, spinal interneurons and afferent feedback. Muscle force, simulated based on motor neuron activity, determined limb movement which gave rise to afferent feedback from muscle spindles and Golgi tendon organs. A series of simulation was performed in which a sinusoidal current (1-12 Hz in steps of 1 Hz) or the sum of these 12 sine waves was imposed to the motor neuron pool to study their output. This series of simulations was repeated with different offsets of the neural drive implying different average contraction levels. Linearity was assessed based on two criteria: 1) the amount of power in the neural drive to the muscle at the imposed frequency with respect to the total, and 2) the degree to which the sum of the neural drives for the 12 simulations with single sine waves imposed was equal to the neural drive reflecting the simulation with the combined neural input of all 12 sine waves. The power at frequencies outside the imposed sine wave decreased gradually as the contraction level increased. For example, at 5% of the maximum voluntary contraction level (MVC), this power was on average 5.4±10.8% of the power at the frequency of the imposed sinusoid, but only 1.9±3.1% at 25% MVC. Similarly, the average relative error between the power of the sine waves when imposed individually or combined decreased from 59.9±31.6% (5% MVC) to 22.2±25.5% (25% MVC). In conclusion, the motor neuron pool integrates and transmits descending commands and afferent input in an approximately linear way, especially for high excitatory input. This observation has implications for our understanding of cost functions used

to estimate optimal patterns of muscle activation, as greater contraction levels may imply a more reliable control. References: [1] Wolpert et al. Nat Rev Neurosci 2011 [2] Negro & Farina. J Physiol 2011 [3] Mileusnic et al. J Neurophysiol 2006

Title: Decorrelated neural drive to muscle from highly consistent inputs of specific sensory pathways in the *in vivo* cat

Authors: *C. K. THOMPSON[1], F. NEGRO[2], M. D. JOHNSON[1], M. R. HOLMES[1], L. C. MILLER[1], D. FARINA[2], C. J. HECKMAN[1];

Abstract: The motor unit (MU) provides a 1:1 linkage between the discharge of a spinal motoneuron and the activation of muscle fibers. Recent hardware and computational advances have allowed for the accurate decomposition of a large number of concurrently active MU spike trains. Using these approaches, statistical tools, such as coherence, can be used to infer qualities of the synaptic input received by the spinal motor pool. For example, a significant amount of MU coherence a given frequency ranges indicates that the motor pool is receiving common synaptic input at those frequencies. Here we assess the degree of coherence induced by three forms of evoked synaptic drive using the unparalyzed, unanesthetized, decerebrate cat. With force and 64-channel EMG collected from isolated hind limb muscles, we first applied small amplitude (~80 um) trains of vibration at frequencies from 80 to 200 Hz to the soleus tendon and measured the evoked motor output from the homonymous soleus muscle. Second, we stimulated the caudal

cutaneous sural nerve at frequencies ranging from 2.5 to 200 Hz and measured the evoked motor output from the ipsilateral medial gastrocnemius and soleus muscles. Third, we stimulated the distal branch of the superficial peroneal nerve at frequencies from 2.5 to 200 Hz and measured the evoked motor output from the contralateral soleus muscle. Offline, the multichannel EMG activity was decomposed into corresponding MU spike times using automated algorithms, and coherence between composite MU spike trains was calculated. Tendon vibration produced strong MU coherence at the vibration frequency, ipsilateral cutaneous activation produced moderate amounts of coherence at the stimulation frequencies, and contralateral cutaneous activation produced an insignificant amount of coherence, except for the very lowest of stimulation frequencies. These data are consistent with the presumed anatomy of spinal pathways: Tendon vibration has strong monosynaptic connections, ipsilateral cutaneous pathways are internuncial with relatively few interneurons, while contralateral cutaneous cutaneous pathways may contain relatively larger number of interneurons. Though the anatomical substrate underlying these polysynaptic pathways is unresolved, it appears a putative increase in the number of synaptic relays can serve to decorrelate the neural drive to muscle, despite highly consistent inputs. These finding suggest the anatomical connections to spinal motoneurons may have an important role shaping the frequency content of muscle force generation.

Center, Georg-August Univ., Göttingen, Germany

Abstract: Muscle force is regulated by the activation of motor units. Quantifying the discharge patterns across multiple motor pools can provide insight into the sources of synaptic drive underlying motor output. For example, the onset/offset hysteresis among high and low threshold motor units can provide a surrogate measure of intrinsic excitability of spinal motoneurons (delta-f). Recent data from ramp contractions in the upper extremity demonstrate a 2-fold increase the delta-f estimates of extensor (triceps) motoneurons versus flexor (biceps) motoneurons. Here we present our initial work assessing the onset/offset hysteresis of motor units from multiple lower extremity muscles. With the subjects secured to a custom isometric frame, 12 forces and moments were measured from 2 6-degree of freedom sensors to derive the torques generated at the hip, knee and ankle joint centers. The frame was positioned at a 30% angle from the horizontal so that the subject was semi-recumbent. From here, subjects performed 2-3 bouts of ramp contractions to 20% of maximum volitional torque with the assistance of auditory and visual feedback. Electromyographic (EMG) activity was collected from the soleus (Sol), medial gastrocnemius (MG), lateral gastrocnemius (LG), and tibialis anterior (TA) using 64-channel surface array electrodes. Offline, the multichannel EMG activity was decomposed into motor unit spike trains using an automated decomposition algorithm. Comparisons between the onset/offset hysteresis were made between 205, 33, 113, and 295 appropriate motor unit pairs for the Sol, MG, LG, and TA, respectively. In both participants, the Sol and LG demonstrated lower measure delta-f estimates than both the MG and TA. Such measures were consistent across repeated contractions and mode of contraction. Delta-f estimates for MG motor units were nearly identical during isolated plantarflexion and knee flexion contractions (3.57 versus 3.45 pps). Despite apparent stability in intrinsic excitability, unpaired t-tests revealed the average slope of the rate-rate plots among motor unit pairs was lower (0.82 versus 1.22) and the difference in recruitment time was greater (2.7 versus 1.3 s) during performance of knee flexion versus plantarflexion. These changes in the activation of the motor pool are consistent with alterations in the distribution of the effective synaptic drive towards high threshold MG motor units during knee flexion as compared to plantarflexion. These data provide initial hypotheses regarding the organization of the excitability of lumbar spinal motoneuron pools - intrinsic excitability varies across, but not within, lower extremity motor pools for a given task.

Title: Force fluctuations and motor unit activity during a handgrip task in individuals with chronic stroke and multiple sclerosis

Authors: ***M. JOSHI**[1], J. PETERSON[1], A. HYNGSTROM[2], S. STRATH[1], A. SWARTZ[1], F. NEGRO[3], D. FARINA[3], K. KEENAN[1];

Neurosci., Georg-August Univ. of Göttingen, Göttingen, Germany

Abstract: Introduction Variability in force during steady voluntary contractions is most commonly reported to increase in individuals with chronic stroke and multiple sclerosis (MS) relative to healthy controls. Interestingly, studies have shown an increase in discharge rate variability in MS, though reduced discharge rate variability on the paretic side in chronic stroke. The finding of decreased motor unit discharge variability in chronic stroke is confounding as experimental and computational studies have established positive associations between force fluctuations and discharge rate variability. However, few studies have examined motor unit activity and force fluctuations concurrently in these two populations. The purpose of our study was to compare the performance of chronic stroke and MS subjects to neurologically intact subjects on a handgrip force steadiness task while recording motor unit activity in forearm muscles. **Methods** Handgrip force was measured in 8 stroke, 10 MS and 21 healthy subjects using a MSP 300 sensor (Measurement Specialties, Hampton, VA). The steadiness task consisted of 2 trials holding a force at 5% of maximal for 30 s with visual feedback. High-density surface EMG (128 channels) was recorded from wrist flexors and extensors using the EMG-USB2 system (OT Bioelettronica, Torino, Italy). EMG was decomposed using the convolution kernel compensation technique. Force steadiness and motor unit discharge rate variability were computed as the coefficient of variation (CV) of force and discharge rate, respectively. **Results** CV of force on the paretic side in stroke (7.5 ± 11.3%) was increased compared with the non-paretic side in stroke (1.4 ± 0.6%; $p = .002$), MS (1.0 ± 1.5%; $p < .007$), and healthy controls (0.9 ± 1.0%; $p < .002$). There were no differences in the CV of force between MS, healthy controls, and the non-paretic side in stroke ($p > .167$). Preliminary analysis of EMG data includes decompositions of action potential trains from 46 motor units in controls, 29 in the paretic and 25 in the non-paretic side in stroke, and 84 in MS. The CV of discharge rate on the paretic side in stroke (12.8 ± 6.9%) was similar compared with the non-paretic side (15.4 ± 9.8; $p = .088$), but decreased compared with MS (18.3 ± 6.6%; $p < .001$) and controls (19.9 ± 6.9%; $p < .001$). **Discussion** The increased force fluctuations observed on the paretic side in stroke were not

associated with increased discharge rate variability. This indicates other mechanisms likely contribute to increased force fluctuations for the handgrip task in stroke, possibly low-frequency modulation of motor unit discharge rates within and across muscles, and altered motor unit recruitment patterns.

Title: The effect of a visuospatial memory task on measures of postural control and motor unit activity in young and older adults

Authors: *J. J. PETERSON, K. G. KEENAN;
Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Background: Choice step response time (CSRT), postural sway, and the ability to hold a steady force are predictors of postural control and falls risk in older adults. Performance of a secondary cognitive task has been reported to decrease postural control. However, most studies focus on the influence of a secondary task on postural sway during quiet standing, which may not sufficiently challenge postural control. Of the few studies that have studied the effect of a secondary cognitive task on stepping, only one has used a visuospatial (VS) memory task. The purpose of this study was to quantify the influence of a VS task on three measures of postural control. **Methods:** 16 young (26.2 ± 4.9 yrs) and 13 older (75 ± 6.9 yrs) adults performed the CSRT, postural sway, and a dorsiflexion force steadiness task under two conditions: with and without a VS task. The VS task involved visualizing and remembering the location of a star within a 2×2 grid. 20 trials of the CSRT were performed and response times were averaged across trials. Two 30 s postural sway trials were performed in three bilateral stances and mean velocity of the center of pressure was calculated. For the dorsiflexion steadiness task, a target force of 5% maximum voluntary contraction was held for two trials of 30 s and the coefficient of variation of force was quantified. High-density surface EMG was collected from tibialis anterior

using a 64-channel electrode (OTBioelettronica, Torino, IT) during the postural sway and steadiness tasks, then decomposed to obtain motor unit spike trains. **Results:** CSRT was slower when performed with the VS task compared to performance of the CSRT alone for young (1023 ± 234 ms and 815 ± 160 ms, respectively; $p < .001$) and older (1583 ± 262 ms and 1120 ± 176; $p < .001$) adults, with a greater increase in older adults ($p < .001$). Postural sway was not altered ($p = .85$) by the addition of the VS task. Force fluctuations were greater for older adults than young adults (7.1 ± 1.2% and 2.7 ± 1.1%, respectively; $p = .014$), and were increased in the older adults ($p < .001$) with the VS task (8.3 ± 6.9%) compared to without the VS task (6.0 ± 6.5%), with no change in young adults ($p = .472$). Preliminary analysis of EMG collected during the steadiness task from five young and five older adults found higher discharge rate variability ($p < .001$) for the older (16.2 ± 6%) than for the young (14.3 ± 6.3%) adults, but no change with VS task ($p = .319$). **Conclusions:** Practical implications are that tasks requiring VS memory may adversely influence postural control, though this effect is task specific and appears to disproportionately affect older adults. In addition, motor unit discharge behavior influences the age differences in postural control.

Title: The notion of central fatigue: findings from a simulation study

Authors: *P. CONTESSA[1], A. PULEO[2], C. J. DE LUCA[1];
[1]Delsys Inc, Natick, MA; [2]Politecnico di Torino, Torino, Italy

Abstract: The sources of exercise-induced muscle fatigue remain subject to debate. There is general agreement on the influence of peripheral factors on muscle fatigue, i.e. factors within the muscle that impair the fiber contractile mechanism [1]. Central factors of muscle fatigue arising within the Central Nervous System (CNS) have also been hypothesized but have not yet found direct empirical evidence [2]. They are suggested to cause central fatigue by diminishing the

central drive to the motoneuron pool and limiting muscle performance. We developed a simulation model to investigate whether central factors of muscle fatigue are required to explain the motor unit and muscle force behavior observed during fatiguing isometric contractions in human subjects. The model simulates the firing behavior of motor units and the muscle force during isometric voluntary [3] and electrically elicited contractions [4] performed with the first dorsal interosseous muscle. Only peripheral factors of fatigue were included as a time-dependent decrease in the amplitude of the force twitches of the active motor units [3]. We replicated empirical protocols of fatiguing maximal [5] and sub-maximal contractions [6] during which central fatigue has been suggested to develop. Central fatigue was estimated based on the amplitude of the muscle force elicited by electrical stimulation during the voluntary efforts, a method known as the twitch-interpolation technique [2]. The simulations of maximal voluntary contractions indicated questionable assumptions associated to the notion of central fatigue. They showed that maximal muscle force evocable by supra-maximal electrical stimulation is always greater than maximal voluntary muscle force; and that sub-maximal voluntary force does not necessarily represent a failure of the CNS to drive motoneurons adequately (i.e. maximally), as implied by the notion of central fatigue. We also found that a model based exclusively on peripheral factors of muscle fatigue can reproduce the force behavior commonly attributed to central factors during fatiguing sub-maximal voluntary contractions. Our analysis does not directly refute the concept of central fatigue. However, it raises significant and fundamental concerns about the interpretation of the proposed causes of central fatigue. Title: Evidence that synchronized motor unit firings are epiphenomena of the onion skin property not common inputs

Authors: *J. C. KLINE[1,2], C. J. DE LUCA[1,2];
[1]Delsys, Inc, Natick, MA; [2]Biomed. Engin., Boston Univ., Boston, MA

Abstract: The majority of the literature on the synchronization of motor unit firing attributes its occurrence to physical presynaptic inputs shared by motoneurons. Yet, there is a lack of empirical evidence confirming the notion that common inputs actually elicit synchronized firing instances under normal voluntary conditions. In our previous studies we provided statistical arguments questioning common inputs as the cause of synchronization. In our present work, we designed an experiment to explicitly test if, during voluntary contractions in human subjects, synchronized motor unit firing instances can be accounted for by the common input notion. Our experiment involved an isometric contraction paradigm consisting of two force plateaus; one greater than the other. Recorded surface electromyographic (EMG) signals were processed using our decomposition and error reduction algorithms to extract the firing instances of motor units active during voluntary contractions. We found that the average amount of synchronization measured between the same motor unit pairs active during both force levels decreased as the force level increased. The current documented framework of the common input notion provides no explanation that can account for these results. Therefore, we set out to identify a more probable explanation for synchronization. We compiled a data set of motor unit firings across different human subjects, muscles and force levels. Our analysis of 17,546 motor unit pairs - a data set more than an order of magnitude greater than any previously published - enabled a comprehensive study of synchronization across populations of concurrently active motor units with diverse firing properties. We found that the amount of synchronization between motor unit pairs varied depending on the sensitivity of the motor units to voluntary excitation, as indicated by the slope of the firing rate as a function of force. The inverse hierarchical arrangement of motor unit firing rates demonstrated by De Luca and Contessa (2012) classifies the synchronization-sensitivity relationship across different muscles and force levels. These findings substantiate the proposition that occasionally coincident firing instances, often referred to as synchronization, are merely naturally occurring epiphenomena of the Onion Skin property of motor units. Thus, it is not meaningful to attribute a physiological purpose to the incidence of synchronization.

Title: Onion skin and common drive of motor units during voluntary dynamic contractions

Authors: *C. J. DELUCA[1,2], S. S. CHANG[1], S. H. ROY[1], J. C. KLINE[1], S. H. NAWAB[3]; [1]Delsys, Inc., Natick, MA; [2]Biomed. Engin., [3]Electrical and Computer Engin., Boston Univ., Boston, MA

Abstract: Over the past three decades various algorithms used to decompose the electromyographic (EMG) signal into its constituent motor unit action potentials (MUAPs) have been reported. The use of these algorithms has been vital to advancing the field of motor control demonstrating such properties as the onion skin of firing rates and the common drive of motor units. However, to date all algorithms have been limited to decomposing EMG signals from isometric contractions. In this report we describe a successful approach at decomposing the surface electromyographic (sEMG) signal collected from cyclic (repeated concentric and eccentric) dynamic contractions during flexion/extension of the elbow and during gait. The increased signal complexity introduced by the changing shapes of the MUAPs due to relative movement of the electrodes and the lengthening/shortening of muscle fibers was managed by an incremental approach to enhancing our established algorithm for decomposing sEMG signals obtained from isometric contractions. We used machine-learning algorithms and time-varying MUAP shape discrimination to decompose the sEMG signal from an increasingly challenging sequence of pseudo-static and dynamic contractions. The accuracy of the decomposition results was assessed by two verification methods that have been independently evaluated. The firing instances of the motor units had an accuracy of approximately 90%, with a MUAP train yield as high as 25. Preliminary observations from the performance of motor units during cyclic dynamic activities indicate that during repetitive concentric and eccentric contractions the control of motor units is governed by the same rules as those evidenced during isometric contractions. As the contraction increases from a relatively lower angle to a higher one, motor unit firing rates are regulated in a hierarchical manner according to the onion skin property: that is motor units first recruited to fire during relatively low contraction angles reach higher firing rates than other motor units recruited at greater contraction angles. This behavior is preserved across multiple cycles and is present in dynamic contractions of the elbow and during gait. Additionally, motor unit firing rates varied in unison with each other and were correlated with changes in the contraction angle corroborating evidence of a common drive to the motor units. In fact the relatively high degree of cross-correlation observed between firing rates of different motor units indicates that the common drive is a dominant motor unit control scheme during dynamic activities.

Title: Changes in motor unit recruitment threshold and firing behavior after pairing high frequency repetitive transcranial magnetic stimulation with robot-assisted movement practice following stroke: a pilot study

Authors: *T. D. IVANOVA[1], K. J. MILLER[1,3], A. GALLINA[1], N. J. SNOW[2], J. L. NEVA[2], N. M. H. LEDWELL[2], Z. G. XIAO[4], C. MENON[4], L. A. BOYD[2], S. J. GARLAND[1];

Abstract: High-frequency repetitive transcranial magnetic stimulation (rTMS) can alter motor cortical excitability following stroke. Similarly, robotic-assisted intensive movement practice has been advanced as a therapy for stroke. However, the impact of combining these interventions on motor unit (MU) recruitment and firing behavior is not known. This study investigated the effects of simultaneous application of rTMS, over the ipsilesional primary motor cortex, with robotic-assisted active wrist extension practice (rTMS+RW). Four participants with chronic stroke (Fugl-Meyer upper extremity scores 8-30/66) completed 30 repetitions of 5Hz rTMS+RW. Muscle activity was recorded from the paretic extensor carpi radialis (ECR) and extensor carpi ulnaris (ECU) with two high-density surface electromyography (HDsEMG) 64-channel grids during isometric handgrip contractions. Two maximal voluntary contractions (MVC) and 3 ramp-and-hold contractions to 30% MVC were performed before and after rTMS+RW. HDsEMG was decomposed using MatLab-based decomposition software DEMUSE 4.0. Recruitment threshold (RT) as a percentage of MVC, MU firing frequency over the first 4

spikes (initial firing frequency, IFF) and over 2s during the holding phase of the ramp (mean firing frequency, MF) were calculated for each MU that was present both before and after rTMS+RW. The ability to modulate the firing rate was examined by subtracting the IFF from the MF. The participants demonstrated a 20% increase in MVC on average after rTMW+RW. Twenty-five wrist extensor MUs (16 ECR and 9 ECU) were identified with recruitment thresholds before rTMS+RW ranging from 0.2 – 30%MVC. Changes in MU RT after rTMS+RW were observed in 22/25 MUs despite comparable rate of force increase during the ramp contractions (3.4 vs 3.6%MVC/s, before and after rTMS+RW, respectively). RT decreased in 12 MUs by a mean of 14%MVC, increased in 9 MUs by 3%MVC and remained unchanged in 3 MUs. The MF increased by a mean of 2Hz (n=25), with larger MF increases (3.5Hz) being observed in the 12 MUs with a lower RT after rTMS+RW. The firing rates (n=25) showed larger modulation over the course of the ramp contraction after (8.3Hz; MF-IFF) than before rTMS+RW (4.2Hz). A single session of rTMS+RW was associated with changes in MU firing behaviour in the paretic ECR and ECU that suggest improved recruitment and modulation of MU firing. However, this was not consistent across participants. A full-scale crossover study is underway to determine the effects of combined rTMS+RW intervention compared to robotic-assisted active training alone. Future work should address which individuals respond to rTMS+RW after stroke.

Title: Assessing motor unit number and motor unit action potentials in hemiparetic hand muscles from F wave responses

Authors: ***X. LI**[1], M. FISHER[3,4], W. Z. RYMER[5,6], P. ZHOU[2,7];
[2]Physical Med. and Rehabil., [1]Univ. of Texas, Houston, TX; [3]the Hines VAH, Maywood, IL;

[4]Loyola Univ. Stritch Sch. of Med., Maywood, IL; [5]Rehabil. Inst. of Chicago, Chicago, IL; [6]Northwestern Univ., Evanston, IL; [7]Biomed. Engin. Program, Univ. of Sci. and Technol. of China, Hefei, China

Abstract: The F-response was used in this study to assess changes in the first dorsal interosseous (FDI) muscle after a hemispheric stroke. The number of motor units and their sizes were estimated bilaterally in 12 stroke survivors by recording both the compound muscle action potential (CMAP), and F wave responses. These F waves were induced by applying a large number of electrical stimuli to the ulnar nerve. The amplitude distribution of repeater F waves or individual motor unit action potentials (MUAPs) were also compared between paretic and contralateral muscles. When averaged across all the subjects, a significantly lower motor unit number estimate was obtained for the paretic FDI muscle (88 ± 13) compared with the contralateral side (139 ± 11) ($p < 0.01$). Pooled surface MUAP amplitude analysis demonstrated a right-skewed distribution for both paretic (kurtosis 3.0) and contralateral (kurtosis 8.5) muscles. When normalized to each individual muscle's CMAP, the surface MUAP amplitude ranged from 0.22% to 4.94% (median 1.17%) of CMAP amplitude for the paretic muscle, and from 0.13% to 3.2% (median 0.62%) of CMAP amplitude for the contralateral muscle. A significant difference in MUAP outliers was also observed between the paretic and contralateral muscles. The findings of this study suggest that there is significant motor unit loss and muscle structural reorganization after stroke.

Title: The effect of strength training on maximal motor unit discharge properties

Authors: *Z. K. POPE, G. M. HESTER, F. M. BENIK, J. SELLERS, J. M. DEFREITAS; Oklahoma State Univ., Stillwater, OK

Abstract: The physiological adaptations to strength training have been the focus of many research investigations. The general consensus suggests that changes occur not only within the muscle, but also within the nervous system structures which govern its' behavior. **PURPOSE:** To evaluate changes to maximal motor unit (MU) discharge properties in response to an 8 week

strength training intervention. **METHODS:** Surface electromyography (EMG) from 10 subjects was detected from the Vastus Lateralis muscle during maximal voluntary isometric knee extensions both before and following 8 weeks of dynamic strength training. The EMG signals were decomposed into their constituent MU action potential trains to determine the following properties for each MU: A.) recruitment threshold (RT – the relative force at the MU's first discharge), B.) mean discharge rate (MDR – obtained during peak force production), and C.) action potential size (AP_{SIZE} – calculated as the peak-to-peak amplitude). MU data from all the subjects were then pooled together and averaged into 5% intervals based on RT. Linear regression analyses were performed on both the pre- and post-training data to obtain regression coefficients for the following relationships: MDR vs. RT and AP_{SIZE} vs. RT. **RESULTS:** A total of 481 MUs were detected (209 pre + 272 post). Following training, maximal force production increased significantly by 11.0% ($p < 0.01$). Essentially no difference was observed for the relationship between MDR vs. RT following training ($y = -0.218x + 26.061$; $R^2 = 0.8937$ and $y = -0.2204x + 27.002$; $R^2 = 0.8727$ for pre- and post-training, respectively). However, the regression coefficients calculated for AP_{SIZE} vs. RT were affected as a result of strength training ($y = 3e^{-06}x + 7e^{-05}$; $R^2 = 0.8333$ and $y = 7e^{-06}x – 3e^{-05}$; $R^2 = 0.8727$ for pre- and post-training, respectively). Moreover, a qualitative, visual inspection of the regression lines suggests that AP_{SIZE} for MUs with high RTs (i.e. RT > 50%) were most affected by the strength training. **CONCLUSIONS:** Our findings indicate that the increased maximal force production following 8 weeks of strength training was not due to an increased MU discharge rate. These data do, however, suggest that the relationship between AP_{SIZE} vs. RT was positively affected by strength training. This may be interpreted as a training-related MU adaptation, particularly in high RT MUs, elicited by a repetitive, strong neural drive to resist heavy loads. Physiologically, the increased AP_{SIZE} of high RT MUs may suggest an enhanced excitability of the sarcolemma and/ or an increase in sarcolemma area due to muscle fiber hypertrophy.

Title: Motor neuron studies using multielectrode arrays

Authors: *A. THARANEETHARAN, M. HARRINGTON;
Delaware State Univ., Dover, DE

Abstract: Motor neurons are one of the classic model systems in neuroscience. While it has been known for 60 years that the neurotransmitter released at neuromuscular junctions is acetylcholine, evidence has been accumulating that motor neurons release multiple neurotransmitters in a spatially segregated way - acetylcholine at neuromuscular junctions and both acetylcholine and glutamate at inter-neuronal synapses in the spinal cord. Recently published work from our lab and others has shown that in cultures of motor neurons grown in the absence of contact with muscle cells, excitatory neurotransmission in the culture is entirely through glutamate. These results indicate that the neurotransmitter phenotype of motor neurons is plastic. We have used transgenic mice expressing a yellow fluorescent protein and channelrhodopsin 2 fusion protein (mhChR2::YFP) under the control of the choline acetyltransferase (ChAT) promoter to assess synaptic function of primary motor neurons in culture. A second model used was a double floxed ChR2 lentivirus in spinal ventral horn cultures from a Chat-Cre mouse model. A third model used were motor neurons differentiated from iSPCs and transduced with a ChR2 lentivirus. We used the 64-electrode, MED64 multielectrode array to characterize network activity resulting from photostimulation of ChR2 expressing motor neurons. Using immunofluorescence we found changes in ChAT expression from early postnatal cultures as compared to embryonic cultures, while MED64 recordings also show changed bursting activity in postnatal as compared to embryonic. Our results highlight interesting variations between the synaptic activation and network properties of motor neurons established in culture during embryonic development as compared to cultures of motor neurons that have matured in the spinal cord. These findings pose interesting implications upon the use of primary motor neuron cultures and differentiated stem cells as model systems and potential therapeutics for motor related neuropathologies.

Title: Modulation of motor units during repeated contractions post-stroke

Authors: *S. A. MURPHY[1], R. BERRIOS[1], S. HUNTER[1], F. NEGRO[2], D. FARINA[2], A. NELSON[3], K. KEENAN[4], B. SCHMIT[1], A. HYNGSTROM[1];
[1]Marquette Univ., Milwaukee, WI; [2]Gottingen Univ., Gottingen, Germany; [3]Med. Col. of Wisconsin, Milwaukee, WI; [4]Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The purpose of this study was to use high density surface EMG (sEMG) recordings to quantify stroke-related effects of a serotonin antagonist (cyproheptadine) on motor unit firing behavior during repeated sub-maximal knee extensor contractions. A high density (64 channel) sEMG was used to record and extract single motor unit firing behavior in the vastus lateralis muscle of 6 individuals with chronic stroke and 8 controls during repeated ramp and hold isometric knee extension contractions. Each subject performed the protocol under two different conditions on different days: a single dose of cyproheptadine (8 mg) and a placebo (double blind, crossover design). During the torque decline phase of the ramp and hold cycles for the placebo condition, paretic motor unit firing rates were increased with subsequent contractions (6.19±0.35 pps vs 7.89±0.66 pps, $P < 0.05$) compared to controls (6.95±0.40 pps vs 6.68±0.41 pps). This corresponded with decreasing rates of torque decline for the paretic leg with successive contractions as compared to the control leg. In contrast, in the cyproheptadine condition, there was no significant difference in firing rates between the first and last repetitions for the paretic (7.79±0.86 pps vs 7.65±0.91 pps) or control groups (7.45±0.45 pps vs 7.32±0.41 pps). This also corresponded to increasing rates of torque decline for both the paretic and control legs with subsequent ramp and hold cycles for the cyproheptadine condition. These results suggest that regulation of declining forces may be impaired post stroke due to increased firing rates of paretic motor units. Ingestion of a serotonin antagonist may decrease motor unit firing rates and help regulate the rate of force decline with subsequent contractions post-stroke. Moreover, these abnormal firing behaviors may be due to changes in the intrinsic electrical properties of paretic motoneurons and can be modulated with serotonergic drugs.

Title: Anabolic steroid exposure during adolescence alters the response and the physiological parameters of neurons in the lateral anterior hypothalamus of the male hamster

Authors: *T. R. MORRISON[1], R. SIKES[2], R. H. MELLONI, Jr.[1];
[1]Psychology, [2]Physical Therapy, Northeastern Univerisity, Boston, MA

Abstract: Syrian hamsters exposed to anabolic/androgenic steroids (AAS) during adolescence consistently show increased aggressive behavior when tested during early adulthood. Previous data from our lab have shown that the activity of neurons in the latero-anterior hypothalamus (LAH) is sensitive to vasopressin (AVP), serotonin (5HT), and dopamine (D2-receptor selective) ligands, i.e., three neurochemical systems known to modulate aggression. These data are important in understanding how substances that affect AAS-induced aggression influence the circuitry of aggressive behavior. Despite these data, little is known about how AAS exposure alters the basal neurophysiology of cells in the LAH. In female adolescent mice, AAS exposure has been shown to alter the distribution of neuron response types (i.e., bursting, regular, and irregular firing neurons) within the central amygdala that regulate cells within the bed nucleus of the stria terminalis (BNST) (Oberlander, 2012). Interestingly, the LAH is the center of the AAS-induced aggression circuit in adolescent hamsters, and has been shown to share reciprocal connections with various regions of the brain associated with both aggression and anxiety including the BNST and amygdala. In the present study, we used extra-cellular single neuron recording techniques to record the electrophysiological activity of cells within the LAH of the aggressive, adolescent AAS-treated male hamsters. Preliminary data indicate that AAS exposure increases the mean and median interspike interval of regular firing neurons and also alters the proportion of neuronal types within this region, most notably by decreasing the number of bursting neurons. These data shed further light on how developmental exposure to AAS affects the physiology of neural substrates controlling aggression adding further detail to our model circuit(s) that underlies adolescent AAS-induced aggressive behavior.

Title: Early postnatal blockade of corticotropin-releasing hormone 1 receptor prevents aggressive behaviors in the low MAOA activity x early stress interaction model of aggression

Authors: *M. BORTOLATO, S. C. GODAR, L. J. MOSHER, H. STRATHMAN; Pharmacol. and Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: Ample evidence has shown that monoamine oxidase (MAO) A, the major enzyme for the metabolism of serotonin and norepinephrine, plays a key role in pathological aggression. MAO A-deficiency in humans and rodents is associated with high levels of brain monoamines and a greater severity of aggressive and antisocial traits, however, complete gene deficiency is very rare and may not present the optimal conditions to model aggression. A host of studies have reported that individuals carrying low MAO A activity polymorphic variants who were subjected to early maltreatment have a significantly more susceptible to develop aggression and antisocial behavior. These findings underscore the importance of gene (low levels of monoamine oxidase A) x environment (early neglect or abuse) interactions in the pathogenesis of aggression. We recently generated a novel model mouse based on this gene x environment interaction by subjecting non-aggressive MAO A hypomorphic mutant mice (MAO ANeo) to early stress (ES) from postnatal day 1 through 7. In particular, early stress consisted of daily maternal separation (~3h) and a saline (or vehicle) injection. ES markedly increased aggression in MAO ANeo, but not in WT mice. To investigate the neurobiological underpinnings of this interaction, we examined the role of the corticotropin-releasing hormone 1 (CRH1) receptors, in view of their importance in the regulation of stress mechanisms in the brain. We found that selective CRH1 receptor blockade during the first postnatal week significantly reduced aggression in MS-MAO ANeo mice. Taken together, these data provide a potential molecular mechanism to explain how low MAO A activity and early childhood maltreatment interact in the pathogenesis of aggression.

Title: P2X7 knockout mice display less aggression which is associated with alterations in microglial number and morphology

Authors: *S. TODD[1,3,2], A. BOUCHER[3,2], F. WALKER[6,7], I. MCGREGOR[4], M. BENNETT[2], M. KASSIOU[5], J. ARNOLD[2,3];
[1]Pharmacol., [2]Brain and Mind Res. Inst., Sydney, Australia; [3]Pharmacol., [4]Psychology, [5]Chem., Univ. of Sydney, Sydney, Australia; [6]Sch. of Biomed. Sci. & Pharm., The Univ. of Newcastle, Newcastle, Australia; [7]Hunter Med. Res. Inst., Newcastle, Australia

Abstract: The P2X7 receptor is an ATP-binding ligand gated ion channel found predominantly on microglia and to a lesser extent on neurons. This receptor has been associated with increased susceptibility for depression, and P2X7 knockout mice show resistance to behavioral despair. This might be explained by the role of P2X7 receptors on microglia which when activated release inflammatory cytokines such as interleukin-1 beta. Central cytokines also increase aggressive behavior, implying that P2X7 may also alter aggression. Here we aim to observe whether P2X7 knockout mice display altered aggressive behavior and if this is associated with changes in microglial number and morphology. WT and P2X7 knockout animals underwent the resident-intruder behavioural test and were scored for aggressive behaviours. Iba-1 immunohistochemistry was also performed to examine the influence of P2X7 genotype on aggression-induced microglial density and morphology by comparing highly aggressive (high numbers of aggressive behaviours and biting) to minimally aggressive mice (low instances of aggressive behavior with no biting). Microglia were imaged and analyzed for number and average pixel density per microglia as an approximation of complexity. P2X7 mice were significantly less aggressive than WT mice. A significant effect of P2X7 genotype was found in the 4 regions - the nucleus accumbens shell, medial posteroventral amygdala, dorsomedial and lateral part of the PAG. In all cases the P2X7 mice showed higher numbers of microglia compared to WT mice regardless of behavior exhibited. However in a further 8 regions - the ventrolateral septum, caudate putamen, nucleus accumbens core, paraventricular thalamic nucleus, lateral hypothalamus, CA3 of the hippocampus, medial posterolateral amygdala and dorsolateral PAG - a significant interaction effect was found between P2X7 and aggression. While in WT mice higher aggression was associated with a decrease in microglial number

compared to low aggressors, highly aggressive P2X7 knockout mice either had no change or higher numbers of microglia compared to low aggressors. When examining the average pixel density per microglia as an indication of morphology, a significant interaction effect was found in the caudate putamen, and nucleus accumbens shell and core. WT aggressive mice tended to have enlarged microglia compared to low aggressive mice, but the opposite was observed in P2X7 mice. These results show that the P2X7 receptor plays a role in aggressive behavior associated with alterations in microglial density and morphology.

Title: A Thai tale: artificial selection for aggression in the siamese fighting fish Betta splendens

Authors: *D. GONÇALVES[1], C. HUANG[2], F. LAM[1], M. PODLESNA[1], L. S. W. LEI[2], S. M. Y. LEE[2];
[1]Univ. of St. Joseph, Macau, Macao; [2]State Key Lab. of Quality Res. in Chinese Med. and Inst. of Chinese Med. Sci., Univ. of Macau, Macau, Macao

Abstract: The Siamese fighting fish Betta splendens has been selected for fighting contests across more than two centuries in Thailand and other Asian countries. This has produced domesticated strains of B. splendens notoriously different from wildtypes. This artificial selection procedure has presumably favored genetic variations that promote the phenotypic expression of traits that increase aggression and the probability of winning fights. Because original wildtype phenotypes still occur in nature, the comparison of fighting strains with wildtypes offers the opportunity to identify the genetic, behavioral, endocrine and neuronal mechanisms that have been selected for promoting aggressive phenotypes in the domesticated strains. Males from a fighting strain were obtained from a commercial breeder and compared with males captured in the wild. As predicted, males of the fighting strain were more aggressive than wildtypes in a mirror challenge, both in the frequency of aggressive displays and in the persistence of aggressive behaviors towards the mirror image. Males of both the fighting strain

and wild types markedly increased the production of testosterone (T) and 11-ketotestosterone (11KT) in response to the mirror image. There was a trend for fighters to have higher levels of 11KT, but not of T, when compared with wildtypes. Finally, the gene expression profile in whole brains of wildtypes subject to the mirror test was compared with controls using Ion Torrent sequencing and differential gene expression analyses. In brief, around 9 Gb base-pairs were yielded and, 94,163 transcripts were de novo assembled using Trinity, with 54.3% of the transcripts annotated to known proteins. Parallel to the results obtained for androgens, the mirror challenge produced a significantly altered brain gene expression profile with over 8,269 unique transcripts being differentially expressed. KEGG analysis revealed differences in numerous important pathways between males expressing aggression and controls, including cytochrome P450, gluconeogenesis and immune-related pathways. The study shows that artificial selection of wildtype B. splendens was successful in generating an aggressive phenotype, suggests that selection acted at the level of the androgen response and provides data on genetic pathways regulating aggressive behavior in this species. In addition, the study provides the first annotated transcriptome for B. splendens.

Title: Sex differences in the effects of dominance status on serotonin (5-HT) and vasopressin (AVP) cell activity in Syrian hamsters (Mesocricetus auratus)

Authors: *J. I. TERRANOVA[1,2], Z. E. SONG[1,2], T. E. LARKIN[1,2], N. S. HARDCASTLE[1,2], A. NORVELLE[1,2], H. E. ALBERS[1,2];
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Ctr. for Behavioral Neurosci., Atlanta, GA

Abstract: 5-HT and AVP containing neurons are essential components of the circuitry that controls aggression. In male hamsters, microinjection of 8-OH-DPAT, a 5-HT1a receptor agonist, into the anterior hypothalamus (AH) profoundly *inhibits* aggression, whereas microinjection of AVP *stimulates* aggression. Conversely, in females, microinjection of 8-OH-

DPAT into the AH profoundly *stimulates* aggression, whereas microinjection of AVP *inhibits* aggression. These data suggest that 5-HT and AVP are critical components that underlie the neural control of aggression in both sexes. However, how endogenous AVP and 5-HT circuits are recruited during an aggressive encounter is unknown. Moreover, no published studies on hamsters have considered contributions of sex differences or dominance relationships to 5-HT and AVP activity during an agonistic encounter. Thus, the goal of this study is to investigate endogenous 5-HT and AVP cell activity in neural regions that project to the AH with regards to sex and dominance status. We predicted that 5-HT cell activity would be reduced in dominant males and increased in dominant females, whereas AVP cell activity would be increased in dominant males and reduced in dominant females. Hamsters were isolated for 2 weeks and handled daily for 1 week. Females were monitored for estrous stage and tested during diestrus. Hamsters were paired with a partner of the same sex and weight in a resident-intruder paradigm for 15 minutes or moved to an empty, dirty cage as a control. Dominance status was determined by observing at least 3 consecutive submissive behaviors by one animal during the encounter. Pairs were excluded if a clear dominance hierarchy was not established. Tissue was processed with immunofluorescence for 5-HT, AVP, or c-Fos, a marker for neural activity, and analyzed using confocal microscopy to ensure accurate colocalization of 5-HT and AVP with c-Fos. We measured AVP cell activity in the medial supraoptic nucleus (mSON), nucleus circularis (NC), and paraventricular nucleus and 5-HT cell activity in the anterior dorsal raphe (DRNa), posterior dorsal raphe (DRNp), and median raphe nuclei. 5-HT activity was higher in the DRNa and DRNp in dominant females compared to controls and subordinates (2.3% vs. 0.70% & 0.63% 5-HT activation, respectively). AVP activity was higher in the mSON and the NC in dominant males compared to controls and subordinates (mSON: 21.72% vs. 13.72 % & 17.37% AVP activation, respectively; NC: 71.94% vs 33.84 % & 24.72% AVP activation, respectively). Our data suggest endogenous 5-HT and AVP circuits are crucial for aggression and are modulated by both sex and dominance status. (This work was supported by NSF IOS-0923301)

Title: The role of sex differences and social experience in the regulation of arginine-vasopressin (AVP) V1a receptors and aggressive behavior in Syrian hamsters (Mesocricetus auratus)

Authors: *A. P. ROSS, T. LARKIN, E. Z. SONG, H. E. ALBERS;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Social isolation increases aggression in both male and female hamsters. In males, AVP increases aggression by acting on V1a AVP receptors in the anterior hypothalamus (AH). In females, however, AVP decreases aggression in the AH. The following experiment investigated the effects of social isolation on V1a receptor number in the AH. Male and female Syrian hamsters were housed individually or with 2 other hamsters for 4 weeks. To measure aggressive behavior, each hamster was paired with a same-sex nonaggressive intruder in a neutral arena for 5 min. Brains were collected immediately and processed for receptor binding using autoradiography. Social isolation increased aggression in both males and females. V1a receptor binding in the AH was greater in socially isolated males compared to those housed in groups. In contrast, there was no difference in V1a receptor binding in the AH between females that were socially isolated and those that were group-housed. The data support the hypothesis that social isolation increases aggression in males by increasing the number of V1a receptors in the AH. In contrast, the effects of social isolation on aggression in females are not mediated by the effects of social isolation on the number of V1a receptors. In a second experiment we investigated the effects of social isolation on the dose-response properties of AVP. For this experiment, male and female Syrian hamsters were again housed individually or with 2 other hamsters for 4 weeks. During the 4th week, all hamsters were implanted with guide cannula aimed at the AH, and estrous cycle was determined in female hamsters. Each hamster was then injected with 0.009, 0.09, 0.9, or 9 μM AVP. All hamsters were given each dose in a counterbalanced order 4 days apart. To measure aggressive behavior, each hamster was paired with a same-sex nonaggressive intruder in a neutral arena for 5 min immediately after each injection. Aggressive behavior and flank marking were scored for each hamster. Preliminary results indicate that social isolation increased aggression, but had no effect on flank marking. These results indicate that sex and social experience play important roles in the vasopressinergic regulation of aggression and social communication. This work was supported by NSF-IOS-0923391.

Title: Social experience modulates the ability of GABAA receptor activation to induce aggression in male Syrian hamsters (Mesocricetus auratus)

Authors: *J. BORLAND[1,2], T. E. LARKIN[1,2], A. NORVELLE[1,2], H. E. ALBERS[1,2];
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Ctr. for Behavioral Neurosci., Atlanta, GA

Abstract: Social isolation can produce dramatic dysfunctions in social behavior such as enhancing responsivity to social stress and increasing aggression. The mechanisms underlying these effects of social isolation are not well understood. The lateral septum is well known to have an inhibitory effect on aggression and we have recently demonstrated that GABAA activation induces aggression by acting within the lateral septum. As a result, in the following experiment we tested the hypothesis that social isolation modulates the ability of GABAA receptors within the lateral septum to induce aggression. Male hamsters (N=54) were implanted with guide cannula aimed at the lateral septum. Half of the subjects were socially isolated, and half were group-housed (4 per cage) for 4 weeks before behavioral testing. Hamsters were injected with the GABAA agonist muscimol (10mM/200 nl) or saline into the lateral septum and then tested 10 minutes later in a neutral arena with a smaller sex matched non-aggressive intruder for 5-min. As expected, the duration of aggression was significantly larger in the socially isolated hamsters compared to those housed in social groups. The duration of aggression was significantly ($p=.018$) greater in the socially isolated hamsters injected with muscimol (93.6 ±17.3 sec) than in the socially isolated hamsters injected with saline (41.9 ±14.4 sec). In contrast, there were no significant differences ($p=.998$) in the duration of aggression between socially housed hamsters injected with muscimol (1.2 ±1.2 sec), versus those injected with saline (6.0 ±5.8 sec). These data demonstrate that social experience can dramatically alter the ability of GABAA receptors in the lateral septum to increase aggression.

Title: Behavioral studies of basic emotions

Authors: *F. WANG, Mr.[1,2], S. GU[3];
[1]Univ. Rochester, Rochester, NY; [2]Psychology, Nanjing Univ. of Traditional Chinese Med., Nanjing, China; [3]Nanjing Normal Univ., Nanjing, China

Abstract: Emotional mental disorders are a leading cause of disabilities worldwide. Despite the obvious importance of emotion for human existence, the controversy still abounds over the definition of emotion, the number of basic emotions that exit, whether different basic emotions have different physiological signatures. The controversy prevents the diagnosis and treatment of affective disorders. In this paper we proposed some theories about basic emotions and proposed neuromodulators as the neural substrate for the basic emotions. First, we propose five basic emotions: happiness, sadness, anger and fear, and missing. They depend on whether the things or situations are fit for our needs, and how they fit for our needs, which are presented in the emotional circumplex model. Second, we propose that neuromodulators are the neural substrates for the basic: dopamine-happiness; serotonin-sadness; norepinephrine-arousal (anger and fear); Acetyl choline-missing. Third, we found that fear and anger are twin emotions, which result from the same neuromodulator NE, and have similar behavioral and somatic reactions. And they are interchangeable, fear lead to anger, and anger is vent of fear. Therefore, fear and anger are the two sides of a coin; or double edges of a sword. Last, we speculate a new psychotherapy method, using emotion to cure emotional diseases. For example, induce anger to cure phobia. In all, I think this paper helps clarify many things about the basic emotions, and can help us understand our everyday emotional changes.

Title: Behavioral effects of prenatal oxytocin manipulation in mice

Authors: *T. V. MILLER[1], S. TAMBORSKI[2], H. K. CALDWELL[1,2];
[1]Sch. of Biomed. Sci. Kent State Universit, Kent, OH; [2]Dept. of Biol. Sci., Kent, OH

Abstract: Male oxytocin knockout (Oxt-/-) mice have increased intermale aggression when born to Oxt-/- dams, but not when born to heterozygous (Oxt+/-) dams. Moreover, oxytocin receptor knockout (Oxtr-/-) mice also have increased intermale aggression, whereas mice with a conditional oxytocin receptor knockout (OxtrFB/FB), in which the gene is not excised until approximately three weeks postnatal, show normal levels of intermale aggression. These observations have led us to hypothesize that oxytocin during fetal development acts to organize the neural circuitry that underlies aggressive behavior. Based on previous work in which we mapped the developing oxytocin system, we hypothesize that blocking oxytocin's ability to bind to the oxytocin receptor at embryonic day (ED) 14 and/or ED16 will result in increases in intermale aggression in adulthood. To test this hypothesis, we injected an oxytocin receptor antagonist (OTA) into the lateral ventricles of fetal C57/BL6 mice at ED14 and ED16; after birth, and upon reaching adulthood, these mice underwent three resident-intruder tests 1 day apart to test for aggressive behavior. Our preliminary results suggest that that treatment with an OTA can affect adult aggressive behavior.

Title: Pre-weaning behavioral manners in prenatal bisphenol A treated rats

Authors: T. FUJIMOTO, *S.-I. HIRANO, Y. NISHIKAWA;
Osaka Dent. Univ., Osaka, Japan

Abstract: Bisphenol A (BPA) is well known as an environmental endocrine disrupter. Our previous studies showed that pre- and postnatal administration of low-level BPA impaired gender differences in the open-field behavior of rats. BPA also induced depression-like behavior and enhanced the response to predator odor after maturity. In this study, we focused on behavior

in the pre-weaning period. We administered low-level BPA (1.5 mg/kg/day) to prenatal rats, and examined their behavior at 8 and 20 days of age using the predator fox odor. We first examined the spontaneous behavior without fox odor, and then tested the same parameters in the presence of the odor. At 8 days of age, twitching, pivoting, head movement, crawling and immobility were observed for 2 minute. In the presence of the fox odor, decreases in head movement and increases in immobility were seen in female rats in both the control and BPA groups. However, the effect was pronounced in the BPA rats. The number of animals that displayed the crawling response was decreased by the fox odor only in the BPA rats. At 20 days of age, rearing, locomotor activity, grooming and immobility were observed for 3 minute. Among the spontaneous behaviors, gender differences were observed in locomotor activity of the controls but not in the BPA rats. Under the fox odor, the rearing and the locomotor activity were decreased, while immobility was increased in females in both the control and BPA groups. Grooming scores were not significantly affected by gender, treatment or fox odor. At 24 days of age, each of the four groups (control-male, control-female, BPA-male and BPA-female) was divided into two groups, one in which the blood was collected immediately, and the other in which it was collected after 20 min exposure to the fox odor. Corticosterone levels were higher in the odor-exposure group than in the non-exposure group in both the control and BPA rats. Behavioral changes in the susceptibility to predator odor were observed at both 8 and 20 days of age. We found that the BPA rats and female rats were more susceptible to odor. As in the previous study, we found that the gender difference in locomotor activity was impaired by BPA. This study showed that pre-weaning small size rats could be used for several neurotoxicologic studies.

Title: Early period of development is critical for the effect of monosodium glutamate on decreased aggressive behavior in ADHD model rat

Authors: S. MISUMI, R. MARUMOTO, Y. YOKOYAMA, Y. SHIMIZU, R. NISHIGAKI, H. NAGAI, *H. HIDA;
Nagoya City Univ. Grad Sch. Med. Sci., Nagoya, Japan

Abstract: Attention-deficit hyperactivity disorder (ADHD) is a neurodevelopmental disease, in which dysfunction of mesocorticolimbic dopaminergic system is related to emotional regulation. External stimulus during the period of development such as environment and food might affect emotional formation strongly. We previously reported that oral intake monosodium L-glutamate (MSG), a taste substance for umami, for 5 weeks from postnatal day 25 (P25) to P60 decreased aggressive behavior in ADHD model rat (SHR) and this MSG effect was mediated by nevus vagus from gut, indicating involvement of brain-gut communication in emotional formation. However, the mechanism of the effect of MSG intake during the period of development on decreased aggressiveness in adulthood is still unknown. To investigate the critical period in MSG effect on social behavior, SHR rats (P25) were housed in a isolated condition (one rat per cage) treated with 0.6% MSG for various period until P60: early-treated group (P25-P40), late-treated group (P40-P60), all-period group (P25-P60) and non-treated group. Early-treated group decreased the number of riding (parameter of aggression to unfamiliar rat) compare with control group, which is the same level as all-period group. However, no significant difference was found between late-treated group and non-treated group. Sniffing time (parameter of exploration) failed to change among the each group, indicating that the interest to unfamiliar rat was not effect by MSG treatment. We next investigated plasma oxytocin by ELISA that is recently reported to improve social communication. No significant change of plasma oxytocin level was shown in all groups, and no correlation was also detected between aggressive behavior and the plasma level. Data suggest that early period of development post is critical for the effect of MSG on aggressive behavior in adulthood, although plasma oxytocin fails to explain MSG effect on aggressiveness.

Title: Insights about amygdala and aggression

Authors: *F. V. GOUVEIA[1], C. C. OLIVEIRA[1], L. T. C. SANTOS[1], M. D. J. SENO[1], E. T. FONOFF[2], H. BRENTANI[3], A. MARTINS[3], L. C. D. AMORIM[3], E. ALHO[2], S. P. RIGONATTI[3], M. J. TEIXEIRA[2], R. C. R. MARTINEZ[1];
[1]Intituto Sirio Libanes De Ensino E Pesquisa, Sao Paulo, Brazil; [2]Dept. of Neurology, Div. of Functional Neurosurg. of the Inst. of Psychiatry,, [3]Dept. of Psychiatry, Univ. of Sao Paulo, Med. Sch., São Paulo, Brazil

Abstract: Aggressive behavior is fundamental to compete for food, territory and females that will ultimately results in the maintenance of the animal and the species. It is a heterogeneous behavior that has multiple ways and, in humans, is related to violence, impulsiveness, irritability and hostility. Drug treatment with antipsychotic and anticonvulsant drugs are most commonly used for the control of aggressiveness, nevertheless, there is a small population of patients that displays extremely high levels of aggression and has drug-refractory symptoms. The amygdala is an important structure in the neurocircuitry of aggressive behavior and previous studies using lesions of the amygdala showed improvement in patient condition. However, those studies had many limitations as follow-up, criteria for selecting patients and the surgery techniques were obsolete. As an attempt to reintegrate extremely aggressive patients into society, a judicial law proposed amygdala lesion in three adult men. In order of that and to have a better understanding of the neurobiology of human aggression, we analyzed the levels of different hormones - thyroid-stimulating hormone (TSH), T4, T3, Cortisol, Luteinizing Hormone (LH), Estradiol, Prolactin, Progesterone, testosterone, and sex hormone-binding globulin (SHBG) - before, 1, 6 and 12 months after surgery. Our results showed an average lesion of 59.68% of the amygdala nuclei. There was a positive correlation between the ratio testosterone/cortisol and aggressive behavior ($r2=0.13$, $F(1,7)=1.04$, $p>0.05$) until the 6 months follow-up. There were no statistical differences in all other hormones studied TSH ($F(6,14)=0.96$, $p>0.05$), T4 livre ($F(6,14)=0,022$ $p>0.05$), T3 ($F(6,14)=0.12$, $p>0.05$), LH ($F(6,14)=0.46$, $p>0.05$), FSH ($F(6,14)=0.48$, $p>0.05$), Estradiol ($F(6,14)=1.05$, $p>0.05$), Prolactin ($F(6,14)=0.14$, $p>0.05$), Progesterone ($F(6,14)=0.56$, $p>0.05$), SHBG ($F(6,14)=0,97$, $p>0.05$). Our results showed that partial amygdala lesion reduced aggression one month after surgery and this decreased was accompanied by a reduction in the ratio testosterone/cortisol until the 6 month of follow-up with no alteration in other hormones. Nevertheless, our results pointed out for a transitory effect that last until 6 months of follow-up, and by 12 months those effects were lost.

Title: Understanding adolescent aggressive behavior: clues from the brain's response to laboratory-induced aggression

Authors: Y. LIU[1], *N. G. MUGGLETON[2,3], C.-Y. CHEN[1];
[1]Dept. & Grad. Inst. of Criminology, Natl. Chung Cheng Univ., Chiayi, Taiwan; [2]Inst. of Cognitive Neurosci., Natl. Central Univ., Jhongli, Taiwan; [3]Dept. of Psychology, Goldsmiths, London, United Kingdom

Abstract: Violent offenses often cause both serious problems and danger in society. This type of behavior is often ascribed to problems with the processes involved in inhibitory control. In this study, a Taylor Aggression Task was used, along with event related potentials, to examine the effects of aggressive situations and emotions on inhibitory control. The experiment manipulated the proportion of win and loses on the task and subjects gave and received punishment following successes and failures in order to mimic a social context in the laboratory. The Reactive Proactive Aggression Questionnaire (RPAQ) and Barratt Impulsiveness Scale (BIS) were used to measure the participants' aggression types and their degree of impulsive behavior. The participants included impulsive violent adolescent offenders (experimental group), non-violent adolescent offenders (control group 1) and normal adolescents (control group 2). The RPAQ and BIS showed that the scores of the experimental group were significantly higher than those of both control groups. The behavioral data from the Taylor Aggression Task showed that the experimental group, when performing the task, gave more punishment than did control groups 1 and 2. The punishment scores given by subjects for the first trial, which involved no provocation (i.e. proactive aggression), was higher for the experimental group than for the controls. The percentage of subsequent high punishment scores (scores in the top half of the range) given by the experimental group was also larger than in the two control groups. The N2 ERP component, which can index inhibition, had a significantly lower amplitude for the experimental group and the feedback related negativity amplitude for this group was also significant higher than that of control group 2. The pattern of results suggests that violent adolescents may have a deficit in solving cognitive and emotional conflict and in evaluating social context for the modification of inhibitory control.

Title: Autonomic correlates of reactive and proactive aggression

Authors: *D. DHAMIJA[1], C. TUVBLAD[1,2], A. RAINE[3], L. BAKER[1];
[1]Psychology, USC, Los Angeles, CA; [2]Sch. of Law, Psychology and Social Work, Örebro Univ., Örebro, Sweden; [3]Departments of Criminology, Psychiatry, and Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Heterogeneity in the construct of aggression has motivated researchers to identify sub forms of aggressive behaviors. Two functional forms of aggressive behaviors have been identified: reactive (RA) and proactive aggression (PA). It has been suggested that "hot-tempered" RA may be characterized by an over-active autonomic nervous system and an under-active autonomic nervous system may underlie "cold-tempered" PA (Scarpa &Raine, 2000). However, results from previous studies are both sparse and mixed. The current study investigated the autonomic correlates of these two sub forms of aggression in a community sample of 338 twins between ages of 16-18 years old, based on self-reported RA and PA using the Reactive Proactive Questionnaire (RPQ). Skin conductance and heart rate were measured during a 3 minute rest period as indices of autonomic arousal. Skin conductance responses to auditory orienting stimuli were collected as measures of autonomic reactivity. Multiple regressions were run to assess the associations between RA, PA and the autonomic measures of arousal and reactivity. PA was significantly and inversely related to both resting heart rate skin conductance levels, indicating a decreased baseline arousal for proactively aggressive individuals. PA was also associated with lower average skin conductance orienting response, suggesting hyporeactivity of the autonomic nervous system. RA was significantly and positively associated with resting skin conductance level, suggesting over arousal of the sympathetic nervous system for individuals with higher tendencies for reactive aggression. Results support a distinction between these two sub forms of aggression, and lend support to the theory that

proactive aggression is specifically characterized by autonomic under arousal and hyporeactivity. Evidence for reactive aggression to be characterized as a "hot-tempered" aggression was also found, as indicated by its association with increased skin conductance level.

Title: Postnatal oxytocin reverses selective behavioural and physiological effects of birth delivery by caesarean-section in mice

Authors: *L. H. MORAIS[1,2], Y. E. BORRE[2], A. GOLUBEVA[2], A. P. R. COSTA[2], K. SCOTT[2], G. MOLONEY[2], A. M. PEREZ[2], T. DINAN[2], J. F. CRYAN[2];

Abstract: Recent evidences points to an important role for the microbiome in regulating brain function and behaviour in health and disease. At birth, the infant microbiome is determined by maternal-offspring exchanges of microbiota. Simultaneously, the neuropeptide oxytocin (OXT) activates the newborn immune system responses and may be crucial for the establishment of a lifelong host-microbiome interaction. However, birth by Caesarean section (C-section) results in a different pattern of colonization. Interestingly, children delivered by C-section are more likely to develop immune and metabolic disorders, and more recently a small but significant increase in the propensity to develop autism spectrum disorder has been reported in this population. However,mechanistic insights into the long lasting consequences of C-section on brain-gut axis and behavior remain largely unexplored. The aims of the present study were to assess the temporal effects of C-section delivery on brain gut axis and behaviour in mice throughout their lifespan, and whether early postnatal subchronic subcutaneous treatment with OXT could prevent it. We applied a multi-disciplinary approach using a mouse model of C section, followed

by several behavioural assays and subsequent brain, microbiota and immune analyses. During postnatal days, animals born by C-section exhibited maternal attachment deficits. In adulthood, C-section born animals exhibited stereotyped behaviour, anxiety-like behaviour, deficiencies in social memory, disrupted hypothalamic-pituitary-adrenal axis responsivity, disrupted gastrointestinal motility and permeability, and an exacerbated immune-response. In early-life, OXT administration reversed C-section-mediated maternal attachment impairments. Remarkably, postnatal OXT administration prevented the social deficits, anxiety-like effects and stereotyped behaviour in adulthood, disrupted gastrointestinal motility and gut permeability in the C-section offspring. Taken together, these results demonstrate that C-section induces long-term changes across the brain-gut axis and behaviour. Moreover, our findings indicate that there is an early developmental window sensitive to manipulations of the OXT system that can prevent lifelong impairments induced by the mode of C-section.

Title: Gut microbiota depletion during adulthood in rats: Implications for brain and behavior

Authors: *R. D. MOLONEY[1], A. E. HOBAN[2], G. CLARKE[3], T. G. DINAN[3,4], J. F. CRYAN[2,4];
[2]Anat. & Neurosci., [3]Psychiatry, [4]Lab. of NeuroGastroenterology, Alimentary Pharmabiotic Ctr., [1]Univ. Col. Cork, Cork, Ireland

Abstract: Background: There is growing appreciation for the importance of the gut microbiota in shaping brain function and behavior. Proof-of-principle studies in microbiota-deficient germ-free (GF) animals have played an important role in revealing the alterations reported in stress-related behaviors and neurochemistry. However, the maturation of multiple aspects of host physiology is contingent on normal patterns of gut microbiome assembly and development in early life. In order to more precisely parse the role of the gut microbiota outside of this critical

time window on brain and behavior, we set out to establish a rat model of microbiota depletion via chronic administration of antibiotics in adulthood. In particular, we assess the effects of gut microbiota depletion in adulthood on visceral sensitivity, cognitive and emotional behaviors and biological markers of microbiome-gut-brain axis dysfunction. Methods: Adult male Sprague Dawley rats (n=10/group) were treated with vehicle or a combination of antibiotics for 6 weeks in adulthood and throughout behavioral testing. Behavioral tests commenced after the 6 week antibiotic treatment period and were performed in the following order; elevated plus maze (EPM), open field (OF), novel object recognition (NOR), colorectal distension (CRD), fear conditioning (FC), forced swim test (FST), Morris water maze (MWM). HPLC and qRT-PCR was used to assess changes in key gut-brain axis neuromodulators (tryptophan, monoamines, and neuropeptides) in adulthood. Results: Antibiotic treatment reduced visceral sensitivity to CRD concomitant with decreased corticotrophin releasing hormone receptor 1 (CRHR1) and glucocorticoid receptor (GR) and in the amygdala, a key brain region involved in visceral perception. Moreover, antibiotic-treatment induced a depressive-like phenotype in the FST and induced cognitive deficits in the MWM in parallel with altered tryptophan metabolism and serotonin synthesis (5-HT) in the hippocampus, a critical brain region in emotional processing and cognitive functioning. Conclusion: Microbiota depletion in adulthood by means of chronic treatment with antibiotics impacts visceral sensitivity and depressive and cognitive behaviors as well as key neuromodulators of microbiome-gut-brain axis communication in a manner that is similar to that reported in GF animals. This model may represent an additional strategy for the assessment of the continuous role of the gut microbiota in the modulation of brain and behavior. Finally, these data confirm that the gut microbiota is a significant driving force of behavior and a key neuromodulator of gut-brain axis signaling during adulthood.

Title: Targeting the microbiota-gut-brain axis with prebiotics in mice: A novel strategy for stress-related disorders

Authors: A. BUROKAS[1], R. D. MOLONEY[1], S. ARBOLEYA[2], C. STANTON[2], T. G. DINAN[1], *J. CRYAN[1];
[1]Univ. Col. Cork, Cork, Ireland; [2]Teagasc, Moorepark, Cork, Ireland

Abstract: There is growing evidence for a critical role of the microbiota-gut-brain axis in health and disease. Indeed, modulation of the gut microbiome via probiotic treatment has been postulated to be a novel adjunctive strategy for stress-related psychiatric disorders such as depression and anxiety. The role of prebiotics is less investigated. Prebiotic fibres such as short-chain fructo-oligosaccharides (FOS) and galacto-oligosaccharides (GOS) are known to selectively modulate the composition of the intestinal microbiota, and to stimulate proliferation of lactobacilli and bifidobacteria in the gut. Prebiotics are commonly used in infant milk formula to alter the gut microbiota increasing concentrations of beneficial microbes in the gut and also short chain fatty acids which have been implicated as key signalling microbial metabolites. This study's objective was to test whether FOS and GOS alone or in combination altered behaviour in animal tests of anxiety, depression, cognition, stress response and social behaviour. 4 groups (n=10) of adult C57/Bl6/J male mice were administered with FOS, GOS, a combination of FOS and GOS (FOS/GOS), or water for the duration of the 10-week study; 3 weeks prior to - and 5 weeks during behavioural testing. Two weeks after the last behavioural test brains were harvested and gene expression of plasticity and stress-related genes quantified in hippocampus and hypothalamus. Administration of FOS/GOS decreased depressive-like behaviour in a number of behavioural models including the tail suspension and forced swim tests. Similarly, the administration of GOS and the combination of FOS/GOS decreased anxiety in the open field test and elevated plus maze and blunted stress-induced corticosterone concentrations. Moreover, FOS/GOS selectively increased hippocampal levels of brain-derived neurotrophic factor (BDNF) and GABAB1 receptor mRNA whilst decreasing the concentrations of corticotropin releasing factor mRNA (CRF). Interestingly, these prebiotic-induced behavioural changes were associated with increased caecal concentrations of the short-chain fatty acids acetate and propionate and reduced i-butyrate concentrations. These data show that these two prebiotics were actively influencing gut physiology, blunting the stress hormone response and positively modulating anxiety and antidepressant-related behaviours in healthy mice. It is tempting to speculate that these effects maybe mediated through changes in short chain fatty acid concentrations. Together these findings strengthen the role of gut microbiota supplementation as psychobiotic-based strategies for stress-related brain-gut axis disorders.

Title: Towards psychobiotics for stress & cognition: Bifidobacterium Longum blocks stress-induced behavioural and physiology changes and modulates brain activity and neurocognitive performance in healthy human subjects

Authors: *A. P. ALLEN[1,2,3], W. HUTCH[4], Y. BORRE[3], P. J. KENNEDY[2,3], A. TEMKO[5], G. BOYLAN[6], B. KIELY[8], G. CLARKE[2,3], J. F. CRYAN[3,7], T. G. DINAN[2,3];

Abstract: Introduction: The emerging concept of the gut microbiome as a key regulator of brain and behaviour represents a paradigm shift in neuroscience. Precise targeting of the microbiome-gut-brain axis with psychobiotics - live microorganisms with a potential mental health benefit -is a novel approach for the management of stress-related conditions. Preclinical studies have identified a strain of Bifidobacterium, B. longum NCIMB 41676, as a putative psychobiotic with an impact on stress-related behaviours, physiology and cognitive performance. This study thus investigated whether these preclinical effects could be translated to healthy human volunteers. Methods: Healthy male volunteers (N = 22, Mean age = 25.5 +/- 1.2 years) completed the study.

Participants ingested (2.16 +/-0.20) X 109 CFU of B. longum NCIMB 41676 or placebo daily for four weeks each in a repeated-measures design. Participants completed study visits at baseline, post-placebo and post-probiotic. Acute stress (subjective and cortisol output) was assessed using the socially evaluated cold pressor test, and daily stress was assessed online via a validated questionnaire (Cohen Perceived Stress Scale). Cognitive performance was assessed using the CANTAB platform and neurological activity via resting electroencephelography (EEG). Results: In response to acute stress, B. longum NCIMB 41676 led to a reduction in cumulative cortisol output as well as a blunted increase in subjective anxiety. Self-reported daily stress was also lowered during daily consumption of the probiotic. There was a subtle improvement over placebo in visuospatial memory performance in paired associate learning (PAL) in the B. longum NCIMB 41676 group. Central EEG theta power was lower following B. longum NCIMB 41676 consumption compared to placebo. Conclusions: B. longum NCIMB 41676 is associated with attenuated responses to psychological and physiological stress and a modest improvement in cognitive performance, as well as with altered EEG output in healthy volunteers. These clear but subtle benefits are in line with the predicted impact from preclinical screening platforms and highlight the promise of precision-microbiome manipulation strategies. Further studies are warranted to evaluate the benefits of this putative psychobiotic in relevant stress-related conditions and to unravel the mechanisms underlying such effects.

Title: Regulation of microRNAs in the amygdala by the gut microbiota: implications for brain and behaviour

Authors: ***G. CLARKE**[1,2], A. E. HOBAN[3,4], R. M. STILLING[3,4], F. SHANAHAN[4], T. G. DINAN[2,4], J. F. CRYAN[5,4];

[2]Psychiatry, [3]Anat. and Neurosci., [4]Alimentary Pharmabiotic Ctr., [5]Neurosci. and Anat., [1]Univ. Col. Cork, Cork, Ireland

Abstract: Background: According to the World Health Organisation, an estimated 16% of the population are affected by anxiety disorders which represent some of the most common illnesses experienced today. Anxiety disorders are extremely difficult to successfully treat, which may in part be due to failure to completely understand the aetiology of these disorders. While it is well known that a variety of genetic and environmental factors contribute to the development and severity of anxiety disorders, the ability of the gut microbiota to influence brain and behaviour is a relatively new area of research. One of the most consistent findings is in relation to anxiety-like behaviours and the stress response. Though the molecular mechanisms underpinning these effects remain poorly understood, they may well be due to microbiota-driven alterations in gene expression at the level of the CNS. It is unknown if the gut microbiota also recruits microRNA machinery to wield this influence. The aim of this experiment was to establish if germ-free animals have altered microRNA expression patterns in the amygdala, a key brain region for acquisition and expression of fear and anxiety. Methods: Using Illumina Next Generation Sequencing (NGS), we assessed alterations in microRNA expression in the amygdala of conventional, germ-free and colonized germ-free mice. Relevant alterations in microRNA expression levels were verified by quantitative real-time PCR (qRT-PCR) Results: The microbiota-deficient germ-free animals displayed altered expression of 103 miRNAs in the amygdala compared to conventional animals. However, colonisation of the germ-free animals post weaning normalised the expression of 6 miRNAs, suggesting partial reversibility of the cumulative molecular changes. Within these, miR-182 and mir-183 have been previously linked to amygdala-dependent stress-related outputs in preclinical models. Validation of these alterations by qRT-PCR verified changes in micrRNA expression indicated by NGS. Conclusion: This is, to our knowledge, the first demonstration that the gut microbiota can regulate miRNA expression in the amygdala. Moreover, our results confirm that the microbiota can be successfully targeted later in life to modulate miRNA expression. The analysis of mRNA targets may reveal important molecular pathways for microbiota-gut-brain axis signalling and will be essential in increasing our understanding of the molecular mechanisms underpinning this bidirectional communication. Additional studies are required to verify the exact contribution of these miRNAs to amygdala-dependent anxiety-related behaviours.

Title: Social microbes - the microbiota regulates sociability behaviour through stimulus-induced RNA-based pathways in the amygdala

Authors: *R. M. STILLING[1,2,3], A. E. HOBAN[2,3,1], F. J. RYAN[2,4,1], G. M. MOLONEY[2,3,1], F. SHANAHAN[2,1], G. CLARKE[2,1,5], M. J. CLAESSON[2,4,1], T. G. DINAN[2,5,1], J. F. CRYAN[2,3,1]; [2]Alimentary Pharmabiotic Ctr., [3]Dept. Anat. and Neurosci., [4]Dept. Microbiology, [5]Dept. Psychiatry, [1]Univ. Col. Cork, Cork, Ireland

Abstract: The tight association of the human body with trillions of colonizing microbes that we observe today is the result of a long evolutionary history. Only very recently have we started to understand how this symbiosis also affects brain function and behaviour. We could demonstrate that mice raised without any microbiota (germ-free, GF) throughout development show sociability impairments and altered anxiety along with an amygdalar transcriptional profile

reminiscent of increased neuronal activity. However, it is currently unclear if changes in neuronal gene expression are underlying the observed behavioural alterations. To further elucidate the molecular underpinnings of microbe-brain interaction on the behavioural level, we therefore determined the dynamic transcriptional regulation of GF and GF mice colonised at postnatal day 21 in the amygdala in response to a social interaction experience. Using ribodepleted, stranded, and paired-end RNA-sequencing libraries combined with comprehensive downstream analysis pipeline we determined the amygdalar stimulus-dependent coding and non-coding transcriptome. As expected, conventional control animals show strong upregulation of the well-known stimulus-responsive MAP-kinase pathway in the amygdala in response to social behavioural stimulation. In contrast, in GF mice dynamic was attenuated and, surprisingly, we noticed a marked increase in splicing factors and splicosomal ncRNAs instead. Indeed, as a consequence of enhanced splicing factor production, we find increased alternative exon usage in GF mice upon stimulation. In conclusion, our data suggest that the observed altered behavioural response to a novel social situation is correlated to a differential gene-expression response in the amygdala of germ-free animals, which is likely to be established during early life as a result of absent critical host-microbe interactions. This finding may have far reaching implications for understanding social behavioural dysregulation in neurodevelopmental disorders such as autism and schizophrenia.

Title: The microbiota regulates amygdaloid volume and dendritic length

Authors: *G. MOLONEY[1], P. LUCZYNSKI[2], F. SHANAHAN[2], G. CLARKE[3], T. G. DINAN[3], J. F. CRYAN[4];
[2]Alimentary Pharmabiotic Ctr., [3]Psychiatry, [4]Anat. and Neurosci., [1]Univ. Col. Cork, Cork, Ireland

Abstract: Increasing evidence points to a role of the microbiota in the regulation of brain and behaviour. Germ-free (GF) mice are an important tool to assess the role of the microbiota in brain function. We have shown that GF mice exhibit an exaggerated hypothalamic-pituitary-adrenal (HPA) axis response to an acute stressor and reduced anxiety-like behaviour but the mechanisms behind this phenotype remains unclear. The amygdala is an important structure known to regulate fear and anxiety in the brain and to activate the HPA axis. This implicates the amygdala as a possible target in the microbiome-gut-brain axis but it remains an understudied brain region in this field. The aim of this study was to determine if the volume and dendritic morphology of the amygdala differ in GF compared to conventionally colonized (CC) mice. To study amygdaloid volume, mice were perfused and brains were fixed, sectioned coronally. Dendritic morphology and spinal density was assessed using Golgi-Cox staining. Stereological measures of regions of the amygdala revealed significant expansions of the basolateral (BLA), lateral (LA) and central (CeA) nuclei in GF v CC mice. We also investigated the effect of GF status at the level of single excitatory and inhibitory neurons in the BLA by measuring the length and branching of Golgi-stained. In GF mice, the total dendritic length of stellate neurons was significantly increased while the number of branching points was also increased. Sholl analysis revealed a significant increase in dendritic material in stellate neurons localised to proximal and intermediate dendrites. In BLA pyramidal neurons, total, apical and basilar dendritic length is increased in GF mice. Sholl analysis indicates that dendritic elongation was localized to intermediate dendrites. Spine density was calculated by counting spines on 2-3 50 μm apical and basilar dendritic segments per pyramidal-like neuron. In GF mice, spine density was increased on both apical and basilar dendrites. These findings suggest that the presence of microbiota is critical for normal neurodevelopment of the amygdala and its nuclei and that neural remodelling along the microbiome-gut-brain axis could contribute to the altered behavioural and physiological phenotype observed in GF animals.

Title: Regulation of myelination in the prefrontal cortex by the gut microbiota

Authors: *A. E. HOBAN[1], R. STILLING[1], F. SHANAHAN[2], T. DINAN[3], G. CLARKE[3], J. CRYAN[4];
[1]Anat. and Neuroscience, Univ. Col. Cork, Ireland, [3]Dept. of Psychiatry, [4]Dept. of Anat. and Neurosci., [2]Alimentary Pharmabiotic Ctr., Cork, Ireland

Abstract: Background: Myelination is a critical but vulnerable dynamic feature of normal brain development with implications for mental health and neurodegrenative disease In particular, normal cognition and social functioning appear to be contingent on intact myelination in the prefrontal cortex (PFC), a brain region implicated in multiple psychiatric disorders. Interestingly, social isolation stress results in a decreased myelination in the (PFC). Growing evidence points to a role for the gut microbiome in regulating brain function and behaviour. Studies in microbiota-deficient germ-free (GF) animals, have highlighted the impact the microbiota can have on neurodevelopment. GF animals demonstrate altered anxiety-related behaviours and decreased sociability. Given these overlaps between the microbiota, social, cognitive and emotional behaviour and myelination in the PFC, we aimed to investigate whether GF mice displayed altered myelination in adulthood in this region. Methods: We assessed both at the ultrastructural and transcriptional level changes in myelin sheath thickness and functional myelin sheath components which have been implicated in formation, stabilization, maintenance and remyelination. Using transmission electron microscopy we examined changes in myelin thickness via g-ratio assessment (quantification of myelin thickness relative to axonal diameter). Using qRT-PCR, we assessed expression levels of 6 myelin component genes in the PFC and other relevant brain in conventionally raised, germ-free and germ-free colonised mice Results: Ultrastructural analysis revealed hypermyelination within the PFC of GF mice as indicated by decreased g-ratio compared to conventionally colonised (CON) mice. These mice also displayed increased expression of six different myelin genes only within the PFC. However, colonisation of the germ-free animals immediately post-weaning normalised the expression of these myelin component genes. Coinciding with this increased expression, GF mice displayed altered expression of key myelin and oligodendrocyte regulating genes within the PFC. Conclusion: This is, to our knowledge, the first demonstration that the gut microbiota can regulate myelination. This effect is brain-region specific and occurs only in the prefrontal cortex. Moreover, our results suggest that the microbiota can be successfully targeted later in life to modulate myelination patterns, at least at the transcriptional level. This raises the possibility that targeting the gut microbiota during critical time windows could be a viable approach for treating disorders associated with aberrant myelination patterns.

Title: Gut microbiome alterations in major depressive disorder: relevance to pathophysiology

Authors: *J. R. KELLY[1], Y. BORRE[3], C. O' BRIEN[4], J. DEANE[4], P. KENNEDY[3], S. EL AIDY[3], G. MOLONEY[3], L. SCOTT[1], E. PATTERSON[4], P. ROSS[4], C. STANTON[4], J. CRYAN[2], G. CLARKE[3], T. DINAN[1];
[1]Psychiatry, [2]Anat. & Neurosci., Univ. Col. Cork, Cork, Ireland; [3]Lab. of Neurogastroenterology, Alimentary Pharmabiotic Ctr., Cork, Ireland; [4]Teagasc Food Res. Ctr., Cork, Ireland

Abstract: Background: The biological mechanisms underlying the pathophysiology of MDD involve immune, endocrine and neurotransmitter dysregulation. Preclinical findings suggest that the gut microbiota can modulate brain development, function and behaviour by recruiting the same neuroimmune, neuroendocrine and neural pathways of the brain-gut-microbiome-axis which are considered dysfunctional in MDD. However, the extent to which these preclinical findings translate to clinical populations is currently unknown. The aim of this study was to determine the composition of the gut microbiota and its relationship to immune activity (plasma cytokines), hypothalamic-pituitary-adrenal axis (HPA-axis) function and tryptophan metabolism in patients with MDD compared to healthy control participants. Methods Thirty four patients with DSM IV major depression were recruited, together with 33 healthy subjects matched for gender, age and ethnicity. CRP and a panel of cytokines were measured using MSD. Salivary cortisol levels for assessment of the cortisol awakening response (CAR) were determined by ELISA. Plasma tryptophan and kynurenine were determined by HPLC. Faecal samples were collected for 16s rRNA gene sequencing to determine bacterial community structure and diversity. Results Preliminary analysis demonstrated significant differences in the gut microbiota in the MDD group with a reduced abundance of short-chain fatty acid-producing bacteria. In

parallel patients with MDD showed significantly higher plasma levels of IFN-y, IL-8 , IL-6 , IL-1β , TNF-α , and CRP . In addition, there was a significantly higher CAR (p=0.03) and an elevated kynurenine: tryptophan ratio (p=0.05) in patients with MDD. Conclusion Alterations in the gut microbiota in patients with MDD are pronounced and may drive the prominent pathophysiological features of this disorder. The mechanisms underpinning these effects require further investigation but may be related to an altered production of microbial metabolites such as short chain fatty acids and/or perturbations to intestinal barrier function. Ultimately, these findings may pave the way for therapeutic targeting of the gut microbiome as a viable strategy for novel antidepressant development.

Title: Disruption of the gut microbiota with oral antibiotic reduces core body temperature and disrupts diurnal rhythms of core body temperature and locomotor activity, but not sleep, in adult rats

Authors: S. J. BOWERS[1], R. S. THOMPSON[2], A. MIKA[2], B. N. GREENWOOD[3], *M. R. FLESHNER[2];
[1]Med., Northwestern Med. Sch., Chicago, IL; [2]Univ. Colorado, Boulder, CO; [3]Psychology, Univ. of Colorado at Denver, Denver, CO

Abstract: The bidirectional communication between the gut microbiota and the brain (i.e., the gut-brain axis) can modulate behavior and neurochemical systems. Recent evidence suggests that the absence of gut microbiota throughout development (i.e., gnotobiotic rodents) can affect clock genes in peripheral tissues and serotonin in the brain. Given the important role of clock genes in

regulating diurnal rhythms and serotonin's contribution to sleep and thermoregulation, we hypothesized that depletion of the gut microbiota, using oral antibiotics, may disrupt diurnal rhythms, thermoregulation and sleep. Diurnal rhythms of locomotor activity (LA), activity-independent core body temperature (CBT_{ind}), and sleep (%REM, %SWS, %WAKE, bout frequency/duration) were recorded using *in vivo* biotelemetry in freely moving adult male F344 rats. Rats were given oral antibiotics (4.0 mg/ml streptomycin and 2.0 mg/ml penicillin g) in their drinking water and efficacy was assessed by measuring total aerobic, anaerobic, *Lactobacillus* spp. and *Bifidobacterium* spp. per g of feces using selective culture. After seven days of antibiotic treatment, animals had depleted gut microbiota, reduced overall CBT_{ind} along with increased amplitude of CBT_{ind} diurnal rhythm, and a flattened diurnal rhythm of LA when compared to baseline, while sleep architecture remained unchanged. Circadian rhythms of CBT_{ind} and LA were not phase shifted and did not change in period length after antibiotic treatment. Interestingly, five days after cessation of antibiotic, only *Lactobacillus* spp. remained depleted. Reduced CBT_{ind} and altered diurnal rhythms of CBT_{ind} and LA also persisted. These results support a link between the gut microbiota, temperature regulation and diurnal physiology. Furthermore, they suggest that disruptions to the gut microbiota in adulthood, and any resultant physiological consequences, may be long lasting even if antibiotic administration is transient.

Title: Early life test diet improves NREM sleep and facilitates REM sleep rebound following an acute stressor: The potential role of the gut microbiota, metabolome, and hypothalamic orexin

Authors: *R. S. THOMPSON[1,2], A. MIKA[1,2], R. ROLLER[1], M. GAFFNEY[1], B. N. GREENWOOD[3], P. C. DORRESTEIN[4], R. KNIGHT[5], M. FLESHNER[1,2];
[1]Univ. Colorado Boul, Boulder, CO; [2]The Ctr. for Neurosci., Univ. of Colorado, Boulder, CO; [3]Psychology, Univ. of Colorado, Denver, CO; [4]Chem., [5]Pediatrics, Univ. of California, San Diego, CA

Abstract: Stressor exposure produces maladaptive and adaptive disruptions in the sleep cycle. Stress can produce sleep fragmentation, which is associated with negative health consequences, and REM rebound, which is associated with better psychological recovery after trauma. Prebiotics, a form of dietary fiber, promote the expansion of specific microbial species in the mammalian gut that support stress robustness. Thus, we tested whether a prebiotic test diet would modulate the gut commensal bacteria and their metabolites, and that these changes would be associated with the protection of the sleep cycle following stress. Male F344 rats, postnatal day 24 (P24), were placed on a test diet or a control diet ad-libitum. Biotelemetry devices were implanted on P59, to examine real-time differences in the sleep cycle across rodent development due to test diet. Rats were exposed to an acute stressor on P87 to examine the potential protective effects of test diet on stress-induced disruptions of the sleep cycle. In a separate experiment, male F344 rats were placed on either test or control diet for 4 weeks and brains were collected for *in situ* hybridization analyses. Rats fed the test diet had greater NREM sleep consolidation in early adulthood (P71, P72) compared to control diet. Stepwise multiple regression analysis revealed that greater NREM sleep at P71, P72 was negatively correlated with early life Deferribacteres (P35) in the test diet only ($r = 0.627$). Rats fed the test diet also had enhanced REM rebound following stress (P87) compared to rats fed the control diet. Intriguingly, results from a stepwise multiple regression analysis showed a significant correlation ($r = 0.41$) between increased early life Proteobacteria (P35) and increased REM sleep in the dark cycle after stress (P87), which may be dependent on the interaction between diet and stress ($p < 0.05$) enhancing REM rebound following stress. Ongoing metabolomics analysis may reveal metabolites that could have contributed to the sleep effects observed. Finally, given previous reports of a linear relationship between higher levels of NREM sleep and lower levels of prepro-orexin mRNA, *in situ* hybridization for hypothalamic prepro-orexin mRNA may reveal additional contributions of the test diet on the observed sleep effects. These results demonstrate that test diet consolidated NREM sleep potentially through reduced early life Deferribacteres and conferred stress-protective effects on REM sleep following stress. Our results suggest modulation of the gut microbiota with test diet improves sleep and may reduce stress-induced disruptions to the sleep cycle and could, in part, depend on changes in hypothalamic orexin.

Abstract: Serotonin transporter (SERT) knockout mice have been used extensively in neuropsychiatric research to better understand the role of serotonin signaling in affective disorders. Additionally, the model has illuminated a role for SERT in gut function and metabolic disorders. Given the recognized role of the gut microbiota in host metabolic function and the increasing interest of the microbiome in the gut-brain axis, we sought to characterize how the SERT model genetically constrains the enteric ecological niche in the gut, particularly given the abundance and importance of serotonin in gut physiology and homeostasis. Here we tested the hypothesis that littermates of different genotypes would have differing microbiota which could be perturbed acutely (within 4 hours) by an inflammatory challenge, an injection of lipopolysaccharide. Our experimental approach involved next-generation sequencing, complete blood counts, serum chemistry panels, serum cytokines, serum corticosterone, and behavioral testing. The three major results of this study are that 1) wild-type and SERT knockout littermates have different gut microbiota; 2) the microbiota is highly responsive to inflammatory events occurring the host; and 3) SERT knockout mice have reduced sickness-like behavior in response to an inflammatory challenge. These data underscore the multi-systemic complexity in coordinating behavioral responses to stimuli.

Title: Longitudinal effects of chronic stress on the murine gut microbiota

Authors: A. SHOSKES[1], A. PROCTOR[2], K. BATTANI[1], M. CARDER[1], L. SEMKE[1], V. DURIC[1], G. PHILLIPS[2], *L.-L. YUAN[1];
[1]Dept. of Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA; [2]Iowa State Univ., Ames, IA

Abstract: Emerging evidence supports a bidirectional communication axis between the brain, the gastrointestinal tract, and the microbiota colonizing the gut. Various physical and psychological stressors have been shown to influence the function of the GI tract and its resident microbiota. Furthermore, dysbiosis of GI tract colonization has been associated with different diseases, including depression. We investigated the relationship between chronic stress and the murine gut microbiota by comparing the taxonomic composition before and after chronic stress. Mice were subjected to chronic unpredictable stress (CUS) for six weeks. Fecal samples were collected at different time points before and after CUS. Bacterial genomic DNA was extracted and amplicons representing the V4 region of 16s rRNA genes were amplified and sequenced. We observed phylum level differences: mean abundance of *Bacteroidetes* increased and *Firmicutes* decreased over the chronic stress period. Decreases in abundance of *Bacilli* (a class within *Firmicutes*) and *Lactobacillus* (a genus in *Bacilli*) appeared to contribute to the abundance decrease at the phylum level. No significant difference in alpha diversity was noted, indicating CUS induced abundance changes are unlikely due to differences in the amount of diversity. Changes in the ratio of the phyla *Bacteroidetes* to *Firmicutes* have been found to be associated with metabolic disease and obesity. Our results suggest that genera within *Bacilli* may be targets of prebiotic or probiotic therapies to restore a microbiota associated with well-being. Further studies are currently underway to address whether other forms of chronic stress such as chronic pain, result in similar taxonomic changes in GI resident microbiota.

Title: Social isolation reduces the excitability of neurons in the medial nucleus of the amygdala

Authors: *J. ROSENKRANZ;
Cell. and Mol. Pharmacol., The Chicago Med. School/RFUMS, North Chicago, IL

Abstract: A robust capacity for social interaction can enrich lives and provide buffering from psychiatric disorders. Several psychiatric disorders display features of social withdrawal and impaired social behavior. While social abilities develop across life, there is evidence for critical periods, wherein disruptions of social development lead to long term impairments. In rodents, social isolation after weaning can lead to abnormalities in aggression, interactions with novel rodents, sexual behavior and social learning. One shared commonality between these behaviors is the involvement of the medial nucleus of the amygdala (MeA). The purpose of this study was to test whether post-weaning social isolation (~P21-22) leads to abnormal activity of the MeA. *In vivo* and *in vitro* recordings of MeA neurons from group-reared and isolation-reared rats were compared. Social isolation significantly decreased the firing rate of MeA neurons and decreased afferent drive. Neuronal membrane responsiveness and excitability were decreased in the isolation-reared rats, along with evidence of decreased glutamatergic drive. To test whether these changes were due to stunted maturation of the MeA, neurons were recorded at the initiation of social isolation or at intervals over the course of social isolation. Group housed rats did not display a significant change of excitability between post-weaning and adulthood. In contrast, isolated rats displayed decreased excitability across time. These data indicate that post-weaning social isolation impairs the function of the MeA, but it is not due to a stunting of maturation, rather, it is due to a progressive emergence of impairment. These results are a first step towards understanding the pathophysiology of the medial amygdala in maldevelopment of social behaviors.

Title: Early life stress as a model for sexually dimorphic development of negative symptoms in mice

Authors: *H. GOODWILL, P. LACHANCE, S. TERAMOTO, K. G. BATH;
Brown Univ., Providence, RI

Abstract: Converging evidence from both clinical and experimental studies reveals that females are at increased risk for developing stress-associated pathology, including anxiety and depression. Negative symptoms are some of the most pervasive and treatment resistant across these disorders, in part, because their etiology is unspecified. Recent work has led to the hypotheses that 1) negative symptoms result from altered reward processing, suggestive of abnormal dopamine (DA) signaling in mesocortico/limbic pathways and 2) that midbrain dompaminergic systems are sexually dimorphic in their response to developmental stress. Here, we leverage an early life stress (ELS) paradigm in mice (maternal bedding restriction from P4-P11) to induce negative symptom development exclusively in females, allowing for sex-specific investigation of the molecular substrates of negative symptom development and stress vulnerability. Specifically, female mice exposed to ELS exhibit learned helplessness, measured in the forced swim test; enhanced risk assessment in a novelty induced hypophagia task and decreased exploration of novel contexts in the elevated plus maze in comparison with control animals. These behaviors were not observed in ELS exposed male mice. Additionally, using a newly developed, 24-hour, automated computer-vison home cage monitoring system, we found that ELS exposed females show a reduction in grooming behavior (avolition), walking (lethargy) and increased sleeping (hypersomnia) relative to control-reared animals. Taken together, female mice exposed to ELS develop behavioral profiles that parallel negative symptoms of depression in humans. In these same groups of mice, we carried out extensive realtime qPCR analysis of dopamine signaling molecules in the striatum, VTA and frontal cortex. We found a significant increase in DA receptor D4R mRNA expression exclusively in the frontal cortex of ELS females throughout development and into adulthood. There were no observed differences in mRNA levels of DA transporter, DA beta-hydroxylase, COMT, Darpp-32, or DA receptors D1R, D2R, D3R or D5R between groups. This suggests D4R regulation in the mesocortical DA pathway as a mechanism for sexually dimorphic vulnerability to stress and negative symptom development. Such work offers a possible target for sex-specific treatment of stress-associated disorders and negative symptoms.

Title: Social transfer of pain in the mouse

Authors: *M. L. SMITH, M. M. HEINRICHER, A. E. RYABININ;
OHSU, Portland, OR

Abstract: Clinically significant chronic pain often manifests in the absence of a noxious trigger or tissue damage, and is greatly impacted by social and cognitive factors. Without the ability to trace the stimuli that cause the onset of pain, our understanding of such chronic pain disorders is lacking. Because chronic pain and alcohol dependence are often co-morbid, we examined pain behavior during alcohol withdrawal following a period of voluntary drinking in C57BL/6J mice. Our experiments identify, for the first time, increased sensitivity to mechanical and inflammatory pain stimuli in mice during withdrawal from voluntary alcohol consumption. Remarkably, our studies also reveal a similar pain state in "bystander" mice drinking water and housed in the same room. These bystander mice exhibit hypersensitivity that lacks a nociceptive trigger, and relies solely upon social and environmental cues. Interestingly, bystander mice show no overt signs of generalized anxiety, but demonstrate activation of the anterior cingulate and insula, which are cortical areas that contribute to pain and empathy in humans. Additional experiments reveal that olfactory cues related to hypersensitivity during alcohol withdrawal, but not consumption or intoxication, are sufficient for transfer of this pain state. Finally, hypersensitivity is also induced in bystander mice housed near mice undergoing morphine withdrawal or chronic inflammatory pain. These data expand on the current understanding of the multidimensional nature of social information transfer between animals. Ultimately, these studies demonstrate that withdrawal from voluntary alcohol consumption in mice leads to increased pain sensitivity and provide the first evidence of pain in laboratory rodents that is induced solely by a social stimulus that is independent of injury, stress, anxiety, or emotional contagion.

Title: 12 things you didn't know about high responder/low responder rats, stress coping, and the dorsal raphe. Number 5 will blow your mind!

Authors: *J. COHEN[1], A. E. ATA[2], N. L. JACKSON[2], S. M. CLINTON[2];
[1]Univ. of Alabama at Birmingham Med. Scientist Training Program, Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Stress is one of the most widely studied environmental risk factors for the development of a variety of mental illnesses. Stress coping styles encompass a range of physiological, psychological, and behavioral responses aimed to avoid or tolerate distress, and are broadly characterized as “proactive” (a fight-or-flight response to defeat/escape a stressor) or “reactive” (a withdrawal response to avoid or outlast the stressor). In humans, proactive vs. reactive coping styles convey risk or resilience to psychopathology depending on the type of stress, since each coping style can be adaptive in some circumstances but maladaptive in others. To investigate the neurocircuit and molecular mechanisms underlying different stress coping styles, we utilized selectively bred high-responder (HR) and low-responder (LR) rats. HR/LR rats were selected for on the basis of high and low novelty-induced locomotion, and are a well-developed model for studying individual differences in emotionality and behavior. Here we show that HR rats display a proactive coping style while LRs exhibit a reactive coping style in the defensive burying test. HR rats spend more time burying the probe following a single electric shock (proactive coping), while LR rats spend more time immobile (reactive coping). Dual-labelling immunocytochemistry for c-Fos, a marker of neuronal activity, and tryptophan hydroxylase 2 (TPH2), a marker of serotonergic neurons, revealed that HR rats have higher basal c-Fos activation in TPH2 cells of the dorsal raphe. Following defensive burying, HR rats display an increase in c-Fos/TPH2 dual-labelled cells in the dorsomedial dorsal raphe and ventral dorsal raphe, while LR rats displayed a decrease in the dorsomedial dorsal raphe. Sequencing of microRNAs in the dorsal raphe of HR/LR rats identified 14 differentially expressed miRNAs, including miR-101a. miR-101a was one of the most abundant miRNAs in the raphe and is known to regulate multiple subunits of the polycomb repressor complex, which mediates gene silencing via histone tail methylation. This points to a role for the dorsal raphe and miR-101a in

regulating stress coping style. Future work will further characterize serotonin circuit differences in proactive and reactive coping animals by testing the effects of miR-101a on coping style.

Title: Social disruption produces lasting behavioral adaptations by reducing adult neurogenesis

Authors: *M. OPENDAK[1], L. OFFIT[1], T. J. SCHOENFELD[2], H. CAMERON[2], E. GOULD[1]; [1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Research on social instability has focused on its detrimental consequences, but most people are resilient and respond by invoking various coping strategies. To investigate cellular processes underlying such strategies, a dominance hierarchy of rats was formed and then de-stabilized. Regardless of social position, rats from disrupted hierarchies had fewer new neurons in the hippocampus compared to rats from control cages and those from stable hierarchies. Despite this suppression of adult neurogenesis, no behavioral impairments were observed. Social disruption produced preference for familiar over novel conspecifics, a change that was not linked to impaired memory or increased anxiety. Using the neuropeptide oxytocin as a tool to increase neurogenesis in the hippocampus of disrupted rats restored preference for novel conspecifics to pre-disruption levels. Conversely, reducing the number of new neurons by ablation of adult neurogenesis in naïve transgenic GFAP-TK rats resulted in social behavior similar to disrupted rats. Taken together, these results provide novel mechanistic evidence that social disruption shapes behavior in a potentially adaptive way by reducing adult neurogenesis in the hippocampus.

Title: Early life experience mobilizes DNA transposable elements

Authors: *T. A. BEDROSIAN, C. QUAYLE, F. H. GAGE;
Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The brain exhibits remarkable plasticity in response to environmental experience, particularly during early life. Variation at the DNA level accounts for at least some of this plasticity. For example, in rodents, rapid and permanent epigenetic modifications occur as a result of natural variations in maternal care, which in turn shape the offspring's neuronal and behavioral phenotypes. We hypothesize that structural variation of the genome, particularly through the mobilization of active DNA transposable elements, may be another mechanism through which early life experience contributes to brain plasticity. LINE-1 (L1) retrotransposons are autonomous mobile elements that comprise ~20% of the genome. Most copies are truncated or otherwise mutated in such a way that mobilization is no longer possible; however, there are about 120 active copies in humans and at least 3000 in mice that are capable of mobilizing. It has been suggested that active transposable elements in the genome may allow for germline or somatic DNA rearrangement to occur in a fashion similar to that observed in the immune system. DNA recombination could cause permanent changes in gene expression and neuronal function. We used natural variations in murine maternal behavior as a model to study the effect of early life experience on L1 copy number variation in the offspring. Specifically, we developed an assay using droplet digital PCR to address the hypothesis that differences in maternal care influence L1 copy number in the brain. In addition, we examined L1 gene expression levels at different post-natal time points and DNA methylation levels of the L1 promoter to determine the effect of experience on mobile element regulation. Our results suggest that early life experience mobilizes L1 retrotransposons in the brain. This finding hints at a potential functional role for mobile DNA elements in brain plasticity and in shaping neuronal and behavioral phenotypes.

Title: Sphingosine-1-phosphate receptor dysregulation contributes to depressive-like behavior in stress-susceptible rats

Authors: *B. CORBETT[1,2], S. BELTRAMI[2], S. LUZ[2], N. SUTOYO[2], S. BHATNAGAR[2]; [1]Abramson Res. Ctr., [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Chronic stress promotes depressive-like behaviors in humans. However, not all stressed individuals go on to develop stress related psychiatric disorders. That is, some individuals are resilient to the effects of stress and others are vulnerable to its effects. In a paradigm of chronic social defeat in rats, we have identified subpopulations that are resilient or vulnerable to the neuroendocrine, prodepressive and anxiogenic effects of defeat. However, the mechanisms underlying stress susceptibility and stress induced depressive-like behaviors remain unclear. In order to identify novel neural substrates underlying resilience and vulnerability, we used a targeted PCR array approach. We found that that the expression of sphingosine-1-phosphate receptor 1 (S1PR1) was decreased in the ventral hippocampus of stress-susceptible rats. The expression of S1PR3 was increased in the ventral hippocampus of stress-susceptible rats and the medial prefrontal cortex of stress-resilient rats. We then assessed whether modulation of these receptors regulates behavior in the Porsolt forced swim test using FTY720 (fingolimod), a non-selective modulator of S1P receptors. We injected rats with either vehicle or FTY720 (2.5 mg/kg) immediately following a 15 minute training swim. On the following day, we injected rats both 5 hours and 1 hour prior to a 5 minute test swim. FTY720 decreased immobility and increased climbing durations in the test swim, suggesting an anti-depressant effect of this drug. Adrenalectomy did not alter immobility, swimming, or climbing behaviors in the Porsolt forced swim test in FTY720-treated rats. Furthermore, we found that repeated treatment with FTY720 (2.5mg/kg for 5 days) increased the expression of BDNF in the dorsal and ventral hippocampus as assessed by ELISA. Current studies are assessing whether increasing the expression of S1PR1 and S1PR3 in the hippocampus affects depressive-like behaviors. These results suggest that altered expression of S1P receptors may serve as a regulator of stress susceptibility and that modulating their activity may improve stress induced depressive-like behavior.

Title: Measurement of markers lipid peroxidation in blood serum in response to stressful conditions

Authors: *S. GONZALEZ CANO[1], A. GONZÁLEZ[1], E. BALTAZAR[1], P. AGUILAR-ALONSO[2], G. FLORES[1];
[1]Inst. De Fisiologia BUAP, Puebla, Mexico; [2]Facultad de Ciencias Químicas, BUAP, Puebla, Mexico

Abstract: Recent research shows that academic stress occurs in students at various levels, including UNIVERSITY STUDENTS. It has been shown that this kind of stress plays an important role in the evolution of mental disorders as anxiety, depression and, in severe cases, psychosis schizophrenia type. One theory to analyze is the relationship between psychological stress, biological stress and the development of mental disorders since is known that if the psychological stress is added a system malfunction antioxidant then generate oxidative stress it contributes to the risk of trigger mental illness. The aim of this study was analyze two products of lipid peroxidation, which form part of the process of oxidative stress, these metabolites were Malondialdehyde (MDA) and 4-hydroxyalkenals (4-HDA) which were obtained of blood serum of students of the Faculty of Chemistry of the Autonomous University of Puebla, Mexico. Students of 3 different groups were asked for their consent to participate in this work and were applied surveys of anxiety and depression as well as tests of different types of knowledge as stressful event. The biological sample was obtained by venipuncture blood serum at different stages of the test: before, during and after, assessing lipid peroxidation products. The results obtained from the surveys showed that in the university population exists a high prevalence of anxiety (93% of the surveyed population have mild to severe anxiety) and depression (100% of the surveyed population has some type of depression). As for the results of the biochemical tests, showed that the levels of MDA in one and two groups were elevated during the stressful event declining in the later stage, while for group three were found before the test increased, decreasing in steps during and after. In the case of 4-HDA levels in group one showed a slight increase after the test, to group two an increase was observed during the test and a decrease in the later stage and group three were elevated before examination, decreased during the test and increased after the test. Thereby, in the university population analyzed, the model of

psychological stress tests generated leads to increased production of free radicals and reactive species generating lipid peroxidation. This work is the first step in trying to address the relationship between psychological stress and oxidative stress to identify early markers associated with schizophrenia. . Title: Reminiscing about positive memories buffers acute stress responses and engages the prefrontal cortex

Authors: *M. E. SPEER, H. MANGLANI, M. R. DELGADO;
Psychology Dept., Rutgers Univ., Newark, NJ

Abstract: Recalling happy memories from the past can elicit positive feelings and enhance an individual's wellbeing (Young et al., 2013). One potential adaptive function in reminiscing about the positive past may be the ability to cope with stressors in daily life, such as reducing stress hormone levels (e.g., cortisol). Indeed, behavioral data from our lab lends support to this idea. Individuals who recalled positive memories (N = 33) showed a sharper decrease in cortisol rise 20 min after stress exposure compared to individuals who recalled neutral memories (N = 34). This highlights the beneficial effects of internally generated positive emotion to one's wellbeing. In the present study, we examined neural changes associated with the recall of positive memories after stress, and how it may aid coping with negative affect. To test this, participants described and gave subjective emotion ratings for specific episodic memories of positive (e.g., family vacation) and neutral (e.g., commuting to work) content. Three days later, they returned for the fMRI scanning session. Participants were first exposed to an acute stressor (i.e., socially evaluative cold-pressor task), and then asked to retrieve a subset of the same episodic memories triggered by visual word cues (e.g., family vacation) while in the scanner. The memories were of only positive valence or only neutral valence, creating 2 experimental groups (Positive and

Neutral). To measure changes in cortisol levels over time, salivary cortisol samples were collected at baseline (before stressor), immediately after the stressor (2 min), peak (after recalling autobiographical memories, 20 min), and recovery (50 min). As expected, participants who recalled positive memories rated their memories with greater positive affect and stronger emotional intensity than participants who recalled neutral memories. Preliminary neural analyses comparing high feeling vs. low feeling memories during autobiographical memory retrieval showed enhanced activity in the ventrolateral prefrontal cortex (vlPFC) in individuals who recalled positive memories, but not in individuals who recalled neutral memories. This potentially suggests that the engagement of prefrontal regions previously implicated in cognitive control and regulation may be essential for enhancing positive emotion in response to acute stress. Future analyses will look at these results in conjunction with cortisol and physiological data. Taken together, these findings have implications for using something naturally-occurring like recalling the past as a strategy for buffering negative affect and reinforcing positive wellbeing.

Title: Social isolation reveals a dopamine-independent rewarding motivational response to acute nicotine that is not observed in group-housed mice

Authors: ***T. E. GRIEDER**[1], D. VAN DER KOOY[2];
[1]Inst. Med. Sci., [2]Mol. Genet., Univ. Toronto, Toronto, ON, Canada

Abstract: Drug abuse, specifically nicotine addiction, is a worldwide epidemic that has led to many deaths. Recent research has suggested that social factors play an important role in both the initial response to abused drugs and the transition to addiction. In order to investigate such factors, we used a place conditioning paradigm to examine the effect of single- versus group-housing on the acute conditioned response to nicotine in nondependent C57Bl/6J mice and compared these nicotinic motivational effects with those elicited after dopamine receptor antagonism. Mice that were single-housed (and therefore socially isolated) for two weeks prior to conditioning and pretreated with the dopamine receptor antagonist α-flupenthixol prior to acute nicotine found nicotine rewarding. However, mice that were group housed or were single-housed

only during conditioning did not show this conditioned rewarding response. We also observed that individually housed mice with genetic deletion of the α5 nicotinic acetylcholine receptor (nAChR) subunit, which is important for nicotine's acute aversive effects, behave differently than group-housed litter mates. These results suggest that the stressful experience of social isolation makes single-housed nondependent mice behave as if they are nicotine-dependent and shifts the balance of acute nicotine's aversive and rewarding effects, such that socially isolated mice are more likely to experience the acute rewarding effects of nicotine after blockade of dopaminergic receptors. These results further highlight the important role that social factors play in the motivational response to acute nicotine.

Abstract: Recently, the relation between diet quality and behavior has been discussed. In order to elucidate the effects of diet quality in animal models of depression, we made and analyzed a subchronic and mild social defeat stress (sCSDS) model mice (Goto et al., Behav Brain Res 2014) in two conditions feeding purified diet (AIN-93G) and non-purified diet (MF; standard

laboratory diet). C57BL/6J (B6) male mice were exposed to sCSDS using aggressors of ICR male mice as previously reported. Body weight, food intake, and water intake of B6 were monitored for the experimental periods consisting of 10 days of sCSDS. After the sCSDS, social behavior (stress-vulnerability) and metabolomic profiles of plasma, liver, and cecum contents of B6 were analyzed. Body weight gain, food intake, and water intake of the defeated mice were significantly higher than those of non-stressed control mice in both diet groups. Although the defeated mice showed significantly higher social avoidance behavior to unfamiliar ICR mice in the social interaction test compared with those of control mice, defeated mice fed purified diet showed significantly higher rates of stress-vulnerability than those of defeated mice fed non-purified diet (Goto et al., Nutr Neurosci 2015). These results suggest that diet quality affects the vulnerability to social defeat stress in mice. In addition, metabolomic analysis using CE-TOFMS revealed that levels of four metabolites in the liver of the defeated mice were significantly higher than those of control mice under the feeding condition of purified diet (Goto et al., J Proteome Res 2015). Also, metabolomic analysis using GC/MS revealed that some candidates of molecular markers for stress-vulnerability in the model mice.

Title: Can behavioral inhibition in fish help endure a risky social environment?

Authors: *S. RIISE[1,2], M. VINDAS[2], G. NILSSON[2], Ø. ØVERLI[3];
[2]Dept. of biosciences, [1]Univ. of Oslo, Oslo, Norway; [3]Dept. of Animal and Aquacultural Sci., Norwegian Univ. of Life Sci., Ås, Norway

Abstract: Social subordination is a common model for chronic stress which is often used to study pathologies, such as depression. Subordinates are often characterized by high serotonin (5-HT) signaling and behavioral inhibition. Behavioral inhibition, in turn, is associated with reduced activity levels, suppressed aggression and suppressed neuronal plasticity/neurogenesis. We tested in a teleost model the hypothesis that behavioral inhibition could be advantageous in a risky We conducted three different experiments: (a) Dose-response experiment, in order to

characterize behavioral effects of ketamine in fish, (b) studying the neuroendocrine effects of ketamine with special reference to the possible involvement of the brain 5-HT system, and markers of neuronal plasticity. (c) Testing the consequences of ketamine-induced reversal of behavioral inhibition in a novel social contest. Methods used included microdissection of telencaphalic brain areas, q-PCR and HPLC. Results were as follows: a) the 5 mg/kg dose of ketamine significantly increased locomotion in socially isolated rainbow trout and did not cause any undesired side-effects b) Reduced 5-HT concentrations were evident in the suggested amygdala equivalent dorsomedial pallium (Dm) for ketamine-treated animals. There was also an increase in the proliferating cell nuclear antigen (PCNA) expression in the ventral part of the ventral telencephalon (Vv, suggested homologous to septal areas associated with lateral septum in mammals). c) Ketamine-mediated increased locomotion in subordinate fish resulted in more received aggression in a novel social contest. We here demonstrate that behavioral inhibition under socially risky environments (*i.e.* high aggression) confers and advantage for subordinate animals and is associated with 5-HT signaling in the Dm. We propose that our results are in agreement with the hypothesis that depressive-like behavior may have evolved as a life-history strategy in subordinate animals under highly socially unpredictable environments.

Title: Neuroendocrine responses to social challenges in zebrafish

Authors: ***M. TELES**[1,2], M. GOZDOWSKA[3], E. KULCZYKOWSKA[3], R. F. OLIVEIRA[1,2]; [1]Inst. Gulbenkian de Ciência, Oeiras, Portugal; [2]Neurosciences, Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal; [3]Genet. and Marine Biotechnology, Inst. of Oceanology of the Polish Acad. of Sci., Sopot, Poland

Abstract: The nonapeptides arginine-vasotocin (AVT) and isotocin (IT) which are the teleost homologues of arginine-vasopressin and oxytocin in mammals have been implicated in a variety

of social and stress related behaviours across vertebrate taxa. The actions of these peptides can vary depending on the species, sexes, and social context. To investigate the response of AVT and IT to social challenges we studied agonistic interactions and the establishment of dominance hierarchies in zebrafish. We used an agonistic paradigm where three different behavioural phenotypes emerge: animals could win the interaction (winners), lose the interaction (losers) or have an unsolved interaction by fighting their own mirror image (mirror-fighters). We quantified the levels of both nonapeptides in macrodissected brain areas (i.e. olfactory bulbs, telencephalon, diencephalon, optic tectum, cerebellum, and brainstem) of these three behavioural phenotypes. Our results show that AVT levels increased in the telencephalon, and diencephalon of winners, and in the telencephalon, diencephalon, optic tectum and brain stem of losers. For mirror-fighters differences were only detected in the telencephalon. Isotocin levels were also distinct between the three behavioural phenotypes: in winners only the cerebellum levels increased, in the losers there was an IT increase in the diencephalon and a decrease in the cerebellum, and mirror-fighters showed higher levels in the olfactory bulbs. Thus, one can conclude that AVT and IT are differentially regulated in different brain regions by social interactions. We have also measured cortisol and androgen (Testosterone and 11-Ketotestosterone) levels in response to the social challenge. Our data indicate that real opponent fighters (winners and losers) increased cortisol and 11-KT levels in response to the social challenge, while mirror fighters had no hormonal response, stressing out the pivotal role of the perception of the fight outcome in triggering an hormonal response. In summary, this study illustrates that a highly social model organism also displays a hormonal response to social challenges and that AVT and IT may play a role in socially driven behavioural changes.

Title: A new rodent model to study empathy

Authors: *M. CONTRERAS, C. MEDINA, K. CRUZ, J.-M. FELLOUS;
Psychology, Univ. of Arizona, Tucson, AZ

Abstract: Empathy is as an affective response stemming from the understanding of another individual's emotional state which allows one to respond to social stimuli with appropriate pro-social behaviors. Accumulating evidence indicates that emotional contagion (a basic form of empathy) exists in rodents. Mice are capable of sharing states of fear and pain. In this study we investigated whether rats can display empathy-like behavior in response to a distressed conspecific and if this display may differ depending on whether the conspecific is a cagemate or an unknown rat. We developed a new model of empathy in which animals were trained to obtain food pellets by pressing either of two cued levers in an operant chamber. During the empathy test, one of the levers was programmed to also administer a footshock (0.5 mA, 0.5 sec) to a conspecific animal (cagemate or stranger) which was placed in full view, in an adjacent chamber. Single lever (forced-choice trial) or both levers (free-choice trial) were cued throughout the course of testing. We observed that rats behaved differently depending on the social context. Some rats chose the non-shock lever more often when they were exposed to their cagemate as compared to a stranger, indicating that the social affiliation may have played a role in guiding decision making. We also found that some animals showed a decrease in the rate of bar pressing for both levers regardless of social context, suggesting that they were responsive to the affective state of both the cagemate and the stranger. Finally, other rats did not show any change in the rate of lever pressing during the test period. Our results are consistent with previous findings that rodents are capable of exhibiting empathy-like behaviors. Furthermore, the model captures some of the natural individual differences observed in human empathy. The successful implementation of an operant rodent empathy model will allow for a wide range of new studies that could be useful for advancing our understanding of the neural basis of empathy. We currently are investigating whether the insular cortex, a region that has been associated with interoceptive and emotional processing, is involved in the expression of empathy. The results of this research could be used to guide the treatment of mental disorders in which empathy is deficient.

Title: Effects of social threat on attention and action-related decisions in a realistic social context

Authors: *E. VILAREM[1], J. L. ARMONY[2], J. GRÈZES[1];
[1]LNC, INSERM U960, IEC, ENS, PSL Univ., Paris, France; [2]Douglas Mental Hlth. Univ. Inst. and Dept. of Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: Evolutionary theories suggest that emotional displays serve a communicative function by providing information about the individuals expressing them, or the surrounding environment. Consequently, individuals who more efficiently detect and respond to these signals have a survival advantage. This evolutionary framework implies that 1) emotional signals have co-evolved with recipient's behavioral responses, and 2) that the recipient's response should reflect the social function of the perceived expression. Here, we set out to experimentally address these assumptions. In two experiments, participants faced stimuli reproducing a social environment, i.e. a waiting room with four seats, where the two middle seats are occupied by two individuals, one displaying a neutral expression and the other expressing either anger or fear of varying intensity. We selected these emotions as they both signal the presence of potential threat in the environment, but they differ in terms of their social functions and were suggested to be associated with different approach-avoidance reactions (Marsh *et al.,* 2005). In our first experiment, participants were requested to detect a "T" appearing on either of the two outer seats as we recorded their reaction times. This experiment capitalized on the knowledge that observers' current potential actions impact the appraisal of their environment, notably by enhancing the perception of relevant spatial information (Kirsch, 2015). Thus, if emotional displays are perceived as opportunities for action, and if fearful and angry expressions prompt different motor actions by conveying different signals, the observers' appraisal of space should be differently impacted. Moreover, the observer's choice of action should also be differently impacted, as tested in our second experiment, wherein participants were asked to freely decide where they want to sit by moving their cursor on the screen; here, movement kinematics and pupil dilation were recorded. Results from both experiments indicate that fearful and angry expressions induced opposite effects: anger, by signaling a potential direct threat, resulted in a better "T" discrimination in the opposite side of the scene and avoidance behaviors; in contrast, fear, by warning the observer about a danger in the environment, elicited better "T" discrimination in the same side of the scene and affiliative approach behaviors. Movement kinematics and pupil dilation further support the governance of these behavioral tendencies by distinct mechanisms. Overall, our data suggest that emotional displays promote elaboration of adapted decisions and emotion-specific motor actions.

Title: Surface deformities of right caudate nucleus are associated with verbal abuse in adolescence

Authors: ***D.-W. SHIN**, B. JEONG, S. LEE, J. YOO, T. YOON;
KAIST, Seoul, Korea, Republic of

Abstract: Introduction The specific brain structures which conduct linguistic and emotional functions are connected systematically by structural and functional circuits. Our research team will measure the thickness, surface, volume, shape, etc of specific cerebral cortex and subcortex areas in the peer verbal abuse group and the control group. Through these way, we will find the structural change, related brain networks, and clinical signification. Method We completed a Verbal Abuse Questionnaire targeting 31 high school students. Scores greater than 40 was defined as the peer verbal abuse group and scores less than 40 was defined as the control group. Thickness, surface, volume, shape, etc of cerebral cortex and subcortex were measured using Freesurfer software and FMRIB Software Library(FSL) FIRST tool form brain MRI. Collected data in peer verbal abuse group was compared with those of the control group, then we checked the specific location of significant difference between them. Additionally, we made an attempt to identify the relationship between Verbal Abuse Questionnaire scores and change of cortex / subcortex. Result The analysis of cerebral cortex area expressed that right lateral occipital surface showed a significantly positive correlation between the Verbal Abuse Questionnaire scores and cortical thickness in the peer verbal abuse group. Analysis of subcortex area showed surface deformities and reduced volume of lateral and medial right caudate nucleus in the peer verbal abuse group compared to the control group. Discussion The right lateral occipital surface functions as recognizing subjects from visual information. The thickness of the right lateral occipital surface decreases under conditions of posttraumatic stress disorder associated with strong visual stimulus. However, in the peer verbal abuse group, the thickness of the right lateral occipital surface could increase because of the compensative mechanism searching and avoiding the verbal abusing assailant. The right caudate nucleus in which surface deformities were detected in the peer verbal abuse group is the area which has functional connection between the

frontal and parietal lobe. Deformities of this area suggest dysfunction of front-striatal circuit charging of attention. Because the volume / shape of the caudate nucleus and the Verbal Abuse Questionnaire scores have a significant correlation, the caudate nucleus was also considered as a biomarker related to verbal abuse. We suggest that the verbal abuse could change brain network connected to the right lateral occipital cortex processing visual stimulus and caudate nucleus charging attention.

Title: Repeated and brief social defeat stress during adolescence on behavior and MAX/MYC network

Authors: ***S. CHIAVEGATTO**[1,2], C. E. AMARAL[1,2], R. B. S. SOARES[2], A. S. ALVES[1], L. ALVES-DOS-SANTOS[1,2], L. R. G. BRITTO[1], L. S. RESENDE[1,2];
[1]Biomed. Sci. Inst. - Univ. of Sao Paulo, Sao Paulo, Brazil; [2]Natl. Inst. for Developmental Psychiatry (INCT-CNPq), Psychiatry - Sch. of Med., Sao Paulo, SP, Brazil

Abstract: The MAX network comprises a group of transcription factors whose functions profoundly affect cell behavior, being mostly expressed during neurodevelopment. Inspired by its higher expression in brain regions strongly involved in emotional behaviors, our hypothesis is that this protein might be involved in the cerebral changes caused by stress early in life. Here we used the social defeat, a valuable animal model for bullying in humans to study the influence of social stress during adolescence on behavior and on the transcription factors MAX and MYC. C57BL/6 male mice aged 30 days were subjected to daily social defeat by an adult aggressor in a 30-min session for 21 days. After the first attack (up to 5 min of physical interaction), animals were separated in the cage for the remaining period (threat). At the end, adolescents were relocated to their original cages (group-housed). Behavioral tests were conducted and brains were processed for MAX and MYC expression. Following episodes of social stress, but

maintaining mice in social groups after each defeat, adolescent mice exhibit depressive-like phenotype as shown by a reduced intake towards a 2% sucrose and prolonged immobility time in the forced swim test ($p<0.05$). Molecularly, we show that repeated social defeat causes 30% increase of the transcription factor MAX in the hippocampus (HC). Higher MAX levels are found in the nucleus of most hippocampal neuronal cells. Conversely, MAX is reduced (20%; $p<0.05$) in dorsal striatum (ST), and is not differently expressed in the prefrontal cortex (PFC) of defeated mice. There is a positive correlation between MAX and MYC levels in the three brain areas of non-defeated adolescents ($p<0.05$), which is disrupted in the HC and ST by social stress ($p>0.05$). These results show that this protocol of repeated brief social defeat in adolescent male mice, associated to group-housing, may serve as an interesting animal model to study a subtype of depression dissociated from generalized (non-social) anxiety. Importantly, we show for the first time a dysregulation of MAX network of transcription factors in specific brain areas associated to social stress during adolescence.

Title: Should I stay or should I go? Telencephalic neural correlates for individual behavioral differences in fish

Authors: *M. A. VINDAS[1,2], P.-O. THÖRNQVIST[3], E. HÖGLUND[4], M. GORISSEN[5], B. DAMSGÅRD[6], T. O. NILSEN[1], S. WINBERG[3], G. FLIK[5], Ø. ØVERLI[7], L. O. E. EBBESSON[1]; [1]Uni Res. AS, Bergen, Norway; [2]Dept. of Biosci., Univ. of Oslo, Oslo, Norway; [3]Dept. of Neurosci., Uppsala Univ., Uppsala, Sweden; [4]Section for Aquaculture, Tech. Univ. of Denmark, Hirtshals, Denmark; [5]Dept. of Organismal Animal Physiol., Radboud Univ., Nijmegen, Netherlands; [6]Fac. of Biosciences, Fisheries and Economy, Univ. of Tromsø, Tromsø, Norway; [7]Dept. of Animal and Aquacultural Sci., Norwegian Univ. of Life Sci., Ås, Norway

Abstract: Consistent and correlated behavioral and physiological traits affect how individuals perceive and react to their environment. Perception and processing of salient stimuli is mainly under forebrain control. A comparison of telencephalic areas in differing individual coping styles is still lacking in fish. We selected individuals from a population by their response to increasing hypoxia levels. Fish either left to an adjacent tank (Leavers) or stayed (Stayers). We measured basal and post-stress plasma cortisol levels and conducted *in situ* hybridization for the early activity gene cFOS and brain derived neurotrophic factor (BDNF) expression. We then microdissected activated telencephalic areas: the dorsolateral (Dl; proposed hippocampus homolog), dorsomedial (Dm; proposed amygdala homolog) pallium, and the ventral part of the ventral telencephalon (Vv, proposed lateral septum homolog). We measured basal and post-stress monoamine neurochemistry and gene expression of target genes for the serotonergic and corticotropin releasing hormone (CRH) systems, as well as indicators of neural plasticity/proliferation. We also measured the same target molecules in the whole telencephalon. We found that Leavers reacted with a potentiated cortisol response to acute stress, which together with the previously characterized passive behavioral response to hypoxia, suggests a reactive coping style. Whole telencephalon analysis was limiting and sometimes misleading since possible opposite and/or specific regulation of brain areas are most often masked when pooled together in whole-brain area analysis. Leavers were characterized by higher post-stress serotonergic activity and elevated serotonin receptors and CRH binding protein (CRHBP) expression in the Dm. In the Dl, Leavers had post-stress elevated BDNF and CRH receptor 1 expression and increased BDNF expression in the Vv. Stayers displayed higher dopaminergic activity and elevated basal proliferating nuclear antigen (PCNA) expression in the Dl. Taken together our results suggest that the neurological profile of Leavers is associated with increased behavioral flexibility (active coping) to acute stress, while Stayers express a higher degree of neural plasticity under basal conditions. Elucidating individual differences in neural plasticity and behavior is an important tool in understanding vulnerability to disease and may help elucidate target systems in neuropsychological disorders, such as anxiety and depression. Title: Brain loci relating to the thirst reception in an amphibious teleost, mudskipper

Authors: *S. HAMASAKI[1], Y. FURUKAWA[1], K. UEMATSU[1], M. YOSHIDA[1], T. MUKUDA[1,2];
[1]Hiroshima Univ., Higashi-Hiroshima, Japan; [2]Tottori Univ., Yonago, Japan

Abstract: Terrestrial vertebrates including human perceive thirst and then follow water drinking, to avoid dehydration. Thirst is induced when dipsogenic hormones in systemic circulation act on some circumventricular organs (CVOs), which lack the blood-brain barrier (BBB) in the brain. In teleosts, meanwhile, water intake is thought to be completed only by swallowing reflex in response to dehydration without thirst reception. Thus, thirst reception seems to be a novel and essential sense acquired during an adaptation to land from water in the vertebrate evolution. Mudskippers, amphibious teleosts in brackish water, prefer land to water, showing a long-hour staying on land during the day. However, they go back to water transiently to supply water and electrolytes which have been gradually lost on lands. Because this would be voluntary behavior induced by thirst reception, mudskippers are suitable models to examine functional acquisition of thirst reception in the vertebrate evolution. In this study we searched for the thirst-related brain loci in the mudskippers. To identify the CVOs in the forebrain, mudskippers were intraperitoneally injected with Evans blue dye or sulfo-NHS-biotin, which immediately bind to systemic proteins such as albumin. We found an extravasation of the bound complexes, which cannot pass through the BBB, in the anteroventral third ventricular walls (AV3V) in the preoptic area. Further, an immunohistochemistry for tyrosine hydroxylase and a low vacuum scanning electron microscopic observation revealed that the AV3V contains neurons, which are identified as the anterior part of the parvicellular preoptic nucleus (PPa). To clarify whether the PPa is activated following to osmotic change, salinity of the habitable water was increased from 11 PSU (isotonic) up to 35 PSU (hypertonic). Three hours after exposing in the hypertonic water, water content of mudskipper body has been decreased significantly compared to controls (76.9% in hypertonic, 78.0% in isotonic, $P < 0.01$), indicating that the mudskippers dehydrated in this condition. The number of activated cells in the PPa of the dehydrated mudskippers, identified by c-Fos immunohistochemically, have shown ca. 1.5-fold increase compared to controls ($P < 0.01$). These suggest that the PPa of the mudskippers are activated following to dehydration induced by hyperosmotic exposure. Taken together, the AV3V including the PPa is likely to be a candidate of the ‘thirst center' in the mudskipper brain.

Title: Intracerebroventricular administration of thyrotropin-releasing hormone (TRH) suppresses water intake without affecting feed consumption in the neonatal chicks

Authors: *S.-I. KAWAKAMI, Y. HAYASHI;
Hiroshima Univ. Grad. Sch. of Biosphere Sci., Hiroshima, Japan

Abstract: Exposure to high environmental temperature is known to negatively affect feeding behavior of animals, the brain mechanisms regulating heat stress-induced feeding suppression remain unknown. Thyrotropin-releasing hormone (TRH) is a neuroendocrine tripeptide which is mainly synthesized in the hypothalamus and regulates thermogenesis in the hypothalamus-pituitary-thyroid axis, but it has not been known whether TRH affect feed and/or water intake in the avian brain. Therefore, the aim of the present study was to examine the effect of intracerebroventricular (ICV) administration of TRH or its antagonist (chlordiazepoxide) on feed and water intake of neonatal chicks. The mail layer chicks (5-day-old) were fixed in a headholder that has a fitting pinhole for ICV injection and the solutions (10 μl) were administered free-hand through the pinhole using a microsyringe, according to the procedure of Davis et al. (1979). Feed and water intake were measured at 30, 60 and 120 min after the treatment. In the first trial, chicks with free access to feed and water were ICV injected with one of four doses (0, 12.5, 25 or 50 nmol) of TRH. In the second trial, with free access to water but being deprived of feed for 3 h, chicks were ICV injected with TRH and refed. In the third trial, after being deprived of both feed and water for 3 h, chicks were ICV injected with TRH and rehydrated. In the fourth trial, chicks with free access to feed and water were ICV injected with one of four doses (0, 0.15, 1.5 or 15 nmol) of chlordiazepoxide. In the first, second and third trials, ICV administration of TRH significantly inhibited cumulative water consumption at all doses in layer chicks when compared with vehicle ($P<0.05$). Cumulative feed consumption was unaffected by TRH administration in feed-deprived chicks, but significantly increased in chicks fed ad libitum only at the dose of 50 nmol after 120 min of TRH administration. In the fourth trial, TRH antagonist, chlordiazepoxide, increased cumulative water consumption at the dose of 15 nmol after 60 min of ICV administration, but did not affect cumulative feed consumption in layer chicks. These data suggest that TRH mainly plays an essential role in the control of water intake, not of feed intake, in the brain of neonatal chicks.

Title: CO (carbon monoxide) blockade has different effects on 24h and 48h dehydration-induced hormone secretion and progressive dehydration induces distinct HO-1 (hemeoxygenase type 1) and nNOS (neuronal nitric oxide synthase) transcription patterns

Authors: *J. B. LIMA[1], F. LUCIO-OLIVEIRA[2], R. COLETTI[1], F. M. V. VECHIATO[1], L. L. K. ELIAS[1], J. ANTUNES-RODRIGUES[1];
[1]Physiol., Univ. of São Paulo, Ribeirao Preto, Brazil; [2]Federal Inst. of Education, Sci. and Technol. of Southern Minas Gerais, Muzambinho, Brazil

Abstract: Recently it has been reported evidences of the gaseous molecule carbon monoxide modulation on neuroendocrine and other homeostatic systems. Data from literature have indicated CO as a fine modulator of neuroendocrine response to challenges which disrupt hydrosaline equilibrium such as water deprivation (WD) and salt loading and besides CO system could interact with NO system in these situations. The aim of this present study is to evaluate whether CO blockage in progressive WD leads to different patterns of hormonal secretion and if different times of WD induce distinct HO-1, HO-2 and nNOS transcription patterns. To that, 250g Wistar male rats were submitted to 24h, 48h and 72h of dehydration with free access to chow, then were euthanized and the hypothalamic supraoptic nuclei collected; or, after dehydration time (24h or 48h), they were icv injected with HO inhibitor (ZnDPBG, 200 nmol) or vehicle (Na2CO3, 50 mM), were euthanized after 30 min and, then, the trunk blood collected. We observed that in 24h dehydration only nNOS mRNA level was increased while in 48h WD both HO-1 and nNOS were raised ($F(3, 15) = 7.7$, $p<0.01$; $F(3, 15) = 18.9$, $p<0.0001$, respectively), in 72h the same pattern of 48h WD was observed, the HO-2 mRNA level was not affected by these conditions. Also, we demonstrated that in basal condition (euhydrated animals) the inhibition of central CO formation increased only corticosterone (CORT) plasma concentration with no effect on vasopressin (AVP) and oxytocin (OT) plasma levels, while ZnDPBG injection reverted the 24h WD-induced AVP and OT secretion increase with no effect

on CORT level. Whereas the inhibition of hemeoxigenase reversed 48h WD-induced AVP, OT and CORT secretion increase ($F(2, 33) = 5.0$, $p<0.05$; $F(2, 37) = 3.7$, $p<0.05$; $F(2, 33) = 19.7$, $p<0.0001$, respectively). Together these data suggest that the same manipulation of central CO content can affect differently the neuroendocrine system depending on the hydration state of the animal, so the CO effects could act in time-dependent manner in this experimental protocol.

Title: Activities of hypothalamic nitric oxide synthase (NOS) and cystathionine beta-synthase/3-mercaptopyruvate sulfurtransferase (CBS/3MST) are decreased by NO and H2S in hyperosmolality *in vitro*

Authors: *R. COLETTI, J. B. M. LIMA, F. M. V. VECHIATO, G. ALMEIDA-PEREIRA, F. LUCIO-OLIVEIRA, L. L. K. ELIAS, J. ANTUNES-RODRIGUES;
Physiol., Sch. of Med. of Ribeirao Preto/Usp, Ribeirao Preto, Brazil

Abstract: NO and H2S are gaseous molecules produced in the central nervous system by NOS and CBS/3MST systems respectively. It is already known that water deprivation increases NO and H2S production in the hypothalamus, which, in turn, act inhibiting and increasing vasopressin (AVP) and oxytocin (OT) secretion respectively; additionally, it has already been demonstrated *in vivo* exogenous H2S decreases hypothalamic nitrate content, a NO metabolite, which is typically found increased in response to extracellular hyperosmolality. Nevertheless, little has been shown about NO and H2S actions on their own enzymatic systems. Due to it, we aimed to evaluate *in vitro* NOS and CBS/3MST activities in extracellular hyper- or isotonicity, in the presence or absence of NO and H2S donors. To that, male Wistar rats' (270-300g) medial basal hypothalami (MBH) were collected and kept in isotonic (280 mOsm/Kg H2O) oxygenated

Krebs-Ringer bicarbonate buffer (KRBG) for pre-incubation (37°C, 1L/min carbogenic mixture, 60 min). Then, medium was replaced by new hypertonic (340 mOsm/Kg H2O) or isotonic KRBG, with or without donors of NO (sodium nitroprusside, SNP; 150, 300, 600 μM) or H2S (sodium sulfide, Na2S; 0.1, 1, 10 mM), from which samples were collected for AVP and OT radioimmunoassay. Afterwards, MBH were submitted to specific assays of enzymatic activity in which NOS activity was measured by 14C-citrulline generation from L-14C-arginine and CBS/3MST activity was assessed by sulfides formation from L-cysteine (both corrected by total protein amount). We observed in hypertonicity that tissues exposure to SNP effectively decreased AVP ($F_{3,34} = 3.3$; $p < .05$) and OT ($F_{3,37} = 4,3$; $p < .05$) release at the concentration of 600 μM, besides reducing NOS activity ($F_{3,27} = 9.6$; $p < .001$) at 150, 300 and 600 μM. Similarly, Na2S reduced CBS/3MST activity ($F_{3,15} = 5.9$; $p < .01$) at every concentration tested (0.1, 1, 10 m); however, it increased AVP ($F_{3,26} = 15.4$; $p < .0001$) release at 0.1, 1 and 10 mM, and OT ($F_{3,28} = 4.3$; $p < .05$) at 10 mM only. These data indicate that, although NO inhibits AVP and OT release and H2S stimulates the release of both hormones, both NO and H2S perform similar control by negative feedback on their own enzymatic systems in the condition of extracellular hyperosmolality.

Title: Type-1 cannabinoid receptor agonist decreases hypothalamic and neurohypophyseal hormonal release in response to hyperosmolality *in vitro*

Authors: ***F. M. VECHIATO**[1], R. COLETTI[1], S. G. RUGINSK[2], J. B. M. LIMA[1], L. L. K. ELIAS[1], J. ANTUNES-RODRIGUES[1];

[1]Physiol., Univ. of São Paulo/ Sch. of Med. of Rib, Ribeirao Preto, Brazil; [2]Physiol., Federal Univ. of Alfenas, Alfenas, Brazil

Abstract: Vasopressin (AVP), oxytocin (OT) and atrial natriuretic peptide (ANP) released by the hypothalamus and AVP and OT by neurohypophysis (NH) play important roles in the maintenance of body fluid homoeostasis. The endocannabinoid (ECB) system, mainly the type-1 cannabinoid receptor (CB1R), has also been considered a potential modulator of hydromineral balance. However, the effect of CB1Rs on hyperosmolality-induced hormone release has not been yet well elucidated. Objectives: This study aimed to evaluate the effects of ACEA, a CB1R selective agonist, on AVP, OT and ANP release by the medial basal hypothalamus (MBH) and NH in response to hyperosmolality. Methods and Results: Adult male Wistar rats were euthanized by decapitation, the brain quickly removed and the MBH and NH collected and pre-incubated in 0.5 mL of cold KRBG (Krebs-Ringer bicarbonate buffer) in a Dubnoff shaker (50 cycles per min) at 37°C for 60 min in an atmosphere of 95% O2 and 5% CO2. The medium was replaced with fresh KRBG medium (280 or 340 mOsm/Kg H2O, the latter made by the addition of mannitol or NaCl) containing or not ACEA (0.1, 1.0 or 10 μM). Exposure of MBH and NH to the hyperosmotic medium, regardless of whether hyperosmolality was induced by mannitol or NaCl, resulted in a significant increase in AVP, OT and ANP release. The incubation with ACEA under basal conditions produced no effect on hormone release. However, ACEA promoted a dose-dependent decrease on AVP, OT and ANP release by the MBH and NH under mannitol-induced hyperosmolality. The lowest dose of ACEA that decreased the release of all hormones tested was 10 μM. Therefore, we investigated whether this effect was dependent on sodium extracellular concentrations. Interestingly, ACEA also decreased hormone release by the MBH and NH induced by hyperosmotic stimulus performed with NaCl. Conclusion: Our data showed for the first time that ACEA reduced osmolality-induced AVP, OT and ANP release by the MBH and AVP and OT by NH, regardless of sodium extracellular concentrations.

Title: TRPV channel regulation of supraoptic nucleus neuron activity in lactation

Authors: *C. H. BROWN, Z. JAQUIERY, G. T. BOUWER, R. A. AUGUSTINE;
Univ. Otago, Dunedin, New Zealand

Abstract: Vasopressin promotes water retention by the kidney. Vasopressin secretion is inhibited by reduced plasma osmolality, as well as by increased plasma volume. During lactation, plasma osmolality is reduced and plasma volume is increased but circulating vasopressin is not decreased. Vasopressin release from the posterior pituitary gland is triggered by action potential firing of magnocellular neurosecretory neurons that are mainly located in the hypothalamic supraoptic nucleus and paraventricular nucleus. Vasopressin neuron activity is increased by TRPV channels that are activated by acute increases extracellular osmolality. Here, we tested whether TRPV channels contribute to the spontaneous activity of supraoptic nucleus vasopressin neurons in virgin and lactating rats by microdialysis administration of the TRPV channel blocker, ruthenium red, into the supraoptic nucleus of anaesthetised rats during extracellular single unit recording of vasopressin neuron firing rate. In virgin rats, ruthenium red reduced the firing rate of vasopressin neurons ($P < 0.01$; $n = 9$), but not oxytocin neurons ($P = 0.65$; $n = 5$). Ruthenium red inhibited the firing rate of vasopressin neurons in lactating rats ($n = 7$) to similar degree to that evident in virgin rats ($P = 0.97$). Hence, it appears that the *in vivo* spontaneous activity of vasopressin neurons, but not oxytocin neurons, is driven, in part, by TRPV channel activity and that this intrinsic osmotic drive remains during lactation despite the decreased plasma osmolality evident during lactation.

Title: Sodium intake induced by gabaergic activation in the lateral parabrachial nucleus depends on opioid mechanisms of the central nucleus of amygdala

Authors: G. M. F. ANDRADE-FRANZÉ, *C. A. ANDRADE, S. GASPARINI, L. A. DE LUCA JR., P. M. DE PAULA, D. S. A. COLOMBARI, E. COLOMBARI, J. V. MENANI; Sch. of Dent. - FOAr - UNESP, Araraquara, Brazil

Abstract: The lateral parabrachial nucleus (LPBN) and the central nucleus of the amygdala (CeA) are important central areas involved in the control of sodium appetite. GABAA receptor activation with bilateral injections of muscimol into the LPBN induces 0.3 M NaCl intake in normohydrated rats, an effect abolished by the deactivation of CeA neuronal activity, suggesting that CeA facilitatory mechanisms are important for sodium intake induced by muscimol into the LPBN. The activation of μ opioid receptors in the CeA facilitates 0.3 M NaCl induced by water deprivation or by fluid depletion. In the present study, we investigated the effects of bilateral injections of naloxone (opioid receptor antagonist) into the CeA on water and 0.3 M NaCl intake induced by muscimol injections into the LPBN in normohydrated rats or by sodium depletion (treatment with the diuretic furosemide subcutaneously followed by 24 h of sodium deficient diet). Male Holtzman rats (n = 07-08/group) with stainless steel cannulas implanted bilaterally in the CeA and in the LPBN were used. Bilateral injections of naloxone (40 μg/0.2 μl) into the CeA completely abolished 0.3 M NaCl intake (0.7 ± 0.3 ml/4 h, vs. saline into the CeA: 29.4 ± 2.7 ml/4 h) and water intake (0.3 ± 0.1 ml/4 h, vs. saline into the CeA: 15.0 ± 2.4 ml/4 h) induced by muscimol (0.5 nmol/0.2 μl) into the LPBN. However, naloxone into the CeA did not significantly change sodium depletion-induced 0.3 M NaCl intake (7.4 ± 1.8, vs. saline into the CeA: 13.2 ± 2.0) or water intake (0.2 ± 0.1, vs. saline into the CeA: 1.3 ± 0.6). The present results suggest that the activation of the opioid mechanisms in the CeA is essential for water and hypertonic NaCl intake induced by the blockade of the inhibitory mechanisms with injections of muscimol into the LPBN. Title: Importance of cholinergic and angiotensinergic mechanisms of the subfornical organ for water and sodium intake by hyperosmotic rats treated with moxonidine into the lateral parabrachial nucleus

Authors: *C. F. RONCARI, R. B. DAVID, P. M. DE PAULA, D. S. A. COLOMBARI, L. A. DE LUCA JR., E. COLOMBARI, C. A. F. ANDRADE, J. V. MENANI;
Dept Physiol. and Pathol., UNESP, Araraquara, Brazil

Abstract: Central facilitatory and inhibitory mechanisms are involved in the control of water and sodium intake. Important inhibitory mechanisms for the control of water and sodium intake are modulated by the lateral parabrachial nucleus (LPBN). It has been previously demonstrated that plasma hyperosmolarity, a classic dipsogenic stimulus, can also facilitate sodium intake if the inhibitory mechanisms are deactivated by the injections of moxonidine (α2-adrenoceptor/imidazoline receptor agonist) into the LPBN. Central cholinergic and angiotensinergic mechanisms are involved in the responses induced by plasma hyperosmolarity. The subfornical organ (SFO) is an important forebrain site involved in the control of water and sodium intake. Therefore, in the present study, we investigated whether angiotensinergic and cholinergic mechanisms of the subfornical organ (SFO) are involved on water and 0.3 M NaCl intake by hyperosmotic rats treated with moxonidine into the LPBN. Male Holtzman rats (290-310 g, n = 8) with stainless steel guide-cannulas implanted into the SFO and bilaterally into the LPBN were used. Rats received an intragastric (ig) load of 2 M NaCl (2 ml) and injection of saline, atropine (muscarinic cholinergic antagonist, 2 nmol/0.1 μl) or losartan (AT1 receptor antagonist, 1 μg/0.1 μl) into the SFO, 45 minutes before bilateral injections of vehicle or moxonidine (0.5 nmol/0.2 μl) into the LPBN. Water and 0.3 M NaCl intake was measured for 2 h starting 15 min after LPBN injections. Hyperosmotic rats that received bilateral injections of moxonidine into the LPBN combined with injection of saline into the SFO ingested a significant amount of water (15.1 ± 3.6 ml/2 h, vs. vehicle: 6.3 ± 1.6 ml/2 h) and 0.3 M NaCl (21.4 ± 4.4 ml/2 h, vs. vehicle: 0.7 ± 0.4 ml/2 h). Atropine or losartan injected into the SFO reduced the ingestion of water (2.1 ± 0.9 ml/2 h and 2.5 ± 1.1 ml/2 h, respectively) and 0.3 M NaCl intake (5.0 ± 2.8 ml/2 h and 3.3 ± 2.0 ml/2 h, respectively) in hyperosmotic rats treated with moxonidine injected into the LPBN. The results suggest the involvement of cholinergic and angiotensinergic mechanisms of the SFO on water and sodium intake by hyperosmotic rats treated with moxonidine injected into the LPBN.

Title: Mechanism of clock-dependent activation of thirst neurons in rat

Authors: *C. GIZOWSKI, C. W. BOURQUE;
Res. Inst. of the MUHC, Montreal, QC, Canada

Abstract: Under normal conditions, the sensation of thirst arises when osmosensitive “Thirst” neurons in the OVLT (Organum Vasculosum Lamina Terminalis) become electrically excited by hyperosmolality or hyperthermia, and relay this information to the rostral anterior cingulate cortex. We have shown that mice display a major peak of water intake just prior to sleep, which is independent of increases in core body temperature and plasma osmolality. Since the electrical activity of clock neurons in the Suprachiasmatic Nucleus (SCN) is rising during the corresponding period, we hypothesize that these neurons can mediate an increase in the electrical activity of Thirst neurons in the OVLT. We have previously shown whole-cell current clamp recordings of rat and mouse OVLT neurons that display a prolonged depolarization and excitation in response to repetitive electrical stimulation of the SCN (30s; 10Hz) in slice. Furthermore, we have established that this response is mediated by vasopressin (VP) via the metabotropic V1a receptor. The aim of the present study is to investigate the ionic basis of these events in OVLT neurons, using the patch clamp technique in whole-cell voltage clamp configuration. When tested under voltage clamp, repetitive stimulation of the SCN induced the appearance of a long-lasting inward current which could return to baseline after 20-25 minutes. The average amplitude of the current measured at a holding potential of -50 mV was -5.66±1.68 pA (p=0.008; n=10). Current voltage (I-V) analysis using voltage ramps revealed that the SCN-induced current displayed a reversal potential (Erev) of -24.57 ± 3.41 mV, which was associated with a mean increase in slope conductance, measured near -40 mV, of 0.22±0.04 nS in OVLT neurons (p=0.0006; n=10). This mean increase in slope conductance is significantly attenuated by bath application of SR-45059 (10 μM; selective VP V1a receptor antagonist; 0.05±0.05 nS; p=0.026; n=10). The Erev is unaffected in cells recorded using pipettes containing cesium instead of potassium (140 mM), or varying concentrations of chloride (155 mM or 4 mM). These results indicate the depolarization of OVLT neurons induced by stimulation of the SCN is mediated by the activation of a non-selective cation conductance.

Title: Muscimol injected into the lateral parabrachial nucleus increases potassium chloride intake in the rat

Authors: *J. C. CALLERA[1], L. A. DE LUCA JR[2], J. V. MENANI[2];
[1]Sao Paulo State Univ., Aracatuba, Brazil; [2]Physiol. and Pathology, Sao Paulo State Univ., Araraquara, SP, Brazil

Abstract: We previously demonstrated that the blockade of the inhibitory mechanisms with bilateral injections of muscimol, GABAA receptor agonist, into the lateral parabrachial nucleus (LPBN) results in strong ingestion of water and different mineral solutions containing sodium (0.3 M NaCl or 0.3 M NaHCO3) in a two-bottle test. In the present study, we investigated if muscimol injections into the LPBN would modify the ingestion of other mineral solution (potassium chloride, KCl) in normohydrated, in cell-dehydrated rats by an intragastric load of 2 M NaCl (IG 2 M NaCl) or in rats with sodium depletion (treatment with the diuretic furosemide subcutaneously + sodium deficient food for 24 h). Male adult Wistar rats with bilateral stainless steel guide-cannulas implanted in the LPBN were used (n=5-6/group). Deionized water and 0.3 M KCl intake was measured in two-bottle tests at every 30 min during 240 min, starting 15 min after bilateral injections of muscimol (0.5 nmol/0.2 µl) or saline into the LPBN. Bilateral injections of muscimol into the LPBN increased 0.3 M KCl intake in normohydrated rats (5.1 ± 1.4, vs. saline: 0.1 ± 0.1 ml/240 min), in rats treated with IG 2 M NaCl (20.6 ± 2.7, vs. saline: 1.0 ± 0.6 ml/240 min) and in sodium-depleted rats (8.3 ± 2.9, vs. saline: 0.5 ± 0.1 ml/240 min). Muscimol into the LPBN also increased water intake in normohydrated rats (8.7 ± 4.5, vs. saline: 0.4 ± 0.2 ml/240 min) and in sodium-depleted rats (7.5 ± 3.6, vs. saline: 1.9 ± 0.8 ml/240 min), however, muscimol reduced water intake in the first 150 min of test in rats treated with IG 2 M NaCl (4.9 ± 1.9, vs. saline: 11.2 ± 1.0 ml/150 min). Water and 0.3 M KCl intake was not modified by injections of methysergide (serotonergic receptor antagonist, 4 µg/0.2 µl) into the LPBN. These data show that besides sodium and water intake, muscimol injections into the LPBN also increase 0.3 M KCl intake in normohydrated, cell-dehydrated and sodium depleted rats, suggesting that the activation of GABAA receptors in the LPBN releases the ingestion of different mineral solutions.

Title: Sodium intake induced by acute injection of aldosterone into the 4th ventricle in rats treated with moxonidine into the lateral parabrachial nucleus

Authors: ***S. GASPARINI**, P. A. NASCIMENTO, G. F. LEITE, M. R. MELO, J. V. MENANI, E. COLOMBARI;
Sao Paulo State University. Dep. of Physiol. and Pathology, Araraquara, Brazil

Abstract: Chronic infusion of low dose of aldosterone into the 4th ventricle (4th V) induces robust daily sodium intake, whereas acute injection of aldosterone into the 4th V usually produces no sodium intake. The blockade of the inhibitory mechanisms with bilateral injections of moxonidine (alpha2 adrenergic/imidazoline agonist) into the lateral parabrachial nucleus (LPBN) increases sodium intake induced by different stimuli like central injection of angiotensin II or chronic treatment with deoxycorticosterone. In the present study, we investigated the ingestion of 1.8% NaCl and water in rats treated with acute injections of aldosterone into the 4th V combined with moxonidine into the LPBN. Male Holtzman rats with stainless steel cannulas implanted in the 4th V and bilaterally in the LPBN were used. Rats received two injections of aldosterone (250 ng/2 µl each) or vehicle into the 4th V with one hour interval. Fifteen minutes before the second injection into the 4th V, moxonidine (0.5 nmol/0.2 µl) or vehicle was bilaterally injected into the LPBN. Burettes containing water and 1.8% NaCl were offered to the rats immediately after the second injection into the 4th V. Aldosterone into the 4th V combined with moxonidine into the LPBN induced strong ingestion of 0.3 M NaCl in the next two hours (17.6 ± 3.7, vs. vehicle 4th V + vehicle LPBN: 0.5 ± 0.5 ml/2 h) and also water intake (6.8 ± 2.1, vs. vehicle 4th V + vehicle LPBN: 0.4 ± 0.4 ml/2 h). These data suggest that the inhibitory mechanisms of the LPBN act against the facilitation of sodium intake produced by aldosterone

acutely injected into the 4th V restraining sodium intake in this condition, which is probably not the same in rats treated with chronic infusion of aldosterone into the 4th V.

Title: Effects of selective beta 1- and beta 2- adrenergic receptor activation on salt appetite of rats

Authors: *R. L. THUNHORST[1,2], B. XUE[1,2], T. BELTZ[1], A. K. JOHNSON[1,2,3,4];
[1]Dept Psychology, [2]Cardiovasc. Ctr., [3]Hlth. and Human Physiol., [4]Pharmacol., Univ. of Iowa, Iowa City, IA

Abstract: Isoproterenol is a mixed β1-, β2-adrenergic receptor agonist that causes hypotension, renin secretion and water drinking upon systemic administration. We previously have shown that isoproterenol inhibits the salt appetite of rats. We extended this work to examine the roles of receptor subtypes for this effect. Animals received either 24-hr of sodium depletion, acute diuresis/natriuresis with furosemide or daily injections of DOCA (5 mg/kg bw). Just prior to fluid access, we administered isoproterenol (30 μg/kg, sc) to simultaneously activate β1- and β2-adrenergic receptors, salbutamol (150 μg/kg) to selectively activate β2-adrenergic receptors, and the combination of isoproterenol and the β2-adrenergic receptor antagonist ICI 118,551 (1 mg/kg) to stimulate only β1-adrenergic receptors. Both isoproterenol and salbutamol significantly ($P < .05$) inhibited salt appetite after 24-hr of sodium depletion while the combination of isoproterenol with ICI compound had no effect. Both isoproterenol and salbutamol significantly ($P < .05$) increased thirst acutely after water and sodium depletion with furosemide (a time when animals normally ingest only water) while selective activation of β1 receptors did not. Lastly, selective activation of β2 receptors significantly ($P < .05$) inhibited salt appetite in response to daily mineralocorticoid treatment with DOCA while selective activation

of β1 receptors significantly (P <.05) increased DOCA-induced salt appetite. Therefore, selective activation of β2-adrenergic receptors was consistently associated with decreased salt appetite and increased thirst, while selective activation of β1-adrenergic receptors was associated with increased mineralocorticoid-induced salt appetite.

Title: Sugar consumption by male offspring of rats that consumed sugared water during pregnancy and lactation affects the renal expression of aquaporin 2 in the adulthood

Authors: *V. VELAZQUEZ[1], L. NICOLÁS[2], I. SOTO[3], F. CASTELÁN[2], J. RODRÍGUEZ[2]; [1]Univ. Autonoma De Tlaxcala, tlaxcala, Mexico; [2]Univ. Autonoma De Tlaxcala, Tlaxcala, Mexico; [3]Univ. Veracruzana, Veracruz, Mexico

Abstract: The physiology of the urinary tract achieves the elimination of toxic substances from the organism, particularly in the kidneys. The several types of aquaporins differentially expressed along the kidney are highly relevant for the water transport across the renal tubules. When this process is altered, the organism can present a wide range of renal injuries. The high consumption of sugared drinks have been related with metabolic deseases, including the diabetes mellitus type 2 that is linked to renal failure. The aim of this project was to determine whether the consumption of sugared water during the pregnancy and lactation, alters the expression of the aquaporin 2 in the kidney of adult male offspring. We use females rats that were mated and divided in a control group fed with standard diet and tap water and the experimental group fed with standard diet and 5 % sucrose diluted in tap water (sugared water). At weaning, two male rats were randomly selected per litter; one of them has free access to simple water while the other has free access to the sugared water). The male rats were sacrificed at four months old and the expression of aquaporin 2 of the left kidney was estimated by immunohistochemistry. Preliminary results show an overexpression of aquaporin 2 in the group that consumed sugared water during pregnancy, lactation, and postnatal life. It seems that the consumption of sugar water, even in low concentrations, modifies the renal expression of aquaporin 2. This could be

directly related to water transport in the renal tubules altering the function of the upper urinary tract. Acknoledgements: CONACyT fellowship (Reg. 295860) to VVO.

Abstract: The effects of angiotensin (ANG) II on water and sodium, but not in sucrose, intakes are well known. So, this study investigated the effects of central injection of ANG II on sucrose intake. Therefore, male Wistar rats weighing 280-300g were anesthetized with ketamine (80 mg/kg) and xylazine (7 mg/kg) and a stainless steel cannula was implanted directed to the right lateral ventricle (LV) in the animal's brain. After five days of recovery (water and food ad libitum), 2% sucrose solution was offered to the rats (2h/day: from 2:00 p.m. to 4:00 p.m.). Water and sucrose intakes were measured. The experiments began when the volume ingested per rat during this 2 h seems to be more constant (approximately 15 days). After this period, food was removed and the rats received LV injection of 1 µL of PBS (control) or ANG II (400 ng/µL). After fifteen minutes, they had free access to two graduated burettes containing water and 2% sucrose solution. Water and 2% sucrose intakes were measured at 15, 30, 60, 90 and 120 minutes. The results are expressed as means±SEM. Two way RMANOVA and pos test

Dunnett's were used for statistical analyses. Differences were considered significant at $p<0.05$. ANG II injected into LV increased sucrose intake compared to control group (ANG II 18.2 ± 4.7 vs PBS 9.3 ± 4.2 mL/120min). No significant differences between groups were observed to water intake (ANG II 0.2 ± 0.0 vs PBS 0.2 ± 0.1 mL/120min). The results shows that, when water and sucrose were available, it was not observed the dipsogenic effect of ANG II, but a facilitation on sucrose intake.

Title: Characteristics of a consciousness disturbance in water intoxication in patients with psychoses

Authors: J. NAGAI[1], X. CAO[1], M. TAJITSU[1], A. FUKUI[1], T. YAMADA[1], Y. YAMBE[1], T. MURASE[1], *Y. SUGIMURA[2];

Abstract: Objective: Water intoxication is a type of hyponatremia that frequently occurs in patients with psychoses, the characteristics of which were the focus of the current study. Materials and Methods: Data were retrospectively collected from the medical records of 13 patients with psychoses who developed hyponatremia due to self-induced polydipsia and visited the emergency department of a medical center in Japan between 2009 and 2012. The background of the patients, mental status, serum sodium (Na+) level, and urine output were analyzed. Results: Six of 13 patients were schizophrenic and 11 of 13 patients had taken anti-psychotic medications. The serum Na+ level on admission was 113±5 mEq/L (mean±SD). Patients were treated with hypertonic or normal saline, and the serum Na+ level rose to 129±6 mEq/L after 24 h. The mean increase in the serum Na+ level after 24 h was 15±6 mEq/L, and > 12 mEq/L in 9 patients, including 4 patients in whom the serum Na+ level increased by > 20 mEq/L. The urine output was 6010±2789 mL 24 h after admission. In 7 patients, the serum Na+ level rose to > 130 mEq/L after 24 h, but 4 of the patients had not yet recovered from the consciousness disturbance. Recovery of mental status required 5 days for 1 patient; however, all patients eventually had full recovery of mental status without neurologic complications. There was a positive correlation

between urine output and increased serum Na+ level 24 h after admission (r=0.66, P=0.027). There was no significant correlation between the serum Na+ level and the extent of consciousness disturbance on admission (r=-0.34, P=0.26). There was no apparent correlation between the serum Na+ level on admission and the time required for full recovery from the consciousness disturbance (r=-0.30, P=0.31). Conclusion: Patients with water intoxication had a prolonged consciousness disturbance, even after the serum Na+ level was corrected; however, all patients had full recovery of mental status without sequelae, thus indicating that hyponatremia itself does not cause irreversible neurologic damage. These results suggest that acute water intoxication does not lead to the osmotic demyelination syndrome, even when the Na+ level autocorrects rapidly via aquaresis.

Title: Developing and leveraging cell-based clock models in clock gene discovery

Authors: *C. RAMANATHAN, A. C. LIU;
Dept. Biol., Univ. of Memphis, Memphis, TN

Abstract: In mammals, circadian clocks regulate 24 hr rhythms in most aspects of physiological and behavioral processes. The circadian clocks are present in nearly all cells in the body. Cellular oscillators from different tissue types in mammals share a similar transcriptional and translational negative feedback mechanism. At the molecular level, a dozen core clock genes have been identified that underlie the generation of the circadian rhythms. However, experimental evidence supports the existence of additional clock components or modifiers and revealed cell and tissue type-specific clock functions. These observations prompted us to develop various cell type-specific clock models, including 3T3 fibroblasts, 3T3-L1 adipocytes, and MMH-D3 hepatocytes. Each model has an integrated luciferase reporter that allows for

longitudinal luminescence recording of rhythmic reporter gene expression in high-throughput formats on 96- or 384-well plates using an off-the-shelf luminometer. RNAi-mediated knockdown of canonical clock components in these clock models displayed expected cell-autonomous circadian phenotypes based on their known function, as well as cell type-specific characteristics. We have used these cell-autonomous clock models to screen for clock modifiers including new genes and small molecules. We will present and discuss these recent findings in a greater detail.

Title: Relationship between circadian disruption and cancer: interaction between clock genes and cell cycle genes

Authors: *S. CÁRDENAS ROMERO[1,2], N. SADERI[1], O. RAMÍREZ-PLASCENCIA[1], C. ESCOBAR[2], R. SALGADO-DELGADO[1];
[1]Facultad de Ciencias, Univ. Autónoma De San Luis Potosí, San Luis Potosi, Mexico; [2]Univ. Nacional Autónoma de México, México, Mexico

Abstract: The suprachiasmatic nucleus of the hypothalamus (SCN) provides temporal order to the brain and the periphery, maintaining the oscillating structures synchronized to the light dark cycle. Several epidemiologic studies suggest that people exposed to Circadian Desynchronization (CD) due to shift-work, nocturnal work, light pollution or even jet lag, are more prone to develop certain diseases, some of which have an important inflammatory component and cancer. It has been proposed that these pathologic conditions are due to the uncoupling of the peripheral oscillators with the SCN. However, the mechanisms that link CD to

inflammation and cancer are not known, triggering the question: is there any alteration of clock genes (such as Per2 and Clock) and: a) the cell cycle genes involved in cancer development (such as c-Myc, Cyclin E, p53 and p-21?); b) the production of pro-inflammatory cytokines that are markers for cancer, such as IL-6?. To answer our question, we used male Wistar rats which were assigned to 4 groups: two of them were kept in a L/D photoperiod (12 hours light and 12 hours darkness), while the others two were kept in a L:L photoperiod (24 hours light). One of LD groups and one of the L:L groups were inoculated with 8 million of glioblastoma cancer cells (xenobiotic transplant) between the omoplates. The remaining groups were injected with vehicle. Some of the rats belonging to the last two groups were injected to LPS and IL-6 levels were measured in plasma 90 minutes after the inoculation. Results indicate that CD induced by constant light promotes a tumor growth faster in comparison with rats exposed to a normal light-dark cycle. Preliminary results about the LPS-induced inflammation, show that light is associated with an exacerbated inflammatory response. These results demonstrate that constant light exposure affects clock genes, as well as cell cycle genes and IL-6. On the base of these results, we suggest that many health problems associated with CD might be due to increased inflammatory responses, including cancer.

Title: Trpv1 desensitization disrupts circadian rhythm of clock gene expression in the suprachiasmatic nucleus and peripheral tissues

Authors: *M. O. POLETINI[1], N. A. C. HORTA[1], F. S. M. MACHADO[1], T. S. R. CARDOSO[1], M. S. B. SILVA[1], C. C. COIMBRA[1], S. P. WANNER[1], A. M. L. CASTRUCCI[2]; [1]Federal Univ. of Minas Gerais, Belo Horizonte, Brazil; [2]Univ. of São Paulo, São Paulo, Brazil

Abstract: The search for new pain management/treatment drugs leads to the discovery that TRPV1 blockade increases the internal temperature as a side effect, giving raise to the hypothesis of TRPV1 role on thermoregulation. Circadian changes of internal temperature have been proposed as universal synchronizer of the peripheral clocks without altering the central paemaker through mechanisms that is still unclear. We investigated whether the loss of a functional TRPV1 induced by desensitization disrupts the molecular clock oscillation in peripheral tissues. Rats received an injection of 20 ug/kg body weight ip of resiniferatoxin (RTX) and after five days were euthanized at zeitgeber (ZT) 0 (time of light on), ZT6, ZT12 and ZT18. The total RNA was extracted from the liver, adrenal and microdissections of the suprachiasmatic nucleus (SCN). Relative analyses of clock genes, rPer1 and rBmal1 mRNA, were performed by qPCR. The desensitization abolished the adrenal circadian profiles of rPer1 and rBmal1 expression. This was also observed in liver only for rPer1 expression, although rBmal1 was increased at ZT0. Intriguingly, in the SCN (the central clock), TRPV1 desensitization altered the circadian profile of rBmal1 expression regardless of changes on rPer1 circadian expression. We previously observed that acute blockade of TRPV1 channels decreases corticosterone plasma levels, this may be a secondary signal from peripheral clocks to the central pacemaker, since RTX induced desensitization is restricted to the abdominal cavity. Thus, TRPV1 may mediate the temperature-induced rhythm of peripheral clocks.

Title: The purinergic receptor, P2X7, mediates cell-cell synchrony and clock gene expression rhythms among SCN astrocytes

Authors: *A. C. CAMACHO[1], D. J. EARNEST[2], M. J. ZORAN[1];
[1]Biol., [2]Neurosci. and Exptl. Therapeut., Texas A&M Univ., College Station, TX

Abstract: In mammals, physiological and behavioral rhythms are coordinated by the suprachiasmatic nuclei (SCN) of the hypothalamus. Astrocytes in rat SCN release ATP in a circadian manner. In SCN cell cultures, inhibitors of purinergic signaling disrupt ATP accumulation and clock gene expression rhythms. Further, clock-defective astrocytes are unable to accumulate ATP rhythmically, further suggesting clock-control. We have previously suggested that the ATP receptor, P2X7R, mediates cell signaling and synchronization among astrocytes. Here, we tested whether specific activation of the P2X7R alters ATP accumulation and gene expression rhythms. Application of ATP (10 nM) did not impact PER2::LUC bioluminescence rhythms in mSCN cell lines, which report expression of the clock gene, period2. In contrast, activation of P2X7R with the agonist BzATP (100 μM), a drug that induces robust increases of ATP release in mSCN astrocytes, affected rhythmic PER2::LUC expression in a time dependent way. An immediate, transient alteration in PER2::LUC reporter bioluminescence occurred at all circadian times. However, a sustained increase in rhythm amplitude was only present when BzATP was applied at the peak time of ATP accumulation. Interestingly, rat SCN astrocytes also show enhanced synchronization of ATP release following ATP treatment at this peak. The P2X7R functions in conjunction with the hemichannel protein, Pannexin1 (PANX1). We used immunocytochemistry of P2X7 and PANX1 proteins in mSCN astrocytes to determine expression across circadian time. Immunostaining of both proteins was rhythmic and peaked at times consistent with maximal ATP release. Thus, ATP signaling through the P2X7 purinergic receptor regulates both ATP release and clock gene expression rhythms in SCN astrocytes, suggesting a mechanism of cell synchrony that is both mediated by this purinergic signaling and under robust clock regulation.

Title: A role for Krüppel-like factor 9 in the synchronization of peripheral circadian clocks by adrenal steroids

Authors: J. R. KNOEDLER[1], *R. J. DENVER[2];
[1]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI; [2]Univ. Michigan, Ann Arbor, MI

Abstract: In mammals, cellular circadian rhythms are maintained in part by a core transcription-translation feedback loop driven by the CLOCK/BMAL1 transcription factors. While this loop runs independently of endocrine influences in the central neural pacemaker (the suprachiasmatic nucleus of the hypothalamus [SCN]), in other parts of the nervous system and in peripheral organs it can be reset by glucocorticoids (GC). The core clock genes Per1 and Per2 are directly and rapidly upregulated by GC via direct GC receptor (GR) action. This results in resetting of circadian rhythms, and has been hypothesized to be important for synchronizing circadian rhythms in extra-SCN tissues. The zinc-finger transcription factor Krüppel-like factor 9 (Klf9), an evolutionarily conserved immediate-early GR target gene, shows circadian expression in mouse liver and human keratinocytes. To identify its genomic targets in the hippocampus we conducted RNA-seq and chromatin immunoprecipitation (ChIP) followed by deep sequencing in a mouse hippocampal cell line (HT22). We found that Klf9 acted predominantly as a repressor, with 75% of differentially regulated genes showing reduced expression. In addition, we found that Klf9 associated with several circadian genes, including Per1-3, Dbp, Tef, and Nr1d1. We therefore tested the hypothesis that Klf9 acts as a feed-forward repressor of circadian clock gene expression. Forced expression of Klf9 in HT22 cells delayed GC induction of Per1, suggesting that Klf9 may act as a feed-forward brake on Per1 induction, which we hypothesize is necessary for resetting the clock under conditions of elevated GC. Forced Klf9 expression also repressed the clock output gene Dbp. ChIP assays on HT22 cells synchronized with GC showed association of Klf9 with a Dbp intronic enhancer at a time point that coincided with high Klf9 and low Dbp mRNA, consistent with rhythmic repression of this locus by Klf9. Furthermore, this region has an evolutionarily conserved Klf binding site in close proximity to a conserved CLOCK response element, suggesting that Klf9 and CLOCK/BMAL1 may interact at this locus. Klf9 also showed rhythmic association with the promoter of the circadian cell cycle regulator Wee1 in HT22 cells, suggesting a link between GC, circadian rhythms and cell proliferation. ChIP assays showed that Klf9 associated with the Klf9 binding sites discovered in HT22 cells in mouse hippocampus *in vivo*. We are now investigating whether Klf9 mutant mice display altered circadian gene expression, behavioral rhythms, and responses to stressors. Our findings support that Klf9 is a novel link between the hypothalamo-pituitary-adrenal axis and circadian rhythms.

Title: The circadian modulation of physiology in the praying mantis: a novel insect model system

Authors: *A. E. SCHIRMER, F. R. PRETE, E. S. MANTES, W. BOGUE, A. F. URDIALES, S. A. PATEL, C. CARRION, G. M. PRETE, V. M. SKITAL;
Biol., Northeastern Illinois Univ., Chicago, IL

Abstract: Physiological processes function synergistically as a constellation of integrated, nested systems. Natural selection has shaped these systems such that they establish a dynamic equilibrium giving rise to emergent properties defining life. Understanding these relationships requires studying physiological systems across levels of analysis in sufficiently complex (but tractable) model systems. We have done so successfully using circadian rhythms and the praying mantis model system. Circadian rhythms and their effects on the behavior and physiology of insects have been well described in many common model systems. The influences of these clocks range from the modulation of whole organism behavior to the gating of ion channels in the interneurons of the brain; however, historically little has been done using the praying mantis model system. We used a multilevel experimental approach to determine to what extent circadian rhythms modulate several key physiological and behavioral parameters in the praying mantis, *Hierodula patellifera*. The experiments included chronic electroretinograms (ERG) to assess compound eye sensitivity, photographic colorimetric analyses of changes in compound eye color resulting from the migration of shielding pigments, assessment of the differences between responsiveness to prey-like, computer generated visual stimuli during periods of maximum vs. minimum compound eye sensitivity, and evaluation of temporal changes in gross locomotor

activity on a modified treadmill apparatus. Our results clearly indicate that circadian clocks modulate the target behaviors across all levels of our analyses. Further, when overlaid, graphs depicting all of these parameters peaked early in the dark or subjective dark phases of the light/dark cycle suggesting their functional synchrony. Recently, we have collected data on the patterning of respiratory related abdominal compressions in both restrained and unrestrained mantises. These data, too, suggest that respiratory patterns are synchronous with rest/activity cycles. Taken together, our data strongly suggest the existence of complex interactions between circadian clocks operating at the cellular, cellular systems, and organismal levels in this mantis. These results are an intriguing first step toward revealing the mechanisms that modulate praying mantis physiology and add a unique model system that can be utilized to better understand the organization of circadian systems in general.

Title: Knockdown of prefrontal cortex period1/period2 gene expression impairs diurnal-dependent conditioned fear extinction learning

Authors: *L. R. WOODRUFF[1], L. E. CHUN[2], N. M. VARRA[2], L. R. HINDS[3], B. GREENWOOD[4], C. MCCLUNG[5], R. L. SPENCER[3];
[1]Psychology/Neuroscience, Univ. of Colorado At Boulder, Boulder, CO; [2]Psychology and Neurosci., [3]Univ. of Colorado Boulder, Boulder, CO; [4]Univ. of Colorado Denver, Denver, CO; [5]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Circadian rhythms are highly conserved 24h fluctuations in physiology and behavior. Optimal organismal health relies on the integrity of this system. Anxiety disorders such as post-traumatic stress disorder (PTSD) are often associated with impaired circadian functioning as well as poor conditioned fear extinction learning. We have previously shown that conditioned fear extinction but not conditioned fear acquisition is modulated by both time of day and the presence

of endogenous glucocorticoids (CORT) in adult male rats. Here we examined the relationship between auditory conditioned fear extinction learning, circadian phase, and prefrontal cortex (PFC) core clock gene (Per1/2) expression. Rats maintained on a 12h light:dark cycle were trained and tested across 4 sessions (conditioned fear acquisition, extinction, extinction recall, and fear renewal) that were administered either during the rats' active (zeitgeber time 16_ZT16) or inactive (ZT4) circadian phase. One week prior to testing rats received a microinjection in the infralimbic region of the PFC of either adenoassociated virus (AAV) containing a PER1/2-specific shRNA (PER1/2 KD) construct or a scrambled sequence shRNA (SCR). Neither PER1/2 knock down nor time of day had any effect on conditioned fear acquisition. However, rats trained and tested at ZT16 extinguished conditioned fear faster than those trained and tested at ZT4, regardless of PER1/2 status. Interestingly, SCR ZT16 rats showed superior extinction recall than SCR ZT4 rats, but this superior extinction recall was absent in PER1/2 KD ZT16 rats. In addition, PER1/2 KD rats trained and tested at ZT4 exhibited high freezing levels throughout most of the extinction recall session, suggesting impaired additional extinction learning compared to the other treatment groups. During session 4 (fear renewal) PER1/2 KD ZT4 rats showed much higher freezing and thus greater fear renewal compared to all other groups of rats suggesting an inability of these rats to generalize extinction to a novel context. In general, optimal conditioned fear extinction depends on the time of training/testing as well as normal clock gene expression within the infralimbic PFC. These results emphasize the importance of incorporating a consideration of circadian effects in fear conditioning research and psychotherapy for anxiety related disorders like PTSD.

Title: Circadian clock genes are needed for normal adult neurogenesis

Authors: A. MALIK[1], R. V. KONDRATOV[2], R. J. JAMASBI[1], *M. E. GEUSZ[1];
[1]Dept. of Biol. Sci., Bowling Green State Univ., Bowling Green, OH; [2]Dept. of Biological, Geological, and Envrn. Sci., Cleveland State Univ., Cleveland, OH

Abstract: Adult neurogenesis depends on regulatory signals originating from intracellular and extracellular events. Although daily cycles of neurogenesis have been described in the dentate gyrus (DG) of the hippocampus, the role of timing signals from endogenous circadian oscillator cells during neurogenesis and their importance in learning or memory remain unclear, partly because circadian clocks outside the DG modulate hippocampal functions. Nevertheless, circadian rhythms persist in isolated cultures of hippocampal tissue. To provide a simpler preparation in which circadian oscillators can be examined in greater isolation, neurosphere cultures were prepared from the DG of knockout mice that lack a functional circadian clock and from mPer1::luc mice to identify circadian oscillations. Neurospheres were also prepared from the subventricular zone, another adult stem cell-rich region. Circadian bioluminescence rhythms were recorded in neurospheres maintained in a culture medium that induces neurogenesis but not in one that maintains the stem cell state. Although the differentiating neural stem progenitor cells (NSPCs) of spheres were rhythmic, mature neurons were extremely sparse. Because they are clearly the most abundant cells it is likely that NSPCs are functional circadian clocks generating the bioluminescence rhythm. This conclusion was also supported by immunocytochemistry for mPER1 protein that was localized to the inner, more stem cell-like neurosphere core. Neurospheres from BMAL1 knockout mice displayed unusually high differentiation into glia rather than neurons according to GFAP and NeuN expression, respectively, and very few BetaIII tubulin-positive, immature neurons were observed. The knockout neurospheres also displayed more cell death than wild-type. Neurospheres from mice lacking Cry1 and Cry2 showed significantly reduced growth. This study provides insight into how the circadian clock could be used for gating stem cell proliferation to treat neurodegenerative disorders or impaired brain functions.

Title: Characterization of diurnal core clock gene expression in forebrain glucocorticoid receptor knockout mice brains

Authors: *S. J. MORTON[1], L. E. CHUN[1], L. JACOBSON[2], L. R. HINDS[1], L. R. WOODRUFF[1], R. L. SPENCER[1];
[1]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]Ctr. for Neuropharm. and Neurosci., Albany Med. Col., Albany, NY

Abstract: Circadian rhythms are maintained through the self-regulatory, oscillatory molecular clock, which includes the core clock genes Per1, Per2, and Bmal1. Disruptions to clock gene expression have been associated with numerous mood and behavior disorders including major depression, anxiety disorders, and bipolar disorders. The molecular clock has been well-characterized in the suprachiasmatic nucleus (SCN), the master clock of the body. Many peripheral tissues and extra-SCN brain regions have also been shown to have circadian rhythms in these core clock genes, but considering that the SCN has few direct projections to these brain and body regions, the question remains how the SCN communicates to extra-SCN molecular clocks. Glucocorticoids (CORT) are a potential candidate by which the SCN signals to other brain and body regions as glucocorticoid receptors (GR) are found ubiquitously throughout the brain and body, with the notable exception of the SCN. Furthermore, CORT is released in a diurnal manner, with peak plasma levels occurring immediately upon the animal's active phase. Interestingly, there is a glucocorticoid response element (GRE) in the promoter regions of the Per1 and Per2 genes, which may be a mechanism by which CORT can induce Per1 and Per2 expression, and thereby entrain the molecular clock. We compared clock gene expression in mice that had a conditional forebrain glucocorticoid receptor knockout (FBGRKO) to GR floxed mice to determine the necessity of GRs in diurnal core clock gene expression. FBGRKO (C57BL/6 pure strain of the T29-1 founder line containing Cre+ recombinase transgene) mice have been previously well-characterized to have disruptions in GR expression in the forebrain including the hippocampus, cortex, and nucleus accumbens, while the central nucleus of the amygdala (CEA) had a 50% deletion and the paraventricular nucleus (PVN) was not affected. Mice were sacrificed under basal conditions in the light phase (AM) or dark phase (PM). *In situ* hybridization was used to measure mRNA. Our results show there is a time of day difference in the SCN and PVN for Bma1 and Per1 mRNA expression as well as for Bmal1 mRNA expression in the CA3 subregion of the hippocampus. There was no genotype difference for these brain regions. These results are expected in the SCN and PVN, as hypothalamic GRs would not be affected by the FBGRKO. The lack of evident FBGRKO effect in the CA3 may be due to the fact that GRs are not necessary for diurnal clock gene expression in this tissue. Examination of additional forebrain regions, including the prefrontal cortex, will be examined, as well as examination of Per2 mRNA expression in these mice.

Abstract: While the suprachiasmatic nucleus (SCN) is acknowledged to be the master biological clock, its influence on physiology and behavior is largely mediated via relays in the adjacent subparaventricular zone (SPZ). Most SPZ neurons are GABAergic, and the targets of the SPZ are known (Vujovic et al., JCN, in press). But the relays for specific biological functions remain poorly understood. We recently found a major input from the SPZ to the ventromedial nucleus of the hypothalamus (VMH), which has appositions onto estrogen receptor alpha (ERα) expressing neurons in the ventrolateral VMH. These VMHvl neurons have been implicated in promoting aggressive behavior by male mice. As inappropriate aggressive behavior plays an important role in psychiatric disorders, dementia, and a variety of social situations, it would be important to understand how aggression may be regulated by the circadian timing system. Here we tested the hypothesis that GABAergic transmission from the SPZ onto VMH neurons influences emotional state and gates the timing and scale of behavioral aggression across the 24-h day. Using the Cre-lox system and viral vector injections in transgenic mice, we genetically targeted and deleted VGAT, the vesicular GABA transporter, in the SPZ. This allows for the selective silencing of GABAergic transmission from these neurons *in vivo*. We then assessed levels of aggressive behavior in these mice using the resident intruder paradigm at four different time points: zeitgeber time (ZT)1, ZT7, ZT13, and ZT19 in mice on a 12:12 light-dark cycle (lights on at ZT0). We found that there is a peak of aggressiveness in male mice at ZT13, the early part of their (dark) active phase. VGAT-deletion in the SPZ substantially altered the daily pattern and overall level of aggressive behavior by increasing aggression throughout the day to levels near the peak in control mice. We are currently assessing corticosterone and sleep-wake rhythms in these mice as well, as alterations in these rhythms might also affect aggressiveness. Our data thus far suggest that the circadian timing system actively inhibits aggressiveness of male mice at

certain times of day. Manipulation of this pathway may hold promise for regulating aggressive behaviors.

Title: Diurnal variations in rhythmic clock gene expression across brain regions important for emotional control of male and female rats

Authors: ***L. E. CHUN**, L. R. WOODRUFF, S. MORTON, L. R. HINDS, R. L. SPENCER; Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: The molecular clock consists of a counter-regulatory transcription/translation cycle of positive (bmal1, clock/npas2) and negative (per1/per2, cry1/cry2) components, whose oscillatory nature consists of a 24-hour period. The molecular clock has been well-characterized in the body's master clock, the hypothalamic suprachiasmtic nucleus (SCN). Surprisingly, a limited number of studies have examined clock genes of both the positive and negative components in extra-SCN tissue. Furthermore, there has yet to be a direct comparison of basal clock gene expression in extra-SCN brain regions between female and male rodents. This comparison is warranted, as there are sex differences in circadian rhythms, as well as a greater prevalence of mood disorders associated with disruptions in clock gene expression (e.g., depression, anxiety, post-traumatic stress disorder). This study examined in male and female rats basal clock gene mRNA expression (*in situ* hybridization) of both the positive (bmal1) and negative (per1, per2) components of the molecular clock in brain regions important in emotional regulation (e.g., prefrontal cortex, hippocampus, amygdala), as well as the SCN and the hypothalamic paraventricular nucleus (PVN), the head of the HPA axis. Clock genes were examined at 4-h intervals across a 12:12h light:dark cycle. There was a significant rhythm of bmal1, per1, and per2 mRNA in the SCN, PVN, PFC, subregions of the hippocampus, and the amygdala with a 24-h period (two-way ANOVA, cosinor analysis, $p < 0.05$). Importantly, there were three distinct profiles of rhythmic clock gene mRNA acrophase relationship across the brain regions, suggesting diversity amongst molecular clocks. Furthermore, while the clock gene expression

profiles were generally similar between males and females, there were a few instances where the robustness of clock gene expression differed between the sexes (e.g., females had less robust per1 and per2 mRNA rhythms in the medial PFC, but more robust bmal1 mRNA rhythms in the CA1 and CA3 hippocampal subregions). There was also a general trend for females to be phase-delayed in nearly all brain regions for all clock genes compared to males. Additionally, females with a regular estrous cycle had altered bmal1 mRNA rhythms in the PFC compared to females that were not cycling. There results indicate that oscillatory clock gene expression is widespread throughout forebrain regions involved in emotional control, and that gonadal hormones may modulate these expression patterns.

Abstract: One of the cardinal characteristics of many mood disorders, including Major Depressive Disorder (MDD) and Bipolar Disorder (BP), is the disruption of daily rhythms in sleep and activity. Recently we discovered that a similar disruption occurs in daily rhythms of clock gene expression in the brains of individuals with MDD. To perform this analysis, we organized microarray data from high-quality post-mortem brain tissue by the time of death of the subjects. As a group, the clock gene data from non-psychiatric control subjects showed a clear daily rhythm, and the molecular “time stamp” for any particular individual matched the time that

the individual had died. In contrast, as a group the clock gene data from MDD subjects had either a dampened or non-existent rhythm, and the molecular "time stamp" for MDD individuals differed widely from the time that they had died, suggesting that the MDD subjects were internally "jet lagged" from the rest of the population. We have now extended these analyses to include individuals with BP and Schizophrenia. As a group, we find that BP subjects exhibit disrupted clock gene rhythms in the brain similar to MDD subjects, whereas the disruptions present in Schizophrenia are not as severe. We also find that these patterns hold true even after controlling for other potential confounding factors, including age and gender. This work indicates that psychiatric interventions to improve patient sleep are likely to be enhanced if they simultaneously address the presence of severe circadian disturbance.

Title: Transcriptional regulation of Neuroligin-1 by core clock transcription factors

Authors: *V. MONGRAIN[1,2], E. BÉLANGER-NELSON[1], J. BEAULIEU[3], N. CERMAKIAN[4];
[1]Ctr. for Advanced Res. in Sleep Med., Montreal, QC, Canada; [2]Neurosci., Univ. de Montréal, Montreal, QC, Canada; [3]Ctr. de Recherche de l'Institut Universitaire en Santé Mentale de Québec and Univ. Laval, Quebec, QC, Canada; [4]Douglas Mental Hlth. Univ. Inst. and McGill Univ., Montreal, QC, Canada

Abstract: Introduction: Neuroligin-1 (NLGN1) is a postsynaptic adhesion molecule regulating glutamatergic transmission and sleep. NLGN1 can be expressed in different isoforms since it can contain inserts in two splice sites (A and B). We have shown that sleep deprivation decreases

Nlgn1 expression, in particular that of the Nlgn1 transcript variant containing an insert in splice site B, and the binding of core clock transcription factors to the Nlgn1 gene. Here, we verified the contribution of core clock transcription factors to Nlgn1 expression by measuring Nlgn1 expression in Clock mutant mice and the transcriptional regulation of Nlgn1 by CLOCK/BMAL1 *in vitro*. The contribution of GSK3beta, a regulator of the clock molecular machinery, to Nlgn1 expression was also assessed. Methods: Expression of four Nlgn1 transcript variants (e.g., with insert in splice site A, without insert in splice site A, with insert in splice site B, without insert in splice site B) was measured by quantitative PCR in the forebrain of ClockΔ19/Δ19 mutant and wild-type (WT) mice, sacrificed every 6h starting at ZT2 (2h after light onset). NLGN1 protein level was also measured by Western blot at the same 4 times in Clock mutant mice. To assess the control of Nlgn1 transcription by CLOCK/BMAL1 and GSK3beta, COS-7 cells were transfected with a luciferase reporter plasmid containing Nlgn1 E-boxes. Luciferase activity was measured and normalized to β-galactosidase activity and protein level. Results: The rhythmic expression of Nlgn1 transcripts with and without insert in splice site B was inverted in Clock mutant mice, and the overall expression of the two other variants (with and without insert in splice site A) was decreased compared to WT. Daily rhythm in NLGN1 forebrain protein level was also altered in Clock mutant mice. Luciferase assays revealed that CLOCK/BMAL1 activate transcription driven by the Nlgn1 promoter (4-fold), and this activation was reduced by GSK3beta. Conclusion: Our results suggest that the sleep/wake-dependent regulation of Nlgn1 expression is clock-controlled. The specific E-boxes involved in Nlgn1 transcriptional regulation by CLOCK/BMAL1 are being characterized using site-directed mutagenesis.

Title: The characterization of sleep in mutant mice for EphA4 reveals its implication in the circadian regulation of sleep

Authors: *M. FREYBURGER[1,2], A. PIERRE[1], E. BÉLANGER-NELSON[1], V. MONGRAIN[1,2];
[1]Ctr. for advanced research in sleep medecine, Hop. Sacre Coeur Montreal, Montreal, QC, Canada; [2]Neurosci., Univ. de Montreal, Montreal, QC, Canada

Abstract: Introduction: Sleep is essential for the maintenance of organism homeostasis in mammals and many non-mammalian species. The recovery aspect of sleep seems to be linked to mechanisms controlling synaptic strength. Synapses are finely regulated by the interaction of complex pre- and postsynaptic machineries where adhesion molecules have an important regulatory role. The EphA4 receptor is an adhesion molecule that has been implicated in the regulation of synaptic function and plasticity. The aim of the study is to understand the role of EphA4 in sleep regulation and the impact of sleep deprivation [SD] on its expression. Methodology: 1) Vigilance states (wakefulness, non-rapid eye movement [REM] and REM sleep) duration was measured using electroencephalography [EEG] in mice lacking EphA4 (provided by K. Murai and bred on site). Vigilance states and spectral analysis were computed during 24h baseline and after a 6 hour SD. Ten-week-old mice from the three genotypes (n=16 wild-type [WT], 15 heterozygous [HET] and 13 homozygous mutants [KO]) were implanted with EEG electrodes. EEG was recorded during baseline [BL] and 18h of recovery sleep after 6h SD. 2) Mice from 3 genotypes (wild-type, heterozygous and homozygous EphA4 KO mice) were submitted to SD followed by qPCR and microarray measurements of gene expression in the forebrain. 3) The expression of EphA4 and its partners (EphB2, EfnB2, EfnA3, EfnA3) was measured by quantitative PCR [qPCR] after a 6h SD in 3 different mouse brain regions (cortex [CTX], hippocampus [HP], and a thalamic/hypothalamic [TH/H] region). Results: 1) During the 24h baseline, the duration of wakefulness and non-REM sleep was similar in KO, HET and WT mice. However, KO mice showed a significant reduction in REM sleep duration compared to WT especially during the light period. Spectral analysis during BL reveal a genotype-by-time interaction effect on the non-REM sleep sigma band, and specially in 10-11Hz and 11-12 Hz bins which are related to circadian regulation of sleep, but no difference in the delta band. Preliminary analyses indicate that the EEG response to SD is similar in KO and WT mice. 2) The absence of EphA4 did not significantly impact on SD-dependent increase in Bdnf, Per2, Homer1A, Fos and Arc, but alters the expression of an enzyme involves in epigenetic regulation. 3) The mRNA expression of EphA4 and its partners was not changed by SD in the CTX and in the HP. However, SD significantly increased EphA4 mRNA in the TH/H region. Discussion: These results suggest that EphA4 acts to favor REM sleep and that it could be involved in the circadian regulation of sleep.

Title: Withdrawal from chronic intermittent exposure to ethanol is associated with insomnia in a mouse model of alcohol dependence

Authors: *C. A. BLANCO-CENTURION[1], L. RALSTON[2], M. F. LOPEZ[2], H. BECKER[2], J. WOODWARD[2], P. SHIROMANI[1,3];
[2]Charleston Alcohol Res. Ctr., [1]Med. Univ. of South Carolina, Mount Pleasant, SC; [3]Ralph Johnson VAMC, Charleston, SC

Abstract: The mechanisms behind alcohol-induced insomnia are poorly understood and there is little empirical evidence whether commonly used animal models of alcohol dependence faithfully reproduce the sleep disturbances reported by human alcoholics. The rodent model of Chronic Intermittent Ethanol Exposure (CIEE) produces an escalation in alcohol consumption and withdrawal symptoms that are hallmarks of alcohol dependency in humans. Data from previous animal studies also show that a brief exposure to CIEE can lead to insomnia yet it is unknown whether longer periods of CIEE would also cause protracted insomnia. Longer period of exposure to alcohol exposure is particularly important because in humans alcohol dependence takes years to fully manifest including its effect on sleep. The goal of the present study was to study the time course of sleep/wake behaviors before, during and after repeated cycles of chronic ethanol exposure in mice. In five adult male C57BL WT mice sleep was recorded for a week and then the mice underwent four weekly cycles of CIEE. In each CIEE cycle mice were exposed to ethanol vapors for 16 hr/day for four days. Blood ethanol concentrations (BEC) were measured once in every cycle (day 3). Sleep was continuously recorded across all four cycles of CIEE including the short withdrawals and for at least two months following the last CIEE cycle. BECs averaged around 177 mg/dL across the four cycles of CIEE. During CIEE, sleep was significantly increased during the night and day. However, as early as the first short withdrawal period, mice had insomnia (34% more wake; $P<0.017$) during the lights-on phase (rest period). The insomnia was still present two weeks after the end of the last CIEE cycle (+29%; $P<0.025$). Our results indicate that withdrawal from CIEE quickly produces insomnia that remains many

days after cessation of exposure to alcohol. It supports the use of the CIEE model to identify the mechanisms responsible for the sleep disturbance associated with alcohol dependence. Because insomnia during the withdrawal from alcohol dependence is a significant risk factor for relapse, pharmacological agents that can safely alleviate the insomnia are urgently needed.

Title: Intracellular mechanisms modulating gamma band activity in the pedunculopontine nucleus

Authors: *B. R. LUSTER[1], F. J. URBANO[2], E. GARCIA-RILL[1];
[1]Univ. of Arkansas For Med. Sci., Little Rock, AR; [2]IFIBYNE-CONICET, Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: The pedunculopontine nucleus (PPN) is a component of the reticular activating system, and is most active during both waking and REM (rapid eye movement) sleep. During waking, our cognitive function is driven by high frequency beta/gamma band activity. However, REM sleep manifests similar high frequency on the cortical EEG. We are interested in determining the differences between gamma activity in waking vs REM sleep. We showed that every cell in the PPN plateaus at beta/gamma band frequencies when depolarized. Moreover, this high frequency activity is mediated by high threshold, voltage-dependent N- and P/Q-type calcium channels. We discovered that the PPN contains cell populations which can manifest gamma band frequencies through only N-type, only P/Q-type, or both N- and P/Q-type calcium channels. Other studies suggest that N-type calcium channels are modulated by the cAMP/PK pathway, which also modulates REM sleep. This study was designed to determine the intracellular mechanisms subserving cells with N-type calcium channels in the PPN. Electrical responses were recorded using whole cell patch clamp electrodes on 11-17 day old sagittal rat

brain slices. Intrinsic membrane properties of cells were recorded at 37°C perfused with oxygenated aCSF in an immersion chamber containing the synaptic blockers (SB) gabazine (GABAA antagonist), strychnine (glycine antagonist), CNQX (AMPA/Kainate receptor antagonist), and APV (NMDA receptor antagonist), and also tetrodotoxin (TTX) to block sodium channels. We found that all rat PPN cells (n=13) showed beta/gamma oscillations in the presence of SB+TTX when the membrane potential was depolarized using current ramps. PPN neurons showed beta/gamma oscillations when depolarized above -30 mV, suggesting that their origin may be spatially located beyond voltage-clamp control. In a group of cells tested (n=7), the cAMP/PK inhibitor H-89 along with the P/Q-type calcium channel blocker ω-Agatoxin-IVA combined to inhibit the presence of gamma oscillations (assumed to be N+P/Q cells) ($df=13$, $F=7.04$, $p<0.05$). In another set of cells (n=4), the presence of H-89 had no effect on gamma oscillations while ω-Agatoxin-IVA completely blocked them (assumed to be P/Q-only cells) ($df=7$, $F=0.34$, $p>0.05$). In a final set of cells (n=2), H-89 completely blocked the presence of gamma oscillations while ω-Agatoxin-IVA had no effect on them (assumed to be N-only cells). These results suggest that cells in the PPN that manifest gamma band activity through N-type calcium channels are modulated by the cAMP/PK pathway. We hypothesize that N-only cells are equivalent to "REM-on" cells *in vivo*.

Title: Sleep contributes to double-strand DNA repair in *Drosophila* melanogaster mushroom body cells

Authors: *D. B. BUSHEY[1], G. TONONI[2], C. CIRELLI[2];
[1]Psychiatry, Univ. Wisconsin-Madison, Madison, WI; [2]Dept. of Psychiatry, Univ. of Wisconsin Madison, Madison, WI

Abstract: It was recently found that double-strand DNA breaks (DSB) are induced in young adult mice during natural exploratory behavior, an effect that appears to be mediated by an increase in neuronal activity and reverts the following day (1). In recent experiments we confirmed that exploration induced DSB in mouse cortex, and found that their repair occurred if extended wake with exploration was followed by sleep but not by wake (2). Since neuronal activity increases during wake relative to sleep also in flies, here we tested whether DSB frequency is also dependent on wake time in *Drosophila* melanogaster. We used an antibody targeting phosphorylated H2AV, which accrues at DSB, and measured with confocal microscopy the DSB frequency in the mushroom body cells of flies that were mostly asleep or awake (sleep deprived) during the 12h of the dark period, when flies are usually asleep. In flies that were sleep deprived H2AV foci tended to increase compared to flies that slept over the same time period, suggesting that being awake per se can increase the occurrence of DSB, consistent with the results in mice. In a second experiment, we gamma irradiated flies to induce DSB and then tested whether sleep contributed to DSB repair. As expected, 40 min after irradiation H2AV foci were elevated in the mushroom body cells. H2AV levels returned to baseline levels in flies that were allowed to sleep during the 18 h post-irradiation, but tended to remain elevated in flies that were sleep deprived over the same time period. These results suggest that sleep deprivation impairs the DSB repair pathway.

Title: Effects of sleep and wake on astrocytes

Authors: *M. BELLESI, L. DE VIVO, G. TONONI, C. CIRELLI;
Dept. of Psychiatry, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Astrocytes can mediate neurovascular coupling, modulate neuronal excitability, and promote synaptic maturation and remodeling. All these functions are likely to be modulated by the sleep/wake cycle, because brain metabolism, neuronal activity and synaptic turnover change as a function of behavioral state. Yet, little is known about the effects of sleep and wake on

astrocytes. Here we show that sleep and wake strongly affect both astrocytic gene expression and ultrastructure in the mouse brain. Using translating ribosome affinity purification technology and microarrays (Affymetrix microarray chips; mouse 430 2.0) we find that 1.4% of all astrocytic transcripts in forebrain are state-dependent (3 groups, 6h of sleep during the day (S), 6h of spontaneous wake at night (W), and 4h of sleep deprivation (SD); 6 mice/group). Relative to W and SD, S upregulates few select genes, like Cirp and Uba1, whereas both W and SD upregulate many genes related to metabolism (Adcy10, Ppp1r3c), extracellular matrix (Sdc4, Hpse) and cytoskeleton (Trio, Gem, Synj2). Using serial block-face scanning electron microscopy (4 groups, sleep, wake, 4h sleep deprivation, 5 days of chronic sleep restriction; 3 mice/group) and tridimensional reconstruction of the ultrastructural neuropil of mouse frontal cortex (>100 spines/mouse) we then find that a few hours of wake are sufficient to bring astrocytic processes closer to the synaptic cleft, while chronic sleep restriction also extends the overall astrocytic coverage of the synapse, including at the axon/spine interface, and increases the available astrocytic surface in the neuropil. Wake-related changes likely reflect increased need for glutamate clearance, and are consistent with an overall increase in synaptic strength when sleep is prevented. The reduced astrocytic coverage during sleep, instead, may favor glutamate spillover, thus promoting neuronal synchronization during NREM sleep.

Title: Effects of ghrelin on hypothalamic tuberomammillary nucleus neurons in rats

Authors: D. SHIMA, Y. WAKABAYASHI, *J. KIM, K. NAKAJIMA;
Univ. of Toyama, Toyama, Japan

Abstract: Ghrelin is produced by stomach, other peripheral organs and brain, and acts on GH secretagogue receptors (GHS-Rs) which express in the some peripheral organs and also in some brain regions. Ghrelin has been known as a potent stimulator of growth hormone (GH) secretion and feeding. Recent study also indicates that ghrelin contributes to regulation of sleep-wakefulness, but the mechanisms are not known. Tuberomammillary nucleus (TMN), which involves histaminergic neurons that participates in induction and maintenance of arousal state, also expresses GHS-Rs. However, direct effects of ghrelin on TMN neurons are remained

unclear. Thus, we examined effects of ghrelin on TMN neurons using rat brain slice preparations and whole-cell patch clamp recording technique. Application of ghrelin depolarized TMN neurons in both absence and presence of tetrodotoxin, and the depolarization was blocked by [D-Lys3]-GHRP-6, a specific antagonist for GHS-Rs. The ghrelin-induced depolarization was accompanied by increase of membrane resistance, and decreased under high-K+ extracellular solution and/or presence of KB-R7943, an inhibitor of Na+/Ca2+ Exchanger (NCX). Furthermore, following histochemical study on the recorded neurons demonstrated that more than half of histaminergic neurons were depolarized by ghrelin. These results suggest that ghrelin depolarizes TMN histaminergic neurons postsynaptically via GHS-Rs with a dual ionic mechanism including a decrease in K+ conductance and an activation of NCX, and may contribute to the regulation of sleep-wakefulness via the excitatory effect on TMN neurons.

Title: A delimited node of lateral hypothalamic GABAergic neurons promote wakefulness

Authors: *A. VENNER[1,2], C. B. SAPER[1,2], P. M. FULLER[1,2];
[1]Dept. of Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Neurol., Harvard Med. Sch., Boston, MA

Abstract: The lateral hypothalamus (LH) has long been suggested to play a role in promoting arousal. However, the neurochemical identity of the neurons responsible has remained somewhat elusive. Whilst orexin neurons have been shown to be critical for maintenance of arousal, loss of orexinergic transmission does not decrease overall daily wake quantities per se. Additionally,

melanin-concentrating hormone (MCH) neurons promote REM sleep, rather than wakefulness. We have recently reported that activation of an overlooked population of GABAergic neurons (containing the vesicular GABA transporter, VGAT) within the LH reliably induces continuous wakefulness for several hours in the mouse. It was therefore of interest to more precisely define this population anatomically and determine to what extent it is necessary for normal arousal. To define the wake-promoting LH VGAT population more precisely, we made small microinjections of AAV-hSyn-DIO-hM3Dq-mCherry in and around the LH in Vgat-IRES-cre mice. We implanted these mice for EEG/EMG recording and recorded sleep-wake following i.p. saline and clozapine-N-oxide (CNO; the ligand for hM3Dq) injections. The region of transfected neurons was detected by immunohistochemical labelling against the fusion protein, mCherry. For each mouse, this transfected area was manually projected onto a series of standard sections and correlated with the waking phenotype following CNO injection, enabling construction of a Z-score based heat map. From this heat map, we inferred a delimited node of LH VGAT neurons responsible for mediating the waking phenotype, which comprised a region lateral to the fornix, ventral to the zona incerta, medial to the optic nerve and centered at bregma -1.7. Moreover, these neurons did not co-express orexin or MCH. To determine the extent to which this delimited node of LH VGAT neurons was necessary for normal arousal, we made bilateral microinjections of AAV-hSyn-hM4Di-mCherry (hM4Di) into our defined field of LH VGAT neurons in Vgat-IRES-cre mice. Injections of CNO at 7pm resulted in an apparent reduction of c-Fos in hM4Di+ neurons, confirming that the ligand inhibited hM4Di-containing neurons. Analysis of the EEG in these mice revealed that CNO injection increased NREM sleep by ~60% over the 3-hour post injection period, concomitant with ~15% reduction in wake. Taken together with our previous finding that activation of LH VGAT neurons strongly promotes wakefulness, the reduction in wakefulness observed upon acute inhibition of these neurons suggest that this delimited node of LH VGAT neurons may constitute a previously unrecognised, yet key circuit element, of neural networks regulating arousal.

Title: The slow-wave-sleep promoting parafacial zone counteracts the wake-promoting action of both caffeine and modafinil

Authors: *C. ANACLET, P. M. FULLER;
BIDMC Harvard, Boston, MA

Abstract: We have previously reported that acute and selective activation of GABAergic parafacial zone (PZ) neurons is sufficient to produce slow wave sleep (SWS) and cortical slow wave activity (SWA), independent of the time of day. We further showed that PZ GABAergic neurons project to and inhibit the parabrachial nucleus -> basal forebrain -> cortex pathway, which is a major wake-promoting pathway, and hence may represent a circuit substrate through which GABAergic PZ neurons trigger SWS and modulate the cortical EEG. It however remains unclear if GABAergic PZ neurons are capable of modulating (inhibiting) other wake promoting pathways and circuits. To begin to explore this possibility, we employed two wildly used psychostimulants, caffeine, an adenosine A2A receptor antagonist, and modafinil, to promote wakefulness and asked whether these compounds, known to activate multiple brains areas, could produce wakefulness when PZ GABAergic neurons are active. To test this hypothesis, we placed small bilateral injections of an adeno-associated viral (AAV) vector containing a cre-enabled excitatory receptor system [hM3Dq-AAV10] into the PZ of Vgat-ires-cre mice. As previously reported, injection of the ligand (CNO, 0.3mg/kg, IP, ZT3) produced a rapid and strong increase in SWS and cortical SWA. Also as previously reported, modafinil and caffeine alone induce wakefulness in these same mice. Co-injection of CNO, however, with either caffeine or modafinil, reversed the waking response, resulting in sleep/wake quantity similar to control (saline injection) levels. These results 1) suggest that PZ GABAergic neurons promote SWS by inhibiting not only the parabrachial nucleus but also likely other wake promoting pathways, and 2) provide additional evidence that GABAergic PZ neurons represent a key inhibitory cell population for SWS induction and maintenance.

Title: Cholinergic mechanisms in rat prefrontal cortex promote waking and inhibit sleep states

Authors: *D. PAL[1], D. C. FEDRIGON, III[2], F. ALAM[2], G. A. MASHOUR[3];
[1]Dept. of Anesthesiol., [3]Anesthesiol., [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Electroencephalographic (EEG) and behavioral arousal are associated with increased acetylcholine (ACh) levels in cortex [1]. In contrast, cortical ACh levels decrease during slow wave sleep (SWS) and general anesthesia, two states characterized by slowing EEG frequency and behavioral quiescence [1]. However, it is not known if cortical ACh plays a causal role in the EEG and behavioral state transitions. We hypothesized that cholinergic stimulation of prefrontal cortex (PFC) through nicotine (NIC) or carbachol (CARB) microinjection during SWS will cause EEG activation and increase in the time spent in waking state. Under surgical anesthesia, male Sprague Dawley rats (n=26; 300-350g, Charles River) were instrumented for sleep-wake recordings and unilateral microinjections into PFC (Bregma, anterior 3mm, lateral 0.5mm, ventral 4mm) [2]. Sleep-wake recordings were conducted after injection of either saline (VEH, vehicle control) or one of the following concentrations of cholinergic agonists: 10mM NIC (n=6), 100mM NIC (n=7), 1mM CARB (n=9) or 10mM CARB (n=4). Each rat received only one concentration of either NIC or CARB. All microinjections (200nL) were done remotely during SWS, as determined by electrophysiological and behavioral criteria. The sleep-wake recordings were continued for 4 post-injection hours. The site of injections was confirmed histologically. A t-test or Wilcoxon test was used for the comparison of the effect of the VEH with the cholinergic agonists on sleep-wake states. Compared to the VEH, CARB at 1mM caused a significant increase in wake state and a decrease in SWS during the first post-injection hour. The increase in wake state was due to an increase in the mean duration of wake epochs. There was no effect on rapid eye movement sleep (REMS). Higher concentration of CARB (10mM) produced immediate behavioral seizures. Nicotine, 10mM or 100mM, did not significantly affect the time spent in wake or SWS. However, 100mM NIC significantly decreased the time spent in REMS by reducing the number of REMS epochs. The decrease was significant only during the first post-injection hour. The latency to the onset of REMS was also reduced. Neither NIC nor CARB produced EEG activation. These data suggest that cortical ACh is not a simple correlate of wake state but contributes to the top-down modulation of sleep-wakes states by promoting waking and inhibiting sleep states. This is in contrast to the role of ACh in brainstem where it promotes REMS. Title: Nicotine promotes wakefulness via activation of wake-promoting cholinergic neurons of the basal forebrain

Authors: *A. NAIR[1,2], A. SHARMA[1], I. RICE[1,3], P. SAHOTA[1,4], R. SHARMA[1,4], S. MURUGESAN[1], M. M. THAKKAR[1,4];
[1]Harry S Truman Mem. VA Hosp., Columbia, MO; [2]Ross Univ. Sch. of Med., Portsmouth, Dominica; [4]Neurol., [3]Univ. of Missouri, Columbia, MO

Abstract: INTRODUCTION: Nicotine disrupts sleep through a yet unclear mechanism. The corticopetal basal forebrain (BF) is a major wake-promoting center in the brain. Multiple neuronal subtypes are localized in the BF, including cortically projecting cholinergic and GABAergic neurons. BF wake-promoting neurons express high levels of $\alpha 4\beta 2$ and $\alpha 7$ nicotinic acetylcholine receptors (nACHRs). We hypothesized that one mechanism by which nicotine disrupts sleep is through activation of the BF. METHODS: We used Sprague-Dawley (SD) rats as our animal model and performed three experiments. Nicotine was administered to these nocturnal animals at light onset to simulate smoking in the evening. Experiment 1 examined BF activity following systemic nicotine infusion. c-Fos was used to measure neuronal activation. SD rats were divided in two groups: Control and Nicotine. Just before light onset, nicotine (nicotine group; 0.3 mg/Kg) or saline (controls) was administered subcutaneously. The animals were left undisturbed for two hours and then euthanized to examine c-Fos expression in the BF. Experiment 2 examined the effects of nicotine on sleep. SD rats, implanted with sleep recording electrodes, were given subcutaneous nicotine at light onset. 4 doses of nicotine (0, 0.15, 0.3. 0.6 mg/Kg; randomized order of dose administration) were used to examine the dose response effect of nicotine on sleep. Experiment 3 examined the effects of nicotine on sleep in rats pretreated with a nicotine receptor blocker in the BF. SD rats, implanted with sleep recording electrodes and bilateral guide cannulas in the BF, were given mecamylamine (15 µg/500nl/side) in the BF followed by nicotine administration (0.6 mg/Kg; subcutaneously) at light onset. Rats were left undisturbed for next six hours and sleep was examined. Results: Our results suggest that: 1) systemic administration of nicotine significantly ($p<0.05$) increased activation of the BF; 2) systemic administration of nicotine significantly ($p<0.05$) and dose-dependently disrupted sleep; 3) blockade of nicotinic receptors in the BF attenuated nicotine-induced sleep disruptions. Conclusion: We conclude that nicotine induced activation of the BF may play a role in its disruption of sleep.

Title: Nicotine administration in the wake-promoting basal forebrain attenuates sleep promoting effects of alcohol

Authors: *R. SHARMA, P. SAHOTA, M. THAKKAR;
Neurol., Harry S. Truman Mem. Veterans Hosp. and Uni, Columbia, MO

Abstract: BACKGROUND: Nicotine and alcohol co-abuse is highly prevalent. However, underlying causes are unclear. It has been suggested that nicotine enhances pleasurable effects of alcohol while reducing aversive effects. Recently, we reported that nicotine acts via the basal forebrain (BF) to activate nucleus accumbens and increase alcohol consumption. Does nicotine via the BF suppress alcohol induced aversive effects? We hypothesized that nicotine may act via the BF to suppress sleep- promoting effects of alcohol. **METHODS:** To test this hypothesis, adult male Sprague-Dawley rats were implanted with sleep-recording electrodes and bilateral guides targeted toward the BF. Nicotine [75 pmol/500 nL/side] or artificial cerebrospinal fluid (ACSF; 500 nL/side) was microinjected into the BF followed by intragastric alcohol (ACSF+EtOH and NiC+EtOH groups; 3 g/Kg) or water (NiC+W and ACSF+W groups; 10 mL/Kg) administration. On completion, rats were euthanized and processed to localize injection sites in the BF. **RESULTS**: Statistical analysis revealed a significant effect of treatment on sleep-wakefulness. While rats exposed to alcohol (ACSF+EtOH) displayed strong sleep promotion, nicotine pre-treatment in the BF (NiC+EtOH) attenuated alcohol induced sleep and normalized sleep-wakefulness. **CONCLUSIONS:** Our results suggest that nicotine acts via the BF to suppress the aversive, sleep-promoting effects of alcohol further supporting the role of BF in alcohol-nicotine co-use.

Title: Melatonin promotes sleep by inhibiting orexinergic neurons in the perifornical lateral hypothalamus

Authors: A. SHARMA[1], A. NAIR[1,2], I. RICE[3], S. MURUGESAN[1], R. SHARMA[3], P. SAHOTA[3], *M. M. THAKKAR[3];

Abstract: BACKGROUND: Melatonin promotes sleep, however the mechanism is unclear. Since the perifornical hypothalamic (PF-LH) orexin system is critical for wake promotion, we asked: Does melatonin promote sleep by inhibiting orexin neurons? We used C57BL/6J mice as our animal model and designed four experiments to address this question. METHODS: Experiment 1 examined the presence of melatonin receptors on orexin neurons by double-label immunofluorescence. Experiment 2 examined the effects of melatonin on the activation of orexin neurons. Standard sterile surgical protocol was used to implant bilateral guide cannulas targeted toward the orexinergic PF-LH. Melatonin (500pmole/50 nl/side) was bilaterally infused into PF-LH at dark onset. The animals were euthanized two hour later to examine c-Fos expression (marker of neuronal activation) in orexin neurons. Experiment 3 examined the effects of bilateral PF-LH infusion of melatonin on sleep-wakefulness. Animals were implanted with bilateral guide cannulas and sleep recording electrodes. At the onset of active (dark) period, melatonin (500pmole/50 nl/side) was infused into the PF-LH and its effects on spontaneous bouts of sleep-wakefulness were examined. Experiment 4 examined the effects melatonin receptor blockade on spontaneous bouts of sleep-wakefulness. Surgical and experimental procedures used were as described in experiment 3 except at sleep (light) onset melatonin receptor antagonist, Luzindol, (10pmol/50 nL/side) was administered and its effects on sleep-wakefulness were examined. RESULTS: Orexin neurons express MT1, but not MT2 receptors. Melatonin infusion into the orexinergic PF-LH significantly ($p<0.05$) reduced the number of orexin neurons with c-Fos immunoreactivity, increased NREM sleep and reduced wakefulness during normal active period. Blockade of melatonin receptors by local infusion of Luzindol into the orexinergic PF-LH, during normal sleep period significantly ($p<0.05$) increased wakefulness. CONCLUSIONS: We

suggest that melatonin may act via the MT1 receptors to inhibit orexin neurons and promote sleep.

Abstract: Sleep deprivation (SD) is consider part of new style of live in our modern society that affect children, adolescent, adults and older people. SD is a stress agent with a negative consequences like day sleepiness, alteration in cognitive process- attention, concentration, memorize and learning. SD affects brain plasticity, mood regulation and neurogenesis. This last one issue neurogenesis is well accepted that occurs in brain throughout life in selected areas of the adult mammalian brain, mainly in the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus. Is well documented that consequences of SD at the molecular level are largely unexplored. Hippocampus is particularly region susceptible to ROS and oxidative stress

generation and one source mentioned is SD affecting cellular functions including proliferation, survival, apoptosis, motility, transcription, metabolism and differentiation. By other hand Melatonin (MEL) is an import indole released from the pineal gland, and it possesses important neurobiological actions because is a pleiotropic molecule, some roles include control of seasonal reproduction, regulation of circadian rhythms, besides is an excellent antioxidant. The aim of this work were investigate how MEL and Luzindole (antagonist MT1 and MT2 receptors) can modify MEL content at the hippocampus tissue and if has any influence over neuronal precursors. We administrated oral MEL at 10mg/kg and Luzindole I.P at 5mg/kg for 14 days before and during performance of 96 hours of REM SD by the flower pot technique. Groups were: 1. Control, 2. SD, 3. MEL+SD, 4. Luzindole +MEL+SD and Luzindole+SD. MEL was administrated daily in water consumption and Luzindole once daily at 17:30 and 30 minutes after MEL was given by oral cannula. After 96h of SD we sacrificed by decapitation and quickly we remove hippocampal tissue and stored -80°C until used for HPLC measures. For Immunofluorescence experiments animals received 2 hr. before sacrifice an single injection of BrdU(100mg/Kg) after that were deeply anesthetized (pentobarbital 100 mg/kg) and perfused transcardially with phosphate buffer followed by paraform¬aldehyde (4%). Our results suggest that mice treated with MEL shows major content of MEL in hippocampus tissue by HPLC measures, Luzindole groups shows a slight diminish content of MEL and SD group show minor concentration of MEL of all groups. To respect of neuronal precursors the group with MEL improves BrdU-U/Nestin positives cells in contrasted with SD group. Thus melatonin can be consider a neuroprotective agent against REM SD.

Title: Orexin receptor activation generates gamma band input to cholinergic and serotonergic arousal system neurons and drives an intrinsic Ca^{2+}-dependent resonance in LDT and PPT cholinergic neurons

Authors: *M. ISHIBASHI, I. GUMENCHUK, B. KANG, C. STEGER, E. LYNN, N. E. MOLINA, L. M. EISENBERG, C. S. LEONARD;
New York Med. Coll, Valhalla, NY

Abstract: The ascending arousal system, including cholinergic laterodorsal (LDT) and pedunculopontine (PPT) tegmental neurons and serotonergic dorsal raphe (DR) neurons, plays important roles in regulating wakefulness and sleep. During the waking state, the EEG shifts toward higher frequencies with synchronized intracortical gamma activity (30-60 Hz) - a process associated with high-level cognitive functions. Recently, this ascending arousal system has been proposed as a gamma wave generator, in part, because some neurons produce high-threshold, Ca^{2+}-dependent oscillations at gamma frequencies. However, it is not known whether arousal-related inputs to these neurons generate such oscillations, or whether such oscillations are ever transmitted to neuronal targets. One key input that is critical for maintaining normal wakefulness arises from orexin neurons. Orexin is well known to induce a noisy, depolarizing current in these cholinergic and serotonergic neurons. However, little is known about the frequency composition or function of this orexin-induced noise. To investigate this problem, we used whole-cell patch clamp and dynamic clamp techniques in brain slices obtained from mice expressing Cre-induced fluorescence in cholinergic LDT and PPT, and serotonergic DR neurons. After first validating reporter expression accuracy, we found that the orexin current produced significant high-frequency, including gamma band, input to both cholinergic and serotonergic neurons. We next used a dynamic clamp to add a virtual noisy orexin conductance to cholinergic neurons. This revealed an intrinsic, Ca^{2+}-dependent resonance that peaked in the theta and alpha frequency range (4 - 14 Hz) and extended up to 100 Hz in LDT and PPT cholinergic neurons. This intrinsic resonance emerged at membrane potentials near spike-threshold but below the potential necessary for generating high-threshold, Ca^{2+}-dependent oscillations at gamma frequencies. We propose that orexin current noise and the Ca^{2+} dependent resonance that peaks in the theta and alpha frequency range work synergistically to boost the encoding of high-frequency synaptic inputs into action potentials and to help ensure cholinergic neurons fire during EEG activation. This activity could reinforce thalamocortical states supporting arousal, REM sleep and intracortical gamma.

Title: Influence of SKF38393 on changes of gene profile in rat prefrontal cortex during chronic paradoxical sleep deprivation

Authors: *W. MA;
Second Military Med. Univ., Shanghai, China

Abstract: Chronic paradoxical sleep deprivation (CSD) can induce dramatic physiological and neurofunctional changes in rats, including decreased body weight, reduced learning and memory, and declined locomotor function. SKF38393, a dopamine D1 receptor agonist, can reverse the above damages. However, the mechanism of CSD syndrome and reversal role of SKF38393 remains largely unexplained. To preliminarily elucidate the mechanism of the neural dysfunction caused by CSD, in the present study we used gene chips to examine the expression profile of more than 28 000 transcripts in the prefrontal cortex (PFC). Rats were sleep deprived by modified multi-platform method for 3 weeks. Totally 208 transcripts showed differential expressions in CSD group in contrast to controls; they included transcripts coding for cell killing, immune system and metabolism. Among the 208 transcripts, 120 ones increased their expression and 88 decreased. Fourteen of them could be specifically reversed with SKF38393, including those coding for apoptosis, calcium ion pathway and MAPK pathway. Our findings in the present study indicate that long-term sleep deprivation may trigger apoptosis, stress response and changes of rhythmic regulation in the PFC, and the activation of D1 receptor by SKF38393 might ameliorate these changes via calcium ion pathway and MAPK pathway.

Title: Modafinil robustly activates phasic dopamine signaling in the striatum

Authors: M. J. BOBAK, M. W. WEBER, M. A. DOELLMAN, J. M. ATHENS, D. R. SCHUWEILER, *P. A. GARRIS;
Illinois State Univ., Normal, IL

Abstract: Modafinil (Nuvigil®) exhibits therapeutic efficacy for treating narcolepsy, work-related fatigue, and cognitive deficits. Like other psychomotor stimulants, such as amphetamine and cocaine, modafinil interacts with the dopamine transporter. However, its affinity is lower, and it is less potent in increasing tonic dopamine levels in the striatum as measured by microdialysis. Nevertheless, and also similar to other psychomotor stimulants, the ability of modafinil to increase wakefulness is abolished in dopamine transporter-knockout mice. Another potential target for modafinil is phasic dopamine signaling, which is implicated in reward learning and seeking. During phasic dopamine signaling, burst firing by dopamine neurons elicits transient dopamine signals in dopamine terminal fields. Moreover, amphetamine and cocaine robustly activate striatal dopamine transients. Here we investigated the effects of modafinil on phasic dopamine signaling in urethane-anesthetized rats with fast-scan cyclic voltammetry at a carbon-fiber microelectrode. Electrically and pharmacologically evoked phasic-like dopamine signals were assessed. As shown in Figure 1, modafinil robustly augmented the amplitude of electrically evoked phasic-like dopamine signals in dorsal and ventral striata. Increases were time- and dose-dependent and greater in the dorsal compared to ventral striatum. Electrically evoked phasic-like dopamine signals were further analyzed to assess effects of modafinil on the presynaptic mechanisms of dopamine release and uptake. This analysis demonstrated that modafinil increased dopamine release and decreased dopamine uptake. Furthermore, in the presence of the D2 dopamine antagonist, raclopride, which blocks somatodendritic dopamine autoreceptors and relieves anesthesia blunting of burst firing by dopamine neurons, modafinil elicited dopamine transients in both dorsal and ventral striata. Taken together, these results suggest that activation of phasic dopamine signaling is an important mechanism underlying the clinical efficacy of modafinil.

Title: Lithium decreases the effects of neuronal calcium sensor protein 1 on pedunculopontine neurons

Authors: *S. M. DONOFRIO[1], F. J. URBANO[2], E. E. GARCIA-RILL[1];
[1]Dept. of Neurobio. and Developmental Sci., Univ. of Arkansas For Med. Sci., Little Rock, AR;
[2]IFIBYNE-CONICET, Univ. of Buenos Aires, Buenos Aires, Argentina

Abstract: Whole-cell patch-clamp responses were recorded on 9-13 day old pups from adult timed-pregnant Sprague-Dawley rats. Slices were cut at 400 um and recorded at 370C perfused with oxygenated aCSF in an immersion chamber containing the synaptic blockers gabazine (GABAA antagonist), strychnine (glycine antagonist), 6-cyano-7-nitroquinoxaline-2,3-dione (AMPA/kainate receptor antagonist), APV (NMDA receptor antagonist), and mecamylamine (nicotinic receptor blocker), and also tetrodotoxin to block sodium channels. Our preliminary studies on a group of cells (n=5) show that NCS-1 at 1μM increased the amplitude of gamma band oscillations above control levels at 20, 25 and 30 min ($df=6$, $F=4.13$, $p<0.001$). In another group of cells (n=5) recorded with NCS-1 at 1μM, superfusion with lithium at low concentration (1 μM) reduced the effect of NCS-1 on gamma band oscillations, decreasing oscillations at 25 and 30 min ($df=6$, $F=3.93$, $p<0.007$). Lithium by itself had a blocking effect, reducing amplitude by 30 min ($df=6$, $F=5.5$, $p<0.002$). Human postmortem studies reported over expression of neuronal calcium sensor protein 1 (NCS-1) in the brains of some bipolar disorder patients. Reduced or aberrant gamma band activity has been reported in the same disorder. Bipolar disorder is also characterized by sleep dysregulation, suggesting a role for the reticular activating system (RAS). In a previous study examining the pedunculopontine nucleus (PPN), we found that NCS-1 at 1μM significantly increased the amplitude of gamma oscillations, whereas very high concentrations of NCS-1 (10μM) reduced or blocked gamma band oscillations in these

cells. Lithium been shown to effectively treat the mood disturbances seen in some bipolar disorder patients, although limited by side effects. Lithium was proposed to act by inhibiting the interaction between NCS-1 and inositol 1,4,5-triphosphate receptor protein (InsP). We hypothesized that one mechanism of action of lithium will be able to reduce the effects of over expression of NCS-1 and prevent the down regulation of gamma band activity and restore normal levels of gamma oscillations. These findings taken together resolve the 60 year mystery of one the mechanisms of action of lithium in bipolar disorder and suggest that lithium may reduce the effects of over expressed NCS-1 in bipolar disorder, thereby normalizing gamma band oscillations mediated by P/Q-type calcium channels modulated by NCS-1. In summary, these recent discoveries provide novel therapeutic targets for alleviating some of the arousal and sleep/wake disturbances in this devastating disease.

Title: Optogenetic stimulation of astrocytes in the posterior hypothalamus increases sleep at night

Authors: *D. PELLURU[1], R. KONADHODE[1], N. R. BHAT[1], P. SHIROMANI[1,2];
[1]Psychiatry and Behavioral Sci., Med. Univ. of South Carolina, Charleston, SC; [2]Ralph Johnson VAMC, Charleston, SC

Abstract: A distributed network of neurons regulates wake, non-rapid eye movement sleep (NREM), and rapid eye movement sleep (REM sleep) (Pelluru et al., 2013). Optogenetics has been used to selectively manipulate some of these neurons to produce specific changes in wake, NREM and REM sleep. This has cemented the status of specific neurons in neural circuit models

of sleep-wake regulation. However, there are also glia in the brain, and there is growing evidence that neurons and astroglia communicate intimately to regulate behavior (Frank, 2013). We hypothesized that optogenetic stimulation of glia in posterior hypothalamus increases sleep. To selectively stimulate glial cells, rAAV-GFAP-ChR2-EYFP was microinjected into the posterior hypothalamus of WT mice (n=7) and orexin-KO mice (n=8). As controls a separate group of WT mice (n=5) received rAAV-GFAP-EYFP (no ChR2). Three weeks after gene insertion sleep was recorded and optogenetic stimulation (10 msec pulses; 1mW; one minute on-4 minutes off; for 6h) applied during the first 6h of the lights-off period. Optogenetic stimulation at 10 Hz compared to 0 Hz significantly increased NREM sleep in WT (+68%; $p<0.003$) and orexin-KO (+71.5%; $p<0.01$) mice, and decreased the length of wake bouts along with the time spent in wake in WT and orexin-KO mice. 10Hz stimulation significantly increased REM sleep in WT ($t=2.44$; $p<0.05$) and the orexin KO mice ($t=2.62$; $p<0.022$). There were no changes in delta power. In orexin-KO mice optogenetic stimulation of the astroglia did not change incidence of cataplexy. In control mice (no ChR2), 10Hz stimulation had no effect. This study demonstrates that direct stimulation of glia powerfully induces sleep during the active phase of the sleep-wake cycle and underscores the inclusion of glia in network models of sleep-wake regulation.

Title: Optogenetic activation of galanin neurons in the preoptic area (MnPO, VLPO) in galanin-cre mice does not increase sleep at night

Authors: *R. KONADHODE[1], D. PELLURU[1], C. BLANCO-CENTURION[1], M. LIU[1], C. ROBERTSON[1], P. SHIROMANI[1,2];
[1]Med. Univ. of South Carolina, Charleston, SC; [2]Ralph Johnson VAMC, Charleston, SC

Abstract: Neurons in the ventral lateral preoptic area (VLPO) are selectively active during sleep based on electrophysiology and c-FOS studies (Sherin et al., 1996; Szymusiak et al., 1998). Moreover, lesion of the VLPO neurons produces insomnia (Lu et al., 2000) suggesting that these neurons are necessary for sleep. However, their status in the sleep process is unknown since these neurons have never been selectively manipulated. Most (>80%) of the VLPO sleep active neurons express galanin (Gaus et al., 2002) and can be selectively activated with optogenetics. Therefore, we hypothesized that optogenetic stimulation of these neurons should increase sleep. Galanin-cre mice (n=4; 30 gm) were administered excitatory (rAAV-EF1a-DIO-hChR2 (H134R)-EYFP) opsin into the VLPO (bilateral injection; 750 nl each side) and implanted with sleep recording electrodes. Three weeks later a 48 h baseline sleep recording was obtained (0 Hz). At the start of the lights-off (night) period the mice were stimulated with 5, 10 or 30 Hz (random order) of blue light pulses (10 msec duration). The light pulses were delivered for 1 minute every 5 minutes for 6h, and 36h elapsed between the three stimulation rates. Preliminary data analysis indicates that activation of galanin neurons in POA (10Hz) for the 6h night period has no effect on sleep or wake when compared to baseline (0Hz). 5, and 30Hz stimulation also had no effect on sleep and wake. Histology is pending and will identify the number of galanin neurons containing the EYFP reporter gene, a proxy marker of the light-sensitive channelrhodopsin-2 gene. Our study demonstrates that optogenetic stimulation of galanin VLPO neurons does not increase sleep at night. This contrasts sharply with the optogenetic activation of MCH neurons which induces sleep at night in both mice and rats. It is possible that because VLPO neurons receive direct retinal input they might be prone to induce sleep during the day, the animal's normal sleep cycle.

Title: Correlation between the developmental decrease in REM sleep and N-type calcium channel expression

Authors: *E. E. GARCIA-RILL, S. MAHAFFEY, M. MACNICOL;
Slot 847, Ctr. for Translational Neurosci, Little Rock, AR

Abstract: In the human, rapid eye movement (REM) sleep decreases from 8 hr or 50% of total sleep time at birth, to 1 hr or 15% of sleep time. In the rat, this decrease occurs between 10 and 30 days, with REM sleep increasing at the expense of slow wave sleep, without changes in waking time. We discovered that every cell in the pedunculopontine nucleus (PPN), which modulates waking and REM sleep, manifests beta/gamma band activity, and that this activity is mediated by voltage-dependent high threshold N- and P/Q-type calcium channels. We also found that PPN cells exhibit N only (30%), P/Q-only (20%), and N+P/Q (50%) channels, which suggests that these correspond respectively to "REM-on", "Wake-on", and Wake/REM-on" cells *in vivo*. Our findings suggest that N-type channels modulate REM sleep while P/Q-type channels modulate waking. This study was carried out to determine if N-type and/or P/Q-type calcium channel expression in the PPN changes during the developmental decrease in REM sleep in the rat. We analyzed N- and P/Q-type calcium channel expression at two ages, 10+/-2 days and 30+/-4 days in two regions, the PPN and the hippocampus (HIPP). Brainstem slices were cut at 400 um from anesthetized rat pups (n=30) and 1 mm punches of the PPN and the HIPP were sampled. Groups of 10 animals at each age were sampled and the analysis repeated 3 times. Tissue was harvested in RNAlater and 50 ng RNA was analyzed in triplicate reactions with primers specific to N-type or P/Q-type channels (sequences available upon request), and with control primers to GAPDH and Cyc1 using Power SYBR Green RNA-to-Ct assay mix and a QuantStudio 12k Flex instrument. Data was analyzed using the QuantStudio Software v1.1 and comparisons between groups were carried out using one-way ANOVA with Bonferroni post hoc testing, and differences were considered significant at values of $p \leq 0.05$. We found that the N-type channel was expressed at significantly higher levels in the PPN from 10 day old compared to 30 day old animals (Experiment 1: 410+/-11% SE, n=3, p=0.011; Experiment 2: 368+/-15% SE, n=3, p=0.001, in 10 day vs 30 day PPN). By comparison, expression of P/Q-type channels decreased only slightly over the same developmental period (Experiment 1: 156+/-0.1% SE, n=3, p=0.001; Experiment 2: 222+/-26% SE, n=3, p=0.001 in 10 day vs 30 day PPN). No significant decrease in expression of N-type channels was observed in HIPP (Experiment 1: 117+/-6% SE, n=3, p=0.06; Experiment 2: 122+/-15% SE, n=3, p=0.11, in 10 day vs 30 day HIPP). These results suggest that the developmental decrease in REM sleep may be caused by a decrease in the expression of N-type calcium channels in the PPN.

Title: Sleep deprivation induces morphological changes in the prefrontal cortex in young and old rats

Authors: *F. A. GARCÍA-GARCÍA[1], E. ACOSTA-PEÑA[2], M. MELGAREJO-GUTIERREZ[2,3], I. CAMACHO-ABREGO[3], G. FLORES[3];

Abstract: Sleep is a fundamental state necessary for maintenance of physical and neurological homeostasis throughout the lifespan. Many hypotheses about the functions of sleep have been focused on effects of sleep deprivation on synaptic plasticity at a molecular and electrophysiological level and only a few have studied sleep function from a structural perspective. Moreover, during normal aging sleep architecture displays some changes that could affect normal development in the elderly. In the present study, using a Golgi-Cox staining and posterior Sholl analysis we evaluate the effects of 24 h total sleep deprivation on neuronal morphology of pyramidal neurons from layer III of prefrontal cortex (PFC) from male Wistar rats at two different ages (3 and 22 months old). We found no differences in total dendritic length and branching length in the region analyzed after sleep deprivation. Interestingly sleep deprivation increased spine density in PFC from aged animals. Taken together, our results show that sleep deprivation have different effects on synaptic plasticity and could play a beneficial role in cognition during aging.

Title: Long lasting global suppressed states during slow wave sleep

Authors: *H. MIYAWAKI, K. DIBA;
Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Slow wave sleep (SWS) is characterized by alternations between network UP and DOWN states each lasting on the order of 100 milliseconds. Using large-scale recording from large populations of neurons in multiple brain regions, we observed and characterized an additional state during SWS, which we call the "LOW" state. LOW states were marked by sporadic epochs of suppressed activity with strongly diminished power < 50 Hz in the local field potential and lasting several seconds. During LOW states we observed decreased firing rates, lower incidences and amplitudes of oscillatory events, such as sharp wave ripples, sleep spindles, and slow waves. We initially identified the LOW state in hippocampal region CA1. However, by analyzing additional data from multiple brain regions recorded by Mizuseki et. al. (Neuron 2009) and Peyrache et. al. (Nature Neuroscience 2015) obtained from http://crcns.org, we also identified similar LOW states in the entorhinal cortex in rats, and the post-subiculum and the medial prefrontal cortex, but not the thalamus, in mice. Cross correlation analysis revealed that LOW state were global; they began and ended at the same time across multiple brain regions. LOW states occurred most frequently at the beginning of SWS episodes and were modulated by sleep and waking history. Across extended sleep, the fraction of time spent in LOW states gradually increased. On the other hand, the fraction of LOW states decreased following waking. These results suggest that LOW states may play a function in sleep, by effectively decreasing spiking activity throughout the brain.

Title: A novel assay to screen for genes involved in sleep homeostasis

Authors: N. HOFFNER, L. K. SATTERFIELD, G. A. SEIDNER, *W. JOINER;
Dept. of Pharmacol., UCSD, La Jolla, CA

Abstract: Sleep is an evolutionarily conserved behavior that is essential for survival. However, the need(s) fulfilled by sleep are unknown. The mechanism by which sleep need is sensed and converted to suppression of behavioral arousal is also unknown. This process, which is referred to as sleep homeostasis, can be measured by depriving animals of sleep at night and measuring the duration and intensity of compensatory (or rebound) sleep the next day. To identify genes that contribute to sleep homeostasis we established a novel, high throughput thermogenetic assay in *Drosophila* melanogaster. In this assay, heat-activated TrpA1 channels are expressed transgenically in arousal-promoting neurons, where they are activated at night by a moderate increase in ambient temperature, leading to increased waking. The next morning, temperature is then returned to normal, shutting off TrpA1 channels and presumably returning excitability of targeted neurons to baseline, thus allowing robust homeostatic recovery sleep to occur. Using this assay we then conducted an RNAi-based forward genetic screen to identify mutants that can be sleep-deprived but are unable to mount a compensatory sleep response the next day. The results of our screen confirm that sleep homeostasis is indeed under genetic control. Further elucidating the genetic basis for sleep homeostasis may lead to novel approaches to treat diseases in which sleep structure is affected as well as promoting overall health and well-being.

Title: Altered EEG response to psychomimetic agents in a novel Han Wistar rat strain lacking metabotropic glutamate receptor 2 expression

Authors: *C. M. WOOD[1], D. LODGE[2], A. P. MCCARTHY[3], E. SHANKS[4], E. S. J. ROBINSON[2], K. A. WAFFORD[5];
[2]Sch. of Physiol. and Pharmacol., [1]Univ. of Bristol, Bristol, United Kingdom; [3]Discovery Data Sci., [5]*In vivo* Pharmacol., [4]Eli Lilly and Co., Windlesham, United Kingdom

Abstract: Patients suffering from psychiatric disorders such as schizophrenia, often have sleep disturbances and simultaneous changes in their EEG profiles. Group II metabotropic glutamate receptors (mGluRs) have been implicated in these disorders, with preclinical work showing mGluR2/3 compounds have efficacy in reducing psychosis-like behaviours following NMDA receptor antagonist and hallucinogen administration. Pharmacological and genetic manipulation of mGluR2/3 has also been shown to alter sleep-wake architecture in mice. Recent work has highlighted rat strains lacking mGluR2 protein expression[1]. This study aimed to investigate any changes in sleep/wake or EEG spectral profile in a novel rat strain lacking mGluR2 receptor expression, and examine their response following treatment with the NMDA receptor antagonist ketamine, and $5HT_{2A/C}$ agonist DOI. To assess sleep and EEG waveform activity the SCORE-2000^{TM} bioassay was used. Briefly, individually housed and tethered Charles River Wistar (CR) and HSD Han Wistar rats were monitored for EEG, EMG, locomotor activity, food and drink-related activity and body temperature. These data were recorded concurrently 24 hours before treatment as a baseline and for 30 hours post treatment for subsequent drug effects. Ketamine (10mg/kg, s.c.) and DOI (3mg/kg, i.p.) were administered 5 hours after lights on. No significant baseline differences were seen in sleep/wake parameters between the two strains. Ketamine and DOI both promoted wakefulness following treatment, decreasing NREM and REM sleep in both rat strains, with a reduced effect on REM sleep in the Han Wistar rats following ketamine treatment. Ketamine induced an increase in spectral power of the gamma frequency (30-80Hz) and high frequency oscillation bands (HFO; 130-160Hz). This increase in HFO was potentiated in the Han Wistar rats. Food and drink-related activity were increased in the Han Wistar rats alone following ketamine treatment. DOI induced an increase in HFO in both rat strains, with an attenuated effect in the Han Wistar rats. Psychomimetic drugs increase cortical spectral activity in the high frequency range. Our data demonstrates a divergence in this measure and associated behaviours elicited by the $5HT_{2A/C}$ agonist DOI and NMDA receptor antagonist ketamine, highlighting the importance of mGluR2 receptors in eliciting this response. This correlates with previous reports showing the importance of mGluR2 in the behavioural response to DOI using mGluR2$^{-/-}$ mice. Further work is required to elucidate the precise role played by mGluR2 in these pharmacological effects. 1. Ceolin L et al. (2011) J Neurosci. 31:6721-31.

Title: Modulation of hypothalamic MCH-expressing neurons by pharmacogenetic tools strongly alters the sleep-waking cycle in mice

Authors: *C. VARIN[1], S. JEGO[2], S. ARTHAUD[1], M. LAZARUS[3], T. GALLOPIN[4], P.-H. LUPPI[1], A. ADAMANTIDIS[2,5], P. FORT[1];

Inst. for Integrative Sleep Med., Univ. of Tsukuba, Tsukuba, Japan; [4]Brain plasticity unit, ESPCI ParisTech, Paris, France; [5]Dept. of Neurol., Inselspital Univ. Hospital, Univerity of Bern, Bern, Switzerland

Abstract: Evidence supports a role of hypothalamic neurons expressing melanin-concentrating hormone (MCH) in sleep. These neurons are indeed maximally active during paradoxical sleep (PS) based on Fos immunostaining and juxtacellular unit recordings across the natural sleep-waking cycle in rats. Further, intracerebroventricular MCH infusion induces an increase in both PS and Slow-Wave Sleep (SWS) amounts in rats, whereas acute optogenetic activation of MCH neurons at PS onset extends the duration of PS, but not SWS episodes. To decipher the precise contribution of MCH neurons to SWS and/or PS regulation, we used a pharmacogenetic approach with DREADD tools in male transgenic MCH-cre mice (12 weeks old). These mice were bilaterally injected within the tuberal hypothalamus with either inhibitory (AAV-hSyn-hM4di-mCherry) or excitatory (AAV-hSyn-hM3dq-mCherry) DREADDs and prepared for chronic polysomnographic recordings. Four weeks later, effects on vigilance states were analyzed in response to i.p. CNO treatments. Inhibition of MCH neurons at light onset dose-dependently increased SWS quantities compared to saline, due to a dramatic increase in bout duration whereas excitation of MCH neurons conversely reduced SWS bout duration. Regarding PS, inhibition of MCH neurons did not produce any strong effect. In contrast, their excitation facilitated PS maintenance at light onset and both PS promotion and maintenance when performed at light offset. These data interrogating the circadian control of MCH neuron excitability, we further analyzed effects on sleep of excitation applied at different time across the light-dark cycle. The present results suggest that MCH-expressing neurons may play a key role in the fine-tuning of the sleep-waking cycle by modulating both SWS and PS, in particular by facilitating SWS consolidation and PS promotion and maintenance. Moreover our results indicate that the excitability of MCH neurons is under a strong circadian control.

Title: Development of REM sleep homeostatic drive requires activation of BDNF TrkB receptor in the pedunculopontine tegmentum (PPT)

Authors: *A. BARNES[1,2], R. KOUL TIWARI[1,2], S. DATTA[1,2,3];
[1]Anesthesia Res., Univ. of TN Hlth. Sci. Ctr., Knoxville, TN; [2]Anesthesiol., Univ. of Tennessee Grad. Sch. of Med., Knoxville, TN; [3]Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Selective REM sleep deprivation (RSD) is a novel method previously developed in our laboratory that successfully eliminates 85-95% of REM sleep without reducing slow-wave sleep. Recently, we have shown that RSD increases BDNF expression in the PPT, which potentially contributes to REM sleep homeostasis. In the present study, we investigated the functional role of BDNF TrkB receptor signaling in the homeostatic regulation of REM sleep. Adult male Sprague-Dawley rats were chronically implanted with sleep-wake (S-W) recording electrodes and bilateral guide cannulae for microinjections into the PPT. After surgical recovery, habituation, and baseline S-W recordings, the rats were randomly separated into control and experimental groups (Group 1 and Group 2, respectively). All animals were recorded from 9:00 am to 3:00 pm. Immediately before the recordings, Group 1 rats were microinjected with vehicle control (0.1 µl of 0.9% saline), and Group 2 rats were microinjected with a TrkB receptor inhibitor (30 µmol of K252a). For the first three hours of the recording period, half of each group subjected to RSD, and the other half was allowed to have undisturbed S-W activity. All animals were allowed to have undisturbed S-W activity for the final three hours. To determine the level of BDNF expression in the PPT, half of the animals from each subgroup were sacrificed immediately after the first 3 hours of recording. In the remaining animals, brains were marked and perfused for histological verification of the injection site. Results demonstrated that: a) In the PPT, BDNF expression had a positive correlation with homeostatic drive for REM sleep; b) inhibition of the TrkB receptors in the PPT minimized BDNF expression in the PPT; and c) inhibition of the TrkB receptors in the PPT suppressed selective RSD-induced homeostatic drive for, and rebound of REM sleep. These results, for the first time, suggest that the activation of PPT BDNF TrkB receptors plays a causal role in development of REM sleep homeostatic drive.

Title: Association between cognitive performance, sleep EEG and the BDNF Val66Met polymorphism in children and adolescents

Authors: *F. PUGIN[1], A. METZ[2,3], A. BAUMER[4], M. WOLF[2], A. RAUCH[4], P. ACKERMANN[5], O. JENNI[1], R. HUBER[1];

Zurich, Zuerich, Switzerland; [3]Univ. of Berne, Institute of Complementary Medicine, Switzerland; [4]Inst. of Med. Genet., [5]Inst. of Pharmacol. and Toxicology - Chronobiology and Sleep Res., Univ. of Zurich, Zuerich, Switzerland

Abstract: Objective: In adults, the single nucleotide polymorphism (Val to Met substitution) on codon 66 of brain-derived neurotrophic factor (BDNF Val66Met) has been linked to differences in brain plasticity (e.g., differences in brain structure and higher cognitive performance in Val/Val allele carriers (VV) compared to heterozygotes (VM)). Evidence is accumulating that EEG sleep slow-wave activity (SWA, EEG power < 4.5 Hz) reflects cortical plasticity. Thus, we tested in this study whether the association between cognitive performance and sleep SWA differs between young VV and VM allele carriers. Methods: 27 subjects were recruited; none of them was a Met/Met carrier. In 16 Val allele carriers (VV; age mean ± SD, 13.1y ± 16m) and 11 Val/Met allele carriers (VM; 12.9y ± 19m), fluid intelligence (FI) was assessed with the TONI-IV, and sleep high-density electroencephalography (HD EEG; 128 electrodes) was measured during a night in the sleep laboratory. Results: The VV-group showed a trend towards higher fluid intelligence scores (110.5 ± 13) compared to the VM-group (101.9 ± 7; $p = 0.07$). No

significant group differences in sleep SWA were found. Correlating SWA with FI revealed three regions of interest that were further analyzed. In a frontal and parietal region, SWA correlated positively with FI ($r = 0.4$, $p < 0.05$; both groups pooled). In an occipital region, a negative correlation was found ($r = -0.7$, $p < 0.001$) for both groups pooled, as well as in the VV-group ($r = -0.8$, $p < 0.001$). Conclusion: The trend level group difference in cognitive performance is in accordance with current literature. The associations between FI and sleep SWA may highlight regions of intense plastic changes involved in the maturation of higher cognitive functions. The negative correlation between SWA and FI in the occipital region seems to be driven by the VV group, possibly reflecting differential mechanisms of cortical plasticity in relation to cognition during development in VV carriers with high FI. These preliminary results in children and adolescents indicate that sleep SWA topography shows a distinct relation to cognitive performance in VV and VM allele carriers.

Title: Glutamatergic projection from the medial Prefrontal Cortex to Basal Forebrain - a ChR2-assisted circuit mapping study

Authors: *L. FERRARI, D. PARK, E. ARRIGONI;
Neurol., Beth Israel Deaconess Med. Ctr. - Harvard Med. Sch., Boston, MA

Abstract: The basal forebrain (BF) is an important component of the ascending arousal system and contains a heterogeneous population of neurons, including neurons producing acetylcholine, GABA and glutamate. BF cholinergic neurons are the main cholinergic input to the cerebral cortex, they fire in association with wakefulness and REM sleep and, when activated, they promote cortical activation. These neurons also receive a robust glutamatergic input, which

might contribute to their behavioral state-dependent activity. Here we used a ChR2-assisted-circuit-mapping approach to identify BF neurons targeted by the medial prefrontal cortex (mPFC). We injected an adeno-associated viral (AAV) vector expressing GFP (rAAV8/hSvn-DIO-eGFP) into the BF (MCPO/SI region) of Vglut-ires-cre, Vgat-ires-cre or ChAT-ires-cre mice to express GFP in cholinergic, GABAergic and glutamatergic neurons respectively. We also injected AAV-CaMKIIa-hChR2(H134R)-mCherry into the medial prefrontal cortex (mPFC) to express ChR2 in glutamatergic cortical neurons. We performed whole-cell recordings in BF slices and we targeted MCPO/SI neurons that expressed GFP. We photostimulated cortical axons/terminals that expressed ChR2 using blue-light (473 nm) pulses. Photostimulation of the mPFC input failed to evoke synaptic responses in BF cholinergic neurons but evoked EPSCs in GABAergic and glutamatergic MCPO/SI neurons. These photo-evoked EPSCs were abolished by DNQX, indicating that they were mediated by the release of glutamate and by the activation of AMPA postsynaptic receptors. Previous studies have shown that BF neurons diffusely innervate the cortex, and our results demonstrate functional projections back from the mPFC to the BF. These projections mainly contact GABAergic and glutamatergic neurons but there appears to be no direct innervation of BF cholinergic neurons. Much sleep research emphasizes ascending arousal signals. Our results now demonstrate functionally-important descending projections from the mPFC which may influence behavioral state.

Abstract: The recently-identified circadian mouse mutant, *Zfhx3*$^{Sci/+}$, caused a shortening of the circadian period in mice due to a novel AT motif-dependent circadian axis. Here we provide evidence that this new circadian axis influences processes that are outside the canonical circadian

system. Analysis of the *Zfhx3*$^{Sci/+}$ transcriptome revealed links between the circadian clock, sleep and cognition. *In vivo* assessment of sleep and cognition in *Zfhx3*$^{Sci/+}$ mice demonstrated a defect of sleep homeostasis and short-interval time perception in mutants. We studied how circadian clock differences modify genetic noise in simulated neural networks. Thus, we assessed the dynamics among genetic noise, sleep and circadian rhythms in conditioning daily behaviors. We show here, for the first time, statistical dependency between behavioral/cognitive measures and various biological processes that varies with time of the day. Remarkably, the *Zfhx3*$^{Sci/+}$ mutation changes the dynamics of how the circadian clock and sleep can influence cognitive functioning in time.

Title: Sleep homeostasis, adenosine and glia cells

Authors: *A. V. KALINCHUK[1], J. ZANT[1], P. HAYDON[2], R. W. MCCARLEY[1], R. BASHEER[1];
[1]VA Boston Healthcare System-Harvard Med. Sch., Boston, MA; [2]Tufts Univ., Boston, MA

Abstract: Extracellular adenosine (AD) is an important homeostatic sleep factor which acts in the basal forebrain (BF) via the A1 receptor. During sleep deprivation (SD) the level of AD increases 1.5-3-fold as compared to spontaneous wake, and this increase correlates with the

homeostatic sleep pressure (HSP). The cellular source of AD increase during SD is not well understood, although recent data indicate the importance of AD-triphosphate (ATP) released from glia in SD-induced AD increase. On the other hand, our data show that SD-induced AD depends on nitric oxide (NO) produced in wake-active BF neurons. In this study, to investigate the role of glia in SD-induced AD increase and homeostatic sleep response, we measured AD, NO and ATP in mice with conditional astrocyte-specific expression of the dnSNARE dominant negative protein. Using doxycycline (DOX)-dependent regulation of gliotransmission, we performed measurements in the same animals while they were on the DOX diet (DOX-ON, normal gliotransmission) and 2 weeks after the DOX diet removal (DOX-OFF, reduced gliotransmission). We also compared the homeostatic mechanisms triggered during the light (high HSP) and dark (low HSP) periods. Mice were implanted with EEG/EMG electrodes and microdialysis guide cannula targeting the BF nuclei. Microdialysis samples were collected during the baseline (non-disturbed sleep) days or SD days. In the microdialysates we measured (i) ATP by luciferin-luciferase based assay, (ii) AD using HPLC coupled to fluorescent detector, (iii) NO using a Nitrate/Nitrite (NOx) fluorometric assay kit. During the light period, the SD-induced increase in ATP level observed in DOX-ON condition was eliminated after the removal of DOX diet. SD-induced increases in AD (2X) and recovery NREM sleep/delta power observed in DOX-ON condition were attenuated in DOX-OFF condition, but they were still significantly higher than baseline (AD, 1.6X). SD-induced increase in NOx was not affected by expression of dnSNARE. During the dark period, in DOX ON condition, the SD-induced increases in AD (1.4X) and recovery NREM sleep/delta were significantly lower as compared to changes observed during the light period. In DOX OFF condition, these increases were completely eliminated. Most notably, NOx level was unchanged during the dark period. We conclude that different mechanisms contribute to the SD-induced increase in AD and homeostatic sleep response under high and low sleep pressure. During the light period, when HSP is high, AD increase is preferentially mediated by NO with a moderate contribution of gliotransmission. During the dark period (low HSP) the increase in AD is mostly dependent on ATP released from glia.

Title: Comparing neuronal tracking of speech across wakefulness and sleep

Authors: *S. BEKER[1,2], S. MAKOV[1], O. SHARON[1], N. DING[3], Y. NIR[1], E. ZION GOLUMBIC[2];
[1]Fac. of Med., Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]Gonda Multidisciplinary Brain Res. Ctr., Bar Ilan Univ., Ramat Gan, Israel; [3]Col. of Biomed. Engin. and Instrument Sci., Zhejiang Univ., Hangzhou, China

Abstract: During sleep, external stimuli fail to elicit meaningful behavioral responses and rarely affect perceptual awareness. However, the extent to which the sleeping brain continues to process external stimuli remains unclear. Studies examining ERP responses to brief sounds during sleep yielded mixed results and their interpretation is complicated by the occurrence of k-complexes. Instead, focusing on neuronal tracking of speech may allow (a) to probe sleep processing with continuous stimulation, and (b) to determine how sleep affects different levels of processing (e.g. acoustic vs. phoneme/word segmentation vs. semantic). To test this, we used a variety of speech and vocoded speech stimuli, to manipulate intelligibility to different degrees. In addition, we presented speech in an unfamiliar language. Building on previously established findings that neural tracking of intelligible speech is more robust than non-intelligible speech, here we compared neuronal tracking of intelligible and non-intelligible speech across wakefulness and sleep using high-density (256-channel) EEG. Replicating previous results, in wakefulness we observe neural phase locking to the stimuli around 3-5Hz, which monotonically increased as a function of speech intelligibility at medial-frontal electrodes. In contrast, preliminary results during full-night sleep reveal that the speech tracking response is significantly reduced and does not vary strongly with intelligibility, suggesting that only limited linguistic processing of speech occurs during sleep. More generally, we hope that these paradigms can be adapted to assess residual cognitive processing in other non-responsive states such as anesthesia, disorders of consciousness and neurodegeneration.

Title: A comparative study of circadian rhythms and sleep between African spiny mice (Acomys cahirinus) and house mice (Mus musculus) in single and group housing conditions

Authors: *C. WANG, T. R. GAWRILUK, M. C. KEINATH, S. K. BISWAS, J. J. SMITH, A. W. SEIFERT, B. F. O'HARA;
Biol. Dept., Univ. of Kentucky, Lexington, KY

Abstract: The study of circadian and sleep behavior in different organisms can provide valuable insight for understanding behavioral, physiological and environmental influences on these processes. Interestingly, two species of African spiny mice, Acomys russatus (Golden spiny mouse) and Acomys cahirinus (Cairo spiny mouse) have been reported to exhibit different circadian rhythm patterns in locations where the two species overlap. Both species are primarily nocturnal when not in direct competition, but in areas of overlap A. cahirinus exhibit nocturnal behavior, while A. russatus become more diurnal. However, very few studies on the circadian activity of these species are available and nothing is known of their sleep behavior, which can be the dominant force in driving other diurnal variables. Therefore, we have begun to study one of these species (A. cahirinus) in greater detail alongside the well-studied house mouse (Mus musculus) using a well validated, non-invasive, piezoelectric system, that picks up all movements during wake, and the breathing rhythms during sleep. In these studies, we found A. cahirinus and M. musculus to be primarily nocturnal, but with clearly distinct behavioral patterns. Specifically, the activity of A. cahirinus sharply increases right at dark onset, which is common in nocturnal species, but surprisingly, decreases sharply just one hour later in single cage studies. In group cage studies, the activity of A. cahirinus remained high for a few hours after dark onset. Similarly, the activity of A. cahirinus is more active before middle of the night period than after middle of the night period. These differences may be related to foraging differences between these species, or may be related to the socialized behavior of A. cahirinus and its poorer adaptation to isolation as compared to Mus musculus. Also, we have sequenced and assembled a low coverage genome for A. cahirinus and explored genes known to influence sleep and circadian rhythms in A. cahirinus and M. musculus. We are currently investigating these and other variables that might explain A. cahirinus sleep behavior including a comparison of genomic sequences between these species.

Title: Proboscis extensions during sleep: a new sleep stage in *Drosophila* that clears the brain?

Authors: *B. VAN ALPHEN, A. AUGUSTIN, R. ALLADA;
Dept. of Neurobio., Northwestern Univ., Evanston, IL

Abstract: Despite its relaxed appearance, sleep is an active process where the brain cycles through different stages of activity. Although the exact function of sleep remains the topic of a lively debate, its proposed functions include memory consolidation and metabolite clearance. Sleep in *Drosophila* has all the hallmarks of mammalian sleep, including homeostasis, altered brain activity, stages of lighter and deeper sleep, increased arousal thresholds and a characteristic posture. We discovered a novel sleep stage in *Drosophila*, during which the fly repeatedly and spontaneously extends its proboscis (mouth parts) in a stereotypical manner during inactivity and without any apparent stimulus, e.g, food exposure. Experiments in tethered flies showed that, during these proboscis extensions, arousal thresholds are even higher than during regular sleep, suggesting an even deeper sleep stage. Proboscis extensions are normally an appetitive response, where a hungry fly extends its mouthparts when its gustatory receptors come in contact with sugars. Also, proboscis extensions have also been shown to correlate with CO2 release during flight, suggesting that proboscis extensions facilitate respiration. So why do flies extend their proboscis during sleep? We found that proboscis extensions increase with starvation duration, suggesting a link to appetitive mechanisms, where either gustatory receptors become more sensitized or (more tantalizing) hungry flies replay wake experience. However, we also found substantial evidence that proboscis extensions facilitate a clearing mechanism. Increasing temperature, which would increase a fly's metabolic rate and CO2 production among other effects, increased the rate at which proboscis extensions occur. Also traumatic brain injury, which increases waste products among other changes, resulted in an immediate six-fold increase in proboscis extension rate. These data suggest that, besides for feeding, a fly uses its proboscis as a pump to increase the rate at which hemolymph flows through its body, increasing both gas exchange and metabolite clearance rate. We are currently investigating whether proboscis extension during sleep accomplishes waste clearance to optimize waking brain function and recovery from injury.

Title: Effect of striatal lesions on sleep and motor activity

Authors: *Y.-Y. LAI[1], K.-C. HSIEH[3], Y.-H. CHENG[2], J. M. SIEGEL[2];
[1]Psychiatry, [2]UCLA/VAGLAHS Sepulveda, North Hills, CA; [3]VAGLAHS Sepulveda, North Hills, CA

Abstract: Periodic leg movements (PLMs) in sleep have been reported in 10% of the general population. PLMs are also commonly seen in patients with striatal pathology, such as Parkinson's disease, Huntington's disease, rapid eye movement (REM) sleep behavior disorder, and attention deficit hyperactivity disease. We hypothesize that abnormal basal ganglia activity may cause PLMs. Our previous study showed that cats with lesions of the substantia nigra pars reticulata (SNR) generate PLMs in sleep. The SNR receives GABAergic projections from the striatum via direct and/or indirect pathways. In this study, we show that neurotoxic lesions of the striatum increase phasic motor activity in SWS in the rat. Thirteen young adult male Sprague-Dawley rats, weighing 280-400 g, were used. Among them, 8 rats were NMDA lesioned, 2 rats were sham lesioned, and 3 rats were controls. Under isoflurane anesthesia, electrodes were implanted in the skull to record EEG. Flexible wires were implanted in the hindlimb and neck musculatures to record muscle activity. Striatal or sham lesioned rats were given 50 nl NMDA (0.5 M) or 50 nl artificial cerebrospinal fluid injections into the striatum. Three days of sleep polysomnography were performed after the animal recovered from the surgery. No signs of tremor, rigidity, or bradykinesia in wake were observed in the lesioned animals. However, motor hyperactivity in slow wave sleep (SWS) was observed in all NMDA lesioned rats. The PLM index (PLMI; total number of PLM/total time of SWS/24 hour) in SWS in NMDA lesioned rats was significant different between control and sham lesioned rats ($F(2,10)=53.85$, post hoc $p<0.001$; PLMI, control rats: 9.6 ± 1.5, sham lesioned rats: 6.2±3.6, NMDA lesioned rats: 40.8 ± 12.9). The NMDA lesioned rat showed a circadian pattern of PLM, with higher PLMI in the dark phase than in the light phase (light phase: 36.7 ± 10.2, dark phase: 52.5 ± 17.8; paired T-test,

p<0.01). However, the number of isolated leg movements (ILMs) index in SWS (total number of ILM/total time of SWS/24 hour) was not different between NMDA lesioned and control/sham lesioned rats (F(2,10)=0.103). Striatal NMDA lesioned rats also showed a significant decrease in wake time (F(2,10)=5.27, post hoc p<0.05, minute/24 hour; control rats: 726.9 ± 61.4, sham lesioned rats: 810.2 ± 125.1, NMDA lesioned rats: 644.2 ± 73). We hypothesize that the striatum plays an important role in the control of sleep and motor activity in sleep.

Title: A nap but not quiet rest prevents performance deterioration induced by intensive training

Authors: ***A. B. NELSON**[1], C. MOISELLO[1], D. BLANCO[1], J. LIN[1], P. PANDAY[1], J. P. BORKOWSKI[1], H. H. CHEN[1], M. GADALLA[1], C. FONTANESI[1], G. TONONI[2], C. CIRELLI[2], M. F. GHILARDI[1];
[1]Dept. Physiology, Pharmacol. & Neurosci., CUNY Med. Sch., New York, NY; [2]Psychology, Univ. of Wisconsin- Madison, Madison, WI

Abstract: There is substantial evidence that sleep need occurs locally as a result of the cellular consequences of synaptic plasticity and learning during wake. Recent work in humans and animals showed that intense training in a task leads to a progressive increase in performance errors that are related to the occurrence of local sleep during wake. It is not known whether local sleep is triggered by plasticity like sleep itself or by a temporary neuronal exhaustion triggered by intense activity. In the first scenario, the cumulative cellular costs of increased synaptic strength leads to “tiredness”, i.e., higher energy consumption, greater need of cellular supplies, increased number of synapses. Tiredness can only be overcome by a process of synaptic renormalization that requires sleep. The other scenario implies a temporary neuronal exhaustion or “fatigue” due to momentary rundown of energy resources, depletion of synaptic vesicles/calcium or accumulation of adenosine. Such effects should be rapidly reversible by rest without sleep. Here we test the hypotheses that: 1. extended training on a task that requires intense learning leads to an increase in errors on tests that demand similar neural/cognitive

resources; 2. “tiredness” is the cause of such errors and thus performance can be restored by a nap but not by quiet rest. 16 subjects performed a task involving significant attentional and working memory load (VSEQ) in blocks of 45 minutes in two 4-hour sessions, one in the morning and the other in the afternoon. After each block, we assessed performance in a brief visual working memory test (MEM), which shares the same neural substrates and characteristics as VSEQ and in a motor reaching test (MOT), which taps into motor function. After the morning session, 8 subjects slept for 90 minutes (NAP) and 8 subjects rested quietly with eyes closed (REST). Performance in MEM was similar in the two groups in the morning. In the afternoon session, MEM performance in the REST group significantly degraded. Meanwhile, the NAP group maintained the same performance level across the two sessions, resulting in a significant difference between the NAP and REST groups in the afternoon session. Performance in MOT did not change across group or session. These results demonstrate that intense training leads to task-specific impairments, as performance decayed in MEM but not in MOT. Most importantly, we found that sleep but not quiet rest protects against performance deterioration induced by intensive training. Therefore, performance deterioration is likely due to neuronal “tiredness”, that is, to the increased cellular costs of accumulated synaptic strength, which can only be reversed by sleep.

Title: Effects of social stress on behavior are sleep-dependent

Authors: *C. L. GRAY[1], L. PINCKNEY[1], E. OLIVER[2], K. N. PAUL[1], J. C. EHLEN[1]; [1]Neurosci. Institute, Morehouse Sch. of Medici, Atlanta, GA; [2]Ross Univ. Sch. of Med., Picard, Dominica

Abstract: Sleep disorders are often comorbid with psychological disorders like post-traumatic stress disorder (PTSD). However, the relationship between sleep impairments and the development and maintenance of the behavioral hallmarks that accompany these disorders are mostly unknown. In the present study, we used social stress to induce social avoidance in a mouse model to investigate the role of sleep in the regulation of behavior. Our hypothesis is that sleep changes are necessary for the development and maintenance of social avoidance behavior. We implanted C57Bl6/J mice with electroencephalography and electromyography electrodes, recorded baseline sleep and then subjected the implanted mice to 10 days of social defeat stress using a resident-intruder paradigm. Social avoidance testing and sleep recordings were then performed immediately and 3 weeks after social defeat. We found pronounced changes in sleep-wake architecture that persisted for the 3 weeks following the stress. These changes were characterized by a redistribution of sleep during the 24-hour day and decreased REM-sleep amount. To our knowledge, this is the first mouse model demonstrating sustained changes in sleep and behavior. In addition, both NREM and REM sleep amount during baseline sleep recordings during the first four hours of the dark period significantly increased in mice that developed social avoidance after social defeat. Thus, our findings also provide evidence that changes in sleep-wake architecture predict susceptibility to social avoidance. We are currently investigating the effects of sleep manipulations in this model on behavioral responses to social defeat in order test our hypothesis that sleep changes are necessary for the development and maintenance of social avoidance. Understanding how sleep regulates the neural pathways responsible for social avoidance in our current model is likely to reveal new targets for the treatment of psychological disorders such as PTSD.

Title: Behavioral and wireless electrophysiological characterization of sleep in a lizard, the Argentine Tegu (Tupinambis merianae)

Authors: *P.-A. LIBOUREL[1], S. ARTHAUD[1], B. MASSOT[2], E. VAN REETH[3], A.-L. MOREL[1], M. SDIKA[3], O. BEUF[3], A. HERREL[4], P.-H. LUPPI[1];
[1]Neurosci. Res. Ctr. of Lyon, LYON, France; [2]INL, LYON, France; [3]CREATIS, Lyon, France; [4]MNHN, Paris, France

Abstract: Based on behavioral and electrophysiological characteristics, two distinct sleep states: NREM and REM sleep (or active and quiet sleep) have been identified in terrestrial mammals and birds, both homeotherms. However, whether reptiles, key taxa in understanding the evolution of sleep given their position at the base of the amniote tree, display those states remains unresolved. In order to precisely implant electrodes in specific brains regions, we first constructed a stereotaxic atlas for the argentine Tegu (Tupinambis merianae), based on MRI, micro CT Scanning, and immunohistochemistry. Next, wireless electrophysiological recordings were performed simultaneously with behavioral recordings obtained through four infrared cameras. We recorded EMG, EEG, ECG, EOG, brain and body temperature, and LFP with bundles of 35 µm diameter tungsten electrodes in the medial cortex (hippocampus homologue), the dorsal cortex, the dorso ventricular ridge, and the nucleus sphericus. The first lizard recorded displayed the behavioral characteristics of sleep during the entire night (12h/12h), including a stereotypical posture and a rebound of behavioral sleep after 9 h of gentle handling deprivation compared to the baseline. During the day, the animal displayed a different resting posture compared to sleep. The arousal threshold, or the delay to induce an arousal, was evaluated by activating a vibrator fixed on the head of the animal during 5 s every hour during 3 days. The arousal threshold was significantly higher during the sleep period compared to the diurnal rest. This behavioral state was associated with frequent eye movements (EM), whereas rare phasic EM and slight twitches of the toes where observed during the sleep period. Although the EEG of the lizard did not allow a differentiation between waking and sleeping behavior, the LFP recordings revealed a polymorphic signal in amplitude and frequency. A preliminary spectral analysis show differences depending on the area recorded during the two states. In particular, phasic oscillations in the 9-16 Hz spectral band appeared specifically during sleep. The rebound of sleep that follows the total deprivation was associated with an increase of the low frequency (0-4 Hz) and of the 9-16 Hz bands. Our preliminary results suggest that this lizard displays the behavioral characteristics of sleep. Some behavioral and electrophysiological phasic phenomena were observed during sleep, suggesting that this lizard has a non-homogenous sleep, raising the possibility that active sleep and a quiet sleep could be both present in reptiles.

Title: Sex differences in sleep following footshock stress in mice: an animal model for sleep disturbances after trauma exposure

Authors: *I. KOBAYASHI[1], T. A. MELLMAN[1], E. K. POLSTON[2];
[1]Psychiatry and Behavioral Sci., [2]Physiol., Howard Univ. Col. of Med., Washington, DC

Abstract: Posttraumatic Stress Disorder (PTSD) is a serious psychiatric condition that develops in a significant minority of people exposed to trauma. Women are twice as likely as men to develop PTSD following trauma, but the mechanisms underlying women's greater vulnerability are poorly understood. Specific sleep impairments, including fragmented rapid-eye-movement (REM) sleep, have been implicated in the development of PTSD. In women, poor sleep maintenance was associated with subsequent PTSD in a single study with a small sample size. Increased interest in the role of sleep in the pathogenesis of PTSD has stimulated the development of rodent models that investigate sleep patterns following a trauma-like experience. However, these models have thus far examined only male animals. Therefore, we have expanded this approach to examine sex differences and hormonal influences in post-trauma sleep in mice. Male and female C57BL/6 mice were implanted with bipotential telemetric EEG recorders, and baseline sleep was continuously recorded for 5-6 days for males or one complete estrous cycle for females. Mice then received 15 footshocks over 15 minutes (0.5 mA, 0.5 sec duration) during the first half of their 12 hour light period. Following the footshock session, sleep was again recorded for 5-6 days for males or one complete estrous cycle for females. Sleep data were scored using the EEG recordings and locomotor activity to identify wake, REM sleep, and non-REM sleep (NREM) stages for each 10-sec epoch of recording. Preliminary data based on one male and one female across two days of baseline recordings and two days of post-shock recordings indicated that the percentage of REM sleep during the post-shock light period increased nearly twofold for both animals. During the post-shock dark periods, REM sleep increased in the male and decreased in the female. Analysis of wake and NREM sleep revealed that during both the baseline and post-shock periods, the female had a greater percentage of wake and a lower percentage of NREM sleep during dark periods than the male. During the 1st post-shock light and dark periods, both the male and the female mice had increased wake and decreased NREM sleep compared with their baselines, and this change appeared to be greater in the female than in the male. During the 2nd post-shock light and dark periods, wake and NREM sleep reverted, attaining levels beyond those seen during baseline recording. Our continuing

work will be determining if this possible sex difference in REM sleep during the post-shock dark periods persists, and if the stage of the estrous cycle at the time of footshock influences the sleep responses of females.

Title: Sleep plasticity due to social interactions and mating in *Drosophila* melanogaster

Authors: A. E. DOVE, *C. G. VECSEY;
Biol., Swarthmore Col., Swarthmore, PA

Abstract: Sleep behavior is universal across taxa but the regulatory mechanisms underlying it remain mysterious. *Drosophila* sleep is plastic, and increasing literature suggests that social conditions are a source of such behavioral plasticity. We specifically examined the way sexual interactions affect *Drosophila* sleep behavior, at the level of individual mating events and general cohabitation, or socio-sexual interactions (SSI) between males and females. It was recently demonstrated that female flies experience a post-copulatory reduction in daytime sleep mediated by Sex Peptide (SP) transferred to the female during mating via seminal fluid. After successfully replicating these findings using electronic activity monitors to measure the sleep of individual flies, we discovered that the daytime sleep reduction lasted 6 days post-mating and had no apparent critical period with regard to female age or previous mating experience. We also established that *Drosophila* mating status has no bearing on circadian rhythmicity. This line of research provides evidence that sexual experience can temporarily modify an organism's sleep behavior and raises interesting questions regarding the mechanism by which SP reduces female daytime sleep. Social enrichment via increased population density causes flies to consolidate their sleep into a small number of long-duration episodes - an architectural pattern thought to be beneficial for memory formation. Analogously, we found that increased SSI caused a trend toward more consolidated sleep in both male and female flies - a result consistent with the

presumably increased memory demands in a cohabitating environment. In another non-significant trend, parental SSI appears to promote less consolidated sleep in offspring. These preliminary findings offer the intriguing possibility that social effects on sleep plasticity may involve epigenetic mechanisms. These results expand our understanding of the connection between an organism's sexual experience and its subsequent sleep behavior. Due to the neurochemical similarities between *Drosophila* and mammalian sleep, a biochemical understanding of the molecular basis of these forms of plasticity in *Drosophila* may provide mechanistic insight about social control of our own sleep patterns.

Title: Sleep and recreational psychostimulant use

Authors: ***M. M. SCHADE**[1], M. KRAYNOK[2], H. E. MONTGOMERY-DOWNS[1];
[1]West Virginia Univ., Morgantown, WV; [2]Ohio Northern Univ., Ada, OH

Abstract: Objective: Psychostimulants (PS) used in the treatment of attentional deficit disorders have iatrogenic effects on sleep quality and quantity. Whether these effects extend to recreational (nonmedical) PS use has not been objectively assessed. We aimed to assess the sleep of college student nonmedical PS users and nonusers. **Methods/Analyses**: 14 self-identified PS users and 14 nonusers (N=28) contributed daily urine samples, self-reported PS use and wore a wrist actigraph for one week to quantify sleep. Participants were included as "users" in analyses if they had ≥1 positive urinalysis (n=8). On some days users self-reported (SR) PS but had a negative urine screen; these were considered independently from urine-positive days. Some self-reported users did not use per urine screen or SR (n=6) and were considered separately. Among users who used PS, one night from each of the four night categories (preceding/following use based on urine/SR) was randomly selected for each participant for analyses. Effect sizes were analyzed. **Results**: Effect sizes were large for differences in sleep efficiency (SE) on nights preceding nonuse days among users, users-who-did-not-use and nonusers per both urine (η^2=.10) and SR (η^2=.12). The same was true among users, users-who-did-not-use and nonusers for total sleep time (TST) on nights preceding nonuse per urine (η^2=.12) but not per SR. Among users only, SE preceding use vs. nonuse did not differ meaningfully per urine (d=0.02) or SR (d=0.30);

however, SE on nights following use was worse than nonuse, with considerable effect sizes per urine (*d*=0.55) and SR (*d*=1.08). Users' TST on nights preceding use was shorter vs. nonuse with large effects per urine (*d*=1.03) and SR (*d*=1.07). TST after SR was shorter vs. nonuse with a large effect (*d*=0.82) but this was not found based on urine-positive days (*d*=0.05). **Summary**: Differences in the sleep of PS users, users-who-didn't-use and nonusers may go beyond day-to-day use behavior based on the large effects observed in a comparison of their SE and TST preceding nonuse. For users, SE was lower *after* PS than after nonuse but TST after use did not consistently change. Instead, TST may be a valuable *predictor* of use behavior because of the large effect between nights preceding use vs. nonuse. Users may be attempting to compensate for less sleep by using PS for functional recovery. Alternatively, risk behavior is affected by sleep disruption and could open an avenue for sleep to influence day-to-day use choices.

Title: Effects of acute sleep debt on decision-making in mice

Authors: *E. PITTARAS[1,2,3], M. CHENNAOUI[1,3], S. GRANON[2], A. RABAT[1,3];
[1]Inst. de Recherche Biomédicales des Armées (IRBA), Brétigny sur Orge, France; [2]Inst. des Neurosciences Paris-Saclay (Neuro-PSI), Orsay, France; [3]Equipe d'accueil Vigilance Fatigue Sommeil (VIFASOM), Paris, France

Abstract: Total sleep deprivation impairs many cognitive functions in healthy humans (Chee and coll., 2008) and especially risky decision-making (Killgore and coll., 2006). No studies have questioned if a sleep debt affects such cognitive processes in mice, if individual differences emerge and what are the neurobiological basis behind them. Therefore, in this work, we studied the effect of acute sleep debt on risky decision-making processes in mice. The Mouse Gambling Task (MGT) is a decision-making task under uncertainty and risky situations that lasts 5 days (Pittaras and coll., 2013). In this task, options are more or less advantageous in the long term. MGT is organized in two phases: a phase of exploration (discovery of options) and a phase of exploitation (better knowledge of options). Usually, during the exploration phase, mice do not show any preference between options. However, during the exploitation phase preferences for long-term advantageous options emerge with inter-individuals differences i.e. some animals

show marked preference for long-term advantageous options (safe) or for long-term disadvantageous options (risky) while others make choices in between (average). In this study, we have combined the MGT with an acute sleep debt (23 hours) by using a mobile platform that bounces at random frequency and intensity. We performed this protocol in two different ways: in the first case, one group of mice was sleep deprived before the beginning of the exploitation phase and in the second case, another group of mice was deprived at the end of the exploitation phase. MGT response latency was reduced in both cases. An acute sleep debt had a significant effect on the global animal's preference only when it's applied before the beginning of the exploitation phase. In such situation, inter-individuals differences persisted and behavioral profiles were amplified by the lack of sleep e.g. risky mice insisted even more for choosing long-term disadvantageous option. Finally, based on these observations we assumed that 1) an acute sleep debt has a deleterious effect on risky decision-making processes only when it occurs between the two MGT's phases by reducing global animal's preferences for long-term advantageous options and by amplifying inter-individual choice patterns and 2) such acute sleep debt seems to either increase mice locomotors reactivity (impulsivity?) or appetitive reinforcement.

Title: Time-related changes of jaw-opening reflex excitability in quiet sleep in rats during post-surgical recovery

Authors: *R. ODAI[1], K. ADACHI[2], S. HINO[3], T. SIMOYAMA[3], H. SAKAGAMI[2], S. WATANABE[1], G. J. LAVIGNE[4], B. J. SESSLE[5];
[1]Pediatric Dent., [2]Pharmacol., Meikai Univ. Sch. of Dent., Sakado, Japan; [3]Oral surgery, Saitama Med. Univ., Kawagoe, Japan; [4]Univ. de Montréal, Montréal, QC, Canada; [5]Oral Physiol., Facuty of Dentistry, Univ. of Toronto, Toronto, ON, Canada

Abstract: Motor excitability and sleep stability are both influenced by the impact of surgery in laboratory animals and this can induce variability in outcomes of interest. For example, the excitability of the jaw sensorimotor system is depressed during quiet sleep (QS) compared with quiet awake before sleep (QWBS) in both non-human primates and rats, and the density of slow-wave sleep, a marker of sleep restorative function, is compromised by inflammation, neuropathic pain and post-operative pain. The aim of this study was to determine, in the post-surgical recovery period, the time course of the excitability of the jaw sensorimotor system and the stability of slow-wave/delta electroencephalographic (EEG) activity between awake and sleep states. Six-week-old male Sprague-Dawley rats (n = 9) received wire implantations, under isoflurane general anaesthesia, for electrocardiographic (EKG) recording, electromyographic (EMG) recordings from anterior digastric and masseter muscles, and EEG and electrooculographic (EOG) recordings. The jaw-opening reflex (JOR) was triggered by electrical stimulation of the tongue. Rats were allowed to recover from the surgical procedure for a week to become habituated to the observation environment. Three recording sessions were carried out at post-operative days 7 (D7), 12 (D12) and 16 (D16). Sleep-related electrophysiological features (e.g., EMG, EOG, EEG and EKG) were scored with epochs of 4 sec. During QWBS, the tongue was stimulated (200 μs) to define the threshold of the JOR in three stimulation trials separated by more than 5 min intervals. Then the animal was allowed to sleep freely and the JOR threshold was determined three times during QS as well as during QW after sleep. At D7, the JOR threshold was significantly lower during QS in comparison to QWBS (mean ± SEM: 86.7 ±63.9%, $P < 0.01$). At D12, the JOR threshold was similar between both states. At D16, the JOR was significantly increased during QS in comparison to QWBS (113.4 ±110.0%, $P < 0.05$), suggesting a recovery. Furthermore, during QS, the delta band (a marker of the sleep recovery process) occupied at D7 75.9 ±72.1% of the total EEG distribution of all 4 (delta, theta, alpha and beta) bands, and was reduced at D12 and D16 to 71.1 ±12.6% and 65.0 ±57.9% (NS), respectively, suggesting a return towards normality in association with the recovery process in the post-operative period. These findings suggest that both the excitability of the jaw sensorimotor system and sleep quality are recovered around post-operative days 12 to 16, and that it is essential to control for the effect of surgery on the outcomes of interest in sleep studies.

Title: Quantitative control of arousal via the midline thalamic nuclei

Authors: G. KOMLOSI[1], C. PORRERO[2], P. BARTHO[1,3], A. BABICZKY[1], C. DAVID[1], B. BARSY[1], F. CLASCA[2], L. ACSADY[1], *F. MATYAS[1,4];

Group, Budapest, Hungary; [4]MTA-TTK NAP B Neronal Network and Behaviour Res. Group, Budapest, Hungary

Abstract: Setting the right level of alertness is a key step for shaping behavioral actions. Midline thalamus (MT) was believed to play a crucial role in regulation of arousal. However, no direct experimental evidence was provided to support this assumption and, in addition, the role of thalamus to control arousal has recently been challenged. In this study we identify a midline thalamus selective marker (MSM) and use *in vivo* electrophysiology and optogenetics in MSM-Cre transgenic mice to quantitatively evaluate its role in arousal. MSM was expressed in over 98% of MT cells expressing cFos as a result of elevated arousal states. MSM also specifically labeled the thalamic cells (95-98%) which project to the main forebrain targets of midline thalamus (prefrontal cortex, amygdala and nucleus accumbens). Sindbis-Pal-GFP electroporation of MSM-positive thalamic cells visualized branching axons in multiple forebrain targets. Optogenetic activation of MSM-expressing cells in the paraventricular nucleus of MSM-Cre transgenic mice under urethane anaesthesia induced short latency, reliable multi-unit activation in the target regions, together with cortical desynchronization. In drug-free sleeping condition, brief (10 sec) optogenetic stimulation of MSM-expressing cells at 10 Hz resulted in persistent arousal accompanied by intense locomotion, lasting up to tens of minutes. Stimulation at 1 Hz was not effective. Shorter (1 sec) stimulations with 10 or 20 Hz induced brief micro-arousals, (transient EEG and muscle activation without overt sign of behavioral arousal). These effects were significantly stronger during NREM-sleep than in REM-sleep. Varying the strength of laser pulse demonstrated tight correlation between the parameters of stimulation and the magnitude of evoked effect (duration and onset of EMG/EEG changes) with little variability among the animals. Our results provide direct evidence that selective activation of MT could effectively initiate arousal in naturally sleeping mice. Furthermore, the present findings show MSM-Cre mice can be a powerful tool to investigate questions which require precise regulation of sleep states and arousal, as well as to study the role of MT in various behavioral contexts at the cellular and network levels.

Title: Sleep spindles and memory: optogenetic manipulation of parvalbumin containing GABAergic neurons in mouse thalamic reticular nucleus

Authors: *F. KATSUKI, J. M. MCNALLY, S. THANKACHAN, R. E. BROWN, J. T. MCKENNA, R. E. STRECKER, R. W. MCCARLEY;
Dept. of Psychiatry, VA Boston Healthcare System/Harvard Med. Sch., Brockton, MA

Abstract: Sleep spindles are an 8-15 Hz waxing and waning brain oscillation observed during non-rapid eye movement sleep. Electroencephalographic (EEG) recordings during sleep show that schizophrenia patients have sleep spindle abnormalities, including reduction in spindle number, along with memory consolidation impairment. An increase in spindle activity following learning has also been reported in healthy humans and animals. However, the specific cellular mechanisms controlling spindles and a causal link between spindles and cognitive function are still to be determined. Rhythmic inhibition of thalamocortical neurons by the thalamic reticular nucleus (TRN) is likely the central regulator of spindles. In particular, parvalbumin (PV) containing GABAergic TRN neurons, known to be reduced in schizophrenia patients, may play a key role in the control of spindle generation. Here we tested whether optogenetic manipulation of TRN PV neurons during sleep following learning alters spindle generation and memory performance in mice. AAV-ArchT-GFP was injected into the TRN of PV-Cre mice. In order to assess memory, mice were tested with the novel object recognition (NOR) task which consists of two phases; the familiarization phase and the recall phase. The task measures recognition memory based on the mice's natural tendency to investigate a novel object. To decrease spindles, inhibition of TRN PV neurons was performed via laser illumination (532 nm, 1-min on, 4-min

off) during the 4-hr retention interval between the familiarization and recall phases, which is commonly accepted as a memory consolidation period. EEG/EMG recording was performed during the retention interval to monitor sleep-wake states and spindle activity. Memory performance was compared between inhibition (laser on) and control (no laser) conditions (N=4). Our data suggest that animals spent more time to investigate a novel object than a familiar object in control condition (no laser), indicating that animals successfully recalled an object presented during the familiarization phase. In contrast, recognition memory was significantly impaired following inhibition of TRN PV neurons during the 4-hr retention interval (laser on). Spindle density (a number of spindles divided by the length of retention interval) decreased with inhibition of TRN PV neurons and was positively correlated with NOR performance, whereas average delta power did not decrease with inhibition of TRN PV neurons. These results show that manipulation of spindles by optogenetic inhibition of TRN PV neurons following learning alters memory performance, indicating the role of sleep spindles controlled by TRN PV neurons in memory.

Title: Cortical hyperarousal state in patients with insomnia comorbid with sleep apnea syndrome

Authors: *A. M. PARAMO-BRANDO[1], P. DURAN[2], I. Y. DEL RIO-PORTILLA[3], M. MIRANDA-ANAYA[2], R. HARO[1];
[1]Fac Medicina, UNAM, Mexico City, Mexico; [2]Facultad de Ciencias UNAM, Mexico City, Mexico; [3]Fac. de Psicologia, UNAM, Mexico, Mexico

Abstract: Different studies have reported the coexistence of insomnia and obstructive sleep apnea syndrome (OSAS), in asignificant number of patients. Around 40% to 50% of patients with OSAS suffer insomnia symptoms, nevertheless no much is known about the

physiopathology of this comorbidity. On the other hand, primary insomnia is considered as a sleep disorder caused by combined physiological, cortical and cognitive hyperarousal states, which can interfere with the sleep onset or its maintenance and could produce alterations in diurnal functioning. The cortical hyperarousal, is understood as an extension of physiological alterations, it is defined as elevated alpha, beta and gamma power frequencies (which are typical during wakefulness), as well as in the wake period previous to sleep onset, and in the NREM and REM sleep periods compared to normal sleepers. With regards to insomnia comorbid to OSAS, some authors propose that patients are under a hyperarousal state, in the same way to primary insomnia patients, however only one study has looked forward to characterize its psychological and behavioral pattern with psychometric tests, authors concluded that these patients have a similar arousal pattern that primary insomnia patients. Considering the limited knowledge about the relationship between insomnia and OSAS, we considered important to study this coexistence by means of the characterization of the electroencephalographic (EEG), frequency pattern during the sleep onset period (which consists of the wake previous to sleep onset and the first N1 sleep period), compared to patients with OSAS, with the objective to determine if these patients are under a cortical hyperarousal state proved by means of the quantitative EEG analysis with the Fast Fourier Transform (FFT). For this purpose, we selected 60 seconds EEG artifact free segments, from the wake previous sleep onset and the first N1 sleep stage, in two groups, comorbid insomnia (n=4) and OSAS patients (n=8). Segments were analyzed by one second for each subject, derivation and vigilance states were determined by means of quantitative analysis program POTENCOR. Preliminary results are presented, we observed an elevated beta absolute power and a decreased theta absolute power in the wake previous sleep onset. In the N1 period, we observed an elevated alpha and beta relative power, as well as a relative theta and delta power reduction. We hope to obtain more conclusive results when we complete the proposed subjects sample (n=10), for each groups.

Title: Estradiol modulates sleep, thermoregulation, and cognition in ovariectomized female marmosets

Authors: *N. GERVAIS[1], S. S. VIECHWEG[2], J. A. MONG[3], A. LACREUSE[1];
[1]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA; [2]Dept. of Pharmacology,, [3]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Menopause in women is often associated with hot flashes, sleep disturbance and memory deficits. Reduced circulating levels of 17β-estradiol (E2) during this period may contribute to these symptoms. Studies using animal models support this idea. In the female rat, E2 replacement modulates normal sleep-wake patterns, nighttime core body temperature (Tc), and working-memory performance. However, it is not known whether E2 has similar effects in a more translational primate model. The common marmoset (Callithrix jacchus) is a small diurnal primate well suited for such studies, due to a short lifespan (~ 10 years), high cognitive abilities, and monophasic sleep patterns comparable to those of humans. E2 replacement influences working memory in the marmoset but no study to date has examined whether E2 influences sleep patterns and thermoregulation in this species. The main goal of the present study was to conduct a preliminary examination of the effects of E2 manipulations on sleep patterns, working memory, and Tc in middle-aged ovariectomized female marmosets. Two 6-yr old ovariectomized females were implanted with a telemeter (DSI TL11M2-F20-EET) that records EEG, EMG, and Tc. Sleep patterns (including total duration of REM, NREM, and wake, duration and number bouts), Tc, and performance on the Delayed Response (DR) task were recorded under baseline and E2 replacement (12 μg/kg/day, p.o.) conditions. Compared to baseline, E2 replacement modulated performance on the DR task in a delay-dependent manner. E2 replacement was also associated with lower Tc during the night. The number of nighttime arousals and delta power were both higher in the E2 replacement condition relative to baseline, which is consistent with the idea that E2 improves sleep quality. These preliminary results support the marmoset as a model for studying the relationships between E2, sleep disturbances, working memory deficits and Tc changes that may serve as indicators of hot flashes.

Title: Effects of ethanol consumption and withdrawal on the sleep/wake cycle of high alcohol preferring (cHAP) mice

Authors: *S. HUITRON-RESENDIZ[1], N. J. GRAHAME[3], A. J. ROBERTS[2];
[1]Molec & Cell. Neurosci Dept MB-18 & Mouse Behavioral Assessment Core, [2]Molec & Cell. Neurosci Dept & Mouse Behavioral Assessment Core, The Scripps Res. Inst., La Jolla, CA;
[3]Grad. Studies IUPUI, Indianapolis, IN

Abstract: Sleep disruptions in alcoholics are more common than in non-alcoholic individuals. One of the major problems with using rodents as a model to study the effects of alcohol on sleep is their relatively low voluntary alcohol intake. Recently, crossed High Alcohol Preferring (cHAP) mice were generated, and under a free-choice drinking paradigm these mice show escalating drinking behavior accompanied by intoxication and tolerance. To further characterize the behavioral and physiological profile of these mice, we examined the sleep/wake cycle along an ethanol consumption protocol in male and female cHAP mice. Under isoflurane anesthesia, a standard set of stainless steel screw electrodes was implanted for chronic EEG and EMG recordings. The EEG was recorded from electrodes placed in the frontal and parietal bone over the hippocampus. One wk after surgery, mice were recorded for 24 hr for baseline data, and then recorded at 2, 6, and 10 wk after being exposed to a continuous ethanol/water two bottle choice protocol. The mice consumed roughly 20 g/kg ethanol per day (with females drinking more than males) and blood alcohol levels taken 4 hr into the dark cycle were about 100 mg/dl. Following 1, 2, and 30 days of abstinence, mice were recorded again for 24 hr. The EEG and EMG were stored with a resolution of 128 Hz in the hard drive of a computer for the off-line analysis of the vigilance states and spectral analysis. There were no overall changes in wakefulness or slow wave sleep associated with ethanol drinking or withdrawal/protracted abstinence. However, cHAP mice had a significant decrease in REM sleep 6 wk into drinking ($p = 0.004$), which reversed by 10 wk, suggesting a possible tolerance to the effects of ethanol on REM sleep. Interestingly, the amount of REM sleep was significantly reduced again relative to baseline levels at 1 ($p < 0.0001$), 2 ($p = 0.003$) and 30 ($p = 0.02$) days into withdrawal. These results support other studies showing that the amount of REM sleep is reduced by chronic alcohol exposure, and also suggest that the mechanisms involved in the regulation of REM sleep are uniquely compromised by ethanol.

Title: Analysis of electrophysiological cortical activity during sleep in turtles and lizards

Authors: *J. M. ONDRACEK, A. KOTOWICZ, M. SHEIN-IDELSON, G. LAURENT;
Max Planck Inst. For Brain Res., Frankfurt, Germany

Abstract: Sleep in birds and mammals has been characterized electrophysiologically as the waxing and waning of two alternating phases of brain activity. Slow wave sleep (SWS) consists of high-voltage, low frequency, synchronized activity. In contrast, paradoxical sleep (PS) resembles activity in the awake brain: erratic, desynchronized oscillations of low voltage and high frequency. In some species PS is accompanied by concurrent rapid eye movements (REMs). Reptiles, like birds, belong to the class of sauropsids and probably share a (now extinct) stem amniote ancestor with mammals. Because a homogeneous 3-layer cortex is found in all living reptiles, it is believed to have been present in the common ancestor to mammals and sauropsids. These evolutionary relationships make reptilian brains great models to explore the structural and functional evolution of vertebrate neural circuits [1]. Furthermore, comparative studies of brain structure and development suggest that the reptilian cortex may be homologous to mammalian hippocampus, which has been shown to be involved in memory consolidation during sleep [2]. Although reptiles display clear evidence of behavioral sleep and often assume stereotypical sleep postures, most early investigators failed to detect evidence of SWS in the reptilian cortex. The most consistent EEG correlate of behaviorally defined sleep was reported to be the appearance of intermittent high-voltage spikes (large sharp waves, LSW) arising from background activity, and early studies reported pharmacological similarities between LSWs and spikes arising from the mammalian hippocampus during sleep [3]. To investigate sleep-related electrical activity in the reptilian cortex and its possible similarity to mammalian hippocampal activity, we chronically implanted subdural surface arrays and penetrating depth electrodes to record from the dorsal cortex (DC) of two species of reptiles (Trachemys scripta and Pogona vitticeps). Our data suggest that LFP dynamics during sleep contain, among others, clear bouts of LSWs. In contrast, LFP during active states was characterized by frequent narrow spikes of smaller amplitude. Autocorrelations calculated over long (20 min.) durations of LFP revealed a wide central peak (5s) and multiple sidebands during sleep, and a narrow central peak (<1s) with no sidebands during active states. These results suggest the existence of functional similarities between reptilian cortex and mammalian hippocampus, with potential significance for our understanding of the evolution of sleep brain dynamics in amniotes. Title: Relation between sleep time duration and increase body mass index in a Mexican population

Authors: ***Á. PAVÓN ROSADO**[1], J. E. MOLINA-ALFONSO[2], E. AGUILAR-SÁNCHEZ[2], M. SAAVEDRA-VÉLEZ[3], C. ESCOBAR-BRIONES[4], M. A. MELGAREJO[2];
[1]Facultad de Biologia, Univ. Veracruzana, Xalapa-Enriquez, Mexico; [2]Facultad de Medicina, [3]Inst. de Neuroetologia, Univ. Veracruzana, Xalapa, Mexico; [4]Facultad de Medicina, Univ. Nacional Autónoma de México, Mexico, D.F., Mexico

Abstract: Sleep is considered a restorative, essential and periodic phenomenon in humans that is able to modulate various physiological processes. It is known that sleep plays important roles in the endocrine regulation of hormones involved in the metabolism and as a modulator of all the organism. In this regard, some studies have confirmed that expression of metabolic hormones is affected with decreased total sleep time. Metabolism of glucose and lipid degradation as well as modulation in expression of hormones as ghrelin, leptin, insulin, growth hormone, cortisol, among others, depend on ultradian sleep cycles. The goals of this study were 1) to determine whether a relationship exists between total sleep time and increased body mass index. This latter was considered as a parameter of overweight and obesity, and 2) to correlate the sleep time and anthropometric measurements and clinical tests, as glucose, triglycerides and cholesterol, to associate the parameters of overweight and obesity in a university student population. For these purposes, three surveys were applied to 3128 students of both sexes to measure quality and quantity parameters of sleep, the Epworth scale for measuring daytime sleepiness, the Athens scale for measuring insomnia, and Pittsburgh scale for quality and quantity of parameters of total sleep. Data from these surveys were collected, analyzed (by sex) and were related to anthropometric and clinical parameters. All procedures were conducted following the declaration of Helsinki, and the participants signed an information form. The results showed that subjects who slept less than 4h presented overweight it is related with the increasing of Body mass index

(BMI) in comparison with those males sleeping 8 h. In contrast, there were not statistical differences between sleep hours and BMI in females. In addition, males short sleep increased glucose in comparison with men who slept from 8-9 h presented lower glucose levels. Conversely, there were not statistical differences in females, more clinical data are analyzed. Overall, these results suggest that the reduction of sleep contributes to weight gain and increases the risk to develop metabolic syndrome and diabetes type 2 in a young Mexican population.

Title: An unsupervised brain machine interface to study the maintenance of wakefulness in rodents

Authors: *H. W. STEENLAND[1,2];
[1]Univ. of Lethbridge, Lethbridge, AB, Canada; [2]NeuroTek, Toronto, ON, Canada

Abstract: Sleep can be set aside if a superseding interests, yet there are no rodent models or methods to study how this is possible. Previous studies in rodents show that they can forgo sleep to explore an environment (Gompf et al., JNS 2010) and can even be trained to wake-up from sleep to receive rewards (Wilcox, Physiol & Behav. 1975). A software-hardware platform was developed to detect when an animal is getting drowsy in real-time (based on electroencephalogram (EEG) and electromyographic (EMG) data. Upon detection of drowsiness, one of two tones is played to arouse the animal before they fall asleep. After the tone is played the rodent must maintain arousal in order to receive a reward in the form of medial forebrain stimulation. Should the rodent fail to maintain arousal as detected by desynchronized electroencephalogram, they will not be rewarded. Mice were found to learn this task with 24 hours of unsupervised training (~200trials) in which rodents sleep through the neutral tone and

are aroused and maintain wakefulness for the rewarded tone. Future studies will aim at uncovering the neurobiological mechanism for the maintenance of wakefulness.

Title: Does circadian rhythm contribute towards sleep inertia: a meta - analysis

Authors: *S. NAIR[1], P. SAHOTA[2], M. THAKKAR[2];
[1]Univ. of Missouri-Kansas City Med. Sch., Columbia, MO; [2]HSTMV Hospital/University of Missouri-Columbia, Columbia, MO

Abstract: INTRODUCTION: Sleep inertia is a transient decrease in performance and alertness that occurs immediately after awakening. The effects of sleep inertia are variable and can last from 1 minute to approximately 4 hours upon awakening. These cognitive and performance decrements are severe and can have profound impact on decision making and/or performing critical tasks. Sleep is regulated by the interaction of two processes: Process S or the homeostatic drive that maintains the “constancy” in the amount of sleep and Process C that maintains the timing of sleep. Since the nadir of the Process C occurs in the early morning hours, some previous studies have implicated that circadian rhythm as a major contributing factor in sleep inertia. However, others have been unable to demonstrate that sleep inertia has any circadian rhythm. Thus, to further examine the role of circadian rhythm in sleep inertia, we have decided to perform a meta-analysis. METHODS: Meta-analysis is a statistical method of combining results of individual studies to obtain the most reliable conclusions. In clinical medicine, the power of meta-analysis is indispensable for building feasible and practical guidelines. We’ve started reviewing the literature and are in the process of performing a meta-analysis to further understand the role of circadian rhythm in the development and maintenance of sleep inertia. We have conducted a “PubMed” search using free-text search term “sleep inertia” to identify studies. In addition, we will also perform searches using the first, last, and corresponding authors of any of the reports identified in the initial search. RESULTS: To date, our search has retrieved 149 publication. Our initial preliminary results indicate a role of circadian rhythm in sleep inertia. However, at this time our results are preliminary and the study is ongoing. We expect to

complete the review and the meta-analysis in couple of months and present our findings at the SFN meeting in October.

Title: Ultradian dynamics of electrical brain activity in a zebra finch during sleep

Authors: *A. L. VYSSOTSKI, A. STEPIEN, R. H. R. HAHNLOSER;
Inst. of Neuroinformatics, Univ. of Zurich and ETH Zurich, Zurich, Switzerland

Abstract: Both mammals and birds have two distinguished phases of sleep: slow-wave sleep (SWS), characterized by slow-waves of the large amplitudes in electroencephalogram (EEG), and rapid-eye movement (REM) sleep, characterized by small fast wakefulness-like waves. In humans typically four or five SWS/REM cycles with a period of 70-90 minutes each occur within a night. In zebra finches similar cycles with a shorter period have been detected. However, the mechanisms of this self-organized ultradian periodicity are poorly understood. To get better description of the process we analyzed wide-band electrical brain activity, brain temperature and body movements in sleeping zebra finches. In the first experiment we recorded wide-band (1 Hz - 10 kHz) electrical brain activity from a pair of differential epidural AgCl electrodes (5-25 kOhm) placed over left and right hemisphere respectively in four male zebra finches during several nights. The brain temperature was recorded by the thermistor placed over the left hemisphere, and locomotor was quantified with the help of infrared camera. Recordings were done in sound-proof metallic chamber shielding electromagnetic disturbances. We have found that changes of high-frequency activity (HFA, 0.3-3 kHz) happened synchronously in both hemispheres with the main period of approximately 30 min in all investigated animals. Synchronous changes of activity pointed at centralized control of HFA, suggestively intermediated by the thalamus. Brain temperature changed co-directionally with the HFA,

indicating, as expected, that HFA is associated with increased metabolic activity. Slow-wave activity (SWA, < 4 Hz) dynamics was opposite to those of HFA, consistent with the concept that SWA occurs in the gaps of prolonged neuronal hyperpolarizations and firing. Shorter periods HFA dynamics undergo power law distribution that can be explained by a simple cellular automaton model. In the second experiment, to check how forebrain HFA can be controlled by mesencephalon and diencephalon, we recorded local filed potentials (LFPs) and neuronal activity from nucleus interfacialis (NIf), a part of avian vocal system receiving direct input from the thalamic nucleus uvareformis in a zebra finch during natural sleep. We exploited 16-channel single chunk silicon probe (Neuronexus Inc.) placed in a way that its tip was below NIf in the Field L2a, the middle part was in NIf, and the top-most part was above NIf in the Field L1. Neuronal firing and HFA in NIf had similar to recorded in the previous experiment ultradian rhythm with the main period about 30 min, suggesting common mechanisms of activity modulation in the superficial and deep brain structures.

Title: Misalignment time of sleep affect the glucose levels and Body Mass Index in a young Mexican population

Authors: ***E. AGUILAR**[1], J. E. MOLINA-ALFONSO[1], Á. PAVÓN-ROSADO[2], M. SAAVEDRA-VÉLEZ[3], C. ESCOBAR-BRIONES[4], M. A. MELGAREJO[1];

Abstract: Sleep is an essential process for the brain and the maintaining of metabolism. Inadequate sleep and obesity are important public health problems. Studies provide consistent evidence that recurrent sleep curtailment and shifting time of sleep may increase the risk of obesity and diabetes. In this sense the circadian clock, controls sleep, onset of sleep, also regulates energy homeostasis and the disruption is associated with obesity. The fact that many

people in our society shift their sleep and activity times several hours between the work week and the weekend is comparable to disruption like jet lag. The aim of the present study was to investigate associations between time shift of sleep on working days and free days in the Mexican population, for this purpose a total of 1346 students of Universidad Veracruzana (18-25 years) participated. The study was conducted in according to standards established by the declaration of Helsinki as well as their applied the informed consent. All subjects completed a questionnaire Epworth scale for measuring daytime sleepiness, Athens scale for measuring insomnia and scale parameters Pittsburght for quality and quantity of total sleep. Also to investigate, onsets sleep on working days and free days. Data were classified and related to anthropometric and clinical parameters. The results suggest that time shift of sleep between work days and free days increases the glucose levels(mg/dl), in the group with 4 hours of shift time sleep (90.50+1.5) compared with group 1hour shift time sleep (88.09+1.24) $p<0.05$ and delayed time of sleep increases the Body Mass Index (BMI) . Our data suggest that the difference in a midpoint of sleep on working days and free days, may contribute to weight gain and modify glucose levels, this condition might promote development of obesity and diabetes mellitus.

Title: Intermediate decrease of CSF orexin (hypocretin) and significant obesity in Prader-Willi syndrome patients compared with narcolepsy and idiopathic hypersomnia

Authors: *T. KANBAYASHI[1,2], M. OMOKAWA[1], T. AYABE[3], T. NAGAI[3], A. IMANISHI[1], Y. OHMORI[1], K. TSUTSUI[1], J. TAKAHASHI[1], Y. KIKUCHI[1], Y. TAKAHASHI[1], E. NARITA[1], S. SATO[1], K. TSUKAMOTO[4], S.-I. UEMURA[5], Y. SAGAWA[1], T. SHIMIZU[1]; [1]Akita Univ. Sch. Med., Akita City, Japan; [2]Intl. Inst. for Integrative Sleep Med. (WPI-IIIS), Univ. of Tsukuba, Tsukuba, Japan; [3]Dept of Ped, Dokkyo Med. Univ. Koshigaya Hosp., Koshigaya, Japan; [4]Akita Kaiseikai Hosp., Akita City, Japan; [5]Akita Univ. Grad. Sch. of Hlth. Sci., Akita City, Japan

Abstract: Introduction: Prader-Willi syndrome (PWS) is an acquired neurodevelopmental disorder caused by deletion in chromosome. Patients with PWS often exhibit excessive daytime

sleepiness (EDS), increased appetite, and obesity. As well as in narcolepsy, orexin (hypocretin) may be responsible for the symptoms. However, report regarding the correlation between obesity and orexin level in PWS is scarce. Here we discuss the relationship between obesity and orexin level in PWS patients, compared with narcolepsy and idiopathic hypersomnia (IHS) patients. Methods: We examined orexin levels in the cerebrospinal fluid (CSF) of 10 patients with clinically and genetically confirmed PWS with EDS, compared with 37 cases of narcolepsy patients with cataplexy, and 13 cases of IHS patients. Patients' body mass index (BMI) at the time of CSF examination was determined. All patients are Japanese and aged 15 to 50 years old. Results: CSF orexin level (mean ± S.D.) in PWS, narcolepsy, and IHS was 194 ± 45 pg/ml, 79 ± 75 pg/ml, and 291 ± 74 pg/ml, respectively. BMI (mean ± S.D.) in PWS, narcolepsy, and IHS was 34.4 ± 8.5, 23.4 ± 4.0, and 22.6 ± 2.1, respectively. Orexin level in PWS was significantly higher than narcolepsy, and lower than IHS. BMI was significantly higher in PWS than narcolepsy and IHS. Conclusion: Orexin level and BMI was higher in PWS than narcolepsy patients. Intermediately decreased orexin level in PWS patients suggests that both impaired secretion and receptor function of orexin may play a role in exhibiting symptoms such as sleepiness, increased appetite and obesity.

Title: The effects of short- and long-term sleep loss on biological and psychological measures of health

Authors: *J. L. TARTAR[1], A. I. FINS[2], L. D. HILL[1], M. R. LORENZETTI[2], T. J. A. CRADDOCK[1];
[1]Psychology and Neurosci., [2]Clin. and Sch. Psychology, Nova Southeastern Univ., Fort Lauderdale, FL

Abstract: Despite strong associations between sleep loss and health, there is no clear understanding of the mechanisms through which sleep loss alters the physiological processes that can lead to poor health. In an effort to shed light on the complex sleep-immune-stress relationship we focused on biochemical and psychological factors that previous research suggests might be essential to uncovering the role of sleep in health. To that end, we analyzed the effect of self-reported volitional chronic sleep restriction as well as short term sleep deprivation (SD) on a series of sleep and psychological health measures as well as biomarkers of health including immune functioning/inflammation (IL-1β), stress (cortisol), and sleep regulation (melatonin) in young adult females. We found that across multiple measures, ongoing sleep loss was associated with decreased psychological health and a reduced perception of self-reported physical health. New to our study, we found that volitional CSR was related to increased cortisol and increased inflammation as measured through IL-1β levels. We separately looked at individuals who experienced CSR with and without a delayed sleep time and found that IL-1β levels and cortisol levels were significantly elevated in both groups, relative to those who did not experience CSR or a late sleep time. We did not observe any changes in melatonin across groups and melatonin levels were not related to any sleep measures. Unlike CSR, we did not observe any changes in cortisol with 24 hours of SD. Analyses of inflammation and associated biomarkers of health with SD are ongoing, but preliminary analyses suggest that the effects of SD on inflammation and psychological health mimic those of CSR. Overall, our results show how an increase in a pro-inflammatory process and HPA axis activity relates to volitional CSR, with and without a delayed sleep time and how these mechanisms relate back to psychological and self-reported health.

Title: The effects of citalopram on masseter and neck muscle activities in mice

Authors: Y. NOGAWA[1,3], *A. MOCHIZUKI[1], K. KATAYAMA[2], M. IKEDA[2], Y. ABE[2], S. NAKAMURA[1], K. NAKAYAMA[1], M. KIYOMOTO[1], T. KATO[4], K. BABA[2], N. WAKABAYASHI[3], T. INOUE[1];

Abstract: Bruxism is characterized by involuntary masseter muscle activity during not only sleep state but also awake state. Recently it is reported that depressed patients who take citalopram, which is one of the selective serotonin reuptake inhibitors (SSRIs), for long periods have been frequently associated with bruxism. However, it is not clear whether SSRIs are involved in the induction bruxism. In this study, we first examined the effects of citalopram on activity of the masseter and neck muscles during wakefulness (W), non-rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep in mice. Mice were prepared for chronic recording of electroencephalography (EEG), electro-oculography (EOG), and electromyography (EMG) of the masseter and neck muscles. After recovery and training periods, mice were recorded for 24 h as the control condition. Subsequently osmotic minipumps, which were filled completely with saline (n = 4) or citalopram hydrobromide (16.5 mg/ml, n = 5), were implanted under the skin of the back and saline or citalopram hydrobromide (10 mg/kg/day) were continuously delivered from the minipump. After 5 days of saline/citalopram administration, the recording sessions of the administration conditions were acquired for 24 h. Activities of EEG, EOG and EMG were quantified for each 10-s epoch, and EMG measurements of masseter and neck muscles were normalized using mean activity during total W over 24-h period under control condition. Under the control condition, histograms of masseter and neck activities during W and NREM sleep showed bimodal and unimodal distributions, respectively, and it seemed that the masseter and neck muscle activities during W slightly increased by citalopram administration. Both in the dark and light periods, the mean activities of the masseter muscle during W, NREM sleep, or REM sleep after citalopram administrations were not different from the activities during W, NREM sleep, or REM sleep after saline administration, respectively. Citalopram did not alter the ratios of numbers of the two clusters that were composed of greater and lesser masseter activities in any vigilance state compared with the ratios of the saline administrated group. Similarly, citalopram did not alter the mean activities of the neck muscle in any vigilance state both in the dark and light periods. These results suggest that citalopram using osmotic minipump administration for 5 days may not affect activities of the masseter and neck muscles.

Title: Can sleeping birds preen? Dissociation between sleep-related EEG activity and behavior in pigeons

Authors: *N. C. RATTENBORG[1], D. MARTINEZ-GONZALEZ[1], J. VAN DER MEIJ[1], G. J. L. BECKERS[2], A. L. VYSSOTSKI[3], M. POMPEIANO[4], E. BALABAN[4];

Abstract: Dissociations between sleep-related brain and behavioral states have been observed in mammals, including humans. Like mammals, birds exhibit rapid eye movement and slow-wave sleep (SWS), the later associated with homeostatically-regulated EEG slow-wave activity (SWA). Although elevated SWA has also been observed during some episodes of feather preening in birds, movement artifacts have not been ruled out as an explanation for this activity. Consequently, preening has usually been taken as an indicator of waking in birds. We demonstrate that slow-waves during preening are not movement artifacts, and preening with slow-waves reflects a dissociated state between the forebrain and brain regions controlling preening. EEG and head movements were recorded in domestic pigeons (Columba livia) with a 4-EEG-channel head-mounted data logger (Neurologger 2A) including a 3D accelerometer. Two epidural electrodes were placed on each hemisphere (mesopallium and hyperpallium) and referenced to an ipsilateral electrode on the cerebellum. All signals were sampled at 200 Hz. Behavior was video recorded. During preening, pigeons typically closed their eyes and exhibited rapid, repetitive movements of the head. Preening could occur with waking EEG activity or with high-amplitude, slow-waves (1-3 Hz) similar to those occurring during normal SWS. Individual slow-waves were not correlated with individual preening head movements. Moreover, changes in interhemispheric and intrahemispheric coherence between wakefulness and normal SWS followed a similar pattern during preening with slow-waves. During wakefulness, interhemispheric coherence was higher than intrahemispheric coherence, whereas during normal SWS and preening with slow-waves, interhemispheric coherence decreased and intrahemispheric

coherence increased relative to wakefulness. In conclusion, preening can occur together with SWS-like EEG activity recorded from the forebrain. Preening is likely to involve central-pattern-generating circuitry in the midbrain, brainstem and/or spinal cord that does not require forebrain control, which is why it may be activated in a dissociated fashion during sleep. From an adaptive perspective, given that birds sacrifice visual vigilance during preening, presumably to protect the cornea, it might make sense for them to simultaneously discharge some sleep pressure in the forebrain.

Title: The relationship of sleep-wake and anxiety phenotypes analyzed using genetic mouse models and mice of different ages

Authors: *K. M. HAMRE[1], S. LATTIMER[2], S. S. JOSHI[3], K. D. DONOHUE[3], B. F. O'HARA[3];
[2]Dept. of Anat. & Neurobio., [1]Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN; [3]Univ. of Kentucky, Lexington, KY

Abstract: Sleep and anxiety are interrelated phenotypes with anxiety having the ability to cause sleep disruptions and sleep disruptions contributing to heightened anxiety. While the relationship between these two variables is evident when one is disrupted, the relationship in normal, baseline states has not been fully evaluated. The evaluation of this relationship may provide information about whether individuals with specific sleep-wake characteristics are more or less likely to show increased anxiety phenotypes and vice versa. To test this relationship, 2 experiments were run in mice of differing genetic backgrounds, ages and sexes. Sleep-wake phenotypes were assessed using the non-invasive Piezo system. In experiment 1, adolescent (beginning at approximately 35 days of age) and adult (over 90 days of age) male and female C57BL/6J,

DBA/2J and BALB/c mice (n = 10/ strain/ sex/ age) were tested. The same mice were tested in both to assay sleep-wake and anxiety phenotypes assessed using elevated plus mazes and activity chambers. Sleep-wake phenotypes were measured for 5 days and the Piezo system was easily able to assess sleep in adolescent mice. As expected, strain and sex differences were observed across many of the measures. In comparing sleep-wake phenotypes, there was little difference across the ages suggesting that sleep-wake phenotypes are stable by adolescence in mice. Correlational analyses between sleep-wake and anxiety phenotypes showed only a few significant correlations. The exception was the measure of primary wake onset (when wake percentage increases dramatically, usually near dark onset) which was significantly correlated with many anxiety measures across sexes and ages. Experiment 2 used BXD mice and bioinformatic analyses to assess the relationship between sleep-wake phenotypes and anxiety measures using archived measures found on GeneNetwork.org. Different mice were tested for each phenotype and both males and females were examined for many of the measures. Similar to the results observed in experiment 1, the majority of anxiety measures were not significantly correlated with any of the sleep measures. However, there were several interesting relationships, some of which occurred in a sex-specific manner, including the relationship between adrenal weight and sleep parameters. These results suggest that while globally, the relationship among sleep-wake and anxiety phenotypes are relatively weak, individual measures show strong relationships between the two. This further suggests that these phenotypes may be useful predictors of which individuals with sleep problems are at higher risk for developing anxiety disorders and vice versa.

Title: Caffeine prevents the development of pain hypersensitivity after acute and chronic sleep restriction in mice

Authors: ***C. ALEXANDRE**[1,2], A. LATREMOLIERE[3,2], G. MIRACCA[1], T. E. SCAMMELL[1,2], C. J. WOOLF[3,2];

[1]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]Neurobio., Boston Children's Hosp., Boston, MA

Abstract: The average American adult obtains 15-25% less sleep than optimal, and up to 10% of the adult population have fragmented, non-restorative sleep from sleep apnea or other sleep disorders. Experimental sleep deprivation increases pain sensitivity in healthy, pain-free volunteers, and healthy but sleepy individuals experience hyperalgesia. We examined how sleep disturbance affects pain sensitivity in mice and how it could be reduced. All mice (c57Bl6/j) were instrumented for sleep recordings (EEG/EMG) and allowed 15 days of recovery. After collection of baseline pain measures and sleep-wake behavior, we deprived mice of sleep for 6, 9 or 12 hours (using gentle, minimally-stressful procedures) and then immediately tested their mechanical (von Frey filaments) and heat sensitivity (hotplate at 52C and acetone). Sleep deprivation (SD) sessions were separated by at least 10 days. Control mice (not sleep-deprived) were tested together with the sleep-deprived animals in a blinded fashion. Both mechanical and heat sensitivity dose-dependently increased with the duration of SD, while no changes occurred in control mice allowed to sleep ad libitum. In addition, 5 days of chronic sleep restriction (6 hours SD daily) increased pain sensitivity to a similar degree as 12 hours of acute SD, suggesting that the changes in pain sensitivity are cumulative. As these interventions increase sleepiness, we tested whether medications that improve alertness could reduce or prevent pain hypersensitivity in sleep-deprived animals. We treated mice with caffeine (20 mg/kg i.p.) two hours before the end of an acute SD session (9 hours) and on the 5th day of repeated sleep restriction. Caffeine fully prevented the development of mechanical and heat pain hypersensitivity in both paradigms, but it had no effect on pain sensitivity in mice allowed to sleep ad libitum. We also subjected a group of mice to chronic sleep fragmentation (CSF; 9 hours of automated CSF over 5 consecutive days) to test if disrupting sleep continuity increases pain sensitivity. CSF severely disrupted normal sleep architecture by shortening sleep bouts (mean duration of NREM sleep episode reduced by ~50%) without reducing the total amount of NREM sleep. Sleep fragmentation did not affect pain sensitivity for any modalities tested. Altogether these results suggest that sleep loss, rather than sleep fragmentation, is responsible for the development of pain hypersensitivity. Most likely, sleep loss increases pain hypersensitivity by affecting nociceptive processing within the CNS, and importantly this can be prevented by promoting alertness and reducing sleepiness.

Title: Circadian and sleep-related gene polymorphisms are associated with chronotypes and road accident history in professional bus drivers

Authors: *V. DOROKHOV[1], A. N. PUCHKOVA[1], A. O. TARANOV[1], T. V. TUPITSYNA[2], P. A. SLOMINSKY[2], V. V. DEMENTIENKO[3];
[1]Sleep and Wakefulness Neurobio. Lab., IHNA RAS, Moskva, Russian Federation; [2]IMG RAS, Moskva, Russian Federation; [3]Neurocom, Moskva, Russian Federation

Abstract: Homeostatic mechanisms of the brain as well as circadian clock can significantly influence the person's alertness level. For the drivers reduced alertness may manifest as unperceived increase in road accident risk. Due to individual differences in sleep, biological clock functions and sleep deprivation resistance a person may be better suited to work at a particular schedule. Thus appears the need to assess objective data and search for genetic correlates of fatigability. This study has looked for possible connections between single nucleotide polymorphisms (SNP) and chronotypes and accident history in Russian bus drivers. 237 bus drivers (all male) participated in the study, 188 of them had traffic accident records. The drivers worked on rolling schedule with shifts starting at 3:30, 6:30, 9:30, 12:30, 15:30, 17:30. To assess chronotype we have used a Russian version of Munich Chronotype Questionnaire (MCTQ) and a Sleep-Wake Pattern Assessment Questionnaire (SWPAQ; Putilov, 1990, 2000). SWPAQ measured the scales of morning lateness (M, high score means low activation in the morning) and evening lateness (E, high score means high activation in the evening). 4 SNPs were tested: rs12649507 in CLOCK (associated with sleep length), rs1159814 in RORA and rs4851377 in NPAS2 (associated with chronotype), rs324981 in NPSR1 (associated with sleep onset time). MCTQ assessment revealed high variance in sleep duration (3,9 to 9,9 h), average parameters were close to normal (6,9±1,3 h), and prominent social jetlag (-6,8 to 7,2 h, average 1,7±1,7 h) caused by the shift work. In the SWPAQ correlation between M and E was found ($r=0,34$, $p<0,001$). Correlation analysis (gamma correlation) demonstrated significant results in midsleep time for SNPs in RORA ($r=-0,13$ for A allele) and NPSR1 ($r=0,22$ for C allele). Social jetlag showed connections with SNPs in NPSR1 and CLOCK ($r=0,20$ for A allele and $r=-0,17$ for A allele). Average sleep duration showed no significant connection with the tested SNPs. C allele in RORA gene was also negatively connected with M subscale ($r=-0,16$). We have compares the same SNPs against the drivers' road accident history (presence and number of road accidents, driver's fault). For minor alleles in CLOCK and RORA genes there was a significant negative correlation with the "driver's fault" parameter ($r=-0,35$ and $r=-0,20$ respectively). Carriers of a minor C allele in RORA gene tended to be earlier choronotypes and less prone to

cause road accidents Based on our results we can say that SNPs in CLOCK, NPSR1 and especially RORA genes may contribute to individual differences in chronotype and sleep parameters and through them - to road accident risk.

Title: Analysis of splicing factor Rbfox2 isoforms in the rat cortex and hypothalamus

Authors: *D. A. CARTER, L. M. M. PARTRIDGE;
Cardiff Univ., Cardiff, United Kingdom

Abstract: Rbfox proteins are regulators of gene splicing that bind pre-mRNAs at UGCAUG elements, and effect either exon inclusion, or exclusion, depending upon the relative position of the target site. All three proteins in the Rbfox2 family, RBFOX1 (A2BP1), RBFOX2 (RBM9) and RBFOX3 (NeuN) are widely, although differentially, expressed in the brain, but the diversity of functional activity is not fully appreciated because antibodies cannot distinguish the numerous isoforms of individual Rbfox proteins. We are interested in expression of Rbfox in the adult rat hypothalamus where the post-mitotic neuron marker, NeuN/RBFOX3, is absent in a major population of neurons in the suprachiasmatic nucleus (SCN). Focusing on Rbfox2, we initially showed that cellular RBFOX2 immunoreactivity is abundant across NeuN-negative regions of the rat SCN; therefore RBFOX2 may, at least partially, substitute NeuN-mediated splicing regulation in this cellular population. We have also found evidence of SCN-specific populations of Rbfox2 mRNAs - using RNA sampled from either adult SCN or somatosensory cortex, we amplified and sequenced mRNAs with primers designed around annotated start/stop codons in Rbfox2 ORFs. mRNA population analysis revealed a diversity of sequences; these exhibit both inclusion and exclusion of different exons as well as differential use of cryptic splice sites. Sequence variation in both brain populations is primarily located in C-terminal domain (CTD) coding sequence, changing both the reading frame and use of alternative stop codons in this region. In contrast, the RNA Recognition Motif (RRM) domain was maintained in all Rbfox2 variants sequenced to date. The CTD sequence variations potentially affect a number of CTD functional activities including protein-protein interaction, sub-cellular localization and exon-

inclusion activity. This potential functional variety is interesting in light of our finding that SCN and cortex samples exhibit distinct populations of Rbfox2 mRNAs. As NeuN is known to regulate splicing of Rbfox2, the differential occurrence of Rbfox2 isoforms in the two brain regions may relate directly to NeuN availability. Analysis of intronic sequence around alternative Rbfox2 exons revealed both upstream and downstream UGCAUG elements that are positioned to mediate possible Rbfox family cross-regulation. These studies indicate that the known diversity of Rbfox expression in the adult brain extends to involve cell-type-specific, Rbfox2 CTD activity. A distinct Rbfox2 cohort in the SCN may contribute to a selective splicing program required for functional activity in populations of these hypothalamic neurons.

Title: The suprachiasmatic nuclei, asymmetries and the involvement on non-proestrous events in the regulation of ovulation

Authors: C. C. SILVA[1], D. P. BENITEZ[1], J. C. MUÑOZ[1], G. D. CORTÉS[1], M.-E. CRUZ[1], A. FLORES[1], *R. DOMINGUEZ[2];
[1]BRRU, [2]FES Zaragoza UNAM, Mexico City DF, Mexico

Abstract: GnRH release, and hence ovulation, is timed by neural circadian signals arising from the suprachiasmatic nucleus (SCN) that can only trigger it when converge with estradiol levels characteristic of proestrous day. There is compelling evidence about asymmetries in the involvement of left- and right-hypothalamic structures and also regarding the participation of neural signals regulating ovulation in days other than proestrous, but nothing is known about the participation of the SCN. In order to test the possibility that the SCN sends asymmetric information essential for the regulation ovulation before the preovulatory surge of GnRH, we injured the left- or right-SCN of adult cyclic female rats at 09:00 h of estrous or metaestrous. Animals were sacrificed the next predicted estrous and the ova shed was counted. Sham surgery,

barbiturate anesthetized (25 mg/kg) and intact animals were used as controls. Sample size was 7 but only animals displaying lesions without damage to the contralateral SCN or ipsilateral kispeptin centers were considered for this study. Lesion and sham surgery of either side of the SCN blocked ovulation independently of the stage of the cycle (the proportion of ovulating animals between total animals was: estrous; intact 7/7, anesthesia 7/7 R-sham 3/7, L-sham 1/7, R-lesion 0/7, L-lesion 3/7; metaestrous; anesthesia 6/7 R-sham 0/7, L-sham 2/7, R-lesion 0/7, L-lesion 0/7). This result shows the involvement of the SCN and neural pathways above it in the progress of ovulation. To depict the specific signaling controlled by the SCN on these stages of the estrous cycle, a second batch of rats received the same treatments and then were hormonally primed with either, GnRH (3.7 μg/kg) or estradiol benzoate (10 μg total) at 14:00 h of the predicted proestrous or diestrous, respectively. GnRH restored ovulation, suggesting that both sides of the SCN are needed for proper triggering of the preovulatory GnRH surge and that pituitary and ovarian sensitivity to their ligands remains intact after unilateral ablation of the SCN. Estradiol treatment was effective in rats with surgery performed on estrous (R-sham 4/5, L-sham 4/5, R-lesion 3/3, L-lesion 5/7), but not on metaestrous (R-sham 4/5, L-sham 0/3, R-lesion 0/3, L-lesion 0/3). This result supports our idea that SCN tunes ovulation by regulating other events in addition to the preovulatory gonadotropin surge in an estrous cycle stage-dependent fashion. We suggest that the lack of responsiveness to estradiol priming is the consequence of an impairment in estrogen receptor-α expression in the periventricular area, known to be involved in the integration of circadian and estrogenic signals gating ovulation.

Title: Functional properties of intergeniculate leaflet inputs to the suprachiasmatic nucleus in a novel *in vitro* slice preparation

Authors: ***L. HANNA**, M. HOWARTH, T. M. BROWN;
Neurosci., Univ. of Manchester, Manchester, United Kingdom

Abstract: A subset of intrinsically photosensitive melanopsin expressing-retinal ganglion cells (mRGCs) target an interconnected network of nuclei that together define behavioural and physiological responses to changes in ambient illumination: the suprachiasmatic nucleus (SCN), intergeniculate leaflet (IGL) and the pretectal olivary nucleus (PON). At present, the functional significance of interactions between these various nuclei is unclear. To address this issue, we set out to establish an *in vitro* slice preparation that retains optic tract projections to, and network connectivity between these anatomically dispersed nuclei. We first modelled the axonal trajectories linking the SCN, IGL and PON via X-gal histochemistry in slices prepared from melanopsin reporter mice (Opn4tauLacZ). With this method, we determined that a 600μm thick slice, with a slicing angle of 30 degrees off the coronal plane, was required to preserve retinal projections and most of each nucleus intact. Perforated multi-electrode array recordings revealed that the resulting slices remained viable for >24h *in vitro*, with the SCN exhibiting robust circadian variation in spontaneous electrical activity. Moreover, electrical stimulation of the optic chiasm reliably evoked excitatory (glutamatergic) responses across all retinorecipient nuclei, indicating that retinal projections were maintained in this slice preparation. Importantly, electrical or optogenetic stimulation of the IGL revealed inhibitory (GABAergic) responses in the SCN region and modulated responses to optic tract stimulation, indicating the presence of a functional geniculohypothalamic tract (GHT). In summary, this novel 'non-image forming' (NIF) visual slice preparation represents a useful new tool for understanding the functional connectivity and network organisation of the extended circadian system.

Title: Photic responses of suprachiasmatic nucleus neurons in the Rhesus monkey

Authors: *K. Q. CHANG[1], P. D. GAMLIN[2];
[1]Vision Sci. Grad. Program, Univ. of Alabama At Birmingham, Birmingham, AL;
[2]Ophthalmology, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: The suprachiasmatic nucleus (SCN) is the “master clock” that regulates circadian rhythms in mammals including primates. In rodents, neurons of the SCN are photically modulated by input from the retina that arises predominantly from intrinsically photosensitive ganglion cells (ipRGCs) (Do and Yau, 2010). In macaque monkey, ipRGCs also provide a major input to the SCN (Hannibal et al., 2014), but the photic response characteristics of primate SCN neurons have not been studied to date. Thus, in primates, it is not known how the ipRGC signals that influence SCN neurons are combined and transformed to photically entrain circadian rhythms. Therefore we have initiated a study of the photic response properties of SCN neurons in awake, trained Rhesus monkeys. Using a 6-primary, extended Maxwellian view system, an animal was trained to fixate a central target while we presented stimuli of varying size, irradiance, and spectral composition. Eye movements and pupil diameter were measured binocularly with a video eye tracking system (ISCAN). Once the animal was trained, a recording chamber was placed, and single-unit recording sessions occurred between ZT6-10. The SCN was targeted using MRI and familiar landmarks. Recording locations within the SCN were verified postmortem by micro-lesions combined with Nissl stain and immunohistochemical labeling of SCN neurons for vasoactive intestinal polypeptide. We found that SCN neurons (6 cells) possess a low spontaneous firing rate, display both transient and tonic ON responses to light onset, and possess extensive, generally bilateral, receptive fields. Sustained firing rate increased with increases in retinal irradiance but, for some SCN neurons, the threshold for evoking these responses was substantially greater than that required to evoke a robust sustained pupillary response. Our preliminary data reveal that many SCN neurons possess bilateral receptive fields, which is unusual for retinorecipient neurons in primates, but is seen for some neurons in the pretectal olivary nucleus (Clarke et al., 2003). Furthermore, our data suggests that the majority of SCN neurons in primates are light-activated in contrast to other mammals in which many are reported to be light-suppressed (Jiao et al., 1999). In summary, there appear to be significant differences in the photic responses of primate SCN neurons compared to other mammals. Our findings may provide insight into the human circadian rhythm photic entrainment as well as dysfunction such as jet lag and psychiatric disorders.

Title: CK1 Inhibitor, Longdaysin, has mild effect on behaviors under normal lighting conditions

Authors: *P. FENG[1], A. AKLADIOUS[2], Y. HU[4], P. J. SMITH[3];
[1]Res., Case Western Reserve Univ/Cleveland VA Med. Ctr., Cleveland, OH; [2]Louis Stokes Cleveland DVA Med. Ctr., Cleveland, OH; [3]Louis Stokes Cleveland DVA Med. Ctr., Louis Stokes Cleveland DVA Medical Center, OH; [4]Pul/Medicine, Case Western Reserve Univ., Cleveland, OH

Abstract: Bmal1/Clock heterodimer in the SCN is a well-defined master trigger of the internal circadian clock, which synchronizes biological rhythms and behavioral activities in human and animals. To maintain the rhythmic cycles, there are multiple lines of negative biofeedback that help to terminate the circadian upward phase. Chemicals that affect the feedback lines, affect the features of circadian signals too. It is reported that longdaysin, a CK1 inhibitor, increased the length of circadian cycles. We observed effects of longdaysin on several behaviors under normal light dark conditions. We performed a series of behavioral tests on adult wildtype mice that were housed under controlled conditions. The light dark schedule was 12 hours light and 12 hours dark. Drug was administered through intracerebroventricular route with either 4 µl vehicle (12.5% DMSO) or longdaysin dissolved in vehicle and tested for forced swim test, tail suspension test, social interaction test and novel object recognition test. In order to see if longdaysin has anti-fatigue effects, a weight bearing (bearing a small weight on the back equal to ~7% body weight) swim test was also conducted. Due to a relative long period (25 min) of swim in this test, longdaysin (20 mg/kg) or vehicle was administered through intraperitoneal route after confirmation that the drug was able to cross blood-brain-barrier nicely. Surprisingly, results for immobility were different in forced swim test and in tail suspension test. Compared with the vehicle group, mice treated with longdaysin had significantly longer swim time in the forced swim test but had significantly longer immobile time in the tail suspension test. In novel object recognition test, mice in longdaysin group spent less time with the first object and more time in exploring the second object. In the social interaction test, group differences for the time spent with playmate 1 and playmate 2 were not significant in all measured variables. In weight bearing test, we measured the time to first immobile period (defined as equal to or longer than 3 seconds), the swim time to the second immobile period and the total swim time (i.e., to the third immobile period). Means of group differences were not significant in any of the measured variables. In conclusion, longdaysin treatment has an effect on immobility and novel object recognition but it does not have anti-fatigue effect. More test need to be done for further define the effect of CK1 inhibition on behavioral regulation.

Title: The expression of muscarinic receptor m1AChR of the suprachiasmatic nucleus varies throughout the day

Authors: E. VIEYRA[1], L. MENDOZA-GARCÉS[2], R. DOMINGUEZ[1,2], *M. B. CRUZ[1]; [1]Univ. Autonoma De México, Mexico DF, Mexico; [2]Dept. of Basic Res., Natl. Inst. of Geriatrics, Mexico City, Mexico

Abstract: The "central pacemaker" that orchestrates the circadian rhythms is located in the suprachiasmatic nucleus (SCN) of the hypothalamus. The central cholinergic system regulates the circadian system and modulates the activity of neurons in the SCN. In rats, the SCN receives cholinergic projections from the basal forebrain including the nucleus basalis magnocellularis and the brainstem from the pedunculopontine tegmental nucleus and laterodorsal tegmental nucleus. The role of the muscarinic receptors in the regulation of the SCN is unknown. We have previously shown that the unilateral blockade of muscarinic receptors of the right SCN at the day of proestrus by the microinjection of atropine, resulted in the blockade of ovulation at the next day. Because atropine blocks all the muscarinic receptors, the aims of present study were to analyze the distribution of the m1AChR receptors in the right or left SCN at different hours of the day, on each day of the estrous cycle. For this purpose, we analyzed the number of neurons positive to the m1AChR receptor in the left and right SCN on each day of the estrous cycle of rats sacrificed at 11.00 and 17.00 h. The presence of m1AChR receptors was demonstrated by immunocytochemistry. In animals sacrificed at 11.00 h the number of neurons expressing m1AChR receptors in the right and left SCN of was higher than those sacrificed at 17:00 h (right 133.7±29.5 vs. 44.7±14.6, $p<0.05$ Student's t test; 110.1±30.6 vs.42.6±17.5 n.s.). Present results suggest that expression of the muscarinic receptors m1AChR in the right or left SCN depends on the time of the day. Supported by DGAPA grant IN-220014-3 and CONACYT grant 236908

Title: Localization and circadian expression of GABA transporters in the suprachiasmatic nucleus

Authors: M. MOLDAVAN[1], O. CRAVETCHI[1], M. WILLIAMS[2], R. P. IRWIN[1], S. A. AICHER[2], *C. N. ALLEN[1];
[1]OR Inst. Occup. Hlth. Sci., [2]Depart Physiol & Pharm, Oregon Hlth. Sci. Univ., Portland, OR

Abstract: GABA is the principal neurotransmitter in the hypothalamic suprachiasmatic nucleus (SCN), the master circadian clock. Despite the importance of GABA uptake for GABAergic neurotransmission, the localization and function of GABA transporters (GATs) in the SCN has not been investigated. Western blot analysis, immunohistochemical, and electron microscopic studies demonstrated the presence of GABA transporter 1 (GAT1) and GABA transporter 3 (GAT3) in the SCN. Both GATs exhibited diurnal expression with a nadir at Zeitgeber time (ZT) 12 and peak at ZT 24. By light microscopy, GAT1 and GAT3 were co-localized and distributed throughout the SCN. GAT1 and GAT3 were not expressed in the perikarya of arginine vasopressin (AVP)- or vasoactive intestinal peptide (VIP)-immunoreactive neurons, nor in neuronal processes of the SCN neurons of adult rats labeled with the neuronal marker Neurofilament Heavy Chain. SCN neurons in cell culture (P8) also were immunonegative for GAT1. By electron microscopy, astrocytic glial processes immunoreactive (-ir) for GAT1 or GAT3 surrounded unlabeled neuronal perikarya and axons. GAT1- or GAT3-ir glial cells also enveloped symmetric and asymmetric axo-dendritic synapses. GFAP-immunopositive astrocytes grown in cell culture were immunoreactive for GAT1 and GAT3 - both GATs could be observed in the same cell. These data demonstrate that synapses in the SCN function as a “tripartite” synapse consisting of presynaptic axon terminals, postsynaptic membranes, and astrocytes. This

model suggests that astrocytes expressing both GATs may regulate the diurnal changes of extracellular GABA and modulate the activity of neuronal network in the SCN.

Title: The influence of light on GABAA receptor expression in the suprachiasmatic nucleus of male Syrian hamsters

Authors: ***J. C. WALTON**, J. K. MCNEILL, IV, H. E. ALBERS;
Neurosci. Inst. and Ctr. for Behavioral Neurosci., Georgia State Univ., Atlanta, GA

Abstract: GABAA Receptors (GABAARs) are pentameric ligand gated ion channels and their subunit composition determines channel properties and location on the cell membrane. GABAARs containing the δ subunit are tonically active high-affinity non-desensitizing channels found at extrasynaptic locations, whereas classical phasic inhibition is mediated by synaptic GABAARs containing the γ2 subunit. Recent studies have revealed that expression levels of δ and γ2 subunits may regulate the balance between tonic and phasic inhibition in multiple brain regions. In addition, GABAAδ receptors also have a specific role in the regulation of photic input into the SCN in a circadian phase-specific manner and we have recently shown that the mRNA for these two receptors is expressed in an antiphase circadian rhythm. However, whether these transcriptional rhythms translate into rhythms of GABAAR protein expression in the SCN is unknown. Toward this end, we collected brains from male Syrian hamsters that were exposed to either a 14:10 L:D cycle or constant dark (D:D) at CT/ZT 1, 6, 13, and 19. We then assessed GABAAδ and γ2 expression in the SCN using immunohistochemistry. Both subunits are expressed in a 24h pattern under an L:D cycle, with peak immunoreactivity of both proteins occurring at night. However, when held in constant dark for 10 days this expression pattern was abolished for GABAAδ. Surprisingly, constant darkness inverted the expression pattern of

GABAAγ2, resulting in peak immunoreactivity occurring during the subjective day. Furthermore, GABAAγ2 immunoreactivity was higher during the subjective day under D:D than at night under L:D. Taken together, these results indicate that light may suppress protein expression of both GABAAδ and γ2 in the SCN resulting in a 24h pattern of expression, yet when released from photic inhibition in DD, a circadian rhythm for GABAAγ2 is unmasked.

Abstract: The circadian (~24 h) clock is continuously entrained (reset) by ambient light so that endogenous rhythms are synchronized with daily changes in the environment. Light-induced gene expression is thought to be the molecular mechanism underlying clock entrainment. mRNA translation is a key step of gene expression, but the manner in which clock entrainment is controlled at the level of mRNA translation is not well understood. We found that a light- and circadian clock-regulated MAPK/MNK pathway led to phosphorylation of the cap-binding protein eIF4E in the mouse suprachiasmatic nucleus of the hypothalamus, the locus of the master circadian clock in mammals. Phosphorylation of eIF4E specifically promoted translation of Period 1 (Per1) and Period 2 (Per2) mRNAs and increased the abundance of basal and inducible PER proteins, which facilitated circadian clock resetting and precise timekeeping. Together,

these results highlight a critical role for light-regulated translational control in the physiology of the circadian clock.

Title: β2-mediated inactivation drives the diurnal difference in BK current levels in suprachiasmatic nucleus and regulates circadian rhythmicity

Authors: *J. P. WHITT[1], J. R. MONTGOMERY[2], A. L. MEREDITH[3];
[1]Physiol., Univ. of Maryland Baltimore, Baltimore, MD; [2]Physiol., Univ. of Maryland Sch. of Med., Baltimore, ME; [3]Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Circadian patterning of neural activity in the suprachiasmatic nucleus (SCN) of the hypothalamus, the brain's circadian clock, is achieved through daily regulation of ionic currents, including the BK K^+ current. BK currents are larger at night compared to the day, and the diurnal variation in BK current regulates SCN action potential (AP) frequency and circuit rhythmicity. Of the two BK channel auxiliary subunits expressed in SCN, β2 and β4, we found that loss of β2 (β2 KO) decreased circadian circuit rhythmicity. To assess the influence of β2 subunits on BK current properties and AP activity in the SCN, current and voltage-clamp recordings were made from neurons in acute slices. We found that BK current size was inversely correlated with the number of BK currents showing inactivation. During the day when BK currents were smaller, 65% of neurons exhibited BK inactivation. In contrast, during the night only 35% of BK currents inactivated. β2 KO neurons had a complete loss of BK current inactivation, as well as a reduced daytime AP frequency (1.9 ± 0.2 Hz for WT and 0.5 ± 0.1 Hz for β2 KO). BK current inactivation was restored in SCN neurons through intracellular delivery of a soluble 45 amino acid inactivating "ball" peptide derived from the N-terminus of β2 (β2N). Rescue of inactivation by β2N reduced daytime BK current magnitude to WT levels (42 ± 9 pA/pF for β2 KO/β2N and

36 ± 7 pA/pF for WT) and increased daytime AP firing in β2 KO neurons to levels compared to WT (1.9 ± 0.1 Hz). This increase in firing due to restoration of inactivation was associated with a decrease in the amount of depolarization necessary to reach threshold (ΔV=[Threshold potential - baseline membrane potential]; 8.7 ± 0.8 mV for WT; 11.4 ± 0.3 mV for β2 KO; 8.4 ± 0.5 mV for β2 KO/β2N). These data demonstrate that β2-mediated inactivation of BK currents is required to facilitate higher frequency firing during the day and is necessary for normal SCN circuit rhythmicity.

Title: Diurnal regulation of BK-Ca^{2+} channel coupling in the mouse suprachiasmatic nucleus

Authors: *A. MEREDITH[1], J. WHITT[2];
[1]Dept. of Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Physiol., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: BK K^+ channels are regulated by membrane depolarization and increases in the local intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$). Across neurons and muscle, BK channels have been shown to differentially couple to voltage-gated Ca^{2+} channels of the L-, P-, Q-, and N-type , as well as to ryanodine receptor (RyR)- mediated release from intracellular Ca^{2+} stores. In the suprachiastmatic nucleus (SCN) of the hypothalamus, the brain's circadian clock, both intracellular free Ca^{2+} and voltage gated Ca^{2+} channel (VGCC) currents are regulated in a circadian manner, with greater $[Ca^{2+}]_i$ during the day. We used a pharmacological approach to identify the Ca^{2+} sources for BK current activation in day and night SCN neurons. We found a 69% reduction in BK current magnitude with nimodipine during the day, with a lesser effect at night (10% reduction), suggesting that L-type VGCCs are the primary Ca^{2+} source for BK activation during the day. Conversely at night, when VGCC currents are reduced, we found a significant decrease (76%) in BK current magnitude using dantrolene, which blocks Ca^{2+} release

from RyRs. Thapsigargin, which depletes Ca^{2+} from intracellular stores, caused a similar 79% reduction in BK current, demonstrating that nighttime BK activation is primarily driven by Ca^{2+} release from intracellular stores through RyRs. Consistent with functional coupling between BK channels and these Ca^{2+} sources, the voltage dependence of BK activation was shifted to more positive potentials with nimodipine during the day and both dantrolene and thapsigargin at night. Lastly, BK currents were reduced by ω-conotoxin MVIIC to a similar extent between day and night (40% and 45%, respectively), suggesting that a fraction of BK channels maintain stable Ca^{2+} channel coupling over the circadian cycle. These data demonstrate diurnal regulation of the coupling between BK channels and their Ca^{2+} sources in SCN and suggest that circadian changes in Ca^{2+} coupling could contribute to BK current regulation and its role in circadian rhythmicity.

Title: Identification of firing patterns in SCN VIP neurons that promote VIP release

Authors: ***C. MAZUSKI**[1], E. D. HERZOG[2];
[1]Washington Univ. In St. Louis, Saint Louis, MO; [2]Washington Univ. in St. Louis, St. Louis, MO

Abstract: VIP (vasoactive intestinal polypeptide) expressing neurons are a functionally and anatomically distinct subset of circadian neurons in the suprachiasmatic nucleus (SCN). We hypothesize that distinct firing patterns from VIP neurons are responsible for the release of VIP, which synchronizes and entrains circadian rhythms in firing and gene expression in other SCN neurons. We have characterized spontaneous firing patterns of SCN neurons in response to VIP stimulation by "optically tagging" VIP neurons expressing Channelrhodopsin-2 (VIP-ChR2) following multiday recordings of extracellular electrical activity on multielectrode arrays (MEAs). Preliminary results from SCN neurons cultured on 3 individual MEAs yielded at least 2 distinct classes of neurons based on response to VIP stimulation. The first class, which constitutes approximately 6-10% of neurons, were VIP-ChR2 expressing, because they exhibited increases in firing probability above the 99% confidence interval within 10ms of a light flash for

the entire 20 min stimulation. The second class of SCN neurons changed firing rate and/or pattern during the stimulation but did not fit the temporal criteria for "optically tagged" VIP neurons. These included neurons that decreased firing probability between 10-50ms after a laser pulse in a phase locked manner, suggesting a response to GABA release. Other neurons from the second class rapidly increased or decreased firing rate 2-3 minutes into the stimulation - a change that persisted for the duration of the stimulation. Future analyses aim to identify characteristic spontaneous, circadian, and evoked firing patterns of VIP neurons that result in release of VIP and circadian rhythm entrainment.

Title: The Q175 mouse model of Huntington's disease shows decline in circadian rhythms of SCN electrical activity

Authors: *T. KUDO, C. COLWELL;
Dept. of Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: Many patients with Huntington's disease (HD) exhibit disturbances in their daily cycle of sleep and wake as part of their symptoms. These patients have difficulty sleeping at night and staying awake during the day, which has a profound impact on the quality of life of the patients and their care-takers. For developing treatments of the human disease, knock-in (KI) models offer advantages of genetic precision and control of mutation copy number. Therefore, we used a relatively new model of HD with an expansion of the KI repeats (Q175). In the previous paper, we found Q175 showed circadian disruption in the behavior, but the SCN electric activity is not yet examined. Hence, we examined the SCN electric activity in pre-symptomatic (5 months of age) and symptomatic (7 months of age) Q175 mouse. In pre-symptomatic stage, day-night difference was lost in Q175 mouse, but there was no difference with wild-type mouse during day time. In symptomatic stage, day-night difference was lost and day time firing rates was significantly reduced in Q175 mouse during day time. Together, this data is consistent with the hypothesis that the HD mutations interfere with the expression of

robust circadian rhythms in behavior and physiology. The data raise the possibility that the electrical activity within the central clock itself may be altered in this disease.

Neurosciences, [6]UCL Inst. of Child Hlth., London, United Kingdom; [7]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Background An inherited speech and language disorder with broadly spared cognition but severe articulatory and language production impairments in half the members of the three-generational KE family, has been linked to a selective abnormality in the FOXP2 transcription factor gene (Lai et al, 2001; Vargha-Khadem et al, 2005). However, the orofacial motor control deficits do not sufficiently explain the wide ranging language impairments, suggesting the FOXP2 gene may affect diverse neural pathways underpinning not only speech production, but also language reception in general. In humans, the FOXP2 gene is expressed in brainstem, thalamic and neostriatal structures, while in mice with mutations in this gene, abnormal auditory brainstem evoked responses are reported (Kurt et al, PLoS One, 2012). We aimed to determine whether there are functional deficits in the subcortical auditory pathway by assessing low brain stem, neural and cochlear auditory function in affected individuals. Methods Seven affected members of the KE family (3 females, age range 24-62), were tested with pure tone audiometry, acoustic impedance tests (tympanometry/acoustic reflexes), transient evoked otoacoustic

emissions and auditory brainstem responses (ABR). Results Six of the seven participants had normal audiometric thresholds for their age range. Otoacoustic emissions were present in all and were normal in 11 ears; reductions were attributable to age in two and to noise exposure in one. Acoustic reflexes were normal in six and ABRs in all cases. Conclusions Subcortical auditory pathways are not involved at a clinically significant level in KE family members with a FOXP2 mutation, in contrast to the findings of a study in mice with this mutation (Kurt et al, 2012). Title: The role of intrinsic coupling modes for cognitive processing and cortical communication

Authors: *R. F. HELFRICH[1], H. KNEPPER[1], G. NOLTE[1], C. S. HERRMANN[2], T. R. SCHNEIDER[1], A. K. ENGEL[1];
[1]Univ. Med. Ctr. Hamburg, Hamburg, Germany; [2]Univ. of Oldenburg, Oldenburg, Germany

Abstract: Conscious perception might arise from the dynamic interplay of functionally specialized but widely distributed cortical areas. While previous research mainly focused on phase coupling as a correlate of cortical communication, more recent findings indicated that several different coupling modes might coexist and possibly subserve distinct functions. Here, we studied two coupling modes, namely phase and amplitude coupling, which might differ in their origins, putative functions and dynamics. In a first EEG experiment, participants performed a bistable motion task and we utilized source-space connectivity analysis techniques to study the

functional relevance of different coupling modes for conscious perception. Our results provide correlative evidence that gamma-band phase coupling in extrastriate visual cortex mediates the integration of visual tokens into a coherent percept during ambiguous visual stimulation, while long-range fronto-occipital gamma-band amplitude coupling sustains the horizontal percept during ambiguous motion perception. Additionally, our results suggest that local parieto-occipital alpha-band phase coupling controls the inter-hemispheric information transfer. In a second combined EEG-tACS (transcranial alternating current stimulation) study, we demonstrate the differential modulation of both coupling modes during selective entrainment of distinct spectral components. Our results reveal that entrainment of the low frequency component increased phase-amplitude coupling, where gamma power became preferentially locked to the trough of the alpha oscillation, while gamma-band entrainment reduced alpha power through enhanced amplitude coupling. These results provide causal evidence for the functional role of coupled alpha and gamma oscillations for visual processing and indicate that distinct coupling modes are involved in different cortical computations. The rich spatiotemporal correlation structure of the brain might constitute the functional architecture for cortical processing and specific multi-site communication.

Title: A role for the occipital place area in navigating the local visual environment

Authors: ***F. S. KAMPS**, V. LALL, D. D. DILKS;
Emory Univ., Atlanta, GA

Abstract: Neuroimaging studies have identified multiple scene-selective regions in human cortex, but the precise role each region plays in scene processing is not yet clear. A recent hypothesis, with some empirical support, is that two scene-selective regions - the occipital place area (OPA) and the retrosplenial complex (RSC) - are involved in navigation, while another region - the parahippocampal place area (PPA) - is involved in scene categorization (i.e.,

recognizing a scene as a kitchen versus a beach). Here we test this two streams for scene processing hypothesis by measuring the magnitude of response in each of these regions to both dynamic scene stimuli (i.e., video clips of first-person perspective navigation through a scene) and static scene stimuli (i.e., still images taken from these same movies, rearranged such that motion through the scene cannot be inferred). If a region is involved in navigation, then it should respond more to dynamic than to static scene stimuli, since the dynamic stimuli mimic actual navigation through the local visual environment. By contrast, if a region is involved in categorization, then it should respond similarly to the dynamic and static stimuli, since dynamic information does not help to categorize a scene (e.g., a kitchen is a kitchen whether one is moving through it or standing still within it). Indeed, we found that OPA responded significantly more to dynamic than static stimuli, relative to PPA, consistent with OPA's role in navigation and PPA's role in categorization. However, RSC also responded less to dynamic than static stimuli, relative to OPA, suggesting a division of labor even within the navigation stream. Taken together, these findings i) are consistent with the two streams for scene processing hypothesis (i.e., navigation and categorization), and ii) further suggest a novel division of labor within the navigation stream, with one system (including OPA) particularly responsible for navigating the local, immediately visible environment.

Title: Correlation of gamma-band brain activities with subjective confidence in the 3-D object perception from motion

Authors: *S. IWAKI;
Natl. Inst. Adv Indust Sci. & Tech., Tsukuba, Ibaraki, Japan

Abstract: Two-dimensional optic flow is a cue to perceive 3-D object embedded in the natural scene, (3-D structure from motion: 3DSFM) [1][2]. In this study, we manipulated parametrically

the coherence of randomly moving dots to create different levels of 3-D perception to study associated changes in perception and the brain activity. Specifically, we focused on the correlation between EEG activities and the subjective confidence of 3DSFM. Nineteen subjects participated in the study. All experimental procedures were in compliance with the iRB of AIST. Visual stimuli consisted of 1000 random dots inside a spherical area, which started to move 500 ms after the onset of presentation with various motion coherences. The coherence of the motion across dots varied from 0 to 100 %. A fully (100%) coherent stimulus had all the dots moving as if they belonged to a spherical surface rotating along a randomly tilted axis, and in the other (x % coherent) conditions, movement direction of (100 - x) % of dots were randomized. The subjects were required to reply the tilt angle of the rotation axis and to rate subjective confidence of the answer by a 0 to 10 scale. The stimulus related EEG epochs of 2 s including 0.5 s pre-stimulus baseline, were recorded with a sampling rate of 1 kHz. The results of the correlation analysis between the subjective rating of the confidence of the 3-D object perception and EEG time-frequency representation showed that there was significant positive correlation between fronto-parietal 40 Hz gamma-band power and the subjective confidence. It is reported in the previous studies that transient gamma-band responses are modulated by dopamine system in the human brain [3] which biases the subjective confidence in perceptual tasks [4]. The current results suggest that gamma-band synchrony in the fronto-parietal regions plays an important role in perceiving confidence during 3DSFM. Title: Magnetoencephalographic correlates of perceptual state during auditory bistability

Authors: *R. D. SANDERS[1], J. WINSTON[2], G. BARNES[2], G. REES[2];
[1]Dept of Anesthesiol., Madison, WI; [2]Univ. Col. London, London, United Kingdom

Abstract: Background: Bistable perception occurs when two alternative experiences can be derived from the same physical stimulus; the neural correlates of different subjective experiences can be correlated with observed electrophysiological differences between the alternative states. This may have practical application in studying perception during states of altered consciousness. Here we used a bistable auditory stimulus to determine whether the two perceptual states could be distinguished electrophysiologically at the individual participant level. Methods: Fourteen participants underwent magnetoencephalography (MEG) while reporting their perceptual experience resulting from listening to a continuous stream of auditory tones, a previously well-characterized bistable stimulus. MEG data were analyzed both in sensor space and after source reconstruction in unconstrained analyses (based on the five sources of maximum posterior variance) and within a priori identified regions of interest: right and left auditory cortex (rAC and lAC) and right posterior intraparietal sulcus (rIPS). Results: Participants reported bistability with a similar overall proportion of the two alternative percepts (52% v. 48%). In sensor space, electrophysiological discrimination between the percepts was possible in 11/14 participants (79%). Unconstrained source space analysis also showed significant differences between percepts in 11/14 participants, predominantly based on sources in the temporal lobe. Source space analysis restricted to a priori identified ROIs showed discrimination was possible in the rAC (9/14), lAC (2/14) and rIPS (1/14). Conclusions: MEG can be used to objectively define the neural correlates of consciousness for auditory experience at the single participant level.

Title: 10 Hz perceptual echoes propagate as travelling waves in the human brain

Authors: *D. LOZANO-SOLDEVILLA, R. VANRULLEN;
Univ. Paul Sabatier, CNRS-UMR 5549, Toulouse Cedex 9, Ctr. de Recherche Cerveau et Cognition (CerCo), Toulouse Cedex, France

Abstract: Recent evidence suggests a key role for alpha oscillations (8-12Hz) in visual perception: both the amplitude and the phase of these oscillations can be related to perceptual outcome. It is still unknown, however, whether the alpha rhythm influences sensory processing uniformly, with the same phase across all affected locations, or whether its rhythmic influence propagates across the retinotopic space with systematic phase variations, i.e. like a travelling wave. We have previously revealed that alpha rhythmic activity produces a long-lasting perceptual "echo" of the visual stimulation (VanRullen & Macdonald, Curr Biol, 2012). Electroencephalography (EEG) was recorded from human observers while the luminance of a peripheral disc fluctuated randomly as a white noise sequence. Cross-correlation between the luminance sequence and the EEG time series revealed strong ~10Hz reverberations in occipito-parietal sensors that could last beyond lags of 1s. When two discs with random luminance sequences were simultaneously presented in the left and right visual hemifields, it was possible to extract two independent "echo" functions in response to each of the two stimulation sequences. Here, we re-analyzed the original dataset from VanRullen & Macdonald (2012) to probe the existence of systematic phase variations across visual and/or cortical space, i.e. the existence of travelling waves. In one analysis, we compared for each participant (n=10) the analytic phase of the alpha oscillatory echoes recorded in response to the left vs right-hemifield luminance sequences. Across participants, we found highly consistent phase differences, such that for parietal sensors, the ipsilateral sequence was always represented with a positive phase lag relative to the contralateral sequence. In another analysis, we mapped the analytic phase of the echo response to a given stimulus sequence across neighboring scalp (sensor) locations. Again, we found consistent phase differences, with ipsilateral parietal sensors presenting a positive phase lag relative to contralateral parietal sensors. In both analyses, the phase lag ranged from pi/4 to pi/2 radians, corresponding approximately to a 15-25ms temporal delay. In short, alpha perceptual echoes travel rapidly (within a quarter-cycle) from contralateral to ipsilateral visual representations. These findings represent, to our knowledge, the first evidence for alpha travelling waves across the cortical representation of retinotopic space in the human brain.

Title: The role of the perirhinal cortex in tactile perception and memory in the blind

Authors: *L. CACCIAMANI, L. T. LIKOVA;
Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: The perirhinal cortex (PRC) is a medial temporal lobe structure that has been implicated in visual object processing during both perception and memory (e.g., Murray et al., 2007). For instance, prior research has found that the PRC is activated during the visual perception of novel objects, but reduces its activation in response to those objects if they are made experimentally familiar (Henson et al., 2003). Here, we investigated the PRC's role in tactile perception and memory in the absence of visual input. To do so, we used the Cognitive-Kinesthetic Drawing Method (Likova, 2012; 2014) to train 5 blind subjects on a memory-guided drawing task which has been shown to produce notable improvements in spatiocognitive performance and cortical reorganization in low-level "visual" regions. The tasks were (20s each): perception via tactile exploration/memorization (EM) of experimentally novel raised line drawings of objects and faces, tactile memory retrieval via drawing (MD), and a scribble motor control (S). FMRI was conducted during these tasks before and after a week of the drawing training. Blood oxygen level dependent (BOLD) activity in the PRC was assessed for task-dependent differences in activation from pre- to post-training, i.e., when the drawings were novel vs. familiar, respectively. In every subject, a suprathreshold ($z > 1.96$, $p < .05$) cluster of voxels in bilateral PRC was found during both EM and DM tasks in which activation was significantly ($p < .05$) reduced post-training vs. pre-training. No significant effects were observed in the PRC during the motor control task. These results indicate that BOLD activity was suppressed upon the novel line drawings becoming familiar via the training, suggesting that the PRC is involved in tactile object processing in the blind as it's involved in visual object processing in the sighted. Moreover, its involvement is evident during both perceptual (EM) and mnemonic (DM) tasks. This study sheds light on tactile object representations in a structure typically assessed in the visual modality, and suggests that the reorganization towards tactile representations that occurs at low levels in the blind brain extends to higher-level associative areas as well.

Title: Neural fusion of sensation and expectation

Authors: *M. F. PANICHELLO[1], N. B. TURK-BROWNE[2];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: Expected visual stimuli are perceived faster and more accurately, but how? Sensory cues and expectations may independently contribute information about perceptual features to decision-making processes. Alternatively, information provided by sensory cues and expectations might be integrated into a "fused" feature representation (in a process analogous to maximum likelihood estimation) prior to perceptual decision-making. In Experiment 1, we approached this question using a psychophysical approach in which we assessed the impact of a predictive tone and face stimulus on perceived gender. We first used a training task to map a continuous range of tone frequencies onto a distribution of face stimuli ranging in gender from strongly masculine to strongly feminine. We next tested for fusion by measuring the sensitivity of participants in a gender discrimination task as we varied the strength of sensory cues (i.e., faces of varying gender) and expectation cues (i.e., tones of varying frequencies). Differences in gender could be conveyed by differences in the visual stimuli (stimulus-alone condition), the predictive tones (expectation-alone condition), or both (congruent condition). The fusion model predicts that sensitivity in the congruent condition should exceed the quadratic sum of the sensitivity in the stimulus- and expectation-alone conditions. Furthermore, the performance of a fusion mechanism will suffer when sensory and expectation cues conflict (incongruent condition), while an independence mechanism will be unaffected. Consistent with a fusion mechanism, discrimination sensitivity exceeded quadratic summation in the congruent condition and incongruent cues impaired performance. In Experiment 2, we used fMRI to examine at which stage of processing such fusion may be occurring in the brain. We again trained participants to map tones onto gender and then showed them tone-face pairs. Rather than asking them to perform a gender discrimination task, however, we instead trained a linear classifier to decode gender based on local patterns of BOLD activity for each of our four trial types (stimulus-alone, expectation-alone, congruent, incongruent). A tentative whole-brain searchlight analysis revealed worse decoding for incongruent trials in cortical regions associated with visual and auditory processing and conflict monitoring, following one of the predictions of the fusion

account. These findings complement prior studies on cue combination, suggesting that expectation can be an important cue in guiding perception.

Title: Evidence for genetic regulation of the human parieto-occipital 10 Hz rhythmic activity

Authors: ***H. M. RENVALL**[1], E. SALMELA[2], J. KUJALA[1], O. HAKOSALO[2], J. KERE[2,3], R. SALMELIN[1];
[1]Aalto Univ., Espoo, Finland; [2]Univ. of Helsinki, Helsinki, Finland; [3]Karolinska Institutet, Stockholm, Sweden

Abstract: Human cerebral cortex shows several intrinsic oscillations that can be characterized with noninvasive neuroimaging methods such as magnetoencephalography (MEG) and electroencephalography (EEG). The most prominent of them is the 10-Hz "alpha" rhythm recorded over the parietal and occipital cortices. The cortical sources of alpha activity in humans have been located around the parieto-occipital sulcus, and intracortical recordings in dogs have revealed simultaneous activity in the thalamic nuclei, suggestive of involvement of the two brain regions in the rhythm generation. The rhythm is strongly attenuated by opening of the eyes, and it has important functional roles e.g. in visual attention and imagery. Its reactivity has been widely used to probe cortical functions both in healthy and clinical populations. Several EEG studies have demonstrated the high heritability of the rhythm, but little is known about its underlying genetic determinants. To uncover the possible genetic determinants of the parieto-occipital 10-Hz rhythm in a normal population, we measured spontaneous brain activity with MEG in 210 individuals (from 100 families) while the subjects had their eyes closed and open. The cortical activity was recorded with 306-channel Elekta Neuromag neuromagnetometer, and amplitude spectra at each channel were calculated using FFT. DNA was extracted from blood samples and genotyped with Affymetrix 250K array. In the analyses we used genotypes for more

than 28000 markers. Brain activity was quantified from the difference spectra between eyes-closed and eyes-open conditions. Width of the main spectral peak at ~10 Hz, peak frequency, and peak strength were measured at the maximum channels over the left, middle and right parieto-occipital cortices. In accordance with earlier EEG studies, peak strengths of the rhythm were highly heritable ($h2 > 0.75$). Variance component-based analysis of the genomic markers revealed linkage for both the strength and the width of the spectral peak. The strongest linkage was detected for the width of the spectral peak over the left parieto-occipital cortex on chromosome 10[q23.2] (LOD = 2.814, nominal $p < 0.03$). This genomic region contains several functionally plausible genes, including GRID1 and ATAD1 that regulate glutamate receptor channels mediating synaptic transmission, NRG3 with functions in brain development, and HRT7 involved in serotonergic system, circadian rhythm, and sleep. Overall, our results demonstrate the potential of genetic analysis in linking macroscopic cortical phenotypes with the molecular level through association with specific genes.

Abstract: Interoceptive signals conveying information regarding the state of the body are processed in the insular cortex and this has been suggested to underlie self-awareness. However it is not known whether interoception impacts also visual awareness and whether this also involves the insular cortex. Here, in a series of 10 experiments including 170 participants we show that the relative timing of visual stimuli with respect to the heartbeat modulates visual awareness and that this is related to insular activity. Our psychophysical results showed that

awareness for visual stimuli synchronous to participants' heartbeat was suppressed compared to the same stimuli presented asynchronously to their heartbeat. Two high resolution fMRI experiments showed that the insular cortex was sensitive to both visible and unseen cardio-visual stimulation, showing reduced activation for synchronous cardio-visual targets. Finally, neuropsychological data from a patient with insular damage showed that heartbeat-related suppression of visual awareness was abolished by insular damage. Our results show that interoceptive insular processing impacts visual awareness, demonstrating the role of the insula in bridging interoceptive and exteroceptive awareness. Our data support an account based on predictive coding in which the sensory consequences of self -generated interoceptive signals are suppressed in the insular cortex.

Title: Human perception of statistical significance and effect size

Authors: *B. R. SHETH[1], J. S. PATEL[2];
[1]Dept Elec, Comp Eng, [2]Dept Biomed Engg, Univ. Houston, Houston, TX

Abstract: Statistics are ubiquitous in our Big Data age. Today, statistical literacy is a requirement for all. Most judgments are fast and based on perception, however. Therefore, we asked: How sensitive is human perception of statistics? In experiments, we displayed scatter plots of dots chosen from two Gaussian probability distributions that had different means or variances (but not both). 1) Across trials, effect size (mean1 - mean2/√variance) and statistical significance (p-value from KS test) were co-varied. We asked if naïve observers (Os) were sensitive to this combined statistical manipulation. The two dot clusters were displayed in the same figure (fig.) in red and blue colors. The means or variances of the underlying distributions varied (as did the difference between them, hence the effect size and p-value measured using Kolmogorov-Smirnoff test varied as well) across trials. Os (N=12-15) judged the two clusters as "different" on >30% of trials when the effect size was zero and the p-value insignificant on all trials (false positives), but "same" on >50% of trials when the effect size was moderate and the p-value significant on 100% of trials (misses). The proportion of "different" perceptual

judgments increased with difference in mean or variance of the two distributions but the slope of increase was significantly flatter as compared to that for "different" statistical judgments. Thus, response bias cannot account for the results (also, confidence ratings were typically flat with change in mean or variance). When the clusters were displayed in two different figs side by side, the correspondence between human data and statistics improved little. 2) Effect size and statistical significance were independently varied. In two separate figs presented side-by-side, red and blue clusters were shown in each fig. One of the two figs had more dots than the other (numbers of red and blue dots displayed in each fig. were same). In one fig. compared to the other, the difference between the two clusters it contained was more significant (due to more dots) despite a smaller effect size of the difference (due to smaller difference in means or variances of the two distributions). Os had to choose the fig. for which red and blue dot clusters differed more. If effect size (statistical significance) drives perception of difference, Os will overwhelmingly choose the larger effect size (smaller p-value) fig. Instead, Os (N=25) chose the larger effect size fig. on 33-51% (over a range of differences in effect size) of trials. Our work shows we are largely insensitive to statistical significance and effect size. We will test if learning can cause long-term improvements in sensitivity to statistics.

Title: Synesthetes are more sensitive to cross-modal correspondences than non-synesthetes

Authors: M. MARTINEZ, *S. A. LACEY, K. MCCORMICK, K. SATHIAN;
Emory Univ., Atlanta, GA

Abstract: Synesthesia is a phenomenon in which experiences in one sensory or cognitive domain are consistently associated with automatic, involuntary experiences in a second domain. The most common form is grapheme-color synesthesia which involves consistently experiencing a specific color when seeing a particular letter or number. These synesthetic associations are idiosyncratic, i.e., different synesthetes may experience different colors in relation to the same letter. However, synesthetic associations are not totally random: similar graphemes tend to evoke

similar colors. Since non-synesthetes may also exhibit similar, albeit weaker, associations, synesthesia may be at one end of a spectrum. Cross-modal correspondences refer to the tendency of a stimulus in one modality to be linked with a seemingly unrelated stimulus in another modality. For example, people commonly associate high (low) pitch with high (low) spatial elevation, or with small (large) size. Similarly, people associate certain pseudowords (e.g., "lomo") with rounded shapes and others (e.g., "keke") with spiky shapes. Since synesthesia also involves associations between two different domains or modalities, we hypothesized that synesthetes are more sensitive to cross-modal correspondences than non-synesthetes. We tested this hypothesis using the implicit association test (IAT) to examine pitch-elevation, pitch-size, and pseudoword-shape correspondences in the visual and auditory modalities. In the IAT, participants learn to associate two responses with the same response key, with specific pairings rotating across blocks of trials. Pairings are either congruent (e.g., high pitch/small size) or incongruent (high pitch/large size). On each trial, a single stimulus is presented in one modality, and participants make speeded responses, which are faster when the key associations are congruent and slower when incongruent, i.e., there is a congruency effect for cross-modal correspondences (Parise & Spence, Exp Brain Res 2012). Participants (n=27) completed the online Synesthesia Battery (SB: Eagleman et al., J Neurosci Meth, 2007); 12 were classified as synesthetes, with various kinds of synesthesia, and 15 as non-synesthetes. Synesthetes had larger congruency effects than non-synesthetes for all three correspondences in both modalities. Interestingly, the strength of synesthetic associations, as measured by the SB, was uncorrelated with congruency effects on the IAT. Consistent with our hypothesis, synesthetes are more sensitive than non-synesthetes to cross-modal correspondences, supporting the notion of quantitative differences along a spectrum.

Abstract: Interaction with the environment involves the perception of sensory stimuli (e.g., object recognition, scene perception) and relating these percepts to an existing knowledgebase as well as past experiences. For example, it is not useful to recognize a kitchen without having the associated knowledge that this is where people cook and eat; that where there is an oven, a refrigerator will likely be nearby; and within the refrigerator there is food. Previous studies have demonstrated that objects with strong contextual associations (e.g., an oven) activated regions of the ventral medial temporal cortex (VTC) - mainly within regions of the parahippocampal region spreading into lingual and fusiform areas - along with other regions in the retrosplenial complex and transverse occipital place area, to a greater extent and magnitude than objects with weak contextual associations (e.g., folding chair). This difference in activation can occur automatically during object recognition and may provide feedback in support of the recognition process. Understanding this brain activity within a framework of associative processing may provide a bridge for explaining why both high level visual processes and episodic memory activate the same regions of the VTC. However, the causal link between episodic, associative, and high level visual processes has not been established. In this study, we used intracranial electrocorticography (ECoG) in a patient who suffers from intractable epilepsy to investigate the characteristics of associative processing of objects in regions of the VTC. Here, we report that implanted electrodes along the medial left fusiform demonstrated a significant differential signal when recognizing objects with strong contextual associations compared with recognizing objects with weak contextual associations (peak broadband gamma difference $p < 0.05$). To test the nature of this effect, direct electrical stimulation was applied to this region. The stimulation resulted in the patient experiencing hallucination-like episodes that occurred during word and object recognition. When asked to describe what the patient had experienced he said things like “It reminded me of something from my past, like I went through a bunch of pictures in my mind”; and “It was...trying to connect to a different picture that was like it.” These results demonstrate that VTC plays a causal role in visual associative and episodic processes the can emerge during object recognition. In addition, these results may suggest a role of associative processing in the nature of hallucinations.

Title: Early responses discriminate global differences revealed by ecog

Authors: *R. WU;
Inst. of Biophysics, Beijing, China

Abstract: Our previous studies have demonstrated that the visual system is sensitive to topological changes, such as the appearance and disappearance of holes in a figure. Accumulating results based on fMRI indicate that anterior temporal areas may underscore the advantages in perception of global properties such as topological differences. However, the lack of high-resolution timing information in fMRI makes the argument unsettled. Traditional ERP/EEG has high temporal resolution, but its spatial resolution is poor. To understand the neural mechanism of topological processing with a high temporal-spatial resolution, we use ECoG (electrocorticogram) from intracranial electrodes while epilepsy patients are monitored for seizure detection. Epilepsy patients implanted with intracranial electrodes for seizure detection purpose were invited to participant this study. There are 284 electrodes in the temporal lobe we recorded. ECoG was recorded by a MicroMed SD128 system at a sampling rate of 512 Hz. Stimuli were 37 pairs of figures (composed from 22 figures) randomly presented for 200 ms each with an interval of 600 - 1200 ms between pairs. Subjects were required to attend to one side of the visual field cued by the arrow at the center of the screen and press a button whenever they found the current figure was the same shape as the previous one. Neural responses as ERPs for different figure pairs were aligned to the onset of the second figure and averaged after notch filtering, baseline correction and artifact reduction. A moving-window t-test was applied to test the difference between figure groups. Neural responses in anterior temporal areas can discriminate global differences as early as about 50 ms after stimulus onset. More electrodes showed shorter latency for topological changes, and the pattern to some degree agreed with the functional hierarchy of the geometrical figures. The distribution of the first 40 electrodes with shortest latency showed different patterns for topological changes, compared with affine or

Euclidean changes ($P < .005$ and $P < .05$, respectively, rank sum test). Shortest responses of topological changes were not modulated by attention.

Title: What does functional brain imaging reveal?

Authors: *C. C. LEITH[1], L. ROBBINS[2], L. SIEGEL[3], S. OUYANG[4], H. SUN[1]; [1]Neurodynamics Res. Inst., Highland Park, IL; [2]Robbins Headache Clin., Chicago, IL; [3]Illinois Bone & Joint Inst., Chicago, IL; [4]Univ. of California, Los Angeles, CA

Abstract: Introduction: Modern functional brain imaging studies have been dominated by hemodynamics-based approaches. A huge amount of effort and energy has been spent in watching local blood events in attempts to find a correlation with neural impulse events and further with a thing commonly believed as brain function such as perception, awareness or cognition. Paradoxically, this chain of inferences may be much weaker than what most investigators would admit. We argue with our data: this is indeed the case. Method: We used our adapted diffusion tensor imaging approach (aDTI) [1] to image chronic pain in chronic migraine (CM, 20 patients) and fibomyalgia (FMS, 20 patients) as well as matched healthy controls. As aDTI did not use the blood flow surrogate, we removed the first uncertainty - neurovascular coupling in the inference chain. Thus, we gained the basis to ask what neural impulse events detected in our patients really represented. Result: Both the CM and FMS groups in comparing with the control group had abnormal baseline neural impulse loci in cerebral white matter fibers in the central pain matrix (a popular term that lumped a few activation loci together). The FMS group had additional loci ($p < .001$) in the fiber tracts of the orbitofrontal cortex and brainstem. Also, in the brainstem of the CM group, additional multiple loci of abnormal baseline activity ($p < 0.001$) were found in the cerebral peduncle, in the middle cerebellar peduncle, in the midline midpons, and in the upper medulla. Conclusion: Our pain study aims at exploring the mechanisms of perception, awareness and cognition as most published functional brain studies do explicitly or implicitly. We all resort to a similar inference chain. Although aDTI discards the blood-flow surrogate, fundamental questions remain: What is exactly brain function? What does functional brain imaging reveals? Our Human Brain Mapping Metamodel [2] helps in starting

addressing these questions, as summarized in the figure. There is no direct information passage from impulses to senses.

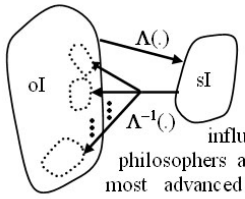

Fig. Human Brain Mapping Metamodel [2] that helps to draw the following conclusion. We take it as granted that the brain is the seat for perception, awareness and cognition, under the overwhelming influence of generations of psychologists and philosophers as well as the modern explorers with the most advanced tools such as MRI. This brain seat "intuitive" has been leading us seeking centers, streams, grandma cells, or arbitrators in the frontal cortex. That is, we are looking for brains in the brain while ignoring understanding a highly distributed system in the correct way. Psychoactive agents, chronic pain medicine, or a great part of neuroscience drugs share a rather peculiar common feature: multiple indication and limited efficacy on a particular. DBS or rTMS shares the same features. Stimulation or disruption? Current theories cannot settle the debate. As a result, even the groundless Freudian "unconscious" is still taken as a basis for certain therapy. Our metamodel hints that a collective of distributed extracerebral actuation may give rise to perception, awareness and cognition. As such, if we do a brain parenchyma transplant (not whole head), hypothetically, the one with the new brain would see self and others as strangers and the world very distorted at best. It is time to question our inherited intuitive that does not apply beyond the fact that the brain is just a wiring center.

Title: Pre-attentive change detection of sound intensity is affected in first episode depression but not in recurrent depression

Authors: *E. RUOHONEN, J. L. O. KURKELA, P. ASTIKAINEN;
Dept. of Psychology, Univ. of Jyväskylä, Jyvaskyla, Finland

Abstract: Depression is associated with abnormal cognitive processing of emotional information but recent research suggests that this bias exists also in the level of basic physical feature processing. In the auditory modality, there is some evidence that dysfunction in brain's protecting mechanism for loud sounds would be associated with depression. However it is not clear whether processing of sound intensity as such or change detection mechanism is affected in depression. In order to test this, we studied auditory evoked potentials (AEPs) in patients diagnosed with either first episode (n=17) or recurrent depression (n=25) and compared their brain responses to healthy controls' (n=21) data. In the experimental design frequently presented low intensity sounds (60 dB) were rarely and randomly replaced by high intensity sounds (80 dB). In the other stimulus block the intensities for the frequent and rare sounds were reversed. The sounds were 100 ms in duration and 1000 Hz in frequency and were presented with randomly varying onset to onset interval of either 450, 500 or 550 ms. AEPs were extracted from two time windows: at 90-140 ms (N1) and at 150-200 ms (mismatch negativity, MMN) post-stimulus interval. N1 was larger in amplitude to rare high intensity, but not to rare low intensity sound, compared to the frequent sound. N1 amplitude was also different between the groups. First episode depression group showed larger N1 responses to rare sounds, irrespective of their intensity, compared to recurrent depression group and control group. MMN, which is a correlate of automatic change detection, was larger in amplitude for both, low and high intensity, rare sounds. There were no group differences in the MMN response, however. Results suggest that central auditory processing of sound intensity, especially change detection mechanism, is affected in first episode depression. This dysfunction is however recovered in those who have recurrent depression. This finding, although based on cross-sectional data, may indicate that compensatory mechanisms can normalize depression-related perceptual dysfunction in the course of time.

Title: Effect of tDCS on rubber hand illusion in relation to schizotypal parsonality

Authors: *N. YODA, T. IGARASHI, S. SHIMADA;
Meiji Univ., Kawasaki, Kanagawa, Japan

Abstract: The rubber hand illusion (RHI) is an illusion in the integration of visual and tactile stimuli of the self-body. It is known that the temporo-parietal junction (TPJ) is crucially involved in self-body representation and the occurrence of RHI. In this study, we applied transcranial direct current stimulation (tDCS) to left TPJ to investigate whether it modifies the quality of RHI in relation to the degree of schizotypal personality, which is characterized as a predisposition to schizophrenia. Thirty right-handed healthy subjects (7 female, aged 21.0 ± 1.7) participated in the experiment. Subject's level of schizotypal personality was examined by means of the Japanese version of the Schizotypal Personality Questionnaire (SPQ). The subjects put their right hand on the table, and the rubber hand was placed 15 cm leftward from their hand. The subjects watched delayed image (100, 300, or 500 ms) of the rubber hand that was filmed using a video camera. Two paintbrushes were used to simultaneously stroke the index finger of the subject's own hand and that of the rubber hand at approximately 0.5-1 Hz. The stimulation period was 3 min. After each session, subjects completed RHI questionnaire, which in 9 items, identical to that used in the previous study (Botvinick & Cohen, 1998). The subject first underwent a RHI session for each delay condition (pre-stimulation sessions), followed by 10 min tDCS stimulation (1 mA). The subject then underwent the second RHI session for each delay condition while applying tDCS throughout the session (post-stimulation sessions). Subjects were randomly assigned to the anodal, cathodal, or control "sham" groups. The stimulation was induced with a pair of saline-soaked surface sponge electrodes ($35cm^2$) and delivered by a battery-driven constant current stimulator. For the stimulation of the left TPJ, the anodal or cathodal electrode was placed over a point midway between T3 and P3 (international 10/20 system). The reference electrode was placed over left prefrontal cortex (a point midway between F3 and FP1). The result on questionnaire data showed that differential (pre - post-stimulation) RHI score (item 2) showed a significant difference between the anodal and cathodal groups in the 500ms delay condition ($t(18) = 2.28$, $p < 0.05$). This indicates that the subject in the anodal group felt more RHI after stimulation. In addition, we found positive correlations between the RHI score (item 2) and a SPQ subscale score ("No Close Friends") in the anodal group in 500ms delay condition ($r = 0.75$, $p < 0.05$). These results suggest that tDCS to left TPJ can alter the experience of RHI, which can be further modulated by schizotypal personality.

Title: Repetition probability effects on neural repetition suppression are dependent on context predictability

Authors: *A. PAJANI[1], V. DE GARDELLE[2,3], S. KOUIDER[4];
[1]Dept. d'Etudes Cognitives, Ecole Normale Supérieure, CNRS, Paris, France; [2]Ctr. d'Economie de la Sorbonne, CNRS & Univ. Paris 1, Paris, France; [3]Paris Sch. of Econ., Paris, France; [4]Dept. d'Etudes Cognitives, LSCP (ENS, CNRS), Paris, France

Abstract: Several recent functional Magnetic Resonance Imaging (fMRI) studies have shown that the probability of stimulus repetitions, P(rep), influences the degree of Repetition Suppression (RS): the neural response to repeated stimuli is decreased to a greater extent in high compared to low P(rep) blocks. In line with predictive coding theories, this has been interpreted as a modulation of high-order contextual expectations: when repetitions are more likely, brain responses to repeated stimuli are suppressed as a result of expectation suppression. An alternative account of those results would rely on the existence of a constant 'default' repetition prior in the brain, rooting in the relative stability of our visual environment, which precision would vary depending on the overall predictability of the context. In all studies of P(rep) effects, context predictability covaries with repetition probability: in alternation trials, the first stimulus can be followed by any other, hence the identity of the second stimulus of a pair is globally harder to predict in low P(rep) blocks. As a consequence, the 'default' repetition prior would be applied with lower precision, resulting in less suppression for repeated stimuli. We posit that if alternations become predictable, that is, if a stimulus A can either be repeated (25%) or followed by a given stimulus B (75%) instead of any other exemplar, stimulus repetitions would lead to RS to a similar extent as in high P(rep) blocks. We investigated this hypothesis with fMRI, using face stimuli and focusing our analyses on the fusiform face area (FFA). On each trial, participants were presented with either the same face twice or two different faces, in 3 experimental contexts: high P(rep) (75%), low P(rep) (25%) & unpredictable alternations, and low P(rep) (25%) & predictable alternations. The latter were learnt during a behavioral training session. We used long Inter-Stimulus Intervals (7 seconds, jittered) in order to dissociate brain responses to the first and second face of each pair using a General Linear Model, and computed RS as the difference between responses to the first and second face of repeated trials.

Consistently with previous studies, RS was strong in 'high P(rep)' blocks, while it was decreased in 'low P(rep) & unpredictable alternations' blocks. Crucially, RS was present in 'low P(rep) & predictable alternations' blocks to a similar extent as in 'high P(rep)' blocks. This supports the hypothesis of a 'default' repetition prior that is applied with variable strength depending on the overall predictive context of the block, rather than a modulation of the prior itself as a function of P(rep).

Title: Decoding perceived duration in various sensory modalities from MEG-EEG data

Authors: ***T. W. KONONOWICZ**, V. VAN WASSENHOVE;
CEA, NeuroSpin Center, INSERM, Univ. Paris-Sud, Gif S/ Yvette, France

Abstract: The sensory modality affects duration perception (Penney, Gibbon, and Meck, 2000). For instance, for the same physical durations, auditory stimuli have often been reported to be perceived as longer and more accurately than visual stimuli (Penney et al., 2000; Van Wassenhove, Buonomano, Shimojo, Shams, 2008). In the context of internal clock, which integrates temporal pulses to provide an estimate of elapsed time, auditory dominance is conceived to result from the enhanced pacemaker rate. The premise of the internal clock model is that there is a common mechanism involved in timing irrespective of sensory modality. On the contrary, modality specific models propose specific mechanisms for each modality. This problem has frequently been tackled by using perceptual learning approach where subjects are extensively trained on one modality and tested other modality in order to check whether training improves performance on tested modality. Behavioral data have not provided any evidence for transfer from the visual to the auditory modality (Lapid, Ulrich, & Rammsayer, 2009; Bratzke, Seifried, & Ulrich, 2012). Yet, transfer from the auditory to the visual modality has been found (Bratzke et al. 2012), suggesting auditory dominance in timing. However, psychophysical

methods are not sufficient to reveal neural underpinnings of such intersensory transfer. Therefore, we asked participants to discriminate time intervals demarcated by auditory, visual, or audiovisual markers while recording brain signals using EEG and MEG. On each and every trial the standard duration (700ms) was presented, followed by the presentation of the comparison interval (630, 700, 770ms; 10%, 80%, 10% of all trials respectively). We used support vector machines algorithm (Pedregosa et al., 2011) to decode MEG activity to discriminate the subjectively perceived 'short' and 'long' durations. Preliminary data show that sensory-specific responses predict subjective perception of duration when training and testing the algorithm is performed within the same modality. Specifically, above chance level classification has been found around 100ms after the duration onset and suggesting that the early components contribute to the duration perception. Importantly, to evaluate predictions of the internal clock model and modality specific models we will train classifier on one modality and assess classification accuracy in the other modality to assess whether early and late components contribute to transfer of timing mechanisms between modalities.

Title: Gist perception in the presence of information overflow

Authors: *K. MOGI;
Sony Comp Sci. Lab., Shinagawa-Ku, Japan

Abstract: One of the salient constraints on the cognitive processes in the brain is that there is an overflow of information (e.g. Lau & Rosenthal 2011, Block 2011), so that only a subset can be represented in the cognitive system. Seen from the volume of information processed, higher cognitive processes in the brain handle gradually less information. In the visual system, it is estimated that about 10^10 bits/sec of information is registered at the retina, about 6x10^6 bits/sec of information leaves the retina, and about 10^4 bits/sec of information reaches the layer IV of area V1 (Raichle 2010). In visual perception, there is empirical evidence to suggest that not all the information present in the visual field is processed in the cognitive system. In change blindness (Simons and Levin 1997), the subject is unaware of large changes in the visual field. In inattentional blindness (Mack and Rock 1998), the subject fails to register a salient object in the

scene. Given these constraints, in order to adapt to the various relevant elements in the environment, the brain needs to encode and react to the overflow of information in an efficient way. Barlow (2001) argues that redundancy reduction is one of the fundamental principles behind cognition. Friston (2009, 2010) proposes the free energy principle to understand how the cognitive systems are organized and function. There is evidence that the visual system is able to support gist perception (Oliva 2005, Cohen et al. 2011), while discarding the details. Here I present a model to account for the nature of "gist" in the cognitive processes in the presence of information overflow. The gist is formulated as an effective minimization of Bayesian "surprise" (Friston 2009) in the processing of information. Effective gist perception is formulated as one of the most significant selection pressure on consciousness. I argue that sensory qualia evolved to give a repertoire of gist representation, the combination of which would give an effective picture of the environment even when a majority of information coming from the environment is lost through the adaptation to the information overflow.

Title: Applications of transcranial direct current stimulation for the military: An overview

Authors: *A. MCKINLEY[1], L. K. MCINTIRE[2], J. NELSON[2];
[1]Air Force Res. Lab., New Carlisle, OH; [2]Infoscitex, Dayton, OH

Abstract: With increases in reliance on remotely piloted vehicles and automation, a growing number of military jobs are beginning to resemble traditional office settings and require a new, nontraditional skill set. In the Air Force, much of the mission emphasis has shifted to surveillance, intelligence, and reconnaissance (largely conducted by remotely piloted aircraft) due to the seemingly insatiable demand for such sorties. Remotely piloted aircraft operators and the supporting image analysts have long shifts (up to 12 hours a day, 6 days a week) to try to keep up with demand. Looking for targets over a long period of time is both tedious and effortful requiring intense sustained attention/vigilance. Unfortunately, the ability to find such targets degrades over time, a phenomenon known as the vigilance decrement. Likewise, acute and

chronic fatigue stress can further reduce performance. Given that misidentifying or not detecting the targets can potentially put lives at risk, investigating new methods of reducing the performance declines has been an area of interest for the Air Force. Over the past several years, we have examined the efficacy of transcranial direct current stimulation (tDCS) to modulate attention, accelerate learning, and mitigate the effects of fatigue. We have discovered that tDCS has a large effect on target detection accuracy in a variety of vigilance tasks and this effect is repeatable and not dependent on the particular vigilance task. Specifically, tDCS extends vigilance performance by at least two fold. Likewise, we have found that small changes in the position of the anode did not significantly influence the performance outcomes. We have also found that tDCS significantly reduces the effects of fatigue on vigilance performance and that the effect lasts three times longer than caffeine. Likewise, there are beneficial effects on training, specifically for image analysts. Analysts receiving tDCS during training performed 25% better on their tests than analysts receiving sham tDCS. This effect has since been replicated at two different laboratories and appears to be robust and reliable. It is likely these effects may have been caused by improvements in attention. Greater attention during training often leads to improved retention following training. Taken together, tDCS has shown great promise for improving aspects of cognition that are important for existing and emerging military jobs. Determining the longevity of the effect and the effects of chronic stimulation remain critical research questions to tackle before such an intervention can be considered for deployment.

Title: fMRI time-course analysis of the immediate post-orgasmic phase in men

Authors: ***K. ALLEN**[1,2], W. BIRBANO[2], N. WISE[2], E. FRANGOS[2], B. KOMISARUK[2]; [1]PWP, Princeton Univ., Princeton, NJ; [2]Psychology, Rutgers Univ., Newark, NJ

Abstract: Few neuroimaging studies have investigated the “refractory period” in men, which is the epoch after orgasm/ejaculation during which most men do not respond to genital stimulation with a second orgasm. In the present study, we report evidence of two distinct epochs within this refractory period. Using functional Magnetic Resonance Imaging (fMRI), we collected data as research participants self-stimulated to orgasm. They specified the start and end of orgasm using

a button press and were asked to press the button again to indicate when they felt that they had "recovered" from orgasm. Our time-course analysis indicates that this initial refractory period begins as a distinct pattern of distributed activity at the end of orgasm and persists for a period of a few seconds to several minutes. Its initiation is characterized by a rapid attenuation of orgasm-related neural activity across many brain areas that include amygdala, hippocampus, insula, anterior cingulate cortex, anterior hypothalamus, paracentral lobule and S II. The end of this initial period is characterized by a brief spike in neural activity across similar areas. Analysis of neural activity in men during the refractory period may provide insight into the mechanism(s) of anorgasmia.

Title: Manipulating gamma oscillations in the human visual cortex with MEG based neurofeedback

Authors: N. MERKEL[1], G. BLAND[1], *W. SINGER[1], M. WIBRAL[2];
[1]Max Planck Inst. For Brain Res., D-60528 Frankfurt/M, Germany; [2]Univ. of Frankfurt, Frankfurt am Main, Germany

Abstract: The brain can learn to modify ongoing activity through neurofeedback (NFB). Since the development of EEG based NFB methods in the late 1960s (Kamiya et al., 1669), an increasing number of studies were devoted to explore this phenomenon both in human subjects and animals. These studies indicate that subjects can learn to deliberately influence the hemodynamic response in specific brain structures (Caria et al., 2010; Sulzer et al., 2013), the power of oscillatory activity in selected frequency bands (Gruzelier, J. 2014) and neuronal discharge rates (Fetz, E. 1969, Clancy et al., 2014). Often NFB training was associated with changes in cognitive functions (Gruzelier, J. 2014). However, little is known about the specificity of these NFB effects in the spatio-temporal domain and on the dynamic mechanisms mediating them. We designed a NFB training protocol for healthy human subjects using magnetoencephalography (MEG). We attempted to restrict training effects to a small volume of visual cortex and to a narrow frequency band to test the specificity of changes and the NFB

training related network dynamics. We used online beamforming techniques to extract the feedback signal in source space. The pitch of a continuous tone feedback signaled the increase of narrow band gamma oscillations relative to oscillations in neighboring frequencies within a selected voxel of the visual cortex. The pitch of the tone increased with gamma-power and was updated every second. Subjects were asked to increase or decrease this pitch in a controlled way. So far, we studied 10 subjects who underwent 10 training sessions each. The NFB training with online beamforming substantially increased the power in the frequency band selected for training in 4 out of 10 subjects. Subjects were able to enhance narrow band gamma activity in early visual cortex in a circumscribed region located within 2.5 cm from the target voxel. As performance improved, beta oscillations became more prominent and synchronized across the right midfrontal and left parietal cortex, presumably reflecting enhanced top-down control by the visual attention network (Buschman & Miller, 2007; Bastos et al., 2014). It is still an open question how different areas interact to form attentional networks (Gross et al., 2004). We expect that this NFB approach will contribute to a better understanding of the mechanisms supporting top-down control of visual gamma oscillations. We further hope to provide tools to selectively tune pathological brain oscillations towards a more homeostatic set-point and thereby balance out disturbed network dynamics, which could underlie certain diseases (Ros et al., 2014).

Title: Neural systems selectively involved in navigation and categorization of scenes

Authors: *A. PERSICHETTI[1], D. D. DILKS[2];
[1]Emory Univ., Atlanta, GA; [2]emory university, atlanta, GA

Abstract: Previous neuroimaging studies have identified three cortical regions involved in human visual scene processing: the parahippocampal place area (PPA), retrosplenial complex (RSC), and occipital place area (OPA). While the exact function each of these regions plays in scene processing remains unknown, it is currently believed that the scene processing system as a whole is a monolithic system in the service of navigation. However, we recently found that while RSC and OPA encode ‘sense’ (left-right) and ‘egocentric distance’ (close-far) information, which are both critical for navigation, PPA does not, challenging the pervasive theory that all of

these cortical regions serve the purpose of navigation. Instead, we propose that scene processing is comprised of two distinct pathways: one responsible for scene categorization (e.g., recognizing a scene as a kitchen, a beach, city hall), including PPA, and the other responsible for navigation, including RSC and OPA. If scene processing is comprised of a categorization stream (including PPA) and a navigation stream (including RSC and OPA), then it should be possible to selectively modulate the two streams by task demands. Specifically, using fMRI, we asked whether PPA would respond more to an image of a scene when a viewer is performing a 'categorization task' on the image than when the same viewer is performing a 'navigation task' on the exact same image, while RSC and OPA would show the opposite pattern. Indeed, preliminary data show a significantly higher BOLD response in PPA during the categorization task than to the navigation task, relative to OPA and RSC. By contrast, OPA responded significantly more during the navigation task than the categorization task relative to PPA and RSC. Such a double dissociation strongly suggests distinct cognitive and neural systems that are selectively involved in navigation and categorization of scenes.

Title: Correlation between illusory bistable perception and motion perception under noisy condition

Authors: ***W. CHOI**, M. HWANG, S.-B. PAIK;
KAIST, Daejeon, Korea, Republic of

Abstract: When visual system receives an ambiguous signal such as Necker cube, perceived state switches periodically between two interpretations. This phenomenon is called bistable perception, and has been studied extensively to investigate the working mechanism of sensory perception. Importantly, the reversal time - switching interval between two states - seems to be an important factor to understanding underlying mechanism, but its detailed dynamics is still elusive. In this psychophysics study, we investigated the correlation between the reversal time in

bistable perception of illusory motion and the performance in real motion perception within a subject. Our hypothesis is that the reversal time reveals an intrinsic time scale of a neural circuit for a certain type of functions, such as motion detection and it must be correlated with the information processing time for similar type of tasks. For example, reversal time in bistable illusory motion perception is defined as switching time between the two illusory motion directions, and this process parallels similar tasks, such as motion detection under noisy condition. If fast reversal time means fast processing for a given task, we expect that fast reversal time would be correlated with a better perceptual performance in general. To confirm this idea, we designed human psychophysics experiment using "racetrack" stimulus [1], which can provide both bistable illusory motion perception and real motion perception under noisy conditions. We varied a coherence parameter, c, of the racetrack stimulus so that the experiment condition can be either bistable illusory motion (c=0) or real motion with different amount of noise (c>0). We then examined the relationship between the reversal time in illusory motion condition (c=0) and the correctness in coherent motion condition (c>0). As we expected, subjects who showed fast reversal time for c=0 showed higher correctness for c>0 than those who showed slow reversal time. (N=5, R=-0.9, p=0.03, Pearson's correlation coefficient). This result suggests that the reversal time in bistable perception reveals an intrinsic time scale of a perceptual process, and might be a crucial factor to understand the mechanism of information processing in the brain.

Title: What type of stimulus location information is represented in human hippocampus?

Authors: *A. SHAFER-SKELTON, J. D. GOLOMB;
Dept. of Psychology, The Ohio State Univ., Columbus, OH

Abstract: The hippocampus is thought to be involved in diverse types of spatial processing--researchers have reported spatial maps of an animal's external environment, memory for spatial

relations, and view-invariant representations of scenes. However, there has been little research in hippocampus investigating how the locations of visual stimuli are represented--for example, in eye- or head-centered reference frames. Golomb & Kanwisher (2012) found that throughout visual cortex, stimulus locations are represented in retinotopic (eye-centered) coordinates across fixations. Here we used their paradigm to look in human hippocampus. In two experiments, we used fMRI multi-voxel pattern analysis (MVPA) to compare patterns of hippocampal activity for stimuli presented in different locations. First, we compared within-fixation information: whether there was more information for pairs of stimuli with 1) the same fixation and the same stimulus location, vs 2) same fixation and different stimulus location. Next, we measured across-fixation location information for conditions with different fixation locations, comparing: 3) same retinotopic (eye-centered) stimulus location and 4) same spatiotopic (world-centered) stimulus location vs. 5) different retinotopic and spatiotopic locations. In each block, stimuli were either objects or scenes. Participants pressed a button when the same image repeated twice in a row. Stimuli were arranged horizontally in Experiment 1 and vertically in Experiment 2. We used correlation-based MVPA to compare information present for the 5 pairs of location conditions. Preliminary results suggest that for both experiments, hippocampus may contain information about stimulus location when fixation is held constant, but that this information is only tolerant of changes in fixation for the horizontal stimulus arrangement. Furthermore, when there is across-fixation location information, it seems to be retinotopic. These findings have important implications for our understanding of hippocampus and its role in the processing of visual location information.

Title: An attempt to physiologically measure human magnetoreception

Authors: *A. MATANI[1], S. SHIMOJO[2], J. L. KIRSCHVINK[2];
[1]Grad. Sch. of Information Sci. and Technology, the Univ. of Tokyo, Tokyo, Japan; [2]Caltech, Pasadena, CA

Abstract: Humans have magnetite (Kirshvink et al., 1992) and cryptochromes (Foley et al., 2011), known as magnetic receptors, in their heads. It would not be surprised if they have an unconscious potential for magnetoreception. We thus attempted to physiologically measure human magnetoreception with a precise experiment on the basis of animal behavioral studies and communication theories. We built two Meritt coils and a Helmholtz coil in a Faraday shielded room (Kirschvink, 1992). Appropriate groundings allowed us for applying almost purely magnetic stimuli by reducing capacitive and inductive couplings between the coils and subjects. Subjects were placed in the supine position and their heads were located in the center of the coils. The polar coordinate system was set such that their head and feet pointed north and south, respectively. Note that this setting was free from the geographic north and south; we applied currents to the coils to cancel the geographic magnetic field. In addition to the baseline nulling currents, we applied two kinds of currents to the coils to produce rotating magnetic stimuli: inclination of ±50-degree and declination of ±45-degree with a constant magnitude that was the same as the geographic magnetic field at the experiment site. Thus, subjects were exposed to an up-and-down magnetic north change in the first experiment and a left-and-right magnetic north change in the second experiment. These settings were based on animal behavioral studies; migratory birds seem to respond to inclination magnetic fields (Wiltschko et al., 2005), and rats to declination (Marhold et al., 1997). These two magnetic field changes were coded with a two-valued pseudo random sequence used for a multiple communication. 31-ch electroencephalograms (EEGs) were recorded during the exposures. With mathematical characteristics of the sequence, EEGs were decomposed into 16,383 linear and nonlinear components of an EEG generation model and hence permutation tests were performed by ranking the magnitudes of the components of interest. Three subjects participated in this study. The study received approval from the Ethics Committee of the University of Tokyo and Caltech. All the subjects showed a significant spike-like response at a latency of 0.2 s and one subject showed a significant alpha-ringing for a latency duration of 0.5-0.9 s only for the declination magnetic change in the most fundamental EEG component of interest. With such a nonnegative result, we continue our efforts to detect evidence of human magnetoreception with psychophysiological and neuroengineering approaches.

Title: The speed of posterior alpha-band oscillations predicts the speed of visual perception

Authors: *J. SAMAHA, K. MARISKA, S. CIMAROLI, B. R. POSTLE;
UW Madison, Madison, WI

Abstract: In animal studies, scalp electroencephalographic (EEG) recordings of neural oscillations in the alpha-band (8-12 Hz) have been shown to reflect phasic activity of thalamocortical projections from the lateral geniculate nucleus to primary visual cortex. Experiments in humans have found that the phase of ongoing alpha oscillations predicts visuocortical excitability, conscious perception, and the magnitude of visually evoked responses. This has led to the suggestion that the alpha rhythm reflects the "open" and "closed" cycling of discreet windows of excitability that dictate the speed at which visual information can be sampled. We directly tested this hypothesis by measuring eyes-closed individual alpha frequency in 20 healthy young adults, and then regressing this against an estimate of the "speed" of their perception, derived from a flicker fusion paradigm. Flicker-fusion thresholds were estimated by fitting a psychometric function to the discrimination of single or double flashes at 5 levels of inter-flash interval (10, 20, 30, 40, or 50 ms). Results revealed a strong negative correlation between individual peak alpha frequencies and flicker-fusion thresholds, such that subjects with faster alpha oscillations displayed lower thresholds, indicating faster perception. This effect was specific to alpha-band oscillations measured at posterior electrodes, and to the threshold parameter, not the slope parameter, of the psychometric fits. These results provide support for the idea that thalamocortical oscillation in the alpha-band may pace the phasic updating of visual information.

Title: Repetition enhances the distinctiveness of neural activation patterns

Authors: *J. H. POH[1,2], M. W. L. CHEE[1];
[1]Ctr. for Cognitive Neurosci., Duke-NUS Grad. Med. Sch., Singapore, Singapore; [2]NUS Grad. Sch. for Integrative Sci. and Engin., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Behavioral priming results in speedier performance when a stimulus is repeated and is accompanied by repetition suppression (RS) of sensory responses. While it has been suggested that RS influences information processing by sharpening neural representations, there is presently no direct empirical support for this. Here we hypothesized that repetition will accentuate the unique features that distinguish different visual stimuli, and that this would be evidenced by enhanced pattern distinctiveness to individual pictures. Participants classified a mixture of once repeated indoor or outdoor scenes while undergoing fMRI. The neural representation of each stimulus was computed from voxels within functionally defined PPA. Distinctiveness of each stimulus was defined as 1-r, where r was the mean correlation between that stimulus and every other stimulus (Fig 1a). Repeated scenes elicited faster RT, reduced activation, and an increase in distinctiveness within the PPA (Fig 1b). Critically, repetition suppression was highly correlated with the change in pattern distinctiveness (mean r= .72, p< .001). We also observed strong anti-correlation of signal amplitude and pattern distinctiveness (mean r= - .75, p< .001), suggesting that higher activation relates to neural activation that is common across multiple scenes. As change in distinctiveness might be driven by task demands, we computed distinctiveness separately within- & between- categories. However, this was obviated by the finding of higher correlation for within-category than between- category comparisons (t¬¬¬10 = 14.33, p< .001). Our findings demonstrate that repetition enhances the distinctiveness of activation patterns to repeated scenes while reducing the mean BOLD response, consistent with the sharpening hypothesis where repetition 'prunes' non-specific information from neural responses (Lee & Mumford, 2003).

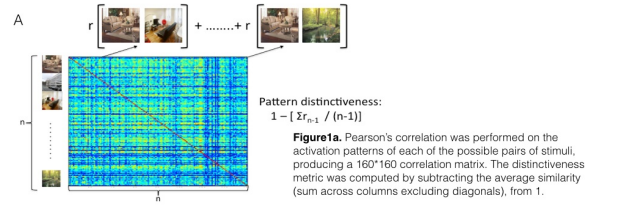

Figure1a. Pearson's correlation was performed on the activation patterns of each of the possible pairs of stimuli, producing a 160*160 correlation matrix. The distinctiveness metric was computed by subtracting the average similarity (sum across columns excluding diagonals), from 1.

Figure1b. In line with previous findings, we observed significant reduction in RT (t_{10} = 5.70 p< .001), and a significant reduction in amplitude of PPA activation (t_{10} =9.88 p< .001). To perform statistical analysis on the distinctiveness scores, all values were z-transformed. As hypothesized, Presentation 2 showed significantly greater distinctiveness than Presentation 1 (t_{10} =6.34 p< .001).

Title: Emotional face processing evokes physiological high frequency oscillations (80-500 Hz) in localized regions of the human brain

Authors: W. CALIBOSO[1], J. J. LIN[2], *B. A. LOPOUR[1];
[1]Biomed. Engin., [2]Neurol., Univ. of California, Irvine, CA

Abstract: Over a decade of neuroimaging work has characterized the neural basis of face perception and identified brain regions that preferentially respond to faces over other stimuli (Collins 2014), including the fusiform face area, occipital face area, posterior temporal sulcus, ventral anterior temporal lobe, and amygdala (Haxby 2000). Electrophysiological studies have found face-specific event-related potentials (ERPs) after the onset of a face stimulus (Allison 1994) and face-induced spectral perturbations in the gamma band (Lachaux 2005). While ERPs have provided information about localized information processing in the brain, this signal-averaging approach may discard oscillatory potentials that are not phase-locked across trials (Engell 2011). Physiological oscillations extending beyond the gamma frequency range have been demonstrated, but their function in cognitive processing has not been fully elucidated (Kucewicz 2014). These transient high frequency oscillations (Ripples: 80-250 Hz; Fast Ripples: 250-500 Hz) have been found to be potentially important tools in the study of cognition and epilepsy (Le Van Quyen 2012). Here we investigate high frequency oscillations evoked during face perception in humans. Twelve subjects undergoing clinical evaluation for epilepsy surgery passively viewed a paradigm to activate face-sensitive regions in the brain (Schacher 2006). The paradigm consisted of alternating 24-second blocks of baseline video clips (serene domestic landscapes) and activation video clips (faces of actors expressing fear with high intensity) for a total of 16 blocks. Target locations for the implanted grid, strip, and depth electrodes were determined solely for the purpose of seizure localization. We analyzed data from a total of 465 bipolar signals, after excluding electrodes within the seizure onset zone and anatomical defects and those having excessive noise. Using an automatic HFO detector (Staba 2002), we compared the rate of ripples and fast ripples during viewing of landscapes versus viewing of fearful faces. In 14 sites across four subjects, we found a significant increase in the rate of ripples during viewing of fearful faces. One site showed a significant increase in the rate of fast ripples during face viewing. Several of these sites corresponded to regions previously associated with face processing, and the additional sites were located in frontal and orbitofrontal regions. These

findings may provide important information about the activity of brain regions during face processing that cannot be inferred from phase-locked ERPs.

Title: Emotional interference of baby vs adult faces on the automatic attention in parenthood

Authors: *V. OLIVEIRA[1], M. GOULART[2], M. K. LUCION[3], P. P. SILVEIRA[4], L. BIZARRO[1];
[1]Programa de Pós-graduação em Psicologia, [2]Inst. de Psicologia, [3]Programa de Pós-graduação em Ciências Médicas: Psiquiatria, [4]Dept. de Pediatria, Faculdade de Medicina, Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: Protecting and nurturing offspring have been crucial behaviors to human evolution. Babies are, hence, salient emotional stimuli to human beings. The study of automatic attention to baby faces is a new research field with potential clinical relevance. The current study compared the emotional interference of baby faces and threat stimuli (adult fearful faces) on the automatic attention in parents and non-parents. Participants were 61 men and women aged 20 to 35 years. Parents (n=33) had a single child aged up to 2 years old. Images of baby and adult faces with different emotional expressions were used in a Go/No-Go task adapted from a paradigm (Pearson, 2010. Psychol Med 40) that assesses attentional bias. In the Go/No-Go task 30 images of 10 different babies with either distress, neutral or happy expressions and 30 images of 10 different adults with fearful, neutral or happy faces were employed as emotional stimuli. Trials sequence started with a screen with an initial fixation cross (750ms) followed by either Go (green cross) or No-Go (red cross) screen with emotional stimuli as background and vertical and horizontal peripheral bars as targets (240ms). A blank screen remained until response was given. Participants were instructed to press spacebar for No-Go trials and answer location of vertical bar pressing “right arrow” or “left arrow” in the keyboard for Go trials. E-prime software controlled trials display and recorded reaction time. Attentional bias indexes (ABI) were calculated for biases towards baby distress, baby vs adult faces (nurturing biases) and adult fear (protective bias). Each ABI was inserted in an univariate ANOVA with variables sex and parental status. Parents showed a higher attentional bias to baby vs adult faces in comparison to non-parents

(mean difference=26.77 ms, F(1)=5.392, p=0.024, eta sq=0.08). No significant effect of sex or parental status was found in the attentional bias to baby distress or in the bias to adult fear. This task was sensitive to parental status influence on attentional bias to babies even in a nonclinical sample. Men and women showed no difference in the preferential processing of baby faces possibly due to sample characteristics. The current outcome contributes to the reduced literature on the implicit processes involved in the care provided to babies by men and women, parents and non-parents. The results might be relevant also to future clinical studies by both indicating new points of enquiry and proposing a new research tool.

Title: Right hemispheric superiority in the conscious face processing: A high-density ERP study with hemifield stimulation

Authors: *N. TAKAMIYA[1,2], T. MAEKAWA[2], K. OGATA[2], T. YAMASAKI[2], E. YAMADA[2], M. TANAKA[2], S. TOBIMATSU[2];
[1]Prefectural Univ. of Hiroshima, Mihara-Shi, Japan; [2]Grad. Sch. of Med. Sci., Kyushu Univ., Fukuoka, Japan

Abstract: [Background] The face recognition is specialized for the right hemisphere in the literature. Our aim was to clarify the right hemispheric superiority in the unconscious and conscious face processing by using high-density ERPs with hemifield stimulation. [Methods] Eighteen right-handed healthy volunteers (9 female, 21-27 years old) were examined. Two types of stimuli (faces and objects) were presented to left or right hemifield in a random fashion. The visual stimuli were presented either in the subliminal (17-ms duration) or supraliminal (300-ms duration) condition using a backward masking paradigm. ERPs were recorded by a 128-ch EEG machine and a repeated measures ANOVA was applied to the latencies and amplitudes of the occipital P100 and occipito-temporal N170. [Results] In the subliminal condition, P100 but not N170 was robustly elicited. There were no significant effects of the stimulus type, presentation

side and hemisphere on the P100 amplitude and latency. In the supraliminal condition, a significant main effect of the presentation side was evident also on the P100 amplitude ($p<.0001$) but not on its latency irrespective of the stimulus type. We also found significant main effects of the stimulus visual field ($p=0.0020$), hemisphere ($p=0.0113$), and a significant interaction on the stimulus visual field and hemisphere ($p<.0001$) for the N170 amplitudes to the face stimuli but not on its latencies.. [Discussion] It is well established that the P100 reflects the function of the primary visual cortex (V1) while N170 is originated from the fusiform face area (FFA). The P100 amplitudes were significantly larger over the contralateral hemisphere regardless of the stimulus type and presentation side in the supraliminal condition but not in the subliminal condition. Thus, the P100 simply reflects the retinotopic organization in the conscious visual processing. Interestingly, the N170 appeared only in the supraliminal condition with the selectivity for face stimulus and right hemispheric superiority. Therefore, right FFA plays an important role for the conscious face processing irrespective of the visual hemifield.

Title: vATL contributes to biographical knowledge of faces via feedback to FFA

Authors: Z. SHEHZAD[1], J. TAYLOR[1], *G. MCCARTHY[2];
[1]Psychology, [2]Yale Univ., New Haven, CT

Abstract: As we learn to recognize a person's face, it's natural to also learn biographical facts about that person such as their name or occupation. In neural models of face processing, linking such person-specific semantic knowledge with perceptual representations of an individual's face is represented in the ventral anterior temporal lobe (vATL). However, some work has also implicated the fusiform face area (FFA) in processing biographical information for a face (e.g., as a feature in face space). Since the FFA and vATL are part of an extended 'face network', it is possible that responses in the FFA to biographical information may reflect bi-directional communication between the FFA and vATL. To disentangle the roles of the vATL and FFA in

face processing, we conducted an fMRI study comparing brain responses to viewing faces for whom participants had learned biographical facts (name, location, occupation) or physical facts (eye color, gender, race). When viewing each face, participant's were asked to recall the facts associated with that face and either made no response (passive viewing task) or responded to knowing a probe fact (question task). To focus our analyses, we selected regions-of-interest in the occipital face area (OFA), FFA, and vATL based on local maxima from a probabilistic atlas of face-selective responses (Engell & McCarthy, 2013). Across both passive viewing and question tasks, we found significantly greater activity in the left vATL (but not in the FFA) for viewing faces associated with biographical facts (biographical condition) versus faces associated with physical facts (physical condition). Increased (undirected) connectivity was observed for the biographical versus physical condition between the R OFA - R vATL, R FFA - R vATL, and L FFA - L vATL, but only for the questions task. Finally, in a directed connectivity analysis based on a linear non-gaussian acyclic model (LiNGAM; Ramsey et al., 2014), we found that feedback signals from left vATL to left FFA significantly increased for the biographical versus physical condition while feedforward signals from left OFA to left FFA and lateral signals from left FFA to right FFA significantly increased for the physical versus biographical condition. Our findings suggest that responses to biographical knowledge of faces is lateralized to the left hemisphere and selective to the vATL. We propose that the vATL represents biographical knowledge of faces through feedforward signals from the FFA to the vATL and feedback signals from the vATL to the FFA contribute to representations of biographical knowledge as features in a face space.

Title: Face and body recognition in dancers and non-dancers

Authors: L. VINGILIS-JAREMKO[1], V. GUIDA[2], S. E. MAGUIRE[3], *J. F. DESOUZA[4]; [1]Psychology, York Univ., Toronto, ON, Canada; [2]Psychology, Ctr. for Vision Res., Toronto,

ON, Canada; [3]Psychology, Univ. of Toronto, Toronto, ON, Canada; [4]Psychology & Biol., York Ctr. For Vision Res., Toronto, ON, Canada

Abstract: The ability to recognize others is critical to our everyday social interactions. Although extensive research has explored the role of the face for person recognition, little has explored the role of the body, which may be used for recognition at a distance. Because bodies may be processed similarly to faces (Rhodes, Jeffery, Boeing, & Calder, 2013; Robbins, Coltheart, 2010; Robbins, Coltheart, 2012), we explored whether body recognition abilities are influenced by visual experience, as are face recognition abilities. We tested two groups with different types of visual experience with bodies: dancers (n=29), who spend much of their time observing and comparing bodies in form fitting clothing to achieve a physical aesthetic, and non-dancers (n=37), who tend to see bodies in more obstructive clothing and spend much of their time in front of computers. Participants viewed images of bodies wearing identical clothing, and after a short break, selected which body from a pair of bodies they had seen before. Participants completed the same task with faces in a separate, counterbalanced block. We hypothesized that dancers would have better accuracy at recognizing bodies, but perform similarly to non-dancers at recognizing faces. First, we found that participants recognized faces better than bodies ($p<0.001$), consistent with previous research (Burton, Wilson, Cowan, & Bruce, 1999). Most importantly, we found that dancers recognized faces and bodies better than non-dancers (main effect of participant group, $p=0.043$). These results suggest that dancers are more accurate at recognizing identity using the body than non-dancers, putatively due to their extensive visual experience with bodies. More accurate face recognition abilities among dancers could result from facilitation effects across brain networks, as bodies and faces are typically seen together.

Title: Neural correlates of dance imagery induced by music

Authors: *M. BRESJANAC[1], V. POLITAKIS[2], B. PANTIć[3], A. VOVK[1], G. REPOVŠ[2];
[1]Univ. Ljubljana Med. faculty, Ljubljana, Slovenia; [2]Univ. of Ljubljana Fac. of Arts, Ljubljana, Slovenia; [3]Gibor, Ljubljana, Slovenia

Abstract: Neural correlates of movement, movement perception and mental imagery of movement have been shown to extensively overlap. The aim of our pilot exploration was to employ music-induced dance imagery to study dance responses to music. Healthy, young adult volunteers (18 non-dancers (7 male and 11 female) and 17 dancers (9 male, 8 female)) were recruited for the fMRI-based study using a 3T scanner. Resting state BOLD signal was recorder first, followed by BOLD signal recordings during blocks of listening to music with instructions on how to respond to it with mental dance imagery. Clips of groovy (dance music) and non-groovy (foreign national anthems) instrumental music were used as stimuli. Immediate feed-back was obtained from the subjects on the extent of experienced mental imagery of dance as well as on their emotional engagement while listening to the music. The subjects' heart rate was simultaneously recorded to provide a physiological measure of arousal. To obtain insight into neural activity underlying mental imagery of movement, movement observation and emotional engagement (without musical stimuli) in the same subjects, BOLD signal was also recorded while participants were instructed to imagine swimming, observing a swimmer, experiencing a passionate kiss, etc. The results revealed interesting behavioural as well as neural activation responses that point to expected commonalities, but also to some less expected differences between dancers and non-dancers in their responses to groovy and non-groovy music.

Title: Do mental rotation and manual tracking share an underlying mechanism?

Authors: *U. B. NUNES[1], R. RUSSELL[2], M. SCHLESINGER[2];
[1]Psychology, Southern Illinois Univ. Carbondale, Carbondale, IL; [2]Psychology, Souther Illinois Univ. Carbondale, Carbondale, IL

Abstract: Mental imagery is a complex human ability that is used in everyday life such as in sports, driving and reading. An important question concerns the specific imaging strategies used during image-based neurocognitive tasks, such as mental rotation. To investigate this question, we measured performance on three tasks that ostensibly recruit different areas of the brain and diverse forms of mental imagery: (1) the standard mental rotation task, (2) the Vividness of Visual Imagery Questionnaire (VVIQ), and (3) a manual-tracking task that includes both visible and occluded moving targets. Our core prediction was that scores on the mental rotation task would be positively correlated with tracking accuracy during both visible and occluded tracking, but that mental rotation performance would not be correlated with VVIQ scores. Our preliminary results confirmed these predictions. Ongoing analyses of these data are directed toward diagnosing distinct imaging strategies during mental rotation and relating these strategies to performance during manual tracking and individual differences on the VVIQ.

Title: The neural signature of self: recognition of self-generated handwriting within the action observation network

Authors: *R. GILRON, R. MUKAMEL;
Tel Aviv Univ., Tel Aviv, Israel

Abstract: Mirror neurons are nerve cells that are active both during action execution and action observation. This neurons are present in a network of distributed areas associated with motor function, including the primary and pre-motor cortices, inferior parietal regions and the supplementary motor area (SMA). This network is often termed the Action Observation Network

(AON). Previous research demonstrates differential activation within the AON when experts (e.g. basketball players, dancers, musicians) observe the performance of actions within their domain of expertise. It has been suggested that actions that are within one's motor repertoire resonate more strongly in the AON. We chose hand writing as a model to examine this issue since each individual is an expert in generating and perceiving his own spatiotemporal dynamics during handwriting. We recorded whole-brain fMRI signals from eight subjects while they viewed pre-recorded dynamic traces of their own and others' handwriting. Using whole brain search light multi-voxel pattern analysis we were able to detect the identity of the observed hand-writing trace, with above 75% classification in a network of sensorimotor regions including left primary motor cortex (subjects were right handed), posterior STS and inferior parietal lobule (IPL). These regions are commonly associated with the AON. Our results, that neural activity within this network during passive observation may play an important role in simulating observed actions. Moreover, they demonstrate that observing the sensory consequences of an action (dynamic hand-writing trace) without the actual agent or effector (a view of the physical hand writing) is sufficient to evoke activity in the action observation network.

Title: Defying the laws of gravity: Motor Imagery of rotation along body axes

Authors: *M. KALICINSKI[1], O. BOCK[1], N. SCHOTT[2];
[1]German Sport Univ. Cologne, Cologne, Germany; [2]Dept. of Sport and Exercise Sci., Univ. of Stuttgart, Stuttgart, Germany

Abstract: Motor Imagery (MI) is described as an active cognitive process during which the representation of a specific action is internally reproduced in working memory from a first-person perspective, without any overt motor output (Decety & Grèzes, 1999). When performing MI tasks with rotation along roll or pitch body axis, one has to imagine movements which are physically impossible on earth as they would defy gravity. The purpose of the present study is to find out whether young adults are able to produce accurate MI of such movements. 68 adult (23.94 ± 3.07 years; male n = 33) participants completed a modified version of the CMI test (Schott, 2013). With eyes closed, subjects were asked to imagine moving their body according to

six consecutive verbal instructions. After the sixth instruction, participants opened their eyes and arranged a flexible doll into the assumed final body configuration. Each shown element of the final body configuration was scored with 1 point when correct. The time in seconds needed to assume the final configuration (response time) was measured. In a first condition, participants were instructed to imagine themselves standing on the ground and received only instructions for moving body segments (CMIground). In a second condition, participants were instructed to imagine themselves floating above ground and received instructions for moving body segments and either one (Group: CMIfloat1) or two (Group: CMIfloat2) full body rotations around the three body axes (CMIfloat). After each condition, participants were asked to rate their subjective visual and kinesthetic vividness of MI. For the mean scores significant condition differences (CMIground = 45.7 ± 4.1; CMIfloat = 41.2 ± 5.3; $F (1, 66) = 62.596$; $p < .001$ $\eta^2 = .467$) emerged, as well as a Group X Condition interaction ($F (1, 66) = 7.506$; $p = .007$; $\eta^2 = .102$): differences between CMIground and CMIfloat were more pronounced in group CMIfloat2. Condition differences could be also shown for response time (CMIground = 10.9 ± 3.8; CMIfloat = 17.0 ± 8.1; $F (1, 66) = 56.694$; $p < .001$ $\eta^2 = .462$) and for vividness ratings ($F (1, 66) = 50.929$; $p < .001$ $\eta^2 = .436$). Our data suggest that it is possible to mentally imagine movements that cannot be executed on earth, but this imagery is more error-prone, especially with increasing complexity due to the amount of body rotations.

Title: Brain mechanisms of exteroceptive and interoceptive integration in bodily self-consciousness

Authors: *F. BERNASCONI[1,2], R. RONCHI[1,2], J. BELLO-RUIZ[1,2], C. PFEIFFER[1,2], O. BLANKE[1,3,2];
[1]EPFL, Lausanne, Switzerland; [2]Lab. of Cognitive Neurosci., Lausanne, Switzerland; [3]Ctr. for Neuroprosthetics, Lausanne, Switzerland

Abstract: Bodily self-consciousness (BSC) refers to the conscious experience of the self within the body. Different bodily information (e.g., vision and touch) are integrated to generate BSC: recently, researchers focused their attention on the signals arising from inside the body

(interoceptive, e.g. heartbeat), and the integration of exteroceptive and interoceptive signals. Despite the importance of these processes, limited data are available about how and where interoceptive (e.g., heart) and exteroceptive (e.g., vision) signals for BSC are integrated in the brain. In this study we have investigated the spatiotemporal brain dynamics underpinning cardio-visual integration in 14 healthy subjects. We recorded visual evoked potentials with electroencephalography (EEG) during the perception of a body or a scrambled-body picture appearing (or not) at the same frequency of participants' heartbeat, and we analysed the brain responses linked to the visual processing. Results showed a global increase in brain response (i.e., global field power) specific for body stimuli presented in synchrony with the heart, occurring at about 200ms after the stimulus onset. No modulation in topographies configuration was observed across conditions. These results suggest that the cardio-visual integration results in an enhanced brain response of similar intracranial generators. Source estimation revealed enhanced activity within the left parietal lobe. In conclusion, these findings indicate that cardio-visual processing leads to an increased integration of external (i.e., picture or a body) and internal (i.e., own heart beat) bodily features that might be relevant for BSC.

Title: The integration of gravity in implicit and explicit motor representations

Authors: *F. LEBON[1,2], E. TRAVERSE[1,2], L. FADIGA[3,4], T. POZZO[1,2,3], C. PAPAXANTHIS[1,2];
[1]INSERM U1093, DIJON, France; [2]Univ. of Burgundy, Dijon, France; [3]RBCS Dept, Inst. Italiano di Tecnologia, Genova, Italy; [4]Section of Human Physiol., Univ. of Ferrara, Ferrara, Italy

Abstract: Mental representation of movement is an important high-level process in motor control. By using transcranial magnetic stimulation (TMS) technique, previous studies have found an increase of corticospinal excitability when imagining (explicit representation, Fadiga et al. 1999; Jeannerod, 2001) or observing (implicit representation, Fadiga et al., 1995) an action. This facilitation suggests the involvement of the primary motor cortex in the mental

representation of the action. The aim of this study was to test whether gravity representation is explicitly (during motor imagery) or implicitly (during action observation) expressed in mental actions. Ten participants were instructed to rest, to actually perform, to imagine, or to observe repetitive flexion/extension of the right forearm in a vertical or horizontal plan in time with a 0.5 Hz metronome. TMS was triggered over the arm representation of the left primary motor cortex when the elbow was at 90°. Motor-evoked potentials (MEPs) were recorded from biceps brachialis muscle of the right arm and their amplitude was considered a marker of corticospinal excitability. We hypothesized that if gravity is integrated in action observation and motor imagery then MEPs should increase during flexion against gravity (concentric contraction), extension with gravity (eccentric contraction), and flexion against inertia in the horizontal plane. We found that MEPs were facilitated in all conditions in comparison to rest (all, $p<0.05$), confirming the facilitation of the motor cortex during motor imagery and action observation. During actual execution trials, MEPs were greater during flexion than that during extension for both horizontal and vertical movements. The amplitude was the greatest while flexing on the vertical plan, showing specific patterns of activation while moving against gravity. During imagined trials, MEPs were greater during flexion than during extension for horizontal movements, but did not differ for vertical movements. This indicates that mental simulation dissociates movements with and without gravity. During observation trials, MEPs were similar during flexion and extension for both horizontal and vertical movements, indicating the absence of muscle specificity related to the movement direction and thus gravity force. Overall, these results show for the first time that gravity force is integrated in the construction of explicit (motor imagery) motor representations but not in implicit (action observation) ones.

Title: Evidence for predictive coding in the human motor system during action observation

Authors: *M. HANSEL-LESMY[1], A. GOLDSTEIN[1], J. M. KILNER[2];
[1]Gonda Brain Res. Ctr., Bar Ilan Univ., Ramat Gan, Israel; [2]Sobell Dept. of Motor Neurosci. and Movement Disorders, Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Previous studies have shown that neurons in the macaque monkey's premotor cortex are active during action observation. These neurons discharge more during observation of transitive action than for intransitive actions and are even activated by partially occluded movement. In concordance with the direct recordings of these 'mirror neurons' non-invasive human neurophysiological and neuroimaging studies have demonstrated that similar areas are active during action observation. Despite much research little is known about the functional role, if any, of the activity in motor regions during action observation. One major theory proposes that our motor systems are active during action observation as they are the best model we have to enable us to predict the sensory consequences of any observed movements. The aim of this study was to test this predictive coding hypothesis by studying the modulation of the motor cortex activity when observing actions that were either occluded or in full view. Suppression of beta oscillations (15-30Hz) have been associated with an increase in activity of the human motor cortex. We used MEG to measure beta oscillations while participants passively observed video clips showing either reaching and grasping of a ball, or miming this same action. Clips started with a 1000ms static frame, showing a hand on the left of the screen either with or without a ball present on the right of the screen. After 1000ms the hand moved to either grasp the ball if it was present or to mime grasping if it was absent. In half of the clips a screen appeared after the static phase and occluded the grasp. Participants knew whether the action would be occluded prior to the trial starting. Here we found that beta oscillations were suppressed both for full viewed movements and partially occluded movements. No significant differences were found between the suppression for transitive and intransitive actions. Surprisingly, although before the hand crossed the occluder the movement was identical for full-viewed and partially occluded actions, beta power was more suppressed when the movement was partially occluded. That is, the same stimulus elicited different modulations of beta power. After the hand crossed the occluder, no significant difference was found between full viewed conditions and partially occluded conditions. Our results indicate that when participants knew that in the future the hand would cross the occluder, they attended more to the visible part of the movement. Our results support the view that during action observation, the motor system activity is not only modulated by the kinematic of the movement but also by the expectations of the observer.

Title: The spatial extent of action sensitive perceptual channels decrease with visual eccentricity

Authors: *L. FADEMRECHT[1], I. BÜLTHOFF[1], N. E. BARRACLOUGH[2], S. DE LA ROSA[1]; [1]Human perception, cognition and action, Max Planck Intitute for Biol. Cybernetics, Tuebingen, Germany; [2]Dept. of Psychology, Univ. of York, York, United Kingdom

Abstract: Actions often occur in the visual periphery. Here we measured the spatial extent of action sensitive perceptual channels across the visual field using a behavioral action adaptation paradigm. Participants viewed an action (punch or handshake) for a prolonged amount of time (adaptor) and subsequently categorized an ambiguous test action as either 'punch' or 'handshake'. The adaptation effect refers to the biased perception of the test stimulus due to the prolonged viewing of the adaptor and the resulting loss of sensitivity to that stimulus. Therefore the more a channel responds to a specific stimulus the higher is the adaptation effect for that certain channel. We measured the size of the adaptation effect as a function of the spatial distance between adaptor and test stimuli in order to determine if actions can be processed in spatially distinct channels. Specifically, we adapted participants at 0° (fixation), 20° and 40° eccentricity in three separate conditions to measure the putative spatial extent of action channels at these positions. In each condition, we measured the size of the adaptation effect at -60°,-40°,-20°, 0°,20°,40°,60° of eccentricity. We fitted Gaussian functions to describe the channel response of each condition and used the full width at half maximum (FWHM) of the Gaussians as a measure of the spatial extent of the action channels. In contrast to previous reports of an increase of midget ganglion cell dendritic field size with eccentricity (Dacey, 1993), our results showed that FWHM decreased with eccentricity (FWHM at 0°: 56°, FWHM at 20°: 29, FWHM at 40°: 26). We then asked whether the response of these action sensitive perceptual channels can be used to predict average recognition performance (d') of social actions across the visual field obtained in a previous study (Fademrecht et al. 2014). We used G(x) - the summed response of all three channels at eccentricity x, to predict recognition performance at eccentricity x. A simple linear transformation of the summed channel response of the form a+b*G(x) was able to predict 95.5% of the variation in the recognition performance. Taken together these results demonstrate that actions can be processed in separate spatially distinct perceptual channels, their FWHM decreases with eccentricity and can be used to predict action recognition performance in the visual periphery.

Title: Perception through action: Where and When. Differentiation of mirror regions using intracranial recordings

Authors: *A. PERRY[1,2], J. STISO[2], E. F. CHANG[3], J. J. LIN[4], J. PARVIZI[5,6], R. T. KNIGHT[1,2];
[1]Psychology, [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Dept. of Neurolog. Surgery and Physiol., Univ. of California, San Francisco, San Francisco, CA; [4]Comprehensive Epilepsy Program, Univ. of California, Irvine, Irvine, CA; [5]Stanford Human Intracranial Cognitive Electrophysiology Program (SHICEP), [6]Dept. of Neurol. and Neurolog. Sci., Stanford Univ. Med. Ctr., Stanford, CA

Abstract: Embodied theories of cognition emphasize the central role of sensorimotor transformations, a correspondence between sensory and motor domains, in the representation and understanding of actions and emotions of others. These theories assume that automatic simulation is required to understand others' actions, and that such simulation may also serve as the basis for imitation. Support for this theory has been provided by reports of mirror neurons in non-human primates. Neuroimaging techniques have been used to study a putative mirror neuron system in humans, and have provided evidence for frontal, parietal and sensorimotor regions that are activated for both performing and viewing goal directed actions. However, most of these studies were limited in either their temporal or spatial resolutions, and so the exact timing of these activations, and how much they actually overlap remain unknown. To address these questions, we utilized the spatial and temporal advantages of intracranial cortical recordings (electrocorticography, ECoG) to test whether neuronal populations in mirror neuron regions are activated during viewing and imitating goal directed actions. We tested 6 participants with intractable epilepsy, who had been implanted with electrode grids over the right or left frontal, parietal and sensorimotor cortexes for pre-operative monitoring. Patients viewed grasping actions towards different objects, and following a rest period of 2 seconds, had to perform the same actions. Increases in spectral power in the high gamma range (70-150 Hz) were used to index cortical activation. Our results show robust high gamma activation in sensorimotor,

premotor IFG and IPL during performance and viewing of motor actions. These activations showed complex temporal patterns: while some sites were active throughout the whole viewing and action conditions, some were active only at the initiation of movement towards the object, and some only for the actual grasp. These results support the role of the existence of a distributed neural network engaged in the perception of others' actions and provide temporal differentiation between different stages of the perception of action.

Title: The role of action context on the neural substrates underlying gesture recognition

Authors: ***N. NATRAJ**[1], S. BASUNIA[1], J. MIZELLE[1,2], L. WHEATON[1];
[1]SCHOOL OF APPLIED PHYSIOLOGY, COLLEGE OF SCIENCES, GEORGIA INSTITUTE OF TECHNOLOGY, Atlanta, GA; [2]Atlanta Veteran Affairs, Atlanta, GA

Abstract: Prior research has shown diffuse representations in the brain for the processing of transitive (tool-based), intransitive (communicative) and meaningless gestures. Specifically, transitive, intransitive and meaningless gestures elicited activations over bilateral posterior parietal cortex, superior temporal cortex, occipitotemporal regions and right pre-supplementary areas. In particular, intransitive gestures elicited greater activations than transitive gestures over the left inferior frontal gyrus. An important confound however, is that the kinematics of the gesture was not controlled in the aforementioned study. For example, the kinematics of waving good bye (intransitive gesture) and wiping a window (transitive gesture) are similar and it is only the action context that discriminates the two gestures. In addition, it is possible that controlling action kinematics can better identify the differences between meaningless and contextual gestures. Thus, overall, it is unclear to what extent the neural substrates underlying gesture recognition are influenced by action context alone. To address this issue, an event-related fMRI study was designed and data was collected from 19 right handed, 20-30 year old subjects across three runs as they viewed static images of an actor performing a right handed gesture. The first

run consisted of neutral gestures devoid of any context at all. In the second run, the exact same gestures were placed in a transitive context. In the third run, the exact same gestures were placed in an intransitive context. fMRI data was analyzed with the FSL software package in Linux. All three gestures elicited activity over occipitotemporal areas, parietal cortex, premotor cortex and supplementary motor areas. However, activations over parietofrontal regions tended to be more left hemispheric lateralized. Kinematically similar gestures in transitive and Intransitive contexts both elicited greater activity over bilateral occipitotemporal and left parietal regions when compared to neutral gestures while neutral gestures elicited greater activity over frontal regions, ostensibly to try and fill in context. Importantly, when contrasting kinematically similar transitive and intransitive gestures directly, results showed greater left posterior parietal cortex activity for transitive context over intransitive context and greater bilateral frontal activity for intransitive context over transitive context. Results here show the importance of action context on the neural substrates underlying gesture recognition.

Title: Motor imagery beyond the motor repertoire: V1 activity predicts capability of kinesthetic motor imagery of complex whole body movements

Authors: ***N. MIZUGUCHI**[1], H. NAKATA[2], K. KANOSUE[1];
[1]Waseda Univ., Tokorozawa, Japan; [2]Nara Women's Univ., Nara, Japan

Abstract: To elucidate the neural substrate associated with capabilities for kinesthetic motor imagery of complex whole-body movements, we measured brain activity during a trial involving both kinesthetic motor imagery and action observation as well as during a trial with action observation alone. Brain activity was assessed with functional magnetic resonance imaging (fMRI). Nineteen novices imagined three types of whole-body movement with the horizontal bar: the Giant Swing, Kip, and Chin-Up. No participant had tried to perform the Giant Swing.

The vividness of kinesthetic motor imagery as assessed by questionnaire was highest for the Chin-Up, less for the Kip and lowest for the Giant Swing. The primary visual cortex (V1) was significantly more activated during kinesthetic motor imagery of the least-vivid Giant Swing than the most-vivid Chin-Up within participants. Across participants, V1 activity during Kip imagery was negatively correlated with vividness of Kip imagery. These results suggest that activity in V1 is dependent upon the capability of kinesthetic motor imagery for complex whole-body movements. Since V1 activity is likely related to the creation of a visual image, we speculate that visual motor imagery unintentionally substitutes for the less vivid kinesthetic motor imagery which occurs with difficult, complex whole-body movements.

Title: Overestimation of body size is not exclusively related to one's own body

Authors: ***M. F. LAUS**[1], B. M. ALVES[2], R. C. M. MOREIRA[2], S. S. ALMEIDA[1], T. BRAGA COSTA[2];
[1]FFCLRP/USP, Ribeirão Preto, Brazil; [2]Nutr. Course, Univ. of Ribeirão Preto, Ribeirão Preto, Brazil

Abstract: It has been suggested that people exhibit greater size overestimation for themselves as compared to mannequins or neutral objects because: (1) perceptual accuracy of body image is primarily predicted by biopsychosocial influences (including one's weight); and (2) judgments of the own size, but not the size of objects, are generally performed by recall-size estimation tasks. These tasks involve a memory judgment rather than visual information, which includes cognitive knowledge and beliefs about body size and shape that may affect perception. Even though Figure Rating Scales (FRS) are extensively used to evaluate accuracy of body size estimation and results have shown a remarkable rate of overestimation among men and women, research using this instrument to evaluate the accuracy in estimating the size of other people has never been conducted. If one or both hypotheses above are true, we expect that individuals will present a more accurate perception when estimating the size of other people compared to the size of their

own body. Using a FRS with 15 drawings of each gender from leaner to heavier bodies, 200 college students (100 men) with different body weights and levels of prescreened body size distortion estimated the size of 4 individuals from the same gender, representing different categories of nutritional status. Results demonstrated that, regardless the size of the stimulus, only 10.75% of the judgments were accurate, 13.25% were underestimated and 76.0% were overestimated. Accuracy of participants' own estimation did not influence the judgments about the size of others ($p > .05$) and participants' own weight also did not influence their judgments about the size of other people ($p > .05$). Overestimation was significantly higher than underestimation or accurate perception for the overweight ($p < .001$) and obese stimuli ($p < .001$), while the underweight stimulus was underestimated by more than 60.0% of men ($p < .001$) and overestimated by only 8.0% of them ($p < .001$). Among women, however, almost 100% of judgments were overestimated for the normal weight, overweight and obese stimuli ($p < .001$), and more than 70% for the underweight stimulus ($p < .001$). In sum, participants' weight and perceived body size were not associated to the degree of inaccuracy of stimuli's sizes, and overestimation occurred even when judgments were performed with visual information available. We conclude that perception of body size may involve unknown factors that lead people to impressively overestimate the size of others. Taken together, our results suggest that overestimation of body size is not exclusively related to one's own body.

Title: Influence of attention and stance on postural control stochastic dynamics

Authors: *G. CHAPARRO[1], Y. MOON[2], D. WAJDA[2], J. SOSNOFF[2], M. HERNANDEZ[2]; [2]Kinesiology, [1]Univ. of Illinois at Urbana Champaign, Urbana, IL

Abstract: As attentional demands increase while maintaining an upright stance, the risk of falling increases, particularly for older adults with neurological conditions. Traditionally, research examining the effects of attention on postural control has focused in deterministic features of postural sway such as the root mean square error and velocity of the center of pressure (COP) in a quiet stance. However, these measures do not capture the changes that may

arise in postural control stochastic dynamics due to the relocation of attention to concurrent cognitive tasks. Furthermore, it is of importance to capture these changes in varying stances to ascertain the interaction between postural control and attentional demands. We expand upon a novel method for evaluating postural control stochastic dynamics, the center of pressure velocity autocorrelation function (COP-VAF), by examining the effects of attention and stance on the COP-VAF. Participants were instructed to 'stand as still as possible', while performing single or dual tasks (i.e., concurrent motor and cognitive tasks) in a bilateral or split stance. Cognitive tasks consisted of recitation of alternating letters of the alphabet in a backwards order. Dual tasks led to increased initial COP-VAF values, decreased minimum values, and increased low frequency processes, consistent with the use of increased compensatory postural responses, COP velocities, and neural control. Thus, the COP-VAF may further our understanding of the underlying mechanisms behind the maintenance of balance in human upright stance.

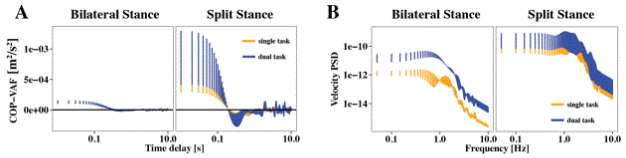

Figure 1. A.) Mean (Standard Error) COP Velocity Autocorrelation function (COP-VAF) trajectories for healthy young adults (N=2, 2 females) in bilateral and split stance under single or dual task conditions. B.) Mean (Standard Error) COP-VAF Power Spectrum Density (PSD) trajectories for healthy young adults in varying task and stance conditions.

Title: The effects of semantic relatedness on long term survival memory processing

Authors: *S. MATTINGLY, J. PAYNE;
Univ. of Notre Dame, Notre Dame, IN

Abstract: Memory may have evolved, at least partially, to preferentially retain and apply information relevant to problems faced by early humans during the Pleistocene era, such as procuring food, shelter, and protection from predators. Several studies have shown that stimuli encoded in a survival mindset (i.e. "survival processing") are better remembered after a brief

delay than a variety of other encoding strategies (such as intentional learning). In order to be useful, however, memory must be applied to situations temporally distinct from encoding. While the underlying proximate memory processes remain equivocal, one theory suggests that the observed memory benefit conferred by survival processing is related to a congruency effect in which items that are semantically related to the encoding condition (e.g. sword in survival encoding condition vs. box in moving control condition) are remembered better. However, it is possible that survival memory relies more on schematic processing than other forms of encoding. In an attempt to test if survival processing relies more on schema and semantic relatedness between items across a long delay, we utilized the survival processing experimental procedure in which participants are instructed to imagine themselves in a grasslands survival scenario (experimental, n=15) or in a moving to a foreign land scenario (control, n=15), and then to encode a list of 30 words by rating them in terms of usefulness to the scenario. 12 hours later, participants completed free recall and recognition memory tests of the 30 original words, along with 15 semantically related foils and 15 semantically unrelated foils. Additionally, participants rated words at recognition on scales of valence and arousal. With the current sample size, we were not able to replicate the generally reported main finding of better memory for 'survival' at 12 hours previously reported, but data collection is still in progress. However, we found a significant group effect: those who encoded stimuli in the survival condition had significantly more false alarms to semantically related compared to semantically unrelated lures ($t(15) = 3.174$, $p<.01$). Within the 'moving' group, there were no differences between false alarm rates of related and unrelated lures. No additional effects were observed between groups on the ratings of utility, valence, or arousal, nor were there any memory effects for ratings of utility, valence, or arousal. This suggests that survival memory over longer time delays may rely more on semantic processing compared to moving condition.

Title: Spatiotemporal pattern similarity during the encoding of context boundaries supports memory for sequential order of events

Authors: I. SOLS[1,2], L. DAVACHI[3], *L. FUENTEMILLA[1,2];
[1]Inst. of Biomedicine Res. of Bellvitge (IDIBELL), Barcelona, Spain; [2]Dept. of Basic Psychology, Univ. of Barcelona, Barcelona, Spain; [3]Dept. of Psychology, New York Univ., New York, NY

Abstract: Given that experience unfolds in a continuous manner over time, how does the experiencing become discretized into cohesive memory representations available at long term? A current proposal involves the detection of contextual shifts or boundaries, which help us form bound memory representations from encoded sequences of events. However, because context boundaries cannot be anticipated during sequence encoding, the neural mechanism supporting the memory formation for sequences of events may take place retrospectively during the detection of contextual boundaries. Here, we asked whether similar spatiotemporal patterns of electrophysiological (EEG) activity elicited during sequential encoding could be detected during the detection of a contextual shift. Participants were enrolled in an episodic sequence task in which series of alternated sequences of object and face pictures were presented, thus using picture category as a contextual boundary during sequential encoding. Behaviorally, we found that memory for the order of events was enhanced within, rather than across context shifts, thus suggesting that boundaries successfully parcel out sequences of events into separate memory representations. Using similar representational analysis on EEG features from distributed electrodes and extended time windows, we found that neural activity elicited during the encoding of sequences of items within a context were identified on neural responses elicited by the encoding of a boundary item. These findings were specific to whether boundary items were preceded by sequences of different items of the same category and not by the mere presentation of repeated items within a sequence, thereby suggesting the results cannot be explained only by neural mechanisms underlying contextual shifts. Current results support the notion that a rapid memory reinstatement of the preceding encoded sequence of events is elicited during context shifts to promote the formation of a bound memory representation.

Title: The neural dynamics of updating and accumulating linguistic conceptual knowledge

Authors: *R. BERKERS[1], M. VAN DER LINDEN[1], D. NEVILLE[1], M. VAN KESTEREN[2], R. MORRIS[3], J. MURRE[4], G. FERNANDEZ[1];
[1]Donders Institute. Radboud Univ. Med. Cent, Nijmegen, Netherlands; [2]Dept. of Psychology, Stanford Univ., Stanford, CA; [3]Ctr. for Cognitive and Neural Systems, Univ. of Edinburgh, Edinburgh, United Kingdom; [4]Dept. of Psychology, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Conceptual knowledge contains principles of how related perceptual features share meaning. This knowledge is acquired by generalization across repeated learning experiences, which is brought to bear on future experiences. Previous studies tracked brain activity with fMRI during the acquisition of conceptual knowledge, but the neural processes instrumental in updating this knowledge are unclear. Here, we systematically tracked conceptual knowledge formation based on an artificial language that was structured by a set of hierarchical associative rules, which were not known to participants beforehand. Specifically, participants learned shape/non-word combinations in an hour-long, scanned learning session (3T MRI). The shapes were simple geometric figures with a specific colour and movement across the screen (three features), and the words consisted of three syllables. For example, a blue circle with and upward moving trajectory was paired with the word: 'NI-JO-TO'. In each trial, first the shape was presented (the cue phase), then participants were asked to select the corresponding tri-syllabic word (the response phase), and lastly the correct non-word was presented (feedback phase). Participants were asked to select the correct syllables for each given shape out of three response options. Across learning, 27 participants learned the associations up till ceiling-level performance. Explicit knowledge of the associative rules was confirmed by a debriefing questionnaire and a test of memory transfer a day later. Next, we modeled the acquisition of conceptual knowledge using a State-Space model, which provided us with trial-by-trial estimates of the current state of knowledge as well as the change of knowledge with respect to the previous trial. We used these two estimates as parametric modulators of BOLD-activity during the cue-response period. In line with previous studies, activity in medial prefrontal cortex, angular gyrus, orbitofrontal cortex and posterior cingulate cortex was modulated by the state of knowledge. Updating of knowledge, on the other hand, modulated activity in a selective region in the right caudate nucleus. Psychophysiological interaction analysis shows that connectivity of this region fluctuated along with these learning parameters with regions in the medial prefrontal cortex and left angular gyrus. This pattern of results is in line with a model where the caudate nucleus is instrumental in driving changes in conceptual knowledge by updating representations in medial prefrontal and angular regions where knowledge is accumulated. These results provide new insight into the dynamics of conceptual knowledge acquisition.

Title: Durable memory through coherent activation patterns and hippocampal-neocortical interactions

Authors: *I. WAGNER, M. VAN BUUREN, L. BOVY, G. FERNÁNDEZ;
Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands

Abstract: Memory durability, or how persistent a memory trace will be, is partly determined while we initially encounter information. During encoding, a network of brain regions that includes medial temporal, lateral prefrontal and ventral visual structures is assumed to show stronger activation for visually presented material that will later be remembered rather than forgotten. Additionally, successful encoding is known to involve enhanced hippocampal-neocortical coupling. Such 'subsequent memory analysis' is often based on memory tests administered briefly after study - which makes claims about the durability of successfully formed memories impossible. In the present study, we aimed at expanding current knowledge by predicting the durability of memories. Thirty-four subjects studied unique picture-location associations inside the MR-scanner and performed a cued-recall test immediately after study, as well as 48 hours later. We defined associations as 'weak' if memory was preserved only during immediate retrieval. 'Durable' memories on the other hand, should persist also 48 hours later. Initial results indicate increased activation in medial temporal lobe, lateral prefrontal, and ventral visual cortex during encoding of durable as compared to weak or forgotten memories. Additionally, using psychophysiological interaction analyses, we found enhanced hippocampal-neocortical coupling during encoding of durable relative to weak memories. On a more fine-grained level, neural patterns within the hippocampus showed significant similarity across trials for both the weak and durable, but not for forgotten associations. We suggest that memory formation for weak and durable memories is supported by increased hippocampal pattern similarity across unique encoding events. Moreover, the formation of durable memories requires enhanced activation and functional coupling within a specific network. These results might indicate the necessity of coherent hippocampal processes that enable initial memory formation, while the formation of durable memories additionally requires embedding of the hippocampus into a more extended network.

Abstract: Introduction: Cognitive neuroscience crucially depends on both human and animal research, as the former targets the main explanandum while the latter provides unique means of investigation. However, few cognitive tasks can be used across species. By utilizing the ratio of the second to the fourth digit (2D4D) as an established anatomical marker of navigational strategy and spatial memory traits, we here show that a virtual reality (VR) version of the Morris water maze (MWM) task is an appropriate human analogue of the classical version used in rodents [1]. Method: We tested 22 male rats using MWM, and 40 male humans using the VR-MWM. For each individual we measured the 2D4D ratio, and for humans we additionally acquired a structural and functional resting state MRI brain scan. We then associated MWM performance to 2D4D ratio, and in humans investigated structural and functional neuronal correlates of it using voxel-based morphometry and seed-based correlational analysis. The resting state analysis used the results from the structural analysis as seed. Results: We found that 2D4D ratio significantly predicted performance for both species in the MWM task. In humans, we found grey matter volume in the right insula to be significantly positively correlated with 2D4D ratio. We further found functional connectivity between this region and the dorsolateral pre-frontal cortex to be significantly positively correlated with MWM performance. Conclusion: Our study demonstrates that the MWM can be utilized across species, as demonstrated by a similar predictive value of the 2D4D ratio for performance in rats and humans. We further provide evidence that 2D4D ratio as a marker of spatial memory performance extents to other animals beyond humans. Finally, we showed that in humans, functional connectivity between the right insula and the dorsolateral pre-frontal cortex links 2D4D ratio and MWM performance at

the neural level. References: [1] Morris, R. (1984). Developments of a water-maze procedure for studying spatial learning in the rat. Journal of neuroscience methods, 11(1), 47-60.

Title: Competing against a familiar friend: Interactive mechanism of the temporo-parietal junction with the reward-related regions during successful encoding

Authors: *H. SUGIMOTO, Y. SHIGEMUNE, T. TSUKIURA;
Kyoto Univ., Kyoto, Japan

Abstract: Learning is enhanced by competitive interactions with others. Previous studies have reported that three processes of social motivation, mentalizing, and reward anticipation are important in the competition such as learning situations. However, little is known about the neural mechanisms how these processes are modulated by social relationships with opponents during encoding of episodic memories. To investigate this issue, we conducted a hybrid-designed fMRI experiment for healthy young adults. In the present study, 24 pairs of familiar friends participated. During encoding with fMRI, participants learned target words in three encoding conditions of Friend, Other, and Self. In Friend, participants encoded words by competing against their friend, in which they were instructed to do their best to learn more words than their friend participating together in the experiment. In Other, participants encoded words by competing against an unfamiliar person, and in Self, participants encoded words without competing against others. During retrieval without fMRI, participants were presented with target and distracter words one by one, and made old/new judgments for the words in high and low confidence. Encoding trials in each encoding condition were categorized into subsequent hits (Hit) and misses (Miss), which were decided by the subsequent memory paradigm. Thus, we

prepared six conditions of Friend-Hit, Friend-Miss, Other-Hit, Other-Miss, Self-Hit, and Self-Miss. In addition, participants rated their subjective feelings of motivation (MO), confidence (CO), mentalizing (ME), pleasantness (PL), and mental distance (MD) in each encoding condition by a visual analogue scale. Three major findings emerged from this study. First, in a 3 (encoding condition: Friend, Other, Self) x 2 (subsequent memory: Hit, Miss) ANOVA, right temporo-parietal junction (rTPJ) activations were significantly greater in Friend than in Other and Self. In a regression analysis for a contrast of Friend-Hit vs. Other-Hit, rTPJ activations were significantly correlated with Friend-Other differences of MO scores. Second, putamen and amygdala activations were significantly correlated with PL scores. Third, functional connectivity between the rTPJ and reward-related regions including the putamen and substantia nigra was significantly higher in Friend than in Other and Self during successful encoding. These findings suggest that interactions between the rTPJ related to the social motivation and the reward-related regions could contribute to the competition during episodic encoding, and that the interactive mechanisms could be modulated by social relationships with opponents.

Title: Individual differences in the motivational modulation of memory are reflected in neural representations of reward context

Authors: *B. D. GELMAN[1], D. ZEITHAMOVA[2,1], A. R. PRESTON[1];
[1]Univ. of Texas At Austin, Austin, TX; [2]Univ. of Oregon, Eugene, OR

Abstract: Memory is influenced by motivation, such as when remembering an event leads to a monetary reward. Prior research suggests that better memory for highly rewarding events may result from the incorporation of motivational context into stored memory representations. However, individuals differ in the degree to which motivational factors, such as reward, influence the ability to remember. One possibility is that individual differences in motivational modulation of memory stem from variability of reward representation within hippocampus and reward centers including midbrain and ventromedial prefrontal cortex (vmPFC). To elucidate the

behavioral and neural sources of individual differences in reward modulation of memory, participants performed a motivated encoding task during fMRI scanning. Participants studied object pairs, each preceded by a reward cue indicating the monetary reward for successfully remembering the object pair. Reward cues varied on the level of reward (penny, dime, and dollar) and the visual form of the cue (picture or word). After scanning, participants performed a cued recall test for their memory of the object pairs, along with a surprise source memory test for the value and visual form of the reward cue associated with each pair. While memory was enhanced for pairs associated with the highest reward value across the group, participants differed in the degree to which object pair memory was influenced by reward. Participants were also able to identify the reward value, but not the visual cue form, associated with individual pairs. Notably, source memory accuracy was correlated with reward modulation of cued recall, consistent with the idea that reward modulation of memory results from enhanced binding of events to their motivational context. Reward sensitivity, as measured by a personality inventory, was highly correlated with reward modulation of cued recall and source memory accuracy, suggesting personality factors may have an important influence on memory processes. Moreover, we found that reward value (irrespective of cue form) could be decoded using multivoxel pattern analysis from encoding patterns in hippocampus, midbrain, and vmPFC, but only for those participants who showed better memory for the high value pairs. These results indicate that individual differences in memory modulation are predicted by both neural representations of motivational information formed during encoding and individual differences in reward sensitivity. Participants who were more sensitive to reward formed distinct memory representations that incorporated the motivational salience of events, resulting in enhanced memory for event details.

Title: Increases in arousal influence encoding processes in valence-specific ways

Authors: *S. M. KARK, E. KENSINGER;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: The amygdala has consistently been associated with arousal-related memory effects (Murty, Ritchey, Adcock, & LaBar, 2011). Prior work has suggested that the effects of arousal on neural processes may depend on valence. For instance, increased connectivity between the amygdala and middle occipital gyrus occurred during encoding of high arousal negative visual stimuli compared to low arousal negative stimuli, while increased arousal was associated with decreased coupling between these regions during encoding of positive visual stimuli (Mickley Steinmetz, Addis, & Kensinger, 2010). In the present functional magnetic resonance imaging (fMRI) study, we extended this research by examining how amygdala connectivity tracked with self-reported arousal ratings during encoding of negative and positive visual stimuli. During fMRI, seventeen participants (aged 19-35) studied line-drawing outlines of International Affective Picture System photos, followed by the complete colorful photo. After a 20-minute delay, participants were shown outlines of the previously studied and new photos and asked to make an old-new recognition judgment. Parametric connectivity analyses examined how amygdala connectivity varied as a function of trial-level post-scan ratings of arousal during successful encoding of negative and positive visual stimuli. For negative stimuli, arousal was associated with strengthened connectivity between the bilateral amygdala and the lateral occipital cortex (BA37); this effect was specific to negative valence. For positive stimuli, arousal was not associated with strengthened amygdala connectivity but instead was associated with weakened connectivity between the bilateral amygdala and the lateral occipital cortex (BA18/19). These findings suggest the strength of coupling between the amygdala and lateral occipital cortex increases linearly with subjective arousal during encoding of negative visual stimuli, while the opposite pattern is true for positive visual stimuli. These results extend prior work that suggests the effect of arousal on emotional memory depends on valence and implicate increased affective-sensory processing during encoding of negative information.

Title: Both rewards and losses retroactively enhance memory for preceding neutral events

Authors: *E. K. BRAUN[1], B. VAIL[1], G. E. WIMMER[2], D. SHOHAMY[1];
[1]Psychology, Columbia Univ., New York, NY; [2]NeuroImage Nord Univ. Clin. Hamburg-Eppendorf, Hamburg, Germany

Abstract: For memory to be adaptive, it is essential to prioritize memory for events that are important for future behavior. However, events that are initially neutral can often lead to important outcomes, raising questions about the cognitive and neural mechanisms by which salient events can retroactively enhance memory. Moreover, it is unknown whether rewarding and aversive outcomes influence memory via similar mechanisms. To test whether behaviorally relevant outcomes retroactively modulate episodic memories, we developed a maze exploration paradigm. Human participants navigated through a series of grid mazes on a computer screen, one maze at a time. One group searched the mazes to find hidden "gold coins" ($1 gain), while a separate group tried to avoid hidden "land mines" ($1 loss). For both groups, the gain or loss outcomes terminated half of the mazes. While navigating through the mazes, participants incidentally encountered images of neutral trial-unique objects. 24-hours after encoding, memory for these objects was tested with a surprise recognition memory test. We found that participants' memory for the objects was retroactively modulated by both monetary gains and losses. In both the gain and the loss conditions, we found an interaction such that participants' memory was enhanced for objects closest to the gain or loss outcome compared to the neutral outcome, with no significant differences between the gain and loss conditions. These findings demonstrate that salient events retroactively enhance memory for the preceding neutral events. The similar effect of both reward and loss on memory raises important questions regarding the shared versus distinct neural mechanisms underlying these phenomena.

Title: Validity of cues predicting reward delivery influences eyegaze behavior and recognition memory for associated novel scenes

Authors: *N. J. CLEMENT, R. ADCOCK;
Duke Univ., Durham, NC

Abstract: In order to make optimal choices, humans must be able to learn whether, and how strongly, stimuli in their environments predict motivationally significant outcomes. Associative models of learning (e.g., Pearce, Kaye, & Hall, 1982) make specific predictions regarding the roles a person's experience of reward and uncertainty play in driving salience and learning. Data from animals (Lee et al., 2006; Esber et al., 2012; Roesch et al., 2012) and humans (Li et al., 2011; Boll et al., 2013) suggest that interactions between regions in the dopaminergic midbrain, striatum, and amygdala support the development of predictive learning over time, and shifts in attention in response to violations of those predictions. The extent to which these systems may interact with hippocampally-mediated activity supporting exploratory behavior and memory remains incompletely characterized. We probed the relationship between cue predictive strength, uncertainty salience, and learning by investigating the encoding of stimuli paired with predictive reward cues that differed in their level of certainty, while collecting eyetracking and BOLD fMRI. One cue consistently predicted the presence of reward on that trial, one predicted absence of reward, and three cues were unreliable predictors of reward. Of the unreliable cues, one cue predicted reward delivery with a constant validity of 50%, one varied in its predictive power over blocks, and one varied in its reward-predictive power over blocks while consistently being paired with a repeated image. The remaining four cues were each paired with trial-unique images. Memory for the images was tested following a twenty-four hour delay. Participants' eyegaze behavior during learning differed as a function of both cue predictive strength and stimulus novelty: participants showed a greater preference to attend to predictive (vs. non-predictive) cues, while also attending less to familiar (vs. novel) images. Gaze behavior was also driven by reward history and expectation-violations: gaze to cues varied as a function of outcome certainty and recent uncertainty Additionally, gaze behavior predicted subsequent memory for incidentally presented images and BOLD data from the hippocampus, both in predicting subsequent memory and in response to novel vs. familiar images. These data suggest a dynamic relationship between the neural and cognitive mechanisms supporting reward learning, uncertainty, and exploration behaviors in support of learning.

Title: Victory triggers memory reactivation during sleep

Authors: *V. STERPENICH[1], H.-D. YANG[2], M. CATSIYANNIS[1], A. RAMYEAD[1], M. VAN SCHIE[1], S. PERRIG[3], D. VAN DE VILLE[4,5], S. SCHWARTZ[1];

Hosp., Geneva, Switzerland; [4]Dept. of Radiology and Med. Informatics, Univ. of Geneva, Geneva, Switzerland; [5]Inst. of Bioengineering, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Abstract: Recent research provides evidence for memory reactivation and consolidation during sleep. We hypothesized that information with a high relevance for future behavior is favored in the competition for reactivation. To test this hypothesis, we manipulated the outcome of two game-like tasks and used a combination of EEG, functional MRI (fMRI) measurements, and neural decoding to analyze task-related activity and sleep data. We could thus track, during distinct stages of human sleep, the spontaneous reemergence of patterns of neural activity corresponding to the games that yielded a successful (or unsuccessful) outcome. Participants were first scanned while they played two games in alternation (a face and a maze game). We programmed the games so that only one of the 2 games would be won (randomized across participants). Then, participants slept in the MRI. A pattern classifier was trained on the data collected during game performance with three main states (face game, maze game, rest). When applied to the independent sleep data, the classification revealed a selective neural replay of the successful game during sleep stage N3. Next, we entered the time-course of the probability of each state as a regressor in a GLM applied to the sleep data. We found that each state, FACE or MAZE, activated regions involved in each task at wake, thus confirming the functional selectivity of the reactivation. Our findings provide a direct demonstration that neural events associated with a favorable behavioral outcome are prioritized for offline memory reprocessing during slow-wave sleep. Figure 1: A. Example of the face and maze games that are manipulated in order to make one won and one lost. B: Sleep data of one subject winning at the face game. The state identified by the classifier and related to the won game is more reactivated during deep sleep. The time course of the slow wave activity (SWA) is correlated to the state related to the won game. C. Sleep data of one subject wining at the maze game.

Title: Human hippocampus forms abstract, pattern separated representations of motivational context during encoding

Authors: ***D. ZEITHAMOVA**[1], B. D. GELMAN[2], A. R. PRESTON[2];
[1]Univ. of Oregon, Eugene, OR; [2]Univ. of Texas, Austin, TX

Abstract: Memory is influenced by motivation, such as a promise of future monetary reward for successfully remembering an event. Monetary reward cues preceding or immediately following an event have been shown to enhance activation within dopaminergic midbrain and the hippocampus, resulting in better memory for the associated event. Furthermore, distributed hippocampal patterns differentiate between events encoded in contexts with different reward cues, supporting the view that information about reward context is incorporated into stored memory representations. However, prior studies addressing this topic have confounded the reward value with the visual appearance of reward cues, leaving unanswered whether

hippocampal responses reflect the visual features of the reward cue or an abstract representation of reward value. Here, we employed a novel reward manipulation to dissociate between these accounts. Participants underwent functional MRI while encoding pairs of objects, with each pair being preceded by a cue indicating the value of the monetary reward the participant would receive if they successfully remembered the pair. Reward cues represented one of three values (dollar, dime, penny), each presented in one of two visual forms (word, picture) across trials. After scanning, participants were given a cued recall test for the associations. Behaviorally, participants remembered pairs associated with the highest reward (dollar) more often than pairs associated with lower rewards (dime or penny), irrespective of the visual form of the reward cue. We then tested which aspects of the cue (value or visual form) were represented in the hippocampus using pattern similarity analysis. Hippocampal encoding patterns were more similar for pairs of trials cued by the same reward value than those cued by different values, even when the visual form of the cue differed. Strikingly, and consistent with pattern separation accounts of hippocampal representations, the encoding patterns were least similar for trials cued by different values when the cues shared the same visual form. This pattern was most pronounced in participants who showed the greatest behavioral sensitivity to reward_better memory for high-value than low-value trials. These results provide a novel demonstration of abstract value representation within human hippocampus, one in which representations of visually similar cues are made distinct to reflect differences between the behavioral relevance of individual events. More broadly, our data illustrate that contextual representations within hippocampus go beyond space and time to include information about the motivational salience of events.

Title: Single-trial learning of novel visual stimuli by individual neurons in the human substantia nigra

Authors: *J. KAMINSKI[1], A. MAMELAK[1], K. BIRCH[1], M. TAGLIATI[2], U. RUTISHAUSER[1,2,3];

Abstract: The ability to distinguish novel from familiar stimuli is essential for learning. Novelty-triggered release of dopamine in the temporal-and frontal lobes by neurons in the substantia nigra is thought to be crucial for the formation of new memories. We investigated this hypothesis by recording individual neurons in the human substantia nigra with microelectrodes during surgery for implantation of deep brain stimulation devices. In 8 patients (11 sessions), we presented a sequence of images and asked them to classify each as novel or familiar. Simultaneously, we recorded single unit neuronal activity in the substantia nigra using microelectrode and intracranial EEG from cortex surface using ECOG strip. The average firing rate of multi-unit activity recorded in the substantia nigra was 23.2 Hz. We isolated in total 39 single neurons, out of which 12 (31 %) showed a visually-triggered response. The majority (8/12, 66 %) decreased their firing rate in response to the onset of the visual stimulus. Further analysis of single unit responses showed that ten units (26 %) responded significantly different to novel compared to familiar pictures, with the majority (70 %) exhibiting higher firing rates to novel stimuli. Additionally we quantified the Spike Field Coherence (SFC) between units in the substantia nigra and intracranial EEG recorded from frontal cortex. We compared novel images as a function of whether they were later remembered or forgotten. This analysis showed that pictures that were later remembered were accompanied by larger SFC in the theta-frequency range relative to images later forgotten. Together, these results show the first evidence from human intracranial recordings that neurons in the substantia nigra are involved in the detection of novel visual stimuli. Additionally, we showed that successful memory formation is correlated with coordination of spike timing of substantia nigra neurons with cortical theta oscillations. These results indicate the important role of the human substantia nigra in the learning of visual stimuli.

Title: Knowledge accumulation improves memory and reorganizes hippocampal - neocortical interactions

Authors: *G. BROD, Y. SHING;
Max Planck Inst. For Human Develop., Berlin, Germany

Abstract: Introduction The better new information can be connected to existing knowledge, the easier it is to learn and, later, remember it. This is assumed to be the case because neocortical schemas can incorporate the new, related information easily, which speeds up binding processes in the hippocampus (HC). An increase in knowledge should thus lead to an enhanced memory for schema-related information, and decreased HC recruitment for memory formation. We tested these notions in a real-world setting using repeated fMRI in a sample of medical students who prepared for their final state examination using an e-learning platform, which gave us detailed information about their knowledge increase. Methods 35 medical students were scanned three months prior to and immediately after the state examination during encoding of face-diagnosis (schema-related) or face-name (schema-unrelated) pairs. Subsequent memory effects were determined using a forced-choice associative recognition task. We tested for changes in brain activation that were larger for the diagnoses as compared to the names, and vice versa (Memory x Time x Condition Interaction). In addition, we tested for changes in coupling between the anterior HC and semantic processing regions using PPI analysis. Results We observed a selective enhancement in memory for schema-related information that was paralleled by a decrease in anterior HC activation (see Figure 1). The HC decrease was related to between-person differences in knowledge increase (as measured by the learning platform). Furthermore, we observed an increase in connectivity between the anterior HC and the left posterior Middle Temporal Gyrus, a brain area that is key to semantic processing. Our results suggest that increased knowledge facilitates binding in the anterior HC, presumably through an enhanced crosstalk with semantic processing areas. Furthermore, they demonstrate a close link between accumulation of knowledge due to intensive learning in a real-world educational setting and changes in brain activation as observed in a laboratory memory paradigm.

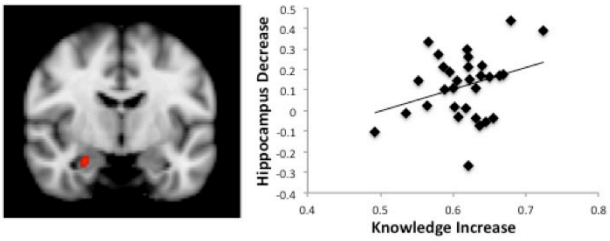

Figure 1. Memory x Time x Condition interaction in the right anterior hippocampus (peak voxel: 26, -8, -20). The HC decrease for the diagnosis condition was furthermore related to between-person differences in knowledge increase (r=.32, p=.04).

Title: Nonlinear dynamical model of human hippocampal CA3-CA1 spike transformation as the computational basis of memory prostheses

Authors: *D. SONG[1], R. E. HAMPSON[2], B. S. ROBINSON[1], V. Z. MARMARELIS[1], S. A. DEADWYLER[2], T. W. BERGER[1];
[1]Biomed. Engin., Univ. of Southern California, Los Angeles, CA; [2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: We formulate hippocampal prosthesis as a closed-loop system that bi-directionally interacts with the hippocampus to restore memory functions. Different from sensory or motor prostheses, the hippocampal prosthesis uses internal brain signals, e.g., spike trains, as inputs and outputs. In order to bypass a damaged hippocampal region to restore its function, the prosthesis should be able to mimic the input-output transformations performed by that region, so that the lost output signals in the downstream hippocampal region (e.g., CA1) can be reinstated based on the input signals recorded from the upstream hippocampal region (e.g., CA3). In this study, we build multi-input, multi-output (MIMO) nonlinear dynamical hippocampal models to replicates the spike-train-to-spike-train transformational properties of the hippocampus. Spike trains are recorded from the hippocampal CA3 and CA1 regions of epileptic patients (n = 10) performing a memory-dependent delayed match-to-sample task. Using CA3 and CA1 spike trains as inputs and outputs respectively, second-order sparse generalized Laguerre-Volterra models are estimated with group lasso and local coordinate descent methods. These models allow parsimonious and accurate representations of the hippocampal input-output functions. Model sparsities are optimized with a 5-fold cross-validation method. Model goodness of fit are evaluated with a Kolmogorov-Smirnov test based on the time-rescaling theorem. Results show that these MIMO models can accurately predict the CA1 spatio-temporal patterns of spikes based on the ongoing CA3 spatio-temporal patterns of spikes on a single-trial basis. These results indicate the strong causal relations between hippocampal CA3 and CA1 activities and that it is possible to use the MIMO models as the computational basis of hippocampal memory prostheses.

Title: Nonlinear dynamical identification of a functional spike-timing-dependent plasticity rule from ensemble hippocampal spiking activities in rats learning a delayed nonmatch-to-sample task

Authors: *B. S. ROBINSON[1], D. SONG[1], R. E. HAMPSON[2], S. A. DEADWYLER[2], T. W. BERGER[1];
[1]Biomed. Engin., USC, Los Angeles, CA; [2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: The computational basis of a hippocampal memory prosthesis can be formed with a nonlinear multi-input, multi-output (MIMO) dynamical model that characterizes the input-output spike train transformation in the hippocampus. In creating such a MIMO model, it is important to consider the effects of activity-dependent plasticity. Here, we augment previous MIMO model identification to include estimation of a pair-wise spike-timing-dependent plasticity (STDP) rule. Model estimation is performed with multi-unit spiking data recorded in-vivo from CA3 and CA1 rat hippocampal sub-regions during the learning of a delayed-nonmatch-to-sample (DNMS) memory task across several sessions. As part of the MIMO model identification, nonlinear feedforward functions are identified for each input that characterize the conditional firing probability of output spiking given that input's spiking events. For the STDP model, a separate set of functions are estimated for how the relative timing of input-output spike pairs change the strength of feedforward connections and the time course of plasticity induction. All model functions are estimated with Volterra kernels, basis function expansion and generalized linear model techniques. The inclusion of the identified STDP rules enhances prediction of CA1 output spiking from CA3 input spiking for certain behavioral sessions. We also demonstrate how several sets of assumptions regarding the structure and stability of the STDP rule vary in ability to capture the dynamics of the observed spiking activity. Furthermore, the identified plasticity

rules provide insights into how a pair-based STDP rule may lead to fluctuations in functional connectivity observed during learning.

Title: Restoring active memory via CA3/CA1 recording and MIMO model-derived CA1 stimulation in human hippocampus

Authors: *R. E. HAMPSON[1], D. SONG[6], B. S. ROBINSON[6], M. R. WITCHER[2], D. E. COUTURE[2], A. M. LAXTON[2], G. POPLI[3], M. J. SOLLMAN[3], D. FETTERHOFF[4], C. A. SEXTON[5], V. Z. MARMARELIS[6], T. W. BERGER[6], S. A. DEADWYLER[1]; [2]Neurosurg., [3]Neurol., [4]Neurosci., [5]Biomed. Engin., [1]Wake Forest Sch. of Med., Winston Salem, NC; [6]USC, Los Angeles, CA

Abstract: We have recently demonstrated that patterned CA1 stimulation based on a multi-input, multi-output (MIMO) model of hippocampal CA3-to-CA1 neural firing facilitated behavioral performance in both rodents (Berger et al., 2011) and nonhuman primates (Hampson et al., 2012). Here we extend this work to humans performing a similar working memory task. Patients who undergo intracranial monitoring with implanted electrodes for epileptic seizure localization provide an excellent model to understand discharge patterns of hippocampal neurons during learning and memory tasks (Suthana and Fried 2012). Since most patients can form and retain working memories even when the hippocampus is altered by epilepsy (Suthana, Haneef et al. 2012), hippocampal neural recordings under these conditions provide a valuable test-bed for studies leading to prosthetics to restore memory encoding and formation in humans. Adult subjects underwent surgical implantation of FDA-approved "macro-micro" hippocampal electrodes (capable of EEG, field potential and single-neuron recording; Ad-Tech Medical Instrumentation Corporation, Racine, WI) for localization of seizures. Inclusion in this study was

voluntary and consented separately from the surgical procedure and all study participants underwent appropriate clinical epilepsy screening evaluations. Electrode localization was confirmed using intraoperative stereotaxic placement and postoperative MRI. Single unit neural activity was isolated and recorded using Blackrock Cervello electrophysiological recording systems; multichannel microstimulation was provided by a Blackrock CereStim R96. Patients performed a visual object and position-oriented Delayed-Match-to-Sample on a touchscreen computer. Patients were tested in one session strictly for CA3 & CA1 neuron recording, and a second session that also included MIMO model-derived CA1 stimulation during the mnemonic encoding phase of the task. Neural and behavioral recordings have yielded a task-related MIMO model of CA3-to-CA1 mnemonic processing (Song et al. 2015 - adjacent poster), similar to that used for the successful tests of MIMO-derived stimulation in rodents and NHPs. These results suggest that this approach provides an appropriate model for development and testing of a neural prosthetic for human memory.

Title: Inter-subject correlation in theta and gamma spectral power predicts memory for details of scientific talks

Authors: E. R. WEICHART, D. M. NIELSON, *P. B. SEDERBERG;
Psychology, The Ohio State Univ., Columbus, OH

Abstract: Previous work has shown that neural synchrony in fMRI activity across participants while viewing naturalistic stimuli predicts subsequent memory performance. In the current study, we sought to extend this finding to electroencephalography (EEG) and into the domain of memory for scientific talks. We collected EEG data while participants viewed three novel videos of informational science talks. After viewing all three talks, participants were asked to answer short answer questions related to content-driven details of the talks. Each question corresponded to a 3- to 15-second portion of the video, during which a specific answer was provided. We

calculated inter-subject correlation (ISC) in spectral power for 6 frequency bands during each question-specific time range to predict the proportion of participants who would correctly answer the individual question later. After first identifying the components comprising weighted combinations of electrodes and frequency bands that were most predictive of ISC, we sought to determine which components and first-level component interactions explained a significant amount of variance in group memory performance on each question. Different combinations of positive and negative ISC across frequency bands and electrodes correlated with subsequent memory performance. For example, one component positively predicted successful memory when gamma ISC was negative and theta ISC was simultaneously positive. Contrastingly, another component showed that memory performance was positively predicted by high gamma ISC localized to the posterior region of the scalp along with simultaneous theta ISC in the occipital region. In still another component, successful memory performance was predicted by negative alpha ISC in the posterior region with simultaneous positive posterior gamma ISC and negative gamma ISC in auditory regions. In future work, this approach will allow us to investigate the aspects of informative video presentations that promote memory, which will be increasingly important as e-learning programs become more common.

Title: A time-dependent effect of post-trial intervention on consolidation of pair association memory

Authors: ***K. LIANG**[1,2], F.-Y. CHENG[2], P.-Y. CHEN[2], T.-L. CHOU[2];
[2]Psychology, [1]Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Memory consolidation is a process that a memory trace becomes stable and resists to disruption over time, which is supported by the evidence that a period of rest without interference after learning would enhance retention of learned materials and the closer in time the

interference to the original learning, the poorer the subsequent memory. However, whether a memory trace in humans becomes more resistant to post-learning interference along with time has been questioned. To address this issue, the present study was designed to examine the time-dependent influence of post-trial intervention on consolidation of associative memory for figure-noun pairs. Two groups of participants were randomly assigned into an immediately intervention group (II, N=15) or a delayed intervention group (DI, N=15) on day 1. In the DI group, participants learned the target list, followed by a one-hour interval of music listening, and then learned an intervention list. In contrast, participants in the II group learned the target list, followed immediately by learning the intervention list, and finally listened to music for one hour. In learning the target and intervention lists, participants were instructed to memorize two different sets of figure-noun association pairs. Retention of the target list was assessed by recognition on two time points: Right after the learning phrase on day 1 to serve as a baseline, and 24 hours later on day 2 to probe memory that has already undergone consolidation. For each participant, memory performance was assessed by recognizing the target pairs from foil pairs (rearrangement of the stimulus and response pairing from the list and not learned on day 1) and indexed by the sensitivity (d-prime) of signal detection analysis. The results showed that the II group showed a greater reduction of the d-prime score for detecting the target pairs from day 1 to day 2 than the DI group. Moreover, participants in the II group showed more false alarms on target recognition after 24-hour consolidation than those in the DI group. Our results indicate that learning an intervention list immediately after the target list produced more interruption of the 1-day memory than listening to music. These findings suggest that consolidation of human figure-noun associative memory is impaired in a time-dependent manner by processing materials similar to and shortly after learning the target ones.

Title: Dynamic phase-amplitude coupling in episodic memory

Authors: A. VAZ[1], R. YAFFE[2], S. K. INATI[2], *K. A. ZAGHLOUL[2];
[2]Surgical Neurol. Br., [1]Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Phase-amplitude coupling (PAC) in intracranial EEG has been proposed as a communication mechanism that reflects coordination of local neuronal populations. This neural phenomenon has been shown to exist ubiquitously in human neocortex, and recent studies have shown that hippocampal PAC plays a role in working and episodic memory as well as in associative learning. However, a functional, task-dependent role of PAC has not been established in human neocortex. Here, we used intracranial recordings to examine PAC for encoding and retrieval periods as 33 participants with electrodes placed for seizure monitoring engaged in a paired associates episodic verbal memory task. We found that memory encoding dynamically modulates PAC in human neocortex. Correct and incorrect encoding exhibited significant differences in PAC in individual electrodes, and in different brain regions when aggregated across subjects. Furthermore, we observed that PAC is modulated in time and across different epochs of the experimental task, and that the extent of PAC is highly correlated with the power of the modulating frequency band. Our data suggest that PAC is a dynamic and task-specific neural correlate of episodic memory in human neocortex.

Title: Iron accumulation and loss of myelin relates to memory performance in the aging brain

Authors: *T. K. STEIGER[1,2], C. ECKART[2], N. BUNZECK[1,2];
[1]Dept. of Psychology, Univ. of Luebeck, Luebeck, Germany; [2]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: In healthy humans, age related structural changes have been demonstrated in a variety of cortical and subcortical brain regions. However, the underlying microstructural mechanisms, e.g. in myelin or iron, and their behavioral consequences remain poorly understood. In this study, we acquired multi-parameter images (MRI) of a group of young (18-32 years) and healthy elderly subjects (55-79 years) to investigate age related structural changes of the dopaminergic mesolimbic system and their relationship to learning and memory performance. Data were analyzed by using voxel-based morphometry (VBM) on grey matter volume, and voxel-based

quantification (VBQ) on magnetization transfer (MT, resembling myelin) and R2* (resembling iron content). Outside the MRI scanner, the elderly subjects performed the 'verbal learning memory test' (VLMT) to assess memory performance. As expected, we observed age-related differences in grey matter volume, MT and R2* within widespread brain regions, including the basal ganglia. Importantly, within the hippocampus there was a positive correlation between MT and R2* in younger and elderly subjects. This relationship was reversed in the nucleus accumbens of the elderly, accompanied by an accumulation of iron. Finally, microstructural changes of MT and R2* within the basal ganglia correlated with learning and memory performance in the elderly in a whole-brain analyses. Our results provide evidence for the notion that iron (R2*) drives myelination (MT) in young subjects, while it leads to oxidative stress and myelin loss in the elderly. Importantly, these microstructural changes relate to learning and memory performance, indicating a close link between the integrity of the dopaminergic mesolimbic system and learning and memory.

Title: Spatial-temporal dynamics of memory formation in children: An electrocorticography (ECoG) investigation

Authors: ***A. T. SHAFER**, R. SCHWARZLOSE, E. ASANO, N. OFEN;
Wayne State Univ., Detroit, MI

Abstract: Episodic memory formation involves the medial temporal lobe (MTL) and lateral prefrontal cortex (PFC). Research using ECoG to examine memory-related neural activity in these regions in adults has shown increases in power for two frequency bands [theta (4-7 Hz) and gamma (30-100 Hz)]. Evidence from non-invasive neuroimaging methods such as functional MRI has shown protracted functional development of PFC, compared to MTL in support of memory formation. However, how memory development is related to local neural activity as can be assessed in ECoG measures by spectral perturbation remains unknown. Here, we examined changes in theta and gamma power for subsequently remembered vs. forgotten scenes in surface

electrodes placed on MTL and lateral PFC in children and adolescents. Data were collected from 8 epilepsy participants who were undergoing extraoperative ECoG as part of clinical management (aged 10-17). Participants studied pictures of indoor and outdoor scenes, and were informed that their memory of the scenes would be tested in a following recognition test. Data were recorded using a 192-channel digital system with platinum grid and strip electrodes (diameter = 4 mm, intercontact distance = 10 mm). Electrode location was determined using FreeSurfer software in conjunction with planar x-ray images and a T1-weigthed MR image. Event-related spectral changes were determined through wavelet time-frequency decomposition for -500 ms pre- to 3000 ms post-stimulus onset. To examine changes over time, standardized power values were binned into 100 ms time windows. Preliminary analysis focused on data sampled from 0 to 1000 ms post-stimulus onset within the left MTL and lateral PFC. Successful memory formation was associated with an early decrease followed by later increase in theta in both MTL and lateral PFC. The later increase in theta differed across regions such that it occurred earlier in the MTL (~200 ms) compared to the lateral PFC (~500 ms). Similar to the results for theta, differences in gamma power (50-150 Hz) for remembered vs. forgotten scenes showed early decreases followed by later increases in both MTL and lateral PFC. However, unlike with theta, the earlier gamma decrease for remembered scenes was sustained for longer in the lateral PFC (400ms, PFC vs. 100ms, MTL), while the later increase was sustained longer in the MTL (300ms, MTL vs. 100ms, PFC). These preliminary findings aid in characterizing neural activity in key brain regions that support successful memory formation in children and adolescents.

Title: Predictability of subsequent retrieval after natural reading of literature: A scalp electroencephalogram study

Authors: *N. SATO;
Future Univ. Hakodate, Hakodate-Shi, Hokkaido, Japan

Abstract: The author recently demonstrated that memory that is formed during the natural reading of literature can be predicted by a scalp electroencephalogram (EEG) analysis. In agreement with previous studies of subsequent memory effects of words and pictures, the increases in theta-band EEG power and decreases in alpha-band EEG power during reading significantly correlated with the subjects' subsequent retrieval. The natural reading of literature is highly associated with daily behavior. Therefore, evaluations of its predictability are of interest for creating EEG applications to monitor reading. In this study, the predictability of EEG data that were recorded during reading of subjects' subsequent retrieval was evaluated. Eight participants (seven males; mean age, 21.1) read four short scientific essays (3,000 characters each) at a natural pace and wrote summary reports of the contents after about 30 min. During the reading, binocular eye movements were recorded, and 26-channel scalp EEG and 4-channel electro-oculogram recordings were made. Artifact-corrected EEG signals were segmented according to fixation onset, and the evoked power was analyzed according to the similarity in a probabilistic language model of the read texts and the summary reports. The recall rate of each word was predicted with EEG signals at a central electrode (Cz), and predictability was tested for each essay with a cross-validation procedure. The cross-validation analysis showed that the retrieval rate that was predicted by the EEG theta and alpha powers was significantly correlated with the observed retrieval rate (mean correlation coefficient, 0.131; range, -0.08 to 0.28; $p = 0.001$, permutation test), and three of the eight subjects showed a significant correlation in the individual analyses. The resulting correlation coefficients were similar to those for previously observed subsequent memory effects for simple memory tasks. These findings confirm the generality of EEG phenomena for subsequent retrieval. For the EEG application perspective, however, the number of subjects with significant correlations in the individual analyses was small. However, when predictions were made by either EEG theta or alpha power, the predictions were worse than those above (mean correlation coefficient, 0.09 for each condition; $p = 0.001$, permutation test). Interestingly, in this analysis, EEG theta and alpha predictability varied in each subject. These results suggest the importance of cross-spectral analyses of EEG data in characterizing subjects' subsequent retrieval and improving predictability.

Title: Can auditory oscillations enhance memory performance by entraining neural oscillations of the same frequency?

Authors: *J. D. CREERY, K. A. PALLER;
Northwestern Univ., Evanston, IL

Abstract: Memory processing depends on neural communication across brain regions. This communication has been associated with neural oscillations at various frequencies. For example, efforts have been made to link memory formation to specific oscillatory activity in scalp and intracranial EEG recordings. Possible causal roles of oscillatory activity in memory functioning have been investigated in humans using oscillatory stimulation in the form of transcranial direct current stimulation (tDCS) and repetitive transcranial magnetic stimulation (rTMS). An alternative strategy is to use oscillatory auditory stimulation instead of oscillatory electromagnetic stimulation. In the current study, we presented pink noise in conjunction with pictures of visual objects in a spatial memory task, and we systematically modulated sound amplitude to include frequency-specific signals. We predicted that auditory oscillations would entrain brain activity in ways that would influence subsequent memory accuracy. We chose to use oscillations at theta and beta frequencies because (a) previous studies showed that these frequencies are associated with memory formation and (b) auditory oscillations have been shown to influence neural oscillations at both of these frequencies. Participants learned 60 object-location associations on a grid background. Objects were randomly presented with one of three types of auditory stimulus: 6-Hz theta oscillations (20 objects), 15-Hz beta oscillations (20 objects), or static noise (20 objects). Each association was learned to a criterion, and after a 15-min break, participants were tested for object-location recall accuracy. Participants were significantly more accurate for objects linked with beta stimulation than those linked with static noise. Intermediate results were found with theta stimulation. These findings support previous evidence suggesting that beta oscillations foster long-term potentiation. Further tests are in progress to isolate the source of these effects (e.g., learning, test, or both) and to examine neural oscillations in concurrent EEG recordings. Overall, these findings demonstrate that memory can be improved using oscillating auditory stimulation during learning and test.

Title: Macular lutein is associated with cognitive performance in preadolescent children

Authors: *K. M. HASSEVOORT[1,2], S. E. ZOLA[3], S. M. MCCORKLE[4], L. B. RAINE[5], N. A. KAHN[4], A. F. KRAMER[1,3], C. H. HILLMAN[1,5], N. J. COHEN[1,3];
[1]The Beckman Inst. of Sci. and Technol., Urbana, IL; [3]Psychology, [4]Nutritional Sci., [5]Kinesiology and Community Hlth., [2]The Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The dietary carotenoid lutein is an important constituent of both macular and brain tissue across the lifespan. While the developmental and neuro-protective roles of lutein have been well characterized in the visual system, recent evidence suggests that lutein may also play an important role in cognitive function. In addition to the macula of the retina, lutein is also preferentially accumulated throughout the CNS and is the predominant carotenoid in early as well as late life (Johnson *et al.*, 2013; Vishwanathan *et al.*, 2014). Macular pigment optical density (MPOD), a measure of macular lutein abundance is correlated with lutein levels in brain tissue (Vishwanathan *et al.*, 2015; Vishwanathan *et al.*, 2013) and is positively associated with performance in a range of cognitive domains, including memory, executive function, and language in adults (Johnson *et al.*, 2013). Furthermore, there is evidence that lutein supplementation improves cognitive performance in older adults. However, no previous study has examined the relationship between macular lutein and cognition in a developing population. The current study investigated this relationship in preadolescent children (N=39; mean age=8.7 years) who underwent MPOD testing and completed a series of cognitive tasks, including a reconstructive memory task. We found that children with higher macular lutein performed better on the memory task, specifically by making fewer "swap errors", a type of relational error that has previously been linked to hippocampal function (Watson *et al.*, 2013). These results are the first evidence that macular lutein is positively associated with cognitive performance in preadolescent children and suggest that increasing dietary lutein has the potential to improve memory in this population.

Abstract: The N2pc ERP component is associated with the deployment of visual attention to regions in visual space (Luck & Hillyard, 1994a, Luck & Hillyard, 1994b). Several hypotheses have been advanced regarding what specific aspect of spatially deployed attention the N2pc reflects (Luck & Hillyard, 1994b; Kiss, Velzen, & Eimer, 2008; Tan & Wyble, 2014). The Localization Hypothesis, the focus of the current study, posits that the N2pc reflects the localization of, or orientation to, relevant visual information in space in preparation for the enhancement of sensory processing. Recent research has supported this hypothesis by demonstrating that the N2pc elicited by target information is eliminated if this target follows a second target in the same location, as a second localization process is unnecessary (Tan & Wyble, 2015). Other research provides evidence that is incongruent with the localization hypothesis. Specifically, a cue that directs attention to a portion of the visual field prior to the occurrence of a target does not eliminate the N2pc for that target, as is predicted by the localization hypothesis (Kiss, Velzen, & Eimer, 2008). However, the stimulus onset asynchrony of the cue (700ms prior to target onset) established a temporal window that may have been too large to capture a single episode of attentional localization. The present study tested the localization hypothesis by using a cue presented within the time course of current theoretical models of attention (Wyble, Bowman, & Nieuwenstein, 2009; Olivers & Meeter, 2008; Nakayama & Mackeben, 1989). A target was presented laterally (right and left), embedded within streams of rapidly presented distractors. Half of the trials contained a target, the other half did not. Within each of these two conditions, on half of the trials, a cue was presented. If both a cue and target were presented, the cue preceded the target by 100ms. Preliminary analyses revealed that the N2pc elicited by a single target embedded in the stream of distractors is

eliminated when preceded by a cue occurring 100ms prior to the target. These results support the hypothesis that the N2pc reflects a visual localization process.

Title: Target detection, following central cues of different reliabilities, is associated with modulations of the P300 and N400 components

Authors: D. VALAKOS[1], D. MYLONAS[1], G. D' AVOSSA[2], *N. P. SMYRNIS[3,1];

Abstract: An important issue in visual attention is how endogenous covert orienting and target detection are affected by an observer's spatial expectations. We examined the effects of partially valid cues, of high and low reliability, on simple detection reaction times and scalp recorded, electrophysiological potentials, evoked by the presentation of luminance targets. The paradigm began with a central arrow cue, which indicated one of four locations, where a target stimulus could appear. The cue could either be reliable or unreliable. Reliable cues indicated the correct target location in 75% of the trials, while unreliable cues indicated the correct target location in 25% of the trials, and were therefore uninformative. Reliable and unreliable cues had different colors, and participants were made aware of the mapping between color and reliability ahead of the testing procedure. Reaction times showed a larger validity effect following reliable than unreliable cues, while the ERPs revealed a P300 significantly bigger for invalid than valid trials, but not further modulated by target probability. Finally, a typical N400 response was found, suggesting the recruitment of domain general processes in target evaluation, at least under conditions of varying spatial uncertainty.

Title: The behavioural and cortical dynamics of reward-driven attentional capture

Authors: *L. TANKELEVITCH, M. F. RUSHWORTH, M. G. STOKES;
Univ. of Oxford, Oxford, United Kingdom

Abstract: Selective attention is the prioritization and facilitation of processing via the enhancement of relevant information at the expense of that less relevant. Although it is often guided by task-relevant goals like searching for food, or captured by intrinsically salient stimuli like a car horn, recent work has shown that attention may also be shaped by reinforcement learning, in which visual stimuli with a history of reward capture attention even when they are task-irrelevant and unrewarded. Here we provide further evidence for reward-driven attentional capture, and investigate its behavioural timecourse and spatiotemporal dynamics in the cortex. Participants first completed a decision-making task in which they chose between different reward-associated visual tokens with the aim of maximizing their monetary payoff. Participants then completed a non-rewarded lateralized target discrimination task involving oriented gratings, in which they also encountered the previously valuable - but now irrelevant - tokens. Critically, a high or low value token could appear either around the target grating (congruent trials) or around the distracter grating (incongruent trials). The tokens appeared at ten different stimulus-onset asynchronies (SOA) relative to the gratings, ranging from 50 ms to 950 ms, allowing us to probe the timecourse of attentional capture via changes in reaction times and accuracy. In line with previous work, there was a significant difference in participants' reaction times between congruent and incongruent trials indicating that attentional capture was respectively facilitating or impairing task performance as a function of congruency. This effect occurred at both short and long SOAs, peaking at 50 ms and 450 ms prior to target onset. Importantly, attentional capture was significant only for high value tokens, implicating the role of reinforcement learning in shaping attentional selection. In a second experiment, we used magnetoencephalography (MEG), aided by structural magnetic resonance imaging (MRI), to probe the spatiotemporal dynamics of reward-driven attentional capture in the visual cortex and frontoparietal attention network. Using the same behavioural paradigm as above, we investigated the modulation of attentional allocation and target processing by the presentation of task-irrelevant tokens with different

reward histories. Our work furthers the understanding of the interaction between reinforcement learning and selective attention.

Title: An electrophysiological dissociation of craving and stimulus-dependent attentional capture in smokers

Authors: *S. E. DONOHUE[1,2], M. G. WOLDORFF[1,2,3,4], J. A. HARRIS[1,2], J.-M. HOPF[1,2], H.-J. HEINZE[1,2], M. A. SCHOENFELD[1,2];

Abstract: In addiction, the motivation to use a specific substance is driven in large part by strong feelings of craving. Additionally, there is behavioral evidence to suggest that attention may be captured by addiction-related images, rendering such stimuli highly salient in a given environment. The neural underpinnings of such attentional capture by substance-related images and how it interacts with craving, however, are largely unknown. Here, we examined the neural correlates of attentional capture by addiction-related stimuli in smokers as a function of craving. To assess these effects, simultaneous EEG and MEG data were recorded in two sessions: one in which participants had just smoked (noncraving), and one in which they had abstained from smoking for three hours (craving). Participants performed a visual search task in which two colored squares were presented on the left and right of fixation, with the task to shift attention to the square of a designated color (the target square) and discriminate the location of the missing corners. In a key non-task-related manipulation, smoking-related and smoking-unrelated images were embedded in the target and distractor squares, such that the shift of spatial attention to the target (reflected by the hallmark attention-related N2pc component) could be examined as a function of the addiction-related image being present in either the target or distractor, present in both, or absent from both. We observed that when the smoking-related image was present in

(versus absent from) the target, participants shifted attention less strongly to the target, as indicated by a decreased amplitude of the N2pc. Such an effect suggests that participants were actively suppressing the smoking-related images by directing attention away from them. Importantly, this effect was not modulated by craving. Craving did, however, influence the earlier P1 index of early extrastriate visual processing at 100 ms, with a higher P1 amplitude when participants were craving versus when they were not craving, likely reflecting a higher level of general arousal. Together, these results provide an electrophysiological dissociation between addiction-related stimulus processing and the more general arousal observed in a state of craving.

Abstract: Reward-associated visual stimuli capture attention, which can be either beneficial or detrimental depending on their relevance to the task at hand. It is well-established that such capture can occur at the level of reward-associated features, such as colors, but recent evidence suggests that this can also occur at the level of object categories. This phenomenon of attentional capture by reward-associated objects may play a central role in substance abuse, although the specific role and neural underpinnings of this effect in the context of addiction are not well understood. The present study investigated the automaticity of attentional capture by smoking-related visual targets in heavy smokers who were in a craving versus a sated state. Simultaneous

MEG and EEG measures of brain activity were taken during an object-substitution masking (OSM) task. In OSM, an array consisting of a number of distracter items, plus a single target appearing in an unpredictable location surrounded by a four-dot target-designating cue, is briefly presented. In half of the trials, the four-dot cue surrounding the target remains on the screen for a short period of time following the offset of the rest of the target/distracter array, which greatly reduces the visibility of the target. In the present study, these targets could be either smoking-related or office-supply-related images. The event-related N2pc MEG/EEG component, a hallmark index of spatial attentional shifts to a visual target, was extracted and tracked across masking conditions as a function of object category, as well as craving state. An enhanced-amplitude N2pc was observed in response to the smoking-related stimuli for all craving and masking conditions, with the exception of unmasked trials within the sated session. These results indicate that enhanced attentional capture by addiction-related images is largely automatic and can occur outside of conscious awareness. However, the results further suggest that this automatic capture of attention can be mitigated under conditions of clear target visibility and substance-specific satiety.

Title: The control of attention is altered in the absence of subjective awareness

Authors: *T. WEBB, M. S. A. GRAZIANO;
Princeton Univ., Princeton, NJ

Abstract: We proposed that awareness is a crucial part of the control mechanism for attention. Many studies have shown that people can pay attention to a stimulus without being aware of it, suggesting that awareness is not needed for attention. However, awareness may still have effects on attention. We hypothesized that the presence or absence of awareness will change the control of attention. To test the hypothesis, we directly compared attention with and without awareness in human subjects performing a Posner task. Metacontrast masking of a visual stimulus was applied such that subjects reported being aware of the stimulus in one condition and unaware of the stimulus in another condition. The stimulus was used as the cue in the Posner task, allowing

us to measure the amount of attention drawn by the stimulus. Attention was measured at five time points during the first 500 ms after stimulus presentation. We found that attention was drawn to the stimulus regardless of whether or not people were subjectively aware of it. However, attention was significantly different in the aware and the unaware conditions. It was not simply the case that awareness was associated with more attention. At one time point, subjects showed significantly more attention to the stimulus when they were unaware of it, whereas at another time point subjects showed significantly less attention to the stimulus when they were unaware of it. The timecourse of attention was changed by the presence or absence of awareness. These differences show that awareness is not an epiphenomenon and that it plays some role in the control of attention.

Title: Transcranial direct current stimulation modulates the attentional blink

Authors: *L. C. RETEIG[1], R. E. LONDON[2], H. A. SLAGTER[1];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Ghent Univ., Ghent, Belgium

Abstract: Our senses are continuously bombarded with more information than the brain can possibly process all the way up to the level of awareness. Hence, selection mechanisms that dynamically gate only goal-relevant information into working memory for further processing and conscious representation are critical for successful goal-directed behavior. In study 1, we examined whether this selection process can be facilitated by transcranial direct current stimulation (tDCS) over left dorsolateral prefrontal cortex (lDLPFC) - a region that plays a key role in working memory and conscious access. Specifically, we examined the effects of tDCS on the size of the attentional blink (AB): a deficit in identifying the second of two target stimuli presented in close temporal proximity in a rapid stream of distractor stimuli. tDCS works by creating a low, constant current between two surface electrodes, and can either increase or

decrease neuronal excitability depending on the kind of stimulation applied (anodal vs. cathodal). 34 subjects performed a standard AB task before (baseline), during and after 1 mA anodal and cathodal tDCS in two separate sessions. We hypothesized that anodal, but not cathodal tDCS over lDLPFC would reduce the magnitude of the AB, possibly as a function of individual baseline AB size. Indeed, while the effects of tDCS were not apparent at the group level, anodal tDCS decreased the AB in individuals with a large baseline AB, but increased the AB in individuals with a small baseline AB. This effect was only observed during (but not after) stimulation, was not found for cathodal tDCS, and could not be explained by regression to the mean. These findings support the idea that lDLPFC plays a critical role in the AB and in conscious access more generally. They are also in line with the notion that there is an optimal level of prefrontal activity for cognitive functioning, with both too little and too much activity hurting performance. In a follow-up combined tDCS-EEG study (study 2), we are currently examining the neural mechanisms underlying the observed anodal tDCS-related changes in the attentional blink. Results from this study will also be presented.

Title: Task-irrelevant novel sounds activate the orienting network of attention and improve performance in children and adolescents with and without ADHD

Authors: *J. TEGELBECKERS[1], A. BRECHMANN[2], C. BREITLING[1], B. BONATH[1], H.-H. FLECHTNER[1], K. KRAUEL[1,3];
[1]Otto Von Guericke Univ., Magdeburg, Germany; [2]Special Lab. Non-Invasive Brain Imaging, Leibniz Inst. for Neurobio., Magdeburg, Germany; [3]Ctr. for Behavioral Brain Sci., Magdeburg, Germany

Abstract: Introduction: Increased distractibility is one of the main symptoms in children with attention deficit hyperactivity disorder (ADHD) and could result from an increased orienting response towards irrelevant stimuli. However, there has been evidence that task-irrelevant novel sounds can have a beneficial effect on cognitive performance in ADHD (van Mourik, 2007). We

aimed to investigate the underlying neural mechanism of attentional modulation by task-irrelevant novel sounds in youth with and without ADHD. **Methods:** 46 children (50% ADHD, age: 11 to 16) executed a visual flanker task during functional magnetic resonance imaging (fMRI, 3T). Two thirds of the task displays were preceded by an auditory stimulus (environmental sound), half of them by a repeated standard sound and half by unique novel sounds. Analyses comprised the investigation of sound modulations on mean reaction times and error rates in the flanker task as well as activation differences between the sound conditions and groups. **Results:** We found a beneficial effect of novel sounds compared to the no sound baseline on reaction times and error rates in both groups. Moreover, novel sounds induced increased activation in the bilateral superior and middle temporal gyri as well as the right inferior frontal gyrus when compared to standard sounds and the no sound baseline. This pattern was comparable for typically developing children and children with ADHD. **Conclusion:** Novel sounds particularly activated the orienting/reorienting network of attention (Fan, 2005) which is engaged in attention orienting to sensory information and attention shifting. As this activation was accompanied by improved performance in an ongoing task, it shows the underlying correlate of the alerting benefits of novel sounds (SanMiguel, 2010). Furthermore, this mechanism seems to be intact in children and adolescents with ADHD indicating that they can benefit from external stimulation under certain conditions despite the disorder specific increased distractibility. **References:** Van Mourik, R. Title: ERP Indices of proactive and reactive attentional control in adult ADHD

Authors: *V. A. GRANE[1], J. F. BRUNNER[2,1], T. ENDESTAD[3], Y. KROPOTOV[4,5], R. T. KNIGHT[6], A.-K. SOLBAKK[1,7];

Abstract: Attention Deficit Hyperactivity Disorder (ADHD) is a prevalent early-onset, neurodevelopmental disorder characterized by inattention, hyperactivity, and impulsivity that is behaviorally maladaptive. The core symptoms persist into adulthood in a substantial number of individuals but may change over time in that difficulties with dynamic attentional control are commonly more pronounced than behavioral impulsivity in adulthood. The objective of this study was to examine whether electrophysiological markers of proactive and reactive attentional control are altered in adult ADHD. We studied event-related potential (ERP) indices of preparatory attention (Cue-evoked P3 and contingent negative variation [CNV]) and reactive response control (P3 Go, N2 NoGo and P3 NoGo) derived from a visual cued Go/NoGo task performed by treatment-naïve adults with newly diagnosed ADHD (n = 33) and a group of age-, sex- and education matched healthy controls (n = 31). The behavioral performance data showed that the ADHD group had significantly more omission errors to Go signals than controls (p = .037), but the groups did not differ in reaction time, reaction time variability, or in NoGo commission errors. The electrophysiological data revealed that ADHD patients did not differ from controls in the Cue P3 or CNV amplitudes. Furthermore, the ADHD patients were indistinguishable from controls in N2 NoGo amplitude. Adult ADHD patients had diminished P3 amplitudes to Go (p = .009) as well as NoGo (p = .035) signals at the central midline location. These ERP results indicate normal preparatory processes (Cue P3 and CNV), and conflict monitoring (N2 NoGo) in adult ADHD patients, but deficient allocation of attentional resources to targets and non-targets as revealed by the attenuated P3 Go and NoGo waves. The electrophysiological results highlight specific information processing deficits in the unmedicated adult ADHD population.

Title: Abnormalities in the direction of attention in space in ADHD are underpinned by weaker right-hemisphere orienting responses- an electrophysiological analysis

Authors: *M. A. BELLGROVE[1], D. P. NEWMAN[1], G. LOUGHNANE[2], S. P. KELLY[3], R. G. O'CONNELL[2];
[1]Monash Univ., Clayton, Australia; [2]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland; [3]Univ. Col. Dublin, Dublin, Ireland

Abstract: Background: An abnormality in the direction of attention in space is an intriguing aspect of the cognitive profile associated with attention deficit hyperactivity disorder (ADHD). Neurologically healthy individuals tend to more efficiently process stimuli presented in the left, compared to right, hemi-field. In ADHD however this advantage is lost or even reversed such that attention is less effectively directed to the left hemi-field. This abnormality is reminiscent of hemi-spatial neglect and implies weaker right hemisphere function in ADHD. Methods: We used electroencephalography (EEG) to investigate the neural processes underpinning the direction of attention in space in ADHD. EEG was recorded from 22 children diagnosed with ADHD and from 29 typically developing control children while they performed a visuospatial attention task. Results: As expected, typically developing controls displayed a significant reaction time advantage for detecting left hemi-field targets, whereas this advantage was lost in ADHD. This difference in spatial bias was reflected in hemispheric asymmetry of the N2pc, an ERP marker of visuospatial attention orienting. Whereas the control children displayed right-hemisphere dominance of the N2pc, particularly for left hemi-field targets, this dominance was lost in the ADHD group. Further, a difference in the centro-parietal positivity (CPP), a marker of perceptual evidence accumulation, was observed between the groups, whereby controls displayed earlier CPP latency for left than right hemi-field targets, whereas the ADHD group did not. Discussion: These data confirm that ADHD children have an abnormality in the efficient direction of

attention to left space, the EEG correlate of which is a reduced right-hemisphere dominance for spatial orienting.

Title: Alpha desynchronization and fronto-parietal connectivity during spatial working memory deficits in ADHD: A simultaneous EEG-fMRI Study

Authors: ***A. LENARTOWICZ**, S. LU, E. LAU, J. T. MCCRACKEN, M. S. COHEN, S. K. LOO;
Univ. of California Los Angeles, Los Angeles, CA

Abstract: Spatial working memory (SWM) is reliably associated with deficits in attention-deficit hyperactivity disorder (ADHD), making it a potential gateway to understanding the neural sources of inattention symptoms. In prior research we have demonstrated that SWM performance, inattention symptoms and ADHD diagnosis are correlated with the degree of occipital, alpha (8-12Hz), event-related desynchronization (ERD) in electroencephalography (EEG) signals of neural activity during the encoding phase of SWM. In the current study we tested whether alpha ERD is correlated with the connectivity of right fronto-parietal network activity that is known to facilitate SWM. To do so, we tested 30 boys (Age=13.9, ADHD=15) on the Sternberg SWM task while concurrently measuring electrical scalp (EEG) and metabolic whole-brain (functional magnetic resonance imaging) measures of brain activity. We used single-trial alpha desynchronization during encoding and a psycho-physiological interaction between this measure and activity in fronto-parietal regions of interest to identify the neural-activity correlates of alpha and the neural-network correlates of alpha modulation, respectively. The results replicate our prior finding of weaker alpha ERD during encoding in children with ADHD. In addition, greater alpha ERD was associated with increased activity within lateral occipital cortices, and enhanced connectivity between right occipital cortices and a fronto-parietal network, which suggests that alpha ERD is a correlate of interactions within an occipito-

parieto-frontal network. The strongest predictor of inattention symptoms and performance was connectivity within right superior occipital cortex, suggesting a target for further study of ADHD-related impairment. Finally, while our study demonstrates for the first time the feasibility of performing EEG-fMRI concurrently for the study of SWM in ADHD, we also found considerable artifact in the EEG data, especially in children with ADHD, which highlights possible limitations and pressing challenges in applying simultaneous EEG-fMRI in this population.

Title: Methylphenidate regulates electrophysiological signals that reduce lapses of attention

Authors: *P. M. DOCKREE[1], M. BELLGROVE[2], R. ABE[2], J. BARNES[3], N. MATTHEWS[3], R. O'CONNELL[4];
[1]Sch. of Psychology and Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland; [2]Monash Univ., Melbourne, Australia; [3]Queensland Brain Inst., Brisbane, Australia; [4]Trinity Col. Inst. of Neurosci., Dublin, Ireland

Abstract: Abstract The mechanisms by which methylphenidate (MPH) reduce episodes of inattention are not fully understood. However, electrophysiological markers that characterise error-prone states provide a means to examine the influence of MPH on dissociable neural signals that foreshadow lapses of attention. In a placebo-controlled, crossover design, we examined the performance of healthy adults (n=36) on a simple target detection paradigm. MPH improved task performance and suppressed α-band (7-11hz) activity across the task. Change in α-band power was also correlated with change in accuracy between MPH and placebo conditions. In the 4s period preceding targets, there was marked changes to attention-relevant signals in the MPH condition (α-band and θ-band suppression and P3 amplitude increases),

which predicted target detection. By contrast, there were no changes to early visual processes (visual P1 and 25Hz steady-state response) indicating that MPH exerts its influence primarily on higher-order endogenous mechanisms instead of facilitating bottom-up sensory processing. These data show the physiological basis by which MPH improves attention offering candidate markers for remediation in ADHD.

Title: Effect of ADHD candidate risk SNPs on cortical thickness in typical children and young adults

Authors: *A. J. KRAFNICK[1], D. A. RINKER[2], T. T. BROWN[3], A. W. TOGA[1], P. M. THOMPSON[2], K. A. CLARK[1];
[1]Lab. of Neuro Imaging, Stevens Neuroimaging and Informatics Inst., [2]Imaging Genet. Center, Stevens Neuroimaging and Informatics Inst., USC, Los Angeles, CA; [3]Dept. of Neurosciences, Univ. of California--San Diego, La Jolla, CA

Abstract: Attention deficit hyperactivity disorder (ADHD) is a complex behavioral neuropsychiatric disorder highlighted by inattentiveness, impulsiveness, and hyperactivity (APA, 2000). There is a strong genetic component with estimates of the additive genetic effects approaching 80% (Faraone et al., 2005). Many genes have been implicated in ADHD, with the most consistently identified genes being related to the catecholamine lifecycle (Akutagava-

Martins et al., 2013; Gizer et al., 2009). Here, using data from the Pediatric Imaging, Neurocognition, and Genetics (PING) study, we investigated how SNPs from ADHD candidate risk genes effect cortical thickness in a group of typically developing children and young adults. 409 subjects (average age 11 years, range 4-21 years; 200 female) from the PING database were processed with Freesurfer (Fischl, 2012) in order to estimate cortical thicknesses for each subject across the whole brain. We identified three SNPs consistently related to ADHD from genes related to the catecholamine lifecycle: rs27072 (dopamine active transporter 1, DAT1; risk allele G), rs4680 (catecholamine-o-methyltransferase, COMT; risk allele G), and rs6314 (serotonin receptor 2A, HTR2A; risk allele A). Based on subject genotypes we were able to compare two genotypes for DAT1 (n = 120 AG, 276 GG) and HTR2A (n = 60 AG, 346 GG), and three genotypes for COMT (n = 83 AA, 226 AG, 100 GG). Of the three SNPs, DAT1 and COMT survived corrected thresholds of $p<0.01$ (vertex) and $p<0.05$ (cluster). For DAT1 (rs27072), subjects with two copies of the risk allele (GG) showed reduced cortical thickness in left orbitofrontal cortex (OFC) compared to subjects with one copy of the risk allele (AG). For COMT (rs4680) there was a main effect of genotype in left lateral occipital cortex, with post-hoc t-tests showing this was due to less cortical thickness in subjects with two risk alleles (GG) compared to subjects with no risk alleles (AA). These results suggest unique contributions of these risk SNPs to variation in cortical thickness in a typically developing population. The left orbitofrontal cortex result for rs27072 (DAT1) is in line with a recent study of another DAT1 polymorphism that found variation in white matter volume here was related to both the polymorphism and executive function (Chung et al., 2015). This suggests that OFC may be of particular interest for investigating the interaction of genetics, executive function, and ADHD. The COMT SNP is more commonly investigated as it has been implicated in several disorders, and occipital cortex has been previously implicated. Future work will need to continue investigating these polymorphisms in multiple imaging modalities.

Title: The “good” choline transporter gene variant? Resilience against distractibility and depression

Authors: Y. ISAACS[1], Z. LIN[1], P. J. DELDIN[1], R. D. BLAKELY[2], *M. SARTER[1], C. LUSTIG[1];
[1]Psychol, Univ. Michigan, Ann Arbor, MI; [2]Pharmacol. & Psychiatry, Vanderbilt Univ., Nashville, TN

Abstract: Forebrain cholinergic systems play a critical role in perception and cognition. While the contributions of cholinergic dysregulation to the severity of cognitive symptoms have been extensively demonstrated, long-standing hypotheses linking such dysregulation with depression remain less well supported. The high-affinity choline transporter is an essential regulatory step for the synthesis of acetylcholine (ACh) and the ability to sustain elevated levels of cholinergic activity. We have previously reported that a single nucleotide polymorphism (SNP) of the CHT gene (SLC5A7; rs1013940) is associated with increased behavioral distractibility on both laboratory and self-report measures, and with reduced right prefrontal brain activation in the face of distraction (Berry et al., 2014, 2015). Another CHT SNP (rs333229; G vs. T base pair substitution at the 3’ untranslated region; 3’UTR) was associated with differences in heart rate variability and corticolimbic reactivity (Neumann et al., 2005, 2006). On this basis GG homozygosity has been suggested as a risk factor for depression but to our knowledge no behavioral correlates have been reported thus far. We found that in individuals homozygous for the major allele at SLC5A7, those with a T allele at the 3’UTR site self-report less boredom in everyday life (Short Imaginal Processes Inventory, Huba et al., 1982) and better sleep (Pittsburgh Sleep Quality Index, 1989), as well as showing dramatically reduced distractibility on a laboratory task. These participants also show a moderate trend (d = 0.68) for lower scores on a self-report measure of depressive symptoms (Patient Health Questionnaire depression subscale, Spitzer et al., 1989). Although these results require replication, they provide the first evidence for behavioral differences associated with variation at the 3’UTR and further reinforce our previous findings that genetic variations of the CHT impact cognitive function and psychiatric risk. Furthermore, these findings suggest relationships between resilience against distraction and against depression.

Title: The effect of alertness on the detection of semantic incongruities and generation of the N400 event related potential

Authors: *E. A. SILVA, JR[1], S. MENESES ORTEGA[2];
[1]Inst. De Neurociencias, Zapopan, Mexico; [2]Neurophysiol. of attention, Inst. de Neurociencias, Univ. de Guadalajara, Zapopan, Jalisco, Mexico

Abstract: Introduction: It is known that alertness and selective attention are strongly related. Therefore, variations in alertness influence the capacity of detection of relevant stimuli. It has been found that different cognitive processes are affected when alertness levels and attention decrease. Nevertheless, it is not yet clear with accuracy if changes in the alertness level, during waking, affect the recognition of semantic incongruities, despite being a complex cognitive process. The aim of this study was to determine whether the detection of incongruent stimuli, evaluated by recording the N400 component, is influenced by the alertness level during waking. Method: ERPs were recorded in three derivations (Fz, Cz, Pz) in 11 male subjects. Seven-word sentences visually presented were used. Each word of the sentence was presented individually. Each sentence can be classified in two ways: congruent, and strongly incongruent. Trials began with a black screen (2 seconds) followed by each word of the sentence. The words were presented for 100 milliseconds with an interstimulus interval of 2 seconds. At the end of each sentence participants had to press the left button to indicate that the sentence was congruent or the right button for the incongruent sentences. In order to determine the level of arousal we analyzed the power spectrum of the brain electrical activity one second prior to the presentation of each congruent or incongruent stimuli. The segments were classified according the type of stimuli (congruent - incongruent) and the alertness (high - low alertness). The averages for each condition were obtained. Difference waves were created by subtract the ERP waveform elicited by the incongruent stimuli from the ERP waveform elicited by the congruent stimuli. A two-way repeated-measures ANOVA (alertness level x derivations) were used to analyze the amplitude and distribution of the N400 component. Results: A significant main effect for alertness was found ($F(1,50)=4.19$; $p<0.05$), with a smaller amplitude when the alertness was low. No significant differences in amplitude were found for Derivations ($F(2,50)=0.71$; $p>0.05$), nor for interaction ($F(2,50)=0.12$; $p>0.05$). Conclusions: The results show that the N400 amplitude is reduced when alertness decreases, which suggest that efficiency in the processing of semantic inconsistencies is reduced with decreasing alertness. Furthermore, no differences on the N400 amplitude were found between derivations in each alert condition, there is no interaction; this could indicate that the circuit underlying the processing related to the generation of N400 are affected equally under reduced alertness.

Title: Influence of gender role on brain lateralization and error detection during a semantic reasoning task

Authors: J.-B. QUILLIEN[1], *R. L. LLOYD[2];
[1]Dept. of Educational Psychology, Univ. of Minnesota, Minneapolis, MN; [2]Dept Psychol & Mental Hlth., Univ. Minnesota, Duluth, MN

Abstract: 42 undergraduates took part in a study investigating the relationship between brain lateralization, gender role, and reasoning. Brain lateralization was measured using a newly developed semantic retrieval task where the names of objects were simultaneously projected to the left, center, and right visual fields (2 words per field). Prior to the task, participants were invited to name each of the 90 objects used in the study. The task was composed of 15 blocks of 6 objects to retrieve. To control for eye gaze, we first verified that the two objects named in the middle of the visual field were remembered, then the number of retrieved objects from the right (left hemisphere projection) or left (right hemisphere projection) visual fields were scored. Gender role was determined using the Bem sex-role inventory, and participants were classified into one of four groups: feminine, masculine, androgynous, or undifferentiated. Participants performed the Remote Associate Task (RAT): finding a target word related to three stimulus word (i.e. Cottage, Swiss, Cake: Cheese). The RAT was coded for correct answers and errors (failure to recognize that the selected word does not work for every stimulus word). Right hemisphere recruitment (Number of objects retrieved from the left visual field/total number of correct answers) was computed and an analysis of variance performed: A significant difference was found among the four groups ($F=3.23$, $p<.05$). Post hoc analyses (LSD) revealed that the androgynous group recruited significantly less information from the right hemisphere than the male and the undifferentiated group. The androgynous group also demonstrated a fewer errors during the RAT. T-tests revealed that the androgynous group had significantly fewer errors than the feminine group ($t=-2.77$, $p<.05$), and nearly significantly fewer errors than the masculine group ($t=-1.85$, $p=.08$. The difference from the undifferentiated group ($t=-1.56$, $p=.13$) was close to one-tail significance. These results suggest that the androgynous gender role is associated with less right hemisphere recruitment. In addition, despite the small sample size, the reasoning data gave us some promising venue to explore. The androgynous group produced significantly fewer

errors during the RAT than the female group; and almost significantly fewer errors than the two other groups. The right prefrontal cortex is often associated with error detection; yet our results suggest that less lateralization toward the right hemisphere is associated with fewer errors in semantic reasoning. Future studies, with larger samples, which replicate our findings is necessary to confirm our findings/interpretation.

Title: Event-related potentials analysis of mental arithmetic processing caused by numerical versus symbolic stimulation

Authors: M. J. FRONDORF, *A. W. CHIU, M. THAKKER, W.-W. JEONG;
Biololgy and Biomed. Engin., Rose-Hulman Inst. of Technol., Terre Haute, IN

Abstract: Early, and late waves exhibited in event-related potentials (ERPs) at around 0-300ms, and 300-500ms after the presentation of questions are associated with mental arithmetic processing (MAP). Unlike traditional P300 oddball experiments where subjects observe visual stimuli passively; the purpose of this research was to determine the difference in the VEP when the subject was presented with an unexpected stimulus while actively visualizing and imaging a particular visual cue. Here we focused our efforts in the evaluation of human subject responses to the presentation of unexpected solutions to mental arithmetic problems in the form of incorrect numerical values or inconsistent form of representation to aid in the study of attention and cognitive functions. Right handed, male subjects with healthy (or corrected) eye sight, between the ages of 18-55 were recruited for this study. In each trial, the subjects were exposed to an arithmetic equation with the answer absent. Each subject underwent 360 trials (80% correct, and 20% incorrect solution). There was a small increase in the amplitude of the averaged VEP 300ms after the onset of unexpected stimulus when the subjects were presented with simple X's and O's, with a much stronger increase in the averaged VEP amplitude (over four times as large as that of the expected stimulus) 500ms after the stimulus onset ($p<<0.01$). When presented with errors in mathematical solutions, the averaged VEP showed a longer latency without any difference in amplitude. For the Mental Arithmetic study, there was no significant increase in the amplitude of the averaged VEP between 250-400ms after the onset of unexpected stimulus. However, there

was a statistically significant delay (~80ms) in the positive peak in the averaged VEP amplitude near 375ms after stimulus onset. The longer latency suggests the possibility of a longer processing time when subjects realized that the answers were not what they had in mind. This research may offer alternative ways to evaluate cognitive function and attention in a quantitative manner.

Title: The role of visuospatial attentional mechanisms during retention of information in visual short-term memory

Authors: ***M. E. VISSERS**[1], R. GULBINAITE[2], B. P. BRAMSON[1], T. VAN DEN BOS[1], H. A. SLAGTER[1];
[1]Brain & Cognition, Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [2]Ctr. de Recherche Cerveau et Cognition, Toulouse, France

Abstract: There is ample evidence showing that attentional control plays an important role during encoding of information in visual short-term memory (VSTM). Yet, at present it remains unclear to what extent the allocation of spatial attention plays a functional role in preserving the content of visual short-term memory after initial encoding. In the current study, we investigated the allocation of visuospatial attention during VSTM retention. Using EEG and frequency tagging of individual stimulus positions, we measured attentional allocation to each stimulus position during VSTM retention, as reflected by amplitude modulations of the SSVEP. In the first experiment we manipulated memory load to differentiate between parallel vs. sequential attention to stimulus positions, and the degree to which this is dependent of memory load. In the second experiment we manipulated the presence of irrelevant stimuli, in order to study attention to locations previously containing relevant vs. irrelevant information. First findings suggest that

attention to relevant stimulus positions occurs in a sequential fashion, suggesting attentional looping over stimulus positions during VSTM retention. Furthermore, positions previously containing relevant stimuli are attended more than positions containing irrelevant stimuli. Using time-frequency decomposition of the EEG-data, we relate the extent of attentional modulation during VSTM retention to activity in the brain networks involved (i.e., inter-electrode α-phase synchronization). Together, our findings provide novel evidence for the importance of visuospatial attention for VSTM, and show that visuospatial attention may serve to preserve memories during VSTM retention.

Title: Working memory allocation reflects task demands during prospective remembering

Authors: *A. MUKERJI[1], J. A. LEWIS-PEACOCK[1,2];
[1]Dept. of Psychology, [2]Imaging Res. Ctr., Univ. of Texas at Austin, Austin, TX

Abstract: Prospective memory can be achieved with proactive control by actively maintaining the goal in working memory or with reactive control by relying on external cues to retrieve the goal when necessary. The flexible choice of strategy involves effort and performance tradeoffs. Prior work has used multivariate pattern analysis of fMRI data in a dual-task prospective memory experiment to profile the allocation of working memory resources underlying task performance. Behavioral metrics indicated that both proactive and reactive control strategies were used for prospective remembering. However, neural readouts of working memory usage indicated a bias towards the more effortful proactive control strategy: goal-related processing during the delay period was predictive of prospective memory performance at the end of the trial. The strength and predictiveness of these readouts were sensitive to changes in task demands, such that goal-related working memory was strongest and most predictive of performance on trials with both (a) lower ongoing task demands and (b) higher prospective memory demands. Yet, the unique influence of ongoing task demands remains unclear. We developed a modified version of this experiment to assess how the dynamic selection of control strategy varies with the attentional demands of the ongoing task. We recorded whole-brain fMRI data every second and

used multivariate pattern analysis to decode the contents of working memory throughout the trials. Each trial began with a picture target (a face or scene), followed by a variable-length sequence of 2-sec memory probes containing four pictures and a field of moving dots. Participants balanced two objectives: 1) to make repeated direction-of-motion judgments about the dots (ongoing task); and 2) to identify when the picture target reappeared (prospective memory task).The motion coherence of the dots in the ongoing task was parametrically varied across trials. As the coherence of the dots increased, the attentional demands of the ongoing task decreased. We hypothesized that a reduction in cognitive load would lead to an increase in proactive control, thus stronger and more predictive goal-related working memory readouts. Pilot results indicate that prospective memory performance remained stable, yet the use of proactive control increased as the ongoing task became easier. This was reflected both behaviorally (slower responses in the ongoing task) and neurally (stronger and more behaviorally predictive readouts of goal-relevant working memory processing). These results highlight that prospective memory control is quite flexible and sensitive to changes in concurrent cognitive demands.

Title: EEG spectral changes during involuntary eyelid closures in resting-state fMRI studies

Authors: *J. L. ONG, C. WANG, K.-K. NG, J. ZHOU, M. W. L. CHEE;
Duke-NUS Grad. Med. Sch., Singapore, Singapore

Abstract: Inadvertent sleep has been shown to occur in a third of subjects studied in task-free fMRI studies, affecting downstream data interpretation (Tagliazucchi and Laufs 2014). EEG remains the gold standard for measuring sleep but simultaneous EEG-fMRI is resource intensive. Spontaneous eyelid closures in fatigued persons correspond to periods of diminished responsiveness to auditory stimuli and reduced functional brain connectivity. Here we investigated EEG features associated with spontaneous eyelid closures in drowsy persons, to consolidate the proposition that monitoring the latter is an excellent alternative to simultaneous EEG-fMRI for task-free fMRI studies. 17 undergraduates underwent two 6-minute task-free

fMRI scans in darkness after a 5h night of sleep. Simultaneous eye video and 64-channel EEG was collected. Eye videos were scored in 4s video epochs from 1-9 using a semi-automated algorithm and collapsed into 3 Eyescore (ES) conditions (ES 1-3: fully closed; ES 4-6: semi opened; ES 7-9: fully opened). Gradient, pulse, eye and muscle artifact removal were performed before re-referencing to the average of both mastoids. The EEG data was then segmented into 4s epochs. Epochs contaminated by heavy movement were removed from further analysis. Subjects were instructed to stay awake and to keep their eyes open. However subjects frequently dipped into microsleeps. EEG power collected during varying degrees of eyelid closure at Cz and O1 is shown in Fig 1. Epochs with lower ESs (greater eyelid closures) were associated with higher delta and theta power but lower beta power. Alpha power increased from ES 1-3 to ES 4-6, but decreased in ES 7-9. These results are in line with prior behavioral-EEG correlations. Even during resting-state studies where no measure of performance is directly observable, periods of decreased vigilance can be obtained by observing eyelid closures. These findings underscore the value of monitoring eyelid closures in order to exclude confounding periods that may contaminate true task-free or baseline data.

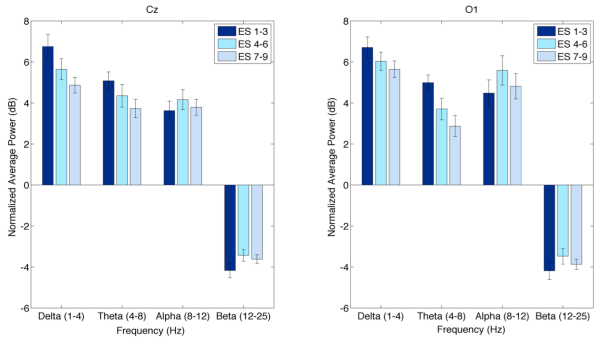

Figure 1 Average normalized power at electrode Cz and O1 by frequency band in 4s-epochs grouped into three eyescore (ES) conditions (ES 1-3: fully closed; ES 4-6: semi opened; ES 7-9: fully opened). Power was normalized by subtracting the mean log spectrum (1-25 Hz) in the ES 7-9 condition. Significant differences (p's < 0.05) were present in the delta (Cz only) and theta bands (Cz and O1), where lower eye scores were associated with greater delta and theta power. The converse was found for the beta band (Cz and O1) where higher eye scores were associated with greater beta power. In the alpha band however, alpha power significantly increased from ES 1-3 to ES 4-6 and decreased again in ES 7-9 (O1 only).

Title: Examination of the effect of light environment on brain activity during visual search task by fNIRS

Authors: *H. TANAKA, T. HIROYASU;
Doshisha Univ., Kyotanabe-Shi, Kyoto, Japan

Abstract: [Purpose] In this study, examination of light environment to improve intelligent productivity and comfort is conducted. It is reported that light environment effects on working efficiency and psychological states of office workers. However, working efficiency and psychological states are processed in the brain and we investigated the effect of light environment on brain activity. Brain activities were measured by functional near-infrared spectroscopy (ETG-7100; Hitachi Medical Corporation). We have constructed the special experimental environment whose light color can be changed. Because of this environment, more channels of fNIRS can be used compared to the former study. [Methods] Under each type of light, cerebral blood flow (CBF) changes in the frontal lobe (22ch) were measured. Task performance was measured on reaction time (RT) without errors. The reaction was assumed as error when subjects made mistakes and could not react while image stimuli were to be submitted. Subjects were divided into two groups by an average of RT in all of the light environment: high performance group (high-group; 6 subjects) and low performance group (low-group; 6 subjects). [Results] In task performance, t-test was conducted and there was significant difference between two groups in all of the light environment (Red: $p<.05$, White: $p<.01$, Blue: $p<.01$). Brain activity by CBF changes during the task was visually confirmed. In White, CBF changes in high-group became constantly more extensively after CBF increased. In Red, CBF changes in high-group increased slowly. On the other hand, the tendency of CBF changes in low-group to increase was observed from the middle of the task team. In Blue, CBF changes in both groups did not increase extensively. [Discussions and Conclusions] In task performance, RT in White was the fastest in both groups. By examination of CBF changes, CBF in many channels became constant after they increased in white. We consider that part where CBF change increase is active. Therefore, it was found that the continual activation of frontal lobe effects on task performance in white. Under different light environment, CBF changes were examined. These results indicated that different light environment effected on brain activity.

Title: Transcranial direct current stimulation (tDCS) affects cognitive performance in only a subset of individuals - inter-individual differences in tDCS responsiveness during complex cognitive training

Authors: *M. R. SCHELDRUP[1], P. DWIVEDY[1], R. MCKINLEY[2], P. GREENWOOD[1]; [1]George Mason Univ., Fairfax, VA; [2]Air Force Res. Lab., 711 Human Performance Wing, Dayton, OH

Abstract: Complex multi-tasks that make simultaneous demands on several cognitive components are required during many real-world operations. It was previously argued that efficient performance of multi-tasks requires coordination of attention between subtasks (Kramer et al., 2005, Strobach et al., 2014). The most effective way to facilitate that coordination has not yet been established. Transcranial direct current stimulation (tDCS) has been used to facilitate single task performance (reviewed in Coffman et al. 2014), but only recently used to facilitate multi-task acquisition (Scheldrup et al., 2014). We hypothesized that in a multitask with verbal and spatial working memory (WM) subtasks, tDCS over left dorsolateral prefrontal cortex (DLPFC) would facilitate verbal WM while tDCS over right DLPFC would facilitate spatial WM. We tested this in a multi-task that simulates aircraft carrier operations - Warship Commander (WSC). Participants were randomly assigned to receive sham, anodal, or cathodal stimulation to either F4 or F3 of the 10-20 EEG system (corresponding with right and left DLPFC). Results indicate that both anodal and cathodal stimulation affected performance but only for a subset of participants. Our results are in concert with recent findings indicating the large role that inter-individual differences play in not only cognitive performance but in responsiveness to tDCS (Jaeggi et al., 2014, Krause and Cohen Kadosh; Lopez-Alonzo et al., 2014). Our results demonstrate the need for adequate behavioral as well as neurophysiological assessments of tDCS responsiveness within a given paradigm.

Title: Only random alarm?! Situation and perspectives on civil aviation security

Authors: *J. K. KRÜGER, B. SUCHAN;
Ruhr-Universität Bochum, Bochum, Germany

Abstract: Examinations of performance of security screeners by the European Commission demonstrated striking results. Nearly every second bag containing a forbidden item (e.g. Improvised Explosive Device) was transferred through security check without any difficulties. Aviation security screeners are responsible for controlling carry-on luggage and customers, here screeners perform amongst others analyses of X-ray images to detect prohibited objects (6). X-ray screening includes the search for very rare and infrequent items (7). This work is performed under highly noisy circumstances with time pressure and high distractibility (2). Screeners have to be very concentrated and focused while visually scanning the image, recognize and categorize the shown items and have to decide quickly whether there are any suspicious objects (3). Attentional functions were assessed by a computerized neuropsychological test battery (TAP 8) in combination with parts of the WMS - III (1) and WMS-IV (4) and a computerized full version of the Mental Rotation Test (5). 50 security assistants working at various German airports were assessed. To assess circadian variability and the influence of shift-work, participants were tested before and/or after working shifts early in the morning as well as in the late evening. Performance of each subtest provided average or marginal average results of the participants for the above mentioned cognitive aspects. Results suggest no significant influence of shift duration, time in day, and time of testing (before versus after work). Contrary to this, were the results of subjective evaluation via visual analogue scales of concentration, motivation, and attention as well as the Stanford Sleepiness Scale. As expected, screeners declared an increase of sleepiness and a depression of the named mental factors with the passing of time. One could argue that the overall fatigue was so severely pronounced that small variations by the time of the day were not enough influential to additionally impact the cognitive ability in a significant manner. Despite modern and cutting-edge technology, it is always the human who makes the last decision whether a handbag contains a forbidden threating item.

Title: A real-time objective assessment of cognitive workload during ambulation

Authors: *E. P. SHAW[1,2], J. C. RIETSCHEL[3], C. G. MCDONALD[4], M. W. MILLER[5], R. J. GENTILI[6,7,8], B. D. HATFIELD[6,7];

Hlth., College Park, MD; [7]Neurosci. and Cognitive Sci. Grad. Program, Univ. of Maryland, College Park, MD; [8]Maryland Robotics Center, Univ. of Maryland, College Park, MD

Abstract: Safe ambulation within a real-world environment often requires the concurrent performance of secondary tasks (e.g. attending to oncoming traffic while crossing a street). Due to limited attentional resources available for cognitive processes, the manner in which such resources are allocated during ambulation is of much interest. In particular, individuals with lower limb amputations may require additional attentional resources to ambulate with their prosthetic limb. Here, we present a novel and objective approach for the assessment of cognitive workload during ambulation in healthy individuals, which will later serve as a baseline for comparison to individuals with unilateral lower limb amputation. In the ongoing study, EEG was recorded from 12 uninjured healthy males performing cognitive tasks of varying difficulty (easy and hard), while seated and while walking on a treadmill in a Computer Assisted Rehabilitation Environment at Walter Reed National Military Medical Center. Attentional reserve was assessed by evaluating the P3a component of the event-related potential, an index of the involuntary orienting of attention, elicited by intermittently presented task-irrelevant novel complex auditory stimuli. To quantify the P3a component, a temporal-spatial principal components analysis was performed. Factor scores were subjected to a 2 x 2 (Task [seated vs walking] x Difficulty [easy vs hard]) repeated-measures ANOVA, which revealed no significant main effects or interaction. These findings suggest ambulation does not impose additional cognitive workload in healthy individuals. However, individuals with lower limb amputation may require additional attentional resources during ambulation. Accordingly, we are initiating an investigation of cognitive workload among these individuals with the same pragmatic approach utilized for evaluating healthy controls, with a plan to collect data for 15 males with unilateral lower limb amputation. We predict ambulation will impose additional cognitive workload in these individuals. This increase in cognitive load is expected to be reflected by diminished attentional orienting, as indexed by the P3a component. The present study provides support for the utility of EEG as an objective real-time assessment of cognitive workload during ambulation within an ecologically valid environment. Title: Time pressure on brain inhibition for emergency driving

Authors: *J.-T. KING[1], C.-H. CHUANG[2], C.-T. LIN[2];
[1]Brain Res. Center, Natl. Chiao Tung Univers, Hsinchu, Taiwan; [2]Brain Res. Center, Natl. Chiao Tung Univ., Hsinchu, Taiwan

Abstract: How to deal with the upcoming emergency situations is a key to avoid car accidents. Previous study used brain imaging to reveal that the efficiency of inhibition function is responsible for copying such situations. However, other factors, such as stress, on driving inhibition are still unknown. Hence, in this study, we aim to get an insight into brain activities of emergency management in stress conditions. To investigate driver's brain responses of inhibition function, a modified stop-signal driving task was implemented in a virtual-reality driving environment. The electroencephalography (EEG) was recorded from 16 subjects as they performed the experimental tasks under normal (without time pressure) and stress (with time pressure) conditions. Given a fixed road distance, each subject was instructed to arrive at the finishing line within a limited time under the stress condition. In signal processing, independent component analysis (ICA) and event-related spectral perturbation (ERSP) analysis were applied to investigate the spectral dynamics of independent brain processes. The behavioral results showed that the stop-signal reaction time (SSRT) was shorter under the stress condition than that under the normal condition. This result indicated that the stress could help to improve the efficiency of inhibition ability. The ERSP results showed that the augmentation of delta (1-3 Hz) and theta (4-7 Hz) powers in frontal and central areas are related to the inhibition mechanism. There is no statistically significant difference between two conditions. However, beta (13-30 Hz) and gamma (30-50 Hz) powers in frontal and central areas increased only in the stress condition. The beta and gamma powers of the central area under the stress condition were significantly higher than those under the normal condition. Because the gamma band is thought to reflect the top down modulation, the time pressure could possibly improve the driving inhibition efficiency by the proactive control which prepares to stop before the signal onset.

Title: Impaired memory and the cocktail party

Authors: *S. KAMOURIEH, R. LEECH, R. WISE;
Imperial Col. London, London, United Kingdom

Abstract: Background 'Top-down' attention is required when listening to a speaker partially masked by background speech. The cortical systems for attention and cognitive control are affected early in the course of cortical neurodegenerative disease. This affects a patient's ability to register what a speaker has said when masked by background speech or noise in social situations. Objectives To investigate impairment in the functional anatomy of the fronto-parietal attentional systems in patients with memory impairment during auditory speech stream segregation (the "cocktail party" phenomenon), using functional magnetic resonance imaging (fMRI). To explore the modulation of top-down cognitive control regions by a central cholinesterase inhibitor. Design/Method 22 healthy volunteers and 31 patients with self reported and objective memory impairment were included in this fMRI study. T2*-weighted gradient echo planar images were collected on a 3T scanner using interleaved silent steady state (ISSS) imaging. The task involved attending to a female speaker, either in the absence or the presence of a masking male speaker, with or without spatial cues. The patient group were scanned twice, 6 weeks apart, with 18 patients started on Galantamine after the first scan. Results A repeated measures ANOVA on behavioural results between the healthy volunteers and patients identified a significant effect of group and condition but no group by condition effect. Univariate analysis identified activity in similar systems between the two groups, but the poorer performance in the patients was reflected by reduced activity in dorsolateral prefrontal cortex and dorsal anterior cingulate. Multivariate analysis identified reduced connectivity between the left superior temporal gyrus with the left fronto-parieto-temporal cortex and the cingulo-opercular network in the patients. The effect of Galantamine was to increase dorsal anterior cingulate cortex response. Conclusions A complaint of poor recent verbal memory is often due to impaired encoding but it also has its origins in poor registration. This is a consequence of impaired high-order systems affected by neurodegenerative diseases. An inability to register verbal information when listening in the presence of distracting background speech will contribute to complaints of 'impaired memory' and social isolation.

Abstract: Delirium, also known by some as “encephalopathy”, is a common and serious clinical syndrome that is associated with significant mortality and increases in healthcare resource utilization. Although early detection of delirium is crucial for improving patient outcomes, it is made difficult due to the lack of quick, easy screening tools. As a result, such syndromes often go undetected in hospital and clinical settings. In this study, we aim to reveal brain function in mildly delirious patients with liver disease by using near-infrared spectroscopy (NIRS), an optical topography system designed to measure the changes in concentration of oxy- and deoxy-hemoglobin in the cerebral cortex. Specifically, we examined these changes in the frontal and temporal areas of the brain during cortical stimulation using tasks for attention and executive function. We found a significant correlation between Hb integral values on NIRS during these tasks and participants’ values on the delirium rating score revised 1998 (DRS-R-98), a commonly used rating scale for measuring delirium. These findings suggest that the NIRS optical topography system might be a useful tool for evaluating and detecting mild delirium.

Title: Disturbance of fast frontoparietal oscillatory activity and hemispheric dysbalance in delirium: evidence for a common pathophysiological framework from a large retrospective quantitative EEG study

Authors: *R. FLEISCHMANN, S. TRÄNKNER, M. RÖNNEFARTH, S. SCHMIDT, S. J. SCHREIBER, S. A. BRANDT;
Dept. of Neurol., Charité - Universitätsmedizin Berlin, Berlin, Germany

Abstract: Objective: Delirium is a common disorder that is associated with increased morbidity. The clinically heterogenous phenotype and lack of objective disease markers are major causes of misdiagnosis leading to considerably variable and potentially detrimental treatment decisions. A better understanding of pathophysiological mechanisms underlying this disorder are necessary to facilitate diagnosis and guide therapy. Methods: We searched the EEG database of a German university hospital between years 2004 and 2014 for recordings of patients diagnosed with

delirium (DSM-V criteria) and age-matched controls (n = 129 and 414, respectively). Normalized total and frequency band specific power spectra of continuous EEG data were compared between conditions (i.e. control vs. delirium) and topographically by ANOVA. Results: There was a significant interaction of CONDITION x FREQUENCY x SENSOR ($F(120,540) = 9.1$, $p < 0.001$) and CONDITION x HEMIPSHERE ($F(2,541) = 26$, $p < 0.001$). Post-hoc analyses revealed that total power was significantly increased centrally and decreased in the right hemisphere in the delirium group ($p < 0.01$). Furthermore, right frontal and parietal fast oscillations were significantly changed (increased gamma and decrease beta power, respectively; $p < 0.01$). Conclusions: This retrospective study yielded specific EEG patterns in patients with delirium that provide correlates of typical behavioral changes and concepts for underlying pathophysiological mechanisms. Spontaneous frontal gamma increase is well described to interfere with working memory and linked to a breakdown of local inhibitory interneuron circuitry. Similar mechanisms possibly account for changes in parietal beta activity since it is inversely correlated with input at gamma frequencies with consequences for sensory perception and integration. Although loss of inhibition provides an appealing pathophysiological model to elaborate on diagnosis and therapy of delirium, current data require confirmation by prospective studies including standardized diagnostic criteria and behavioral tests. Additionally, source reconstruction and neurophysiological characterization of affected networks are required.

Title: Transient left spatial neglect as unique clinical expression of status epilepticus

Authors: *L. VERONELLI, S. BOVO, P. DE GIAMPAULIS, I. PASSARO, M. CORBO; Dept. of Neurorehabilitation Sci., Casa Di Cura Del Policlinico, Milano, Italy

Abstract: Unilateral spatial neglect (USN) is defined as a failure to report, respond, or orient to stimuli presented on the side of space contralateral to a cerebral lesion. It has been widely documented after brain damage to right fronto-temporo-parietal networks, and to lesser degree, to left ones. Seizures and status epilepticus causing USN syndromes are rarely diagnosed. We report the case of BG, a right-handed 76-year-old man, affected by hypertension and diabetes

without previous history of epilepsy, who was hospitalized for post-traumatic intracranial hemorrhagic lesions as a consequence of cardiogenic syncope, due to complete atrio-ventricular block. Anticonvulsant treatment was started as prophylaxis. To treat the atrio-ventricular conduction disease, the patient received definitive pacemaker implantation. At admission to our clinic three weeks after the traumatic event, the neurological examination was normal, excluding slight right hemiparesis. A brain computed tomography (CT) showed the presence of bilateral intraparenchymal hemorrhagic lesions, including right fronto-temporal areas, and a right parieto-occipital subdural hematoma. A comprehensive neuropsychological evaluation detected slight cognitive deficits affecting executive, memory and non-lateralized attentive functions, in absence of signs of USN. Three weeks later, BG presented with acute severe left USN, both clinically and formally assessed through a deep neuropsychological battery. In particular, he showed rightward line bisection error, a large number of left omissions on cancellation and drawing tasks, USN dyslexia, and personal USN. A control CT ruled out the possibility of a new brain lesion. The EEG showed abundant and subcontinous spikes and sharp-waves prevailing in the right temporo-parietal derivations, while the USN was the only clinical correlate (non-convulsive status epilepticus). After adaptation of the anticonvulsant treatment, EEG exams depicted a gradual resolution of the electrical abnormalities and the neuropsychological assessment confirmed the reduction of USN. In conclusion, transient USN was shown to be present as unique clinical expression of non-convulsive epilepsy and resolved after adequate anticonvulsant treatment. This observation provides further evidence that epileptic discharges, due to specific cerebral lesions, could selectively affect cognitive functions, even in terms of attention disorder as USN.

Abstract: This study examined the potential for novel tablet-based tasks, modeled after eye tracking tasks, to detect subtle sensorimotor and cognitive deficits after mild traumatic brain injury (mTBI). Specifically, we examined whether performance on these tablet-based tasks (Pro-point and Anti-point) was able to correctly categorize concussed versus non-concussed participants compared to performance on other standardized tests for concussion. Patients admitted to the emergency department with mTBI were tested on the Pro-point and Anti-point tasks, a current standard cognitive screening test, the Standard Assessment of Concussion (SAC), and another eye movement-based tablet test, the King-Devick® (KD). Within hours after injury, mTBI patients showed significant slowing in response times compared to both orthopedic and age-matched control groups in the Pro-point task, demonstrating deficits in sensorimotor function. mTBI patients also showed significant slowing compared to both control groups on the Anti-point task, even when controlling for sensorimotor slowing, indicating deficits in cognitive function. Performance on the SAC test revealed similar deficits of cognitive function in the mTBI group compared to the age-matched control group; however, the KD test showed no evidence of cognitive slowing in mTBI patients compared to either control group. Furthermore, measuring the sensitivity and specificity of these tasks to accurately predict mTBI with ROC analysis indicated that the novel pointing measures reached good to excellent levels of accuracy, and fared better than current standardized tools for assessment of concussion. Our findings suggest that these rapid tablet-based tasks are able to reliably detect and measure functional impairment in cognitive and sensorimotor control within hours after mTBI. These tasks may provide a more sensitive diagnostic measure for functional deficits that could prove key to earlier detection of concussion, evaluation of interventions, or even prediction of persistent symptoms.

Title: Effects of glottal source modulation on speech perception and production

Authors: *T. SALAZAR, J. BRUMBERG;
Univ. of Kansas, Lawrence, KS

Abstract: The ability to differentiate between self-generated sensory inputs and exogenous sensory stimuli is essential for accurately perceiving the world around us. One of the acoustic characteristics of speech, pitch, is the result of rapid vibration (fundamental frequency) of the vocal folds in the presence of airflow through the larynx during phonation. These vibrations also give rise to harmonic frequencies that provide the spectral basis for acoustic resonance and harmonic structure. Pitch, intensity and timbre (which includes harmonics) are important for separating self-generated speech from other external acoustic information. In auditory processing, the P300 auditory event related potential (ERP) can be evoked through an unexpected deviant associated with a shift/orientation in attention. The neural mechanisms of pitch and intensity perception have been extensively researched using ERPs, but the significance of higher frequency sound qualities such as timbre on speech perception have not been explored. In the present study, the harmonic structure of speech is systematically varied while maintaining equal fundamental frequency. Native English speakers with normal hearing are recorded using electroencephalography (EEG) while they engage in a target recognition task with five modulated glottal source conditions: natural voice, synthesized glottal source, sawtooth, square, whisper. We expect that the P300 ERP amplitudes will be more pronounced when the target stimulus is the natural voice or whisper due to their salience and predict that the synthesized, square and sawtooth conditions will elicit reduced P300 ERPs due to their similarities in sound quality. These results, combined with prior evidence in pitch perception, will provide a comprehensive characterization of the importance of source signal qualities on speech perception and production.

Title: First-pass neocortical processing of language takes only 30 msec: optimising eletrophysiological techniques for capturing transient early brain responses to words

Authors: *Y. Y. SHTYROV, M. LENZEN;
Aarhus Univ., Aarhus C, Denmark

Abstract: The nervous system has developed through evolution to ensure the timely processing of incoming information and appropriate reaction to external stimulation; the speed of this processing is vital for biological survival in the constantly changing and volatile environment. From low-level studies of structural and functional connectivity, it can be inferred that information arriving at the auditory sensory input can in theory be transferred, through a series of relay stations, to high-level associative cortices (including Wernicke and Broca's language areas) within 30-60 ms. Yet, it is commonly accepted in cognitive neuroscience that language, the vital messaging tool used by humans for information transfer, is not processed by the brain until hundreds of milliseconds after the signal arrives at the sensory input. Here, we show that this is a misconception caused, among other things, by the use of analysis techniques inappropriate for registering early transient responses generated by the human neocortex to spoken language. Whereas cognitive EEG and MEG evoked responses are usually analysed with a low-pass filter of 20-40 Hz, earlier brain responses tend to be in a much higher frequency range; for example, P1, the first marked cortical neurophysiological deflection caused by auditory stimuli, requires a high-pass filter of >10 and low-pass of >70 Hz to be reliably registered. To test the putative ultra-early linguistic activity, we recorded EEG responses to a set of meaningful words and acoustically and psycholinguistically matched meaningless word-like stimuli ('pseudowords'). We used the oddball lexical stimulation paradigm, an established experimental design known to elicit (in a later time range) robust EEG indices of neural access to linguistic memory traces (e.g. Shtyrov et al, 2010 J Neurosci). The data were then subjected to a P1-optimised analysis: bandpass-filtered at 10-100 Hz, with artifacts corrected using ICA. We found that all stimuli elicited P1 responses, which peaked on average just 30 ms after the stimulus recognition points and showed a significant amplitude increase for real words as opposed to matched pseudowords, a response enhancement which likely reflects activation of long-term memory circuits for meaningful words. The results suggest that the previously reported neurolexical effects at 100-500 ms reflect secondary and later processes, which are preceded by a first-pass lexical access that takes place in the neocortex already well within 50 ms and can only be captured with appropriate data analysis techniques.

Title: Using principle component analysis to investigate lesion correlates of naming errors post-stroke

Authors: *A. HALAI[1,2], A. WOOLLAMS[2], M. LAMBON RALPH[2];
[1]Dept. of Psychology, [2]Neurosci. and Aphasia Res. Unit, Univ. of Manchester, Manchester, United Kingdom

Abstract: Aphasia classification generally includes deficits in speech fluency (effortful or effortless speech), comprehension (verbal/non-verbal), repetition (word/pseudoword) and the types of errors made during these tasks. Two major classes of errors are routinely investigated; semantic errors relating to the meaning and phonological errors relating to sounds. Lesion mapping studies post-stroke have identified damage to left anterior temporal lobe (ATL) and precentral gyrus (preCG) results in increased semantic and phonological errors, respectively. However, such studies rarely investigate the whole range of naming errors and do not account for the multi-dimensional deficits observed in post-stroke aphasia, such as phonological, semantic and executive-demand impairments. We used a novel combination of principle component analysis (PCA) and voxel based correlation methodology (VBCM) to identify unique lesion sites for naming errors and general language impairments. We coded naming errors during two picture naming tasks (Boston Naming Test and Cambridge Naming Test), performed by 40 chronic left hemisphere stroke cases with aphasia. Errors were categorised into twelve types; semantic, phonemic, neologism, formal, mixed, initial phoneme, dysfluency, circumlocution, not a correct or incorrect, omission and other. Furthermore, we obtained detailed neuropsychological data which included receptive and expressive tests of phonology and semantics and measures of executive-demand. We confirmed previous results by identifying damage to ATL and preCG correlated with semantic and phonological errors. The PCA on a wide range of naming errors produced semantic and phonological error factors, but included three additional factors: 1) circumlocutions/other, 2) dysfluency, and 3) neologisms. Circumlocutions/other errors were correlated to damage to ATL, while dysfluency correlated with the insula. An omnibus PCA including all assessments produced 6 unique factors. Preserved phonological skill results in less phonological and neologism errors, however semantic skill was independent to semantic errors,

which loaded with speech variety. Semantic skill was related to ATL damage, while semantic errors were related to posterior temporal and inferior parietal damage. In addition, factors were identified for working phonological memory, speech quanta and executive-demand. The working phonological memory was related to middle and superior temporal gyrus damage, while speech quanta related with preCG and insula damage. In conclusion, PCA and VBCM can be used in conjunction to investigate the neural substrates of large-scale behavioural data.

Title: Behavioral and neural indices predict different aspects of language learning ability

Authors: ***A. S. FINN**, J. MINAS, S. S. GHOSH, M. LUESSI, C. GOETZ, J. D. E. GABRIELI; MIT, Cambridge, MA

Abstract: We asked whether brain measures improve, above and beyond behavioral measures, the identification of adults who excel in language learning. An additional goal was to understand more precisely which behavioral and neural characteristics were most predictive of learning success, either independently or in combination. 42 native English speakers were taught a novel miniature artificial language in the lab. Prior to learning, participants completed a large battery of cognitive and aptitude measures and completed an fMRI scan while performing three separate tasks and during rest. The artificial language (MAL) was learned somewhat naturalistically over the course of 4 days; participants observed 360 narrated scenes on a computer and repeated the narrations while trying to learn the language, which was comprised of 30 nouns, 4 verbs, 2 determiners, followed subject-object-verb word order, and had regular determiner-word pairings and subject-verb agreement. After each learning session, participants were tested for knowledge of all aspects of the language. Tasks during scanning measured neural recruitment during working memory, skill learning and language processing. Data show that behavioral measures are quite successful at predicting which learners will fall above or below median performance on the measures of grammatical learning, but not successful in predicting which learners will fall above or below median performance on a measure of semantic processing (the meaning and

content of the language). The opposite was true of the brain data, which predicted semantic processing but not grammatical learning. Thus, brain measures can enhance the identification of adult language learners who are more likely to succeed in processing the semantics of a newly learned language. This experiment also provides insight on which behavioral and neural characteristics are most predictive. For behavior, extant aptitude tests, IQ tests, working memory and open-loop (feedback based) forms of skill learning were predictive. Neural regions that were especially sensitive to working memory and sequence learning during scanning were also most strongly related to learning outcomes. In all, this experiment provides the first demonstration that brain measure can help identify successful learning and contributes to our understanding about which aspects of cognitive and neural architecture contribute to learning success.

Title: Interaction of working memory, modality & sentence comprehension in Broca's area: an fMRI study

Authors: ***Y. YI**[1], A. DIAZ[1], C. HOULIHAN[1], L. C. BAXTER[2], G. HICKOK[3], C. ROGALSKY[1];
[1]Speech and Hearing Sci., Arizona State Univ., Tempe, AZ; [2]Barrow Neurolog. Inst. & St. Joseph's Hosp. and Med. Ctr., Phoenix, AZ; [3]Cognitive Sci., Univ. of California, Irvine, Irvine, CA

Abstract: Broca's area is a functionally and anatomically diverse region. The contributions of Broca's area to language comprehension, and sentence processing in particular, remain highly debated. There is however overwhelming evidence that inferior frontal regions are activated during the maintenance and manipulation of verbal information. The present study addresses the possible role of inferior frontal working memory resources in sentence comprehension and how reading versus listening to sentences may engage these regions differently. In a sparse sampling fMRI paradigm, 17 native English speaking, right-handed participants were presented sentences

with either canonical or noncanonical structure in two ways: auditorily (listening via headphones) and visually (reading the sentences with one word presented at a time). The canonical sentences were subject-relative (SR) sentences and the noncanonical sentences were object-relative (OR) sentences. In addition, participants performed a working memory task, with each block consisting of listening to three non-words and then rehearsing the non-words covertly for 10 seconds. Multiple regression analyses were used to identify brain regions modulated by sentence modality and sentence type. We then examined the response properties of these regions during the working memory task. Significant main effects and interactions for modality and sentence type were identified in Broca's area. For both reading and listening, both sentence types elicited activation in a large fronto-temporo-parietal network, including Broca's area. As expected, significantly greater activation for listening than reading was found in bilateral superior and middle temporal gyri, while reading elicited more occipital lobe activation. Notably, reading sentences also elicited more activation than listening to sentences in left inferior frontal (~BA 44) and middle frontal regions. The comparison of OR > SR in the listening condition did not identify any inferior frontal regions at the group level, but in the reading condition the OR > SR contrast identified a left inferior frontal cluster (~BA 45). The left IFG region identified by the visual OR> SR contrast exhibited sustained activation during the working memory task's rehearsal period. The inferior frontal regions more activated by reading than listening also exhibited sustained activation during rehearsal. These preliminary findings suggest that Broca's area is more sensitive to sentence structure in visual than auditory presentation, and the regions of Broca's area that are sensitive to sentence structure are also recruited during articulatory rehearsal.

Title: Frontal lobe language pathways

Authors: *A. A. BOHSALI[1], J. GULLETT[2], T. MARECI[2], D. FITZGERALD[2], B. CROSSON[4], K. WHITE[2], S. NADEAU[3];

[1]Univ. of Florida, Veterans Affairs Res. Rehabil. & Develop., Ocala, FL; [3]Neurol., [2]Univ. of Florida, Gainesville, FL; [4]Emory Univ., Atlanta, GA

Abstract: The present study investigated structural connectivity of Broca's region, a ventral lateral prefrontal cortical area consisting of pars orbitalis (pOrb), pars triangularis (pT), pars opercularis (pO), and inferior precentral gyrus (infPCG) (Hagoort, 2005). To investigate this connectivity we collected structural MRI data (T1 and diffusion weighted images) from 18 right-handed healthy volunteers (8M, mean age=26.5 y.o). T1-weighted scans were used to delineate cortical regions of interest using an automated cortical parcellation procedure in FreeSurfer. This procedure was used to create six regions of interest: pOrb, pT, pO, infPCG, middle frontal gyrus (MFG), and superior frontal gyrus (SFG). White matter pathways connecting these regions were inferred using the Mixture of Wischarts method distributions (Jian & Vemuri, 2007a, 2007b) implemented in an in-house software package written in IDL. We inferred a total of twelve pathways connecting ventral prefrontal cortical areas with MFG and SFG: pO/pT/pOrb/infPCG_SFG pathways (4 pathways), pO/pT/pOrb/infPCG_MFG pathways (4 pathways), pO/pT/pOrb/infPCG -SFG+MFG pathways (4 pathways). After delineating these pathways in each participant individually, we created population maps for each of the pathways by registering them to the common template, MNI152. These population maps were used to examine the amount of spatial overlap across participants. Our results (Figures 1 and 2) showed an anterior to posterior connectivity gradient, where the most anterior aspects of Broca's region (pOrb and pT) project to anterior and middle portions of MFG and SFG, while more posterior Broca's region (pO and infPCG) connected with middle and posterior MFG and SFG. The population maps of these pathways showed a considerable amount of spatial agreement across participants (brighter colors, Figure 2), especially for pO and infPCG pathways. Our results also showed that pO shares the most extensive and robust connectivity with MFG and SFG compared to other areas within Broca's region (p-value<0.001). Taken together, these findings suggest that the cortical areas comprising the anterior to posterior extent of Broca's region are linked to the entirety of frontal convexity cortex by corresponding anterior to posterior arrays of overlapping white matter connections. Moreover, pO appears to be the most extensively connected portion of Broca's region, which may allow it to play a particularly important role in language processing. Our results provide further support for the concept that neural representations are population encoded and they suggest that most of frontal convexity cortex contributes to language function.

Title: The influence of age of acquisition in bilingual reading

Authors: *M. OLIVER[1], M. CARREIRAS[1,2], P. PAZ-ALONSO[1];
[1]Basque Ctr. On Cognition, Brain and Language, SAN SEBASTIAN, Spain; [2]IKERBASQUE, Basque Fndn. for Sci., Bilbao, Spain

Abstract: Neuroimaging evidence has suggested the involvement of left lateralized ventral and dorsal networks in reading. Nevertheless, it is still under debate to what extent different factors can modulate the engagement of key regions within these routes, such as the ventral occipito-temporal cortex (vOT), inferior frontal gyrus (IFG) and superior temporal gyrus (STG). Theoretical accounts suggest that the left vOT is mostly involved in pre-lexical computation of visual word forms, while others consider that it is also involved in integrating visuospatial features with higher-level associations. The present fMRI study sought to investigate the functional dynamics of these networks, as a function of the age of acquisition of their second language or L2 (early, late), language used to read (L1, L2), task demands (perceptual, semantic) and stimuli (word, pseudoword, consonant strings). Thirty-six bilinguals with Spanish as their L1, who learned Basque as their L2, before age 3 (early bilinguals) or after age 6 (late bilinguals), participated. In the scanner, they performed two separate tasks during which they were asked to press a button when they saw a colored letter within a given string (perceptual-task) or when they saw an animal word (semantic-task). Region of interest analyses revealed that the vOT showed stronger activation for words in the L2 versus L1 and in the semantic versus perceptual task. Within the IFG, late bilinguals exhibited stronger pars triangularis activation during word reading in the semantic, versus the perceptual task, across languages relative to early bilinguals, who show this same effect in their L2 but not in their L1. In contrast, pars opercularis showed higher activation for pseudowords than words in the L1, but a stronger activation in the L2 similar across words and pseudowords. The same profile was present in the STG. Functional connectivity analysis revealed that, compared to late bilinguals, early bilinguals exhibited tighter coactivation among ventral regions during word reading in the semantic task, suggesting a more specialized recruitment of this network for semantic processing in this group across languages. Our results suggest that, whereas ventral pathway regions (vOT, pars triangularis) were more strongly recruited for semantic-related processes, regions within the

dorsal pathway (STG, pars opercularis) showed a more phonological pattern of activation. Importantly, functional connectivity analysis indicated that coupling between regions within the ventral network are modulated by task demands and age-of-acquisition of the L2.

Title: Bilingual cortical control of between- and within- language competition

Authors: ***J. BARTOLOTTI**, S. CHABAL, V. MARIAN;
Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstract: Spoken language unfolds gradually over time. As a result, words with similar onsets receive partial activation (e.g., clock activates the phonologically-similar word cloud) and compete for selection during comprehension. In bilingual speakers, this competition can also emerge across languages (e.g., the English word clock activates the Spanish word clavo, meaning nail). Controlling cross-linguistic competition may be more effortful than resolving competition from within a single language, because the cross-linguistic competitor can raise the global activation level of the non-target language, providing an additional level of interference. The current study examined cortical responses to within- and between-language competition in bilinguals to determine how the two types of linguistic interference are controlled. Sixteen highly-proficient Spanish-English bilinguals completed a word recognition task in an fMRI scanner. In each trial, participants heard a spoken English or Spanish word and identified its matching picture in a four-object display using a four-choice handheld button box. In competitor trials, the name of another picture phonologically overlapped with the target, either in the same language (within-language competition) or in the non-target language (between-language competition). In unrelated trials, competitor pictures were replaced by pictures with non-overlapping names in either language. The effect of competition in each condition was assessed

by creating contrast images between Competitor and Unrelated trials. We then analyzed the effect of competition Type (Between-, Within- language) on the Competitor vs Unrelated contrasts (collapsed across languages). In bilateral middle frontal gyrus (MFG), superior frontal gyrus (SFG), and inferior frontal gyrus (IFG), we found greater activation when competition occurred across the bilinguals' two languages compared to when it occurred within the same language. This finding suggests that between-language competition is processed differently than competition within a language and requires more frontal resources to resolve. Greater activation for between- vs within-language competition in right MFG and SFG was also correlated with participants' performance in an offline test of non-linguistic inhibitory control ability (Simon task), suggesting an overlapping mechanism for bilinguals' control of linguistic and non-linguistic interference. These results suggest that bilinguals recruit cognitive resources differently depending on the source of interference, providing insight into how multiple languages interact during spoken language processing.

Title: Dynamics of brain networks during word reading

Authors: ***M. WHALEY**[1], C. KADIPASAOGLU[2], S. COX[1], N. TANDON[2];
[1]Rice Univ., Houston, TX; [2]UT Med. Sch., Houston, TX

Abstract: We recorded electrocorticographic (ECoG) data from 15 patients with intractable epilepsy during a word completion task to precisely describe the spatiotemporal brain dynamics underlying word reading. Using a novel technique of analyzing grouped ECoG, cortical regions distributed throughout the left hemisphere were identified as significantly active versus baseline during our word stem completion task. Activity spread from fusiform to frontal regions, including pars opercularis, pars triangularis, and pre, post, and subcentral gyri during the time period approaching articulation onset (see figure). The ECoG data recorded from electrodes within these regions were fit into linear multivariate autoregressive models (MVAR), which precisely reveal the time, frequency, and magnitude of information flow between localized brain

regions. Grouped network dynamics were quantified by evaluating statistical significance of poststimulus interactions compared to baseline. Results reveal bidirectional exchanges between frontal regions with fusiform, supporting theories that incorporate top-down and bottom-up processing during single word reading. To our knowledge, this is the first application of MVAR for studying grouped connectivity of an ECoG dataset.

Title: How language shapes the brain: cross-linguistic differences in structural connectivity

Authors: ***T. GOUCHA**[1,2], A. ANWANDER[1], J. D. GRIFFITHS[3], L. K. TYLER[4], A. D. FRIEDERICI[1,2];
[1]Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Berlin Sch. of Mind and Brain, Berlin, Germany; [3]Rotman Res. Inst., Toronto, ON, Canada; [4]Ctr. for Speech, Language and the Brain, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Language contributes to the architecture of the human brain. Whereas some of the perisylvian white matter pathways seem to be hard wired, other develop in parallel with language acquisition. However, studies on language-related neuroplasticity have focused on developmental aspects that are transversal to all languages, ignoring possible language

differences. For example, languages like German require online processing of abstract structural information (morphosyntax), anatomically supported by the dorsal arcuate fascicle, whereas languages like English more strongly engage lexical-semantic processing, which involves predominantly ventral fibre tracts. We therefore investigated how languages with different processing demands shape the language network. We compared diffusion MRI scans for three age, sex and education-matched groups with three different native languages: German, English and Mandarin Chinese. Anatomical regions of interest (ROIs) were defined in a template generated for this subject group, both in the inferior frontal gyrus and in the anterior and posterior superior and middle temporal gyri. Using probabilistic fibre tracking, we computed anterior-posterior, fronto-temporal and whole-brain connectivity of these ROIs and compared the respective connectivity strengths and maps of connection probability. We found higher dorsal fronto-temporal connectivity in the German group than in both the English and Chinese groups. Conversely, the English group showed higher ventral connectivity between the posterior temporal cortex and anterior frontal regions. In turn, the medium and short-range connectivity to the neighbouring temporal cortex and to the inferior parietal lobe was higher in Chinese speakers. These differences in connectivity indeed reflect the particular demands of the native language of the individuals as hypothesised. This study is a first indication that the wiring of language-relevant areas depends on the specific demands of each language. Further studies taking into account the genetic background and functional connectivity are needed to understand the implications of the study.

Title: Longitudinal decline in speech in primary progressive aphasia

Authors: *S. ASH, C. YORK, T. BISBING, K. COHEN, F. MIN, E. MORAN, R. WILLIAMS, M. GROSSMAN;
Neurol, Univ. Pennsylvania Sch. Med., Philadelphia, PA

Abstract: Objective: To identify features of spontaneous speech for which progressive impairment is specific to distinct aphasic conditions Methods: We studied 31 patients, including 7 with nonfluent agrammatic primary progressive aphasia (naPPA), 12 with semantic variant PPA (svPPA), and 12 with non-aphasic behavioral variant frontotemporal dementia (bvFTD), and 20 age- and education-matched controls. All patients completed the task of describing the Cookie Theft picture from the BDAE (Goodglass & Kaplan, 1972) at least twice with an interval of at least 9 months. The Cookie Theft descriptions were recorded, transcribed, and analyzed for fluency, grammaticality, syntax, and adequacy of the report of content. Average disease duration at the time of the first recording was approximately 3 years. Results: naPPA patients were impaired relative to controls on all measures at the time of the first Cookie Theft recording. svPPA patients were impaired on measures of fluency, but not on grammaticality or the report of content. bvFTD patients exhibited reduced speech rate and impaired report of content but were not impaired on grammaticality. Patients in all groups were more impaired relative to controls at the time of retest (T2) than they were the first time they performed the task (T1). However, they differed on the performance measures for which they declined relative to their own performance at T1. naPPA patients declined significantly on measures of fluency (speech sound errors and speech rate), but not grammatical complexity. svPPA patients declined in the proportion of grammatically correct sentences they produced. Non-aphasic bvFTD patients declined on speech rate and measures of syntactic complexity. All three groups declined in the adequacy of their reports of the content of the Cookie Theft scene. Conclusions: Significant declines occur in spontaneous speech in both aphasic and nonaphasic patients with neurodegenerative disease. The areas in which the decline is most prominent are distinct in different patient groups. However, in all groups, the progression of disease reduces the patient's ability to perceive and describe the content of the Cookie Theft scene, thus progressively impeding communication at the global level.

Title: Microstructural white matter differences between 6-year old readers and pre-readers

Authors: J. N. ADAMS[1], V. N. KOVACHY[1], K. E. TRAVIS[1], M. BEN-SHACHAR[3], *H. M. FELDMAN[2];
[1]Pediatrics-Neonatology, Stanford Univ., Stanford, CA; [2]Stanford Univ., Palo Alto, CA; [3]English Literature and Linguistics, Bar-Ilan Univ., Ramat Gan, Israel

Abstract: Background: Recent studies reported white matter microstructural differences between individuals who learned to read as adults and those who remained illiterate. Reading is typically learned during early childhood when brain plasticity is pronounced. We set out to examine whether the ability to read in children is associated with differences in white matter microstructure. We hypothesized that compared to peers who had not yet learned to read, 6-year old readers would demonstrate differences in white matter properties within tracts implicated in decoding. **Methods:** We conducted diffusion MRI (dMRI) scans and behavioral tests of intelligence, expressive language, phonological awareness (PA) and reading skills in 33 children (mean age=6.2 years, 10 males). Readers (n=22) were defined as those with a standard score greater than the group mean (>110) on pseudoword reading. Children who read ≤1 word on the same task were defined as pre-readers (n=11). 30-direction dMRI and high resolution T1-weighted data were obtained on a 3T scanner. Six bilateral white matter tracts were identified using deterministic tractography: anterior Superior Longitudinal Fasciculus (aSLF), Inferior Longitudinal Fasciculus (ILF), Arcuate Fasciculus (Arc), Forceps Major (FMajor), Corticospinal tract (CST) and Uncinate Fasciculus (UF). We quantified fractional anisotropy (FA) values along the trajectory of each tract. Group differences in behavioral tests and tract FA were examined with independent samples t-tests. **Results:** Readers and pre-readers did not differ significantly on the basis of socioeconomic status, sex, second language exposure, stage in school, or non-verbal IQ. Readers performed significantly higher on tests of expressive language, PA, and verbal IQ ($p<0.05$). Readers demonstrated significantly higher FA than pre-readers within segments of the left ILF, left aSLF, FMajor, and right UF ($p<0.05$) and significantly lower FA than pre-readers within segments of the right Arc and left and right CST ($p<0.05$). Group differences observed within the left aSLF and right UF remained significant after correcting for multiple comparisons ($p<0.05$, corrected). **Conclusions:** 6-year old readers had both significantly higher and lower FA than pre-readers in several white matter tracts implicated in reading processes. Such group differences may reflect inherent differences in white matter microstructure or variability in

experiences with learning to read. Future longitudinal analyses in this sample will examine whether individual variations in FA observed during the early stages of learning to read are predictive of later reading abilities.

Title: Atypical visuospatial attentional orienting in dysfluent readers during classifying nonword stimuli

Authors: *O. H. LOBERG[1], J. HAUTALA[2], J. HAMALAINEN[1], P. H. T. LEPPANEN[1]; [1]Dept. of Psychology, [2]Agora Ctr., Univ. of Jyvaskyla, University of Jyvaskyla, Finland

Abstract: Recent research on eye-movements has implicated that Dysfluent readers have impaired attentional shift during lexical decision task (Hautala & Parviainen 2014). In modified version of the experiment, we presented to Fluent (N=15) and Dysfluent (N=9) adult readers words, nonwords, lines of symbols and gray rectangle while we registered eye-movements with eye-tracker and brain activation with brain event-related potentials (ERP). Participants were instructed to decide whether the stimulus on the screen was a word or not with a button press. Nonwords were generated by replacing the second or fifth letter within a six lettered word with a rare letter to cause violation to Finnish orthography. In this study we focus on the effects resulting from difference in spatial placement of this orthographical violation within a normal word and how Dysfluent readers differ from Fluent readers. Reaction times to nonwords with orthography violations in the end of the words were later in both groups and that the reaction times of Dysfluent readers were delayed for both stimulus types. Analysis of the first microsaccades(MS) during these stimuli revealed that the first MS tended to be oriented towards the violation, but that Dysfluent readers launched the first MS away from the violation in the word end to the left more often. Analysis of the ERP-components prior to the first MS onset revealed differences between the groups in anterior positive response at 180-240 ms (P2 at electrodes F3-F4) and posterior negative response at 190-240 ms (N2 at electrodes P7-P8). Fluent readers had larger anterior P2 amplitude for the violation in the beginning than for the one in the end of words but for Dysfluent readers this pattern was the opposite. The pattern for the

posterior N2 was very similar in Fluent readers showing stronger response for violation in the beginning, while Dysfluent readers showed again an opposite pattern. These results suggest that Dysfluent readers orient their attention differently to the beginnings and ends of words compared to Fluent readers as both anterior P2 and posterior N2 are linked to feature based attention in the earlier research. The results implicate that attention during word recognition is distributed differentially in Dysfluent readers which leads to atypical critical feature detection during word recognition, which in turn could lead to faulty orienting of microsaccades.

Title: Auditory-motor mapping and phonological processing in the left dorsal speech stream

Authors: *T. MURAKAMI[1,2], C. KELL[2], J. RESTLE[2], Y. UGAWA[1], U. ZIEMANN[3,2];
[1]Fukushima Med. Univ., Fukushima, Japan; [2]Goethe-University, Frankfurt am Main, Germany; [3]Eberhard-Karls-University, Tuebingen, Germany

Abstract: Introduction: Speech models propose an auditory-motor mapping via a left-hemispheric speech-processing stream, yet its detailed contributions to speech perception and production are unclear. Using fMRI-navigated continuous transcranial magnetic theta burst stimulation (cTBS), we virtually lesioned left speech stream components to investigate the issue of their functional contribution of speech processing. **Methods**: In total, 24 healthy right-handed native German subjects participated in this study. Inhibitory cTBS was applied over the posterior superior temporal sulcus (pSTS), the sylvian parieto-temporal region (SPT), pars opercularis of the inferior frontal gyrus (pIFG) and the dorsal premotor cortex (dPMC) consisting of the dorsal stream, and over the anterior superior temporal gyrus (aSTG) of the ventral stream, and an occipital control site. We measured speech-related facilitation of articulatory motor cortex (M1)

excitability, as indexed by increases in motor evoked potential (MEP) amplitude of a lip muscle, and performed speech processing performance tests. **Results**: Speech-related MEP facilitation was disrupted by cTBS of pSTS, SPT, and by double-knockout but not individual lesioning of pIFG and dPMC, and not by cTBS of aSTG or an occipital control site. Virtual lesions of the dorsal stream but not of the ventral stream or the occipital control site increased phonological errors. Disruption of aSTG led to enhancement of semantic errors but not of the dorsal stream or an occipital control site. Performance of syllable and pseudoword repetition correlated with speech-related MEP facilitation, and this relation was abolished with cTBS of pSTS, SPT and pIFG. **Conclusion**: Findings provide direct evidence that auditory-motor mapping in the left dorsal stream causes reliable and specific speech-related MEP facilitation in left articulatory M1. The left dorsal stream targets the articulatory M1 through pSTS and SPT constituting essential posterior input regions and parallel via frontal pathways through pIFG and dPMC, while the ventral stream mainly engages in semantic processing.

Title: Expectation effects in syntactic processing - evidence from ambiguous sentence structures

Authors: *L. KROCZEK, T. C. GUNTER;
Neuropsychology, Max Planck Inst. CBS, Leipzig, Germany

Abstract: Sentence comprehension is a rapid process that takes place within milliseconds after a linguistic input is presented. Generally, it has been hypothesized that the brain enables such efficiency by means of predictive processing. In language comprehension, expectation effects have been demonstrated mainly for the semantic domain. However, processing the syntactic structure of a sentence ("who is doing what to whom") is a crucial part in sentence comprehension. Accordingly, top-down expectations could also play an important role with regards to syntactic structure processing. In the current EEG study a speaker's voice (male, female) was coupled to the expectancy for a particular syntactic structure. Thus, one speaker produced complex Object-Subject-Verb (OSV) sentences with a higher probability than easy Subject-Object-Verb (SOV) sentences (the O-speaker) and vice versa for the other speaker (the

S-speaker). Importantly, experimental sentences were ambiguous towards their syntactic structure up to the sentence final word. We hypothesized that speaker information would make the disambiguation easier. Preliminary analysis showed that participants were sensitive to a particular speaker identity as demonstrated by an increased positivity for the O-speaker compared to the S-speaker that was elicited at a time-point before the actual syntactic structure was disambiguated. ERPs time-locked to the disambiguating final word showed a main effect of structure, with complex OSV structures having a more positive waveform than easy SOV structures. Additionally, the probability of a structure also had an effect approximately 200 ms later in time. Sentences with a congruent speaker-structure pairing (S-speaker/SOV and O-speaker/OSV) showed a greater positivity than sentences with an incongruent speaker-structure pairing (S-speaker/OSV and O-speaker/OSV). These findings suggest that although the participants coupled the probability for a particular sentence structure to a particular speaker, this had no beneficial effect for syntax processing per se. Probably the ambiguity of the sentences led to these results.

Title: Processing meaningful and meaningless verbal material in different languages

Authors: *N. PLAKHOTNYK, S. TUKAIEV, I. ZYMA;
Educational and Scientific Ctr. “Institute of Biology”, Natl. Taras Shevchenko Univ. of Kyiv, Kiev, Ukraine

Abstract: The study of the emotional component of the perception of verbal information in human remains a considerable question as well as identification of possible universal and language-specific EEG characteristics. The purpose of this study was to evaluate phychophysiological changes during the exposure to information in different languages. We recorded EEG activity in 24 subjects, exposed to series of poetic passages in English and Ukrainian languages. The experimental material consisted of W.Shakespeare’s sonnets and L.Carrol’s Jabberwocky poem, which allowed to study phonological aspect of language regardless of lexical aspect as the poem consists mostly of pseudowords. After EEG registration, subjects were asked to evaluate each fragment on the scales "relaxing/activating" and

"distracting/concentrating". We analyzed spectral power (SP) of EEG during rest state and while listening to the poetry. α-rhythm's SP increased in parietal areas and decrease in θ-range while listening to meaningless and meaningful poetry in English and meaningless stimuli in Ukrainian language. This could be related to complexity of the verbal stimulus. β-rhythm's SP increased in the left temporal areas while listening to the meaningless Ukrainian and both English stimuli, which can be explained by the activation of language centers. The increase of β-rhythm's SP in the right hemisphere in response to the meaningful Ukrainian stimulus is consistent with the concept of linguistic stereotype formation that requires relatively fewer brain resources. In the subjects rating meaningful poetic passages as "activating", we observed a statistically significant higher θ and α SP, as compared to those rating the poetic passages as "relaxing". In the case of meaningless poetic passages, the SP of α and θ rhythms was higher in the group evaluating the poetic passages as "relaxing". This study proves that the perception of verbal information depends on the human emotional response, reflected upon the changes in the psychophysiological state of subjects.

Title: Testing for transfer: does lexical training improve performance in a related but non-linguistic task?

Authors: S. VAN HEES, P. M. PEXMAN, I. S. HARGREAVES, L. ZDRAZILOVA, K. MYERS-STEWART, F. CORTESE, *A. B. PROTZNER;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Recently, the issue of whether task-specific training improves performance beyond the trained task has gained attention, likely due to the increasing popularity of brain training programs that claim to improve general cognitive function. However, studies investigating the validity of these claims suggest null or limited effects. It is possible that the lack of effects is a

consequence of the relatively small amount of time spent in training (days or weeks). We investigated training-related transfer in competitive Scrabble players, who dedicate years to training of Scrabble-related lexical skills and have shown enhanced performance in the lexical decision task. To test for transfer we developed a symbol-matching task, in which the letter strings of the lexical decision task were replaced with either a string of all unique non-letter symbols, or a string that included one non-letter symbol presented twice. Strings were presented in horizontal and vertical orientations, and yes/no decisions were required as to whether the string contained a pair of matching symbols. We collected behavioural and fMRI data from 12 Scrabble experts and 12 age matched controls. In terms of behaviour, we analyzed response times with a 2 (group) x 2 (orientation) ANOVA. We found no evidence of behavioural transfer, as Scrabble experts were no faster than controls at correctly identifying match/nomatch trials in either orientation. In terms of brain data, we used behavioural Partial Least Squares (PLS) analysis to examine group dependent differences in the neural networks that support symbol matching, and are associated with Scrabble skill. We used anagramming scores as our index of Scrabble skill, as these scores were correlated with official rankings among the Scrabble experts, and available for both Scrabble and control participants. We identified a common network across groups that correlated with anagramming scores, and included the left middle temporal gyrus and superior medial gyrus, as well as the right precentral gyrus and temporal pole. We also found group differences. Controls primarily engaged left hemisphere language regions (including the inferior frontal, middle temporal, and fusiform gyri) and right hemisphere homologues. In contrast, Scrabble experts engaged regions associated with visuo-spatial imagery, manipulation of information in working memory, and decision-making (including the precuneus, superior parietal lobule, and insula). Overall, the results suggest only domain-specific performance advantages for Scrabble experts, and the brain data have implications for understanding effects of cognitive training and neuro-rehabilitation.

Title: Can you see what I mean? Perceptual and conceptual semantics during words reading

Authors: *V. BORGHESANI[1,2,3], E. EGER[1], M. BUIATTI[3], M. PIAZZA[3];
[1]INSERM-CEA Cognitive Neuroimaging Unit, Gif-sur-Yvette, France; [2]École Doctorale Cerveau-Cognition-Comportement, Univ. Pierre et Marie Curie - Paris 6, Paris, France; [3]Ctr. for Mind/Brain Sci., Univ. of Trento, Rovereto, Italy

Abstract: One of the greatest intellectual abilities of the human kind is that of manipulating symbols by retrieving from long term memory the semantic representation that define what they stand for. Such semantic representations include both perceptual (i.e. prototypical size, shape) and conceptual (i.e. taxonomic category) properties. Do these different components of words meaning dissociate in the brain? Two competing cognitive theories support different predictions: the embodied cognition theory predicts that word meaning is resolved by the reactivation of perceptuosemantic properties are stored in primary sensory-motor cortices (Pulvermuller, 2013), while the abstract cognition theory predicts that word meaning is encoded in abstract format and represented in amodal cortices (Patterson et al., 2007). Behavioral, clinical, computational and neuroimaging investigations have provided indirect support to both theories, thus so far no conclusive results has been shown. To put to test the two theories, we acquired high resolution 3T fMRI images of adult subjects silently reading words referring to concrete entities. Words varied parametrically along four orthogonal dimensions: a purely physical dimension (i.e., the number of letters), a visuo-perceptual dimension (i.e., the average real-world size of the objects the words referred to), an audio-perceptual dimension (i.e., the strength of the association with a prototypical sound) and, finally, a conceptual dimension (i.e., the semantic category and the semantic cluster as derived from subjects' similarity ratings). By means of multivariate pattern analysis (Davis and Poldrack, 2013), we have isolated the contribution of the different dimensions of word meanings to the pattern of activation observed in different brain regions. We found that the visuo-perceptual dimension appears to be encoded in primary and secondary visual regions, while the audio-perceptual dimension in secondary auditory regions. This is in agreement with the embodied theory of cognition and can be hardly accommodated in a purely abstract theory of word meaning. However, conceptual dimensions such as the category or sub-categorical cluster appear to be encoded in anterior temporal regions, in agreement with the abstract theory of cognition, a result that cannot be explained by a purely embodied theory of word meaning. Thus, these findings reconcile contrasting theories of semantic representations as they indicate that both sensory and multimodal association areas play an important role by coding for specific and complementary dimensions of the semantic space.

Title: Electrophysiological investigation of cross-language translation and morphological priming in different scripts

Authors: *W. CHUNG[1], S. KIM[2], M. PARK[1];
[1]Dongguk Univ., Seoul, Korea, Republic of; [2]Nanyang Technological Univ., Singapore, Singapore

Abstract: The Revised Hierarchical Model (Kroll & Stewart, 1994) assumes asymmetric lexical links between first language (L1) and second language (L2) (i.e., stronger links from L2 to L1 than those from L1 to L2). Previous behavioral studies supported the model showing significant masked priming effects when the target was L2 and the prime was L1, but not when the prime was L2 and the target was L1 (e.g., Jiang, 1999). However, recent ERP studies provided controversial evidence for either supporting (e.g., Hoshino et al., 2010) or countering (e.g., Midgley et al., 2009) the model. In addition, a previous study showed that cross-language morphological priming effect was found exclusively for cognate words in Spanish-English bilinguals (Duñabeitia et al., 2013). The current study examined if the pattern of cross-language translation priming is consistent with the asymmetric links between L1 and L2 and if it occurs via morphological decomposition, using event-related potentials (ERPs) and a masked priming lexical decision paradigm with unbalanced Korean-English bilinguals. In Experiment 1, targets were Korean (L1) compound word (e.g., 꿀벌, ″kkwupel,″ *honeybee*), and primes were English (L2) words, either 1) translated whole word (honeybee), 2) translated morphemic constituent (bee), or 3) an unrelated word (e.g., ear). Experiment 2 was the same as Experiment 1, except that the targets were in English (L2) and the primes were in Korean (L1). In behavioral results, the translation priming effect and the morphological priming effect were significant only for L1-L2 (Experiment 2), but not for L2-L1 (Experiment 1). In ERP results, the translation priming effect was found only for L1-L2 on the N150, N250, and reduced N400. The morphological priming effect was found both for L1-L2 and L2-L1 on the reduced N400. Taken together, the results suggest that both cross-language translation priming and morphological priming occurs even between different scripts (between noncognate words), and the effects are stronger when L1 primed L2 as compared to when L2 primed L1. In addition, different time-course between translation priming and morphological priming suggests that cross-language morphological decomposition occurs after translation in bilingual readers.

Title: Cognitive and anatomic double dissociation in the representation of concrete and abstract words

Authors: *K. A. COUSINS[1], M. GROSSMAN[2];
[1]Neurol., [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Here we examine the anatomic basis for representation of abstract and concrete concepts in semantic memory by assessing patients with focal neurodegenerative disease. Evidence from functional imaging studies in controls suggests that there may be an anatomical dissociation between abstract and concrete representations: abstract words more strongly activate left inferior frontal gyrus relative to concrete words, while concrete words more strongly activate left temporal regions than abstract words. We test this dissociation with two patient groups with atrophy specific to these regions, the behavioral variant of Frontotemporal Dementia (bvFTD) and the semantic variant of Primary Progressive Aphasia (svPPA). We administered an associativity judgment task for abstract and concrete words, where subjects select which of two words is best associated with a given target word. Both bvFTD and svPPA patients were significantly impaired for all words compared to controls. Further, controls treated concrete and abstract words equally, but we found a category-specific double dissociation in patients: svPPA patients showed reversal of the concreteness effect (CE), with significantly worse performance for concrete over abstract words, while bvFTD patients showed significantly worse performance for abstract compared to concrete words. We regressed the magnitude of the reversal of CE in svPPA and the CE in bvFTD, with regions of grey matter atrophy. Results demonstrated that reversal of CE is associated with left inferior temporal atrophy in svPPA, while the CE is associated with left inferior frontal atrophy in bvFTD. These results support a model of semantic

memory organization where abstract and concrete words representations are supported by partially dissociable neuroanatomic substrates.

Title: Functional network dynamics of the language system

Authors: *L. CHAI[1], M. MATTAR[2], I. BLANK[3], E. FEDORENKO[4], D. S. BASSETT[1]; [1]Dept. of Bioengineering, [2]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [4]Dept. of Psychiatry, Massachusetts Gen. Hosp., Boston, MA

Abstract: Functional Network Dynamics of the Language System Lucy Chai, Marcelo G. Mattar, Idan Asher Blank, Evelina Fedorenko, Danielle S. Bassett Key brain regions involved in processing language show gross similarity in functional responses to task paradigms and in activity profiles at rest. Conversely, they also display fine-scale dissimilarities that may underpin functional differentiation. However, a cohesive understanding of these functional similarities and dissimilarities has been hampered by the lack of quantitative assessment methods to track the dynamics of cognitive circuits during language processing. In recent promising advances, dynamic network methods have been used to divide large-scale networks into core and periphery regions, with the core regions displaying stable connectivity over time and the periphery regions displaying variable connectivity over time. Here, we apply these methods to the language network to test for the existence of the core-periphery structure and characterize it quantitatively if it is present. We define language-specific regions within healthy human subjects using a

functional localizer, and extract regional BOLD time series from functional magnetic resonance imaging (fMRI) data collected during two different language processing tasks: story comprehension and word/number judgment. We construct dynamic functional networks by computing the time-dependent functional connectivity between all pairs of brain regions in 40s time windows. We then employ dynamic community detection techniques to uncover time-evolving putative functional modules: groups of brain regions with similar BOLD time series. Our results reveal a robust two-module structure that divides the language network into a module composed of left hemisphere regions and a module composed of right hemisphere regions. We characterize the dynamics of this two-module structure with module allegiance, the probability that two regions engage in the same module over time. Via comparison to a null model, we uncover a rigid core composed mainly of left hemisphere regions, and flexible periphery composed mainly of right hemisphere regions. We speculate that these dynamic connectivity features support the specialization in language processing regions. These findings present initial insight into the dynamic activity and functional specificity of the language network.

Title: Information-based connectivity - IBC: a functional connectivity approach using multivariate classification

Authors: *J. M. CORREIA, M. BONTE, L. HAUSFELD, B. M. JANSMA, G. VALENTE; Maastricht Univ., Maastricht, Netherlands

Abstract: Functional connectivity is essential to higher-order cognitive processes encompassing communication in highly connected brain networks. In fMRI signals, functional connectivity is typically investigated using measures of temporal similarities across brain regions. Beyond co-variation of activity, functional connectivity may be extended to include measures of information representation among activity patterns in distinct brain regions. MVPA (multivariate pattern analysis) permits single-trial predictions of experimental conditions based on multiple voxel responses. Combining functional connectivity with the benefits of MVPA is a current challenge in neuroimaging that promises to find information- instead of activation-based communication

between brain regions. Here, we propose a functional connectivity method that exploits MVPA - IBC (information-based connectivity). IBC investigates mutual information independent of activity correlations by assessing consistencies of single-trial predictions between regions. Using fMRI simulations we investigated inter-regional signal properties underlying the principles of IBC. The results showed that IBC is affected by information fluctuations across trials, but not by activity fluctuations. We first validated IBC using fMRI data from a previous MVPA speech perception experiment that highlighted the role of distributed brain regions in the perception of spoken syllables. The IBC method extended previous findings by highlighting communication within sub-networks of speech and language that may underlie transfer of information during speech perception, in particular between auditory, sensorimotor and motor regions. Secondly, we investigated the potential of IBC to find associations between information within simultaneously acquired fMRI and EEG recordings. Neuronal activity generates both synchronized electrical activity captured in high temporal resolution EEG recordings and hemodynamic changes captured by high spatial resolution fMRI recordings. Combining both modalities at the level of neuronal activity is however challenging due to the unknown coupling between these qualitatively different signals. Here, the IBC method was employed to seek associations, at the information level, between spatial fMRI clusters and temporal EEG intervals. IBC allowed us characterizing time-courses of regions of interest obtained by fMRI. Overall, IBC shows the ability to find modulation of information across single-trials, thus help characterizing mutual information within neural networks, such as between different regions of interest and different imaging modalities.

Title: Cross-language associative priming in the bilingual brain

Authors: *T. R. SCHNEIDER[1], F. ISEL[2], A. K. ENGEL[1];
[1]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Inst. of Psychology, Sorbonne Paris Cité - Paris Descartes Univ., Boulogne Billancourt, France

Abstract: The neuronal organization of the mental lexicon in bilingual speakers is dependent on the age of acquisition of the second language. Hierarchical models propose a common conceptual store for both languages and separate lexical stores. Here we investigated whether the neuronal processing of nouns and verbs differs between the first (L1) and second language (L2) dependent on the age of acquisition. We used magnetoencephalography (MEG) to study large-scale neuronal processing in an associative priming paradigm within and across languages. Sixteen French-German participants with early acquisition of the second language (< 3 years) and sixteen French-German participants with late acquisition of the second language (> 7 years) were presented written prime-target word pairs in four language combinations (French-French, French-German, German-French, and German-German). Prime and target words were either associatively related or unrelated and were presented in close temporal proximity (SOA = 300 ms). Event-related fields revealed differences between early and late bilinguals in the priming task involving the superior parietal cortex and the cerebellum (250-450 ms), supporting the notion that the cerebellum is also involved in nonmotor language processes. An interaction between priming direction and language acquisition (early vs. late bilinguals) involved the left temporal cortex (middle and inferior temporal gyrus), the left inferior frontal cortex, the left fusiform gyrus, and the superior parietal cortex between 250 and 450 ms. In early bilinguals amplitudes were larger in the left inferior frontal gyrus and the left lateral temporal cortex especially when the prime word was presented in the non-dominant language. These results suggest that inhibition of the dominant language and/or language switching costs in early bilinguals were larger than in late bilinguals. Taken together, the results support the hierarchical models especially the conceptual mediation model in highly proficient speakers when control of the dominant language is required.

Title: Disparity between Language preference among different types of bilinguals and auditory attentional behavior toward languages with Event Related Potential (ERP)

Authors: *C. KAMEYAMA[1,2], R. SAJI[2], T. OMORI[1];
[1]Tamagawa Univ., Machida-shi / Tokyo, Japan; [2]Tamagawa Univ. Brain Sci. Inst., Tokyo, Japan

Abstract: Bilinguals frequently manipulate two languages in accordance with the circumstances, topics, and interlocutors. However, the definitions of bilingual vary depending on the ability of languages in relation to the knowledge of languages, frequency of use, and duration of exposure. Especially, the age of exposure to the second language is much more controversial due to the age partition. There is one concept of the early bilingual that no one can argue, which is called "Bilingual First Language Acquisition" (BFLA) (De Houwer, 2009). This type of bilingual is exposed to two languages since birth and both languages simultaneously take place in daily life. Consequently, there is no second language in chronological order. In this study, comparing different exposure time for Japanese and English, we investigated the language preference (10-point scaled score for subjective language favor of 3 categories; Conversation for listening & speaking, News for complicated listening, and Study for reading & writing) of 3 different subject groups (36 subjects-18 females & 18 males; mean age: 22; 12 subjects for each group): 1) Japanese monolingual with at least six years of English education from twelve years old (JM); 2) bilinguals, who have Japanese parents, are exposed to English after three years old and have continued bilingual education in Japan (LB); and 3) bilinguals, who have Japanese mother and American father, are exposed to Japanese and English since their birth (BFLA). All subjects were living in Japan at the time of this study. Auditory attentional behavior was also examined by ERP recorded at Fz, Cz and Pz. The result of language preference showed that all subject groups had significant differences between the languages: 1) JM: mean score English = 4.0 & Japanese=9.5, $p < .01$; 2) LB: mean score English=7.9 & Japanese=9.1, $p < .05$; and 3) BFLA: mean score English=8.9 & Japanese=6.8, $p < .01$. However, the ERP results of the attentional language behavior showed that JM and LB had a significant difference for N1 amplitude between two languages ($p<.01$). The significant differences of the amplitude comparison between groups were, JM vs. LB: English P1 $p < .01$; JM vs. BFLA: English P1 $p < .05$ & N1 $p < .05$, Japanese P1 $p < .05$; LB vs. BFLA: English N1 $p < .01$. ERP results showed that even though the English language favor of LB was higher than JM, they had similar N1 amplitude for English. Namely, auditory attentional behavior does not accord with subjective language preference for JM and LB. On the other hand, BFLA had very alike amplitude for both languages. This suggests that BFLA does not pay attention whichever the language comes.

Title: A flexible, adaptive bilateral neural system for semantic cognition: a combined cTBS/fMRI study

Authors: *J. JUNG, M. LAMBON RALPH;
Sch. of Psychological Sci., NARU (neuroscience and Aphasia Res. Unit), Manchester, United Kingdom

Abstract: Semantic cognition reflects a higher cognitive function that sustains semantically-derived behaviours. Although converging evidence implicates bilateral anterior temporal lobes (ATLs) as a crucial component in semantic cognition, the underlying neural interplay between ATLs remains unclear. In the current study, we investigated the bilateral ventral ATL (vATL) semantic system by implementing the combined cTBS/fMRI approach. First, we applied virtual lesions delivered by continuous theta-burst stimulation (cTBS) in healthy participants (10, 4 males, mean age, 22.8 ± 2.9yrs) to test whether cTBS over the left vATL induces similar inhibitory effect to 1Hz rTMS on semantic performance. Then, we applied a "perturb-and-measure" approach in the bilateral vATL system with healthy participants (25, 7 males, mean age, 21.9 ± 3.7yrs). In the behavioural experiment, we observed that compared to cTBS over the control site, the disturbance of the left vATL resulted in slowing effect on semantic processing selectively. In fMRI experiment, we observed that cTBS over the left vATL suppressed neural activity related to semantic processing at the target region and induced the up-regulation in the homologous right vATL as well as the other areas within semantic network. To test whether the up-regulation of the right vATL after a focal perturbation of the left ATL reflects an adaptive short-term plasticity, we used dynamic causal modelling (DCM). DCM analyses demonstrated that cTBS altered the intrinsic connection of bilateral vATL by increasing the facilitatory influence from the right vATL to the left vATL. Our findings support the hypothesis that the perturbation at the left vATL induced the compensatory up-regulation at the homologous right vATL, which feeds into increased facilitatory connectivity in order to adapt the disturbance in the semantic network. These findings imply that after a focal lesion the other brain regions within the task-related network take a more assertive role in its function particularly at the homologous, contralateral area. Thus, our data suggest a flexible, adaptive bilateral neural system for semantic cognition.

Title: School-aged children consolidate foreign language regularities overnight: behavioral evidence and cortical substrates

Authors: *A. NORA[1,2], L. KARVONEN[1,2], T. PARVIAINEN[3], H. RENVALL[1,2], E. SERVICE[4], R. SALMELIN[1,2];
[1]Dept. of Neurosci. and Biomed. Engin., [2]Aalto NeuroImaging, Aalto Univ., Espoo, Finland; [3]Dept. of Psychology, Univ. of Jyväskylä, Jyväskylä, Finland; [4]Dept. of Linguistics and Languages, McMaster Univ., Hamilton, ON, Canada

Abstract: Incidental learning of phonological structures through repeated exposure is an important component of foreign-language learning. Children seem to outdo adults as second-language learners, possibly due to a sensitive period. However, how children differ from adult learners on the neural level is not known. The present study addresses the neural correlates of incidental learning of new phonological forms and foreign language phonotactic regularities in school-aged children and compares the results to similar data collected from adults. Cortical dynamics during perception of novel words were tracked with magnetoencephalography (MEG) in 13 Finnish-speaking children, aged 6-7 years. Participants performed delayed repetition of four-syllable word forms that were presented either four times (80) or only once (80) during the first session, and again on the second day, along with new word forms. Comparison of novel phonological forms that adhered either to the native (Finnish) or to foreign (Korean) phonotactic system was included to explore whether the effects are related to acquisition of specific word forms (in both languages) or more general learning of the foreign language regularities. A separate behavioral experiment assessed repetition accuracy of foreign word forms over two days. Learning of the recurring words manifested as improved repetition both in children and adults. This item-level learning effect was seen cortically as reduced superior temporal activation for repeatedly encountered words at 600 - 1200 ms, in the left hemisphere in adults but in the right hemisphere in children. Notably, only children showed generalized learning of the foreign

language after overnight consolidation. This was seen as improved foreign-language repetition of new and recurring words while the sustained left temporal responses to foreign language stimuli began to resemble responses to native language on the second day. To conclude, children recruited markedly different cortical network populations than adults for learning specific word forms, and only children showed evidence of generalized learning of the foreign language regularities after a consolidation period. The differences in brain activation between age groups may reflect the neural underpinnings of a sensitive period in foreign language acquisition.

Title: The timing of semantic coding in the anterior temporal lobe: temporal representational similarity analysis of electrocorticogram data

Authors: ***Y. CHEN**[1], A. SHIMOTAKE[2], R. MATSUMOTO[3], T. KUNIEDA[4], T. KIKUCHI[4], S. MIYAMOTO[4], H. FUKUYAMA[5], R. TAKAHASHI[2], A. IKEDA[3], M. A. LAMBON RALPH[1];

Sch. of Medicine, Kyoto Univ., Kyoto, Japan

Abstract: Electrocorticograms (ECoG) provide a unique opportunity to monitor neural activity directly at the cortical surface. Ten patients with subdural electrodes covering ventral and lateral

anterior temporal regions (ATL) performed a picture naming task. Temporal representational similarity analysis was used to compare spatio-temporal neural patterns from the ATL surface with pre-defined theoretical models. The results indicate that the neural activity in the ventral subregion of the ATL codes semantic representations from 250 ms after picture onset. The observed activation similarity was not related to the visual similarity of the pictures or the phonological similarity of their names. In keeping with convergent evidence for the importance of the ATL in semantic processing, these results provide the first direct evidence of semantic coding in the ventral ATL.

Title: The enhanced consolidation of foreign word learning by overt pronunciation

Authors: ***N. AOKI**[1,2], S. K. SUGAWARA[1], M. HIROTANI[3], S. OKAZAKI[1], H. YAMAZAKI-KINDAICHI[1,2], T. YOSHIMOTO[1,2], H. YOKOKAWA[4], H. YOSHIDA[5], N. SADATO[1,2];

Abstract: Word learning is an essential part of learning foreign language (Service, 1992). Phonological rehearsal has been believed to be effective in word learning of foreign language (Seibert, 1927). Consolidation process, where encoded memory transforms into a more stable form (Diekelmann et al., 2009), is important for word knowledge maintained across long time scale. Sleep is known to consolidate foreign word learning (Gais & Born, 2006; Schreiner & Rasch, 2014). However, the role of the phonological rehearsal in the consolidation is not known. Here, we conducted the behavioral experiment to detect the effect of phonological rehearsal on the consolidation of word learning, by teasing out the sleep effect. Twenty-eight Japanese native-

speakers were randomly assigned into two experimental groups. A half of them participated the learning session in the evening and the retest session after 12 hours including sleep (Sleep group; n = 14). The others learned in the morning and retested after 12 hours of wakefulness (Wake group; n = 14). Participants learned 60 pairs of nonsense visual object and English monosyllabic auditory pseudo-word as a word with three experimental conditions: with overt repetition (Repeat), through just listening (Listen), and with numerical phonological suppression (Number). In the learning session, participants were asked to continue the learning task until their memory performance of each condition reached above 60%. Memory performance was measured by cued recall task. Group (Sleep and Wake)×Condition (Repeat, Listen, and Number) ANOVA showed no main effect of group nor condition immediately after the learning session. For the retention performance after 12 hours of interval, the main effects of Group and Condition were significant without their interaction effect. Post-hoc comparisons for Condition effect indicated that the words encoded with overt phonological rehearsal (Repeat) were better retained than other conditions (Listen and Number). Present data replicated the sleep consolidation of word learning (Gais & Born, 2006; Schreiner & Rasch, 2014). Independent of sleep, overt pronunciation during encoding enhanced memory retention. Word learning is the formation of audio-visual redintegration, the relationship between any constituent parts of a complex whole and the totality of the whole. A high conditional probability of recall of a ‘‘whole unit’’ given a part of the unit has been recalled is known as redintegrative recall (Tulving & Madigan, 1970). Thus phonological rehearsal conceivably enhances consolidation of a foreign word through adding motor component to the audio-visual redintegration.

Title: An electroencephalographic investigation on linguistic tense and psychological distance to past, present, and future

Authors: *S. TOKIMOTO[1], N. TOKIMOTO[2];
[1]Mejiro Univ., Tokyo, Japan; [2]Shobi Univ., Saitama, Japan

Abstract: This study examines the neural representations of linguistic tenses and of the psychological distances to them. We manipulated Japanese discourses, in which an event was described in the former half in three ways as past, present, or future. The psychological distance to the event was manipulated by Japanese indexicals referring to the event time in three ways as 'kono-hi,' 'sono-hi,' and 'ano-hi.' 'Kono-hi' (this day) and 'sono-hi' (that day) indicate that a speaker is psychologically near and far to the day of the event respectively. 'Ano-hi' (that past day) refers to the day in the past. The discourses were visually presented, and EEG was recorded at the input of the indexicals. The participants were asked to judge the acceptability of the discourse. For the discourses in which a present event (today) was described, 'ano-hi' was less acceptable than 'sono-hi,' and 'sono-hi' than 'kono-hi.' The lowest acceptability of 'ano-hi' is its manifestation to refer to an event in the past. The less acceptability of 'sono-hi' than 'kono-hi' indicates the difficulty in describing the present event from a viewpoint psychologically far from the present. A negative ERP component was observed for 'ano-hi' and 'sono-hi' in the left frontal, and a positivity was observed for 'sono-hi' in the occipital in the latency of 300 to 450 ms in comparison to 'kono-hi.' For the discourses for past events, we found no significant effect in the acceptability judgments, but a negativity was observed for 'kono/sono-hi' in the left frontal from 300 to 500 ms in comparison to 'ano-hi.' Further, a negativity was observed for 'kono-hi' in the central from 500 to 700 ms in comparison to 'sono-hi.' For the future events, 'ano-hi' was less acceptable than 'kono/sono-hi' with no significant difference between 'kono-hi' and 'sono-hi,' which is again the manifestation of 'ano-hi' to refer to a future event. A positivity was observed for 'ano-hi' in the parietal from 400 to 700 ms in comparison to 'sono-hi.' 'Kono-hi' elicited a positivity in the parietal from 400 to 500 ms as an effect of psychological distance in comparison to 'sono-hi.' The ERP components elicited by anomalous 'sono-hi' for the present and 'ano-hi' for the present and the future coincide with the ERP components often observed for semantic and pragmatic anomaly in sentence processing. However, the distribution of our components differs between the present and the future. Further, the ERP effects of psychological distance between 'kono-hi' and 'sono-hi' were observed in different regions and latencies according to the tense. These results suggest that linguistic tenses are neurally coded differently and the psychological distance interact with them.

Title: Neural correlates of implicit language learning in 9-month-old infants

Authors: *J. LIU, C. PONTING, T. TSANG, R. MCCARRON, M. DAPRETTO;
UCLA, Los Angeles, CA

Abstract: Word segmentation is a fundamental aspect of language learning, since the identification of word boundaries in continuous speech must occur before the acquisition of word meanings can take place. Behavioral and ERP studies in infants and adults have demonstrated that a continuous speech stream can be readily segmented based solely on the statistical or prosodic cues available in the input. By adapting a paradigm used in prior behavioral studies with infants, we previously used fMRI in children and adults to examine the neural network subserving the detection of word boundaries. Using the same word segmentation paradigm, here we report from an fMRI study we conducted in 9-month-old infants in order to identify the early signatures of language-related learning. Several studies have previously shown that neural activity related to language processing can be detected in infants as young as 2 days old; to date, however, very little is known about the neural mechanisms underlying language *learning* during infancy. During natural sleep, infants were exposed to three speech streams consisting of concatenated syllables where the statistical regularities and prosodic speech cues were manipulated across three conditions: the Stressed Language condition contained prosodic cues (i.e., stress) in addition to strong statistical regularities (i.e., transitional probabilities), the Unstressed Language condition contained solely strong statistical regularities, and the Random Syllables condition had weak statistical regularities and no prosodic cues. Reliable neural activation in temporal language areas was detected for each speech stream. In particular, the stream containing strong statistical regularities and prosodic cues (Stressed Language) elicited significantly greater activity in medial prefrontal cortex and right superior temporal regions as compared to listening to the speech stream containing only statistical regularities (Unstressed Language) or the speech stream containing minimal statistical cues to word boundaries (Random Syllables). In addition, learning-related signal increases (i.e., increased activity as a function of exposure to each speech stream) varied across conditions and were related to behavioral indices of language development. These findings indicate that the neural signatures of online language-related learning can be detected in 9-month-old infants even during natural sleep. Furthermore, these data show that by 9 months of age, infants are sensitive to both statistical and prosodic cues as reflected in different neural responsivity to the speech streams containing different types of cues.

Title: Cerebellar dysfunction in dyslexia

Authors: ***X. FENG**[1], W. XIE[2], X. MENG[2], M. TIAN[1], G. DING[1];
[1]Col. of Brain and Cognitive Sci., Beijing Normal Univ., Beijing, China; [2]Beijing Univ., Beijing, China

Abstract: Introduction Dyslexia showed dysfunctional activation and disrupted functional connectivity between the cortical regions of reading network. These regions include temporoparietal, occipitotemporal and inferior frontal cortex, as well as the cerebellum which were found to activate in various language tasks. The cerebellum establishes close connections with the frontal, temporal and occipital lobes, forming a dense reciprocal network of crossed cerebro-cerebellar pathways. This neuroanatomical substrate was considered to subserve a recently acknowledged non-motor role of the cerebellum in reading. Neuroimaging studies have identified structural abnormalities and different activation of the cerebellum in dyslexia. To date few functional studies have specifically focused on or discussed the role of cerebellum in reading and the results were inconsistent. In this study we investigated the cerebellar dysfunction in dyslexia by adopting non-motor orthographical and phonological reading tasks. Considering cerebellum's functional topography and rich neural connections, we focused on both functional activation and functional connectivity of cerebellum, and compared them between typical children and those with dyslexia. To improve the alignment of infra-tentorial anatomical and functional areas, we did preprocessing using cerebellar template and suit-toolbox for SPM. Results In orthographical task, we found significant group difference in right cerebellum VI with greater activation in dyslexia than normal readers. We further found the activation in right cerebellum VI was significantly negative correlated with behavior scores in Reading efficiency test in dyslexic group(r=-0.7772), while the correlation with scores in Chinese phonological awareness test was not significant. However, there was no significant group difference in phonological task even the threshold was lowered. Whole-brain connectivity analysis revealed

that dyslexia showed decreased functional connectivity between right cerebellum VI and left thalamus. The functional connectivity between the two regions was positively correlated with behavior scores in Reading Efficiency test in both normal groups(r=0.464) and all groups(r=0.522).

Title: N400 evidence for embodied processing of concrete words after a picture context

Authors: D. SCHMIDTKE, E. SERVICE, R. MAH, *J. F. CONNOLLY;
Dept. of Linguistics & Languages, McMaster Univ., Hamilton, ON, Canada

Abstract: As a sentence unfolds, semantic information accumulated from the surrounding context facilitates the comprehension of upcoming speech. Previous neurolinguistic research has revealed that word recognition is sensitive to prior contextual information that is present in the wider linguistic discourse. The current research used ERPs to investigate whether context effects on word recognition are also influenced by contextual cues that are provided by non-linguistic information. In the experiment 25 participants (20 female) listened to sentences, such as *He could not hide his anger/delight upon hearing the news*, designed such that the alternative critical words were equally acceptable within the local sentence context. These sentences followed a context-providing image rendering one of the critical words semantically anomalous (e.g., an image of a man with a happy expression). Relative to the context-congruent alternative, context-anomalous words elicited an N400 effect that started at 300–330 ms post acoustic word onset. This effect had a typical centroparietal distribution, with a right hemisphere bias. Furthermore, linear-mixed effects regression models revealed that this contextual congruency N400 effect was modulated by the visual perceptibility (concreteness) of the critical word. In congruent contexts, we found that highly concrete critical words elicited more positive-going (smaller N400) waveforms compared to abstract critical words. However, the same effect of concreteness was not observed in context-anomalous trials. The overall results support the claim that an extra-sentence context can yield a strong expectation for a particular upcoming word. Moreover, we

present two extensions to this hypothesis by revealing that for the effect of contextual constraint to arise, the information source of the context need not be provided linguistically. Crucially, we demonstrate the novel finding that a visual-scene contextual constraint effect on word recognition interacts with lexical characteristics such as concreteness. Importantly, these effects hold even when other predictive cues such as word frequency and the semantic plausibility of the local sentence context are accounted for. Taken together, our results show contextual priming of embodied aspects of processing of concrete words.

Title: Comparison of electrocorticography and electrocortical stimulation in mapping classical language areas: a region of interest approach

Authors: *Y. WANG[1], M. S. FIFER[2], A. FLINKER[4], A. KORZENIEWSKA[1], M. C. CERVENKA[1], D. BOATMAN-REICH[1], W. S. ANDERSON[3], N. E. CRONE[1]; [1]Neurol., [2]Biomed. Engin., [3]Neurosurg., Johns Hopkins Univ., Baltimore, MD; [4]Psychology, New York Univ., New York, NY

Abstract: Functional human brain mapping is commonly performed during or prior to invasive brain surgery for the treatment of drug-refractory epilepsy or brain tumors. The current gold standard, electrocortical stimulation mapping (ESM), is time-consuming and often induces afterdischarges or seizures, and it may overestimate eloquent areas due to propagated effects of stimulation. Spectral analysis of passive electrocorticographic (ECoG) signals has recently emerged as a potential alternative to ESM. Many aspects of passive ECoG mapping are attractive in a clinical setting, especially the ability to rapidly evaluate brain function at all recording sites simultaneously. However, investigators have observed less correspondence between ECoG and ESM maps of language than between their maps of motor function. This may be due to the complexity of speech perception and production and the brain dynamics that support them. We

evaluated seven patients who underwent invasive monitoring for seizure localization whose language and motor areas were identified using ESM. Additionally, all patients performed language tasks including visual object naming and auditory word repetition during passive ECoG recordings. The average sensitivity and specificity of ECoG relative to ESM were 69.9% and 83.5%, respectively, similar to previous studies of ECoG language mapping. Because of the potential inaccuracies of ESM for functional localization, we decided to evaluate the accuracy of both ECoG and ESM with respect to cortical regions of interest drawn from the rich literature on the effects of brain lesions affecting speech production and perception, as well as on regions activated on fMRI during language tasks. Using this approach we found that the sensitivity of ECoG was significantly greater than that of ESM (65.6% vs. 47.9%, respectively, $p = 0.0068$, McNemar's test), while the specificity of ECoG was greater than that of ESM, though not significantly so ($p = 0.066$, McNemar's test). In light of these findings, we believe that both ESM and passive ECoG mapping offer approximations of the patient's true functional anatomy and that more studies are needed to understand their comparative utilities in clinical practice.

Title: Stammering and synchronised speech

Authors: *S. MEEKINGS[1], K. JASMIN[2], S. K. SCOTT[2];
[1]UCL, London, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: Speaking in synchrony with another person is usually central to activities that emphasise group cohesion- for example, praying or oath-taking. However, in many people who stutter, the most important consequence of synchronised or 'choral' speech is an immediate and often dramatic improvement in fluency. We used functional magnetic resonance imaging to investigate how synchronous speech is processed in fluent speakers and people who stutter (classified using Riley's Stuttering Severity Instrument, 4th ed). Participants heard either a live

speaker or a pre-recorded voice. They either listened without speaking, read the same sentence aloud (synchronous speech), or read a different sentence aloud (asynchronous speech). In these conditions, questioning determined that participants were not able to distinguish the live speaker from the pre-recorded voice. There was an additional control condition in which subjects spoke on their own with no second speaker. The stammering group were compared to the controls, in whom synchronous speech resulted in bilateral activation in superior temporal gyrus. The auditory suppression response associated with speech in quiet did not occur when typical speakers synchronised with a live speaker. We discuss the implications for various models of stuttering, such as the EXPLAN model and the theory that stuttering may result from an over-reliance on auditory feedback.

Title: Influence of transcranial direct current stimulation on semantic processing

Authors: S. BRÜCKNER, *M. SPITZER, T. KAMMER;
Dept. of Psychiatry, Univ. of Ulm, Ulm, Germany

Abstract: Recently, the investigation of transcranial direct current stimulation (tDCS) effects in the cognitive domain got a great deal of attention. Interestingly, the canonical assumption (anodal excitatory, cathodal inhibitory) from the motor cortex could not generally be transferred to other cortical regions. In this study, we investigated the effects of tDCS on semantic processing. In a between-group-design, subjects received either anodal (n=20), cathodal (to date n=13) or sham (n=20) tDCS. The active electrode was placed over CP5 and the reference electrode on the left shoulder. TDCS was applied for 15min with a stimulation intensity of 1mA. During stimulation, subjects had to perform a simple auditory oddball task to standardize cognitive activity. Two minutes after tDCS, they started to perform a lexical decision task. Since the electrodes and thus the stimulated cortex area is quite large (7x5cm), we controlled for motor cortex modulations using a choice reaction task in the middle and at the end of the lexical decision task. Mean reaction times (RTs) and error rates were analyzed for the anodal and sham group using t-tests. Subjects receiving anodal tDCS show a trend to decreased RTs on pseudowords ($t=2.01$, $p=0.058$), but not on words ($t=1.39$, $p=0.17$) compared to the sham group.

For error rates, there is no difference between the two groups, and no effect of tDCS on reaction times in the choice reaction task ($t=0.95$, $p=0.35$) were found. Since the cathodal group is not finished yet, we refrain from reporting inferential statistics. Visual inspection of the data reveals that cathodal tDCS decreases RTs on both word types, whereas error rates and motor responses are not affected. The effect of excitation seems to be even more pronounced as with anodal tDCS. Our preliminary data are in line with other studies showing that effects of tDCS on motor cortex excitability cannot be transferred to other cortical regions. Although anodal tDCS showed a trend to excitation as expected, cathodal tDCS seems to facilitate semantic processing even more. As a possible explanation, the initial state of the neurons stimulated may play a role for cathodal tDCS effects due to homeostatic metaplasticity, making it necessary to accurately control neuronal activity during stimulation. We will continue our measurements up to 20 subjects in the cathodal group and prepare comprehensive statistics including a split-half analysis to investigate the time course of the effects. Additionally, we will present the results in analogy to those published by our group, where effects of repetitive transcranial magnetic stimulation on semantic processing were shown using the very same lexical decision task.

Title: Establishing task- and modality-dependent dissociations between the semantic and default mode networks

Authors: *G. HUMPHREYS, M. LAMBON RALPH;
Univ. of Manchester, Manchester, United Kingdom

Abstract: The default mode network (DMN) and semantic network (SN) are two of the most extensively studied human neurobiological systems. The DMN includes those neural regions that shows task-related deactivation during many goal directed tasks (i.e., rest > task) in neuroimaging studies. The SN consists of regions that are sensitive to semantic tasks > rest/non-semantic control tasks. There are strong reason to assume a close relationship between the networks, both theoretically and anatomically. Theoretically, the two networks may share

cognitive processing, reflecting the semantic processing that occurs during rest. Anatomically, evidence suggests regions, such as the anterior temporal lobe (ATL) and angular gyrus (AG), are critical to both systems. Nevertheless, despite theoretical and anatomical motivations, the relationship between the SN and DMN has been little studied. Here we directly address this issue by comparing the SN and DMN using a large distortion-corrected fMRI dataset (N=69) including a wide range of semantic and non-semantic tasks varying in stimulus-type (pictures, words, non-semantic items), input modality (visual, auditory), and task difficulty. A distortion-corrected protocol is critical here to account for the signal distortion associated with the ATL. The results illustrated that both networks vary depending on the level of semantic involvement, stimulus-type, modality and task difficulty. Critically, the ATL and AG showed very different responses, despite claims that both AG and ATL are semantic-hubs. Specifically, the left ATL was positively activated relative to rest for all semantic tasks but deactivated during non-semantic task performance. In contrast, the left AG was deactivated for all tasks, with the level of deactivation related to task-difficulty. This finding supports the role of ATL but not AG in semantic representation. Furthermore, the result suggest that rather than sharing a common interest in semantic tasks, the AG and ATL share a common "disinterest" in non-semantic tasks. These data have implication regarding our understanding of task variability in the SN and DMN, and clarify the role of the ATL and AG in both networks, with the ATL as a semantic-hub and the AG showing more domain general sensitivity.

Title: Dissociable intrinsic functional networks support noun and verb processing

Authors: *H. YANG[1,2], Z. HAN[2], L. SONG[3], H. LI[2], Q. LIN[2], Y. HE[2], Y. BI[2];
[1]State Key Lab. of Cognitive Neurosci. and, Beijing, China; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; [3]Rehabil. Col. of Capital Med. University, China Rehabil. Res. Ctr., Beijing, China

Abstract: The neural circuits supporting noun (entity) and verb (event) processing are a central issue underlying language research, with robust evidence indicating widely distributed regions showing different preference for these two classes of items. We conducted two experiments to examine the intrinsic network organizations of these regions and their corresponding behavioral relevance. Experiment 1 explored whether the brain regions previously shown to be selectively activated by noun or verb are intrinsically organized into different functional networks using resting-state fMRI data of 146 healthy adults. Noun- and verb-preference nodes were identified by the activation likelihood estimate (ALE) meta-analyses from 22 imaging studies, resulting in 19 verb nodes and 15 noun nodes. The modularity analysis over these nodes showed that they could be reliably subdivided into three modules across a range of network sparsity (sparsity = 0.4, Q = 0.3, Z = 13.8). The majority (76%) of the nodes converged onto the distinct word-class preferences in the ALE analyses. Furthermore, when evaluating the functional connectivity strength (FCs) within the regions labeled for the two word classes based on the ALE analyses, the average within-class FCs was significantly greater than the average between-class FCs [$t(143) = 24.52$, $P < 0.01$; $t(143) = 18.51$; $P < 0.01$], suggestion that the regions showing activation differences for the two classes are indeed intrinsically organized into different functional networks. Experiment 2 examined the behavioral relevance of the intrinsic noun and verb networks using data from 88 brain-damaged patients. We found that across patients the relative mean FCs based on network identified in Experiment 1 significantly correlated with the relative behavioral performance in the picture associative matching task for verb (action) and noun (tool): modularity-analyses defined network: $r = 0.37$, $P < 0.01$; ALE-analyses defined network: $r = 0.31$, $P < 0.01$. The correlation remained significant even after controlling for the extent of the relative anatomical damage of the two networks, measured by number of voxels being lesioned in the nodes within each network ($r = 0.37$, $P < 0.01$). In summary, we found that noun and verb preference regions from prior studies are intrinsically organized into segregated functional networks and the integrity of such networks could significantly account for relative noun or verb selective deficits as consequences of brain lesion, indicating that noun and verb processing are supported by dissociable large-scale functional networks.

Title: Fluoxetine facilitates consolidation of fear memory extinction through increased DH BDNF and through VH TrkB transactivation

Authors: *C. A. DINIZ[1], L. S. ANTERO[2], L. B. M. RESSTEL[2], S. R. L. JOCA[3];
[1]Pharmachology, Sch. of Med. of Ribeirão Preto - Univ., Ribeirao Preto, Brazil;
[2]Pharmachology, Sch. of Med. of Ribeirão Preto, Ribeirão Preto, Brazil; [3]Physics and chemistry, Sch. of Pharmaceut. Sci. of Ribeirão Preto, Ribeirão Preto, Brazil

Abstract: Purpose: Animal fear conditioning and PTSD depend on an association of the aversive stimulus with a previous neutral stimulus producing an intense conditioned fear response. PTSD patients have decreased hippocampus and impaired hippocampal-dependent cognitive functions, as well as impaired extinction of the conditioned fear response. Selective serotonin reuptake inhibitors are the first line pharmacological treatment for PTSD. In animals, chronic fluoxetine (FLX) treatment impairs renewal, reinstatement and spontaneous recovery of the conditioned response. These effects seem to depend on hipocampal BDNF. Besides, impaired extinction of fear-potentiated startle is observed in conditioned hipocampal BDNF knockout animals. The hippocampus can be divided into ventral hippocampus (VH), more closely related to anxiety and fear response, and dorsal hippocampus (DH), related to cognitive processes of learning and memory. Little is known about a possible distinct participation of DH and VH BDNF content in FLX-induced effects on fear extinction. Methods: Male Wistar rats (250 g) were used. Animals were submitted to conditioning procedure (day 1). Animals were treated with FLX (10mg/kg) or vehicle for twelve days. Chronic FLX, acute FLX and vehicle treatment groups were obtained. One day after the last injection animals were exposed to the extinction protocol (day 14) and in the next day to the extinction memory retention protocol (day 15). Independent groups of animals were submitted to the conditioning procedure and treatment as outlined above, but now the animals were sacrificed rather than exposed to extinction protocol in order to have their HD and VH portion prepared for BDNF protein analysis (ELISA). In another experiment, animals were submitted to stereotaxic surgery 5 days before extinction protocol and bilateral guide cannulas were allocated into DH or VH. K252 (TrkB functional blocker - 10pmol/0.5ul by side) or vehicle were infused into the DH or VH soon after extinction protocol in chronic FLX or vehicle i.p treatment. Results: Only chronic FLX treatment facilitated the extinction memory retention ($F_{2,29} = 2.881$; $p<0.05$). Chronic FLX treatment increased BDNF in DH ($F_{2,21} = 5,198$; $p<0.05$) while acute treatment increased BDNF in VH ($F_{2,16} = 5.796$; $p<0.05$). k252

administered into DH or VH prevented chronic FLX-induced effects on memory consolidation ($F_{3,41} = 4.166$; $p<0.05$) and ($F_{3,13} = 3.533$; $p=0.056$), respectively. Conclusion: Chronic FLX effect on sound extinction memory consolidation might occur through BDNF modulating learning and memory processes within the DH and probably occur also through fluoxetine TrkB transactivation in the VH.

Title: Effect of DREADD-induced activation of the nigrostriatal dopamine pathway during auditory fear extinction on renewal of fear

Authors: *T. M. NICASTRO, N. M. GRAY, C. A. BOUCHET, E. C. LOETZ, B. N. GREENWOOD;
Psychology, Univ. of Colorado Denver, Denver, CO

Abstract: Fear renewal is the return of conditioned fear following extinction in contexts that differ from where fear extinction was learned. The contextual modulation of fear extinction memory contributes to the poor long-term efficacy of exposure therapy for the treatment of anxiety and trauma-related disorders. Prior work suggests that dopamine (DA) could be an important component of fear extinction memory formation; however, the specific neural pathways involved remain unclear, as does whether fear extinction facilitated by DA is resistant to renewal. Burst firing of DA neurons terminating in the dorsal and ventral striatum encode prediction errors which could be important for fear extinction learning. Of these DA target regions, the dorsal striatum could be a region in which DA acts to render fear extinction memory resistant to contextual modulation. Indeed, unlike the nucleus accumbens which receives strong hippocampal afferents, the dorsal striatum is free of contextual modulation from the hippocampus. Viral-mediated gene transfer of designer receptors exclusively activated by designer drugs (DREADD) was used to determine whether selective augmentation of DA signaling in the dorsal striatum during fear extinction can strengthen fear extinction memory and

reduce fear renewal. Male wild-type Long Evans or TH-Cre rats received micro-injections of a CRE-recombinase-dependent DREADD (AAV-hSyn-rM3Dq-mCherry) bilaterally into the substantia nigra pars compacta, which contains DA neurons projecting to the dorsal striatum. DREADDs are activated by the otherwise pharmacologically inert synthetic ligand clozapine-N-oxide (CNO). Therefore, this strategy produces transient augmentation of Gq-protein signaling in infected DA neurons when CNO is injected intraperitoneal (i.p.) and allows for selective activation of DA signaling during fear extinction. After 4 weeks to allow for viral gene expression, rats were exposed to auditory fear conditioning. The next day rats received CNO (1 mg/kg i.p.) 30 minutes before being exposed to auditory fear extinction in a novel context. Fear extinction in the presence of CNO was repeated 24 hours later. The next day rats were placed drug-free into either the familiar extinction context or a novel context and exposed to the auditory stimulus to assess fear renewal. The experiment is currently underway.

Title: Activation of dopamine 1 receptors in the dorsal striatum during fear extinction reduces fear renewal

Authors: *C. A. BOUCHET, T. M. NICASTRO, N. M. GRAY, E. C. LOETZ, F. EYAYOU, B. N. GREENWOOD;
Psychology, Univ. of Colorado, Denver, CO

Abstract: Behavioral treatments for anxiety and trauma-related disorders focus on extinction-based exposure therapy, during which patients are exposed to an anxiety-eliciting stimulus in a safe environment in order to extinguish fear. Exposure therapy has low efficacy, and one factor contributing to the relapse of anxiety following treatment is the fact that extinction memory is context dependent. Thus, exposure to fear-inducing cues outside of the extinction context precipitates the return of fear; a phenomenon termed fear renewal. Identification of means to reduce fear renewal is of the utmost importance to mental health. Dopamine has been implicated

in fear learning and memory processes but the role of dopamine in extinction is not clear. Two terminal regions of dopaminergic signaling, the dorsal and ventral striatum, have been implicated in detection of prediction error which may be an important component of fear extinction learning. Neuroanatomical evidence suggests that the dorsal striatum, unlike the ventral striatum, does not receive strong hippocampal afferents. Therefore, potential manipulations that strengthen fear extinction learning in the dorsal striatum may do so in a manner that is independent of contextual modulation. Further, activation of dopamine 1 (D1) receptors within the dorsal striatum could influence well established fear extinction circuitry. We therefore hypothesize that activation of D1 receptors within the dorsal striatum during fear extinction will reduce fear renewal. To test this, male Long Evans rats were conditioned to fear an auditory stimulus. The next day, rats were exposed to fear extinction training in a novel context. Immediately prior to fear extinction training, rats received bilateral microinjections of the D1 receptor agonist SKF38393 (0.5µg/µl) or saline into the dorsal striatum. Drug- or saline-paired extinction training was repeated the following day. One day following the second fear extinction training session, rats were placed into either the same extinction context or a novel context drug-free and freezing was scored as an index of fear. Activation of D1 receptors in the dorsal striatum during fear extinction reduced freezing in the novel context during test. These data suggest that manipulations to activate the direct pathway neurons in the dorsal striatum during fear extinction can render extinction memory free of contextual modulation and prevent the renewal of fear.

Title: The effect of voluntary exercise during consolidation of auditory fear extinction on renewal of fear

Authors: *F. B. EYAYOU[1], C. A. BOUCHET[2], S. HOLMES[2], T. M. NICASTRO[2], E. C. LOETZ[2], N. M. GRAY[2], B. GREENWOOD[2];

Abstract: Fear extinction learning forms the basis of exposure therapy for anxiety and trauma-related disorders. Unlike fear memories, fear extinction memories are labile and susceptible to relapse phenomenon such as fear renewal. Fear renewal is characterized by the return of conditioned fear responding in contexts outside of the extinction context, even following successful extinction. Prior work suggests that acute exercise either prior to or following the learning of extinction of contextual fear conditioning can enhance memory for fear extinction. Remaining unknown, however, is whether acute exercise can enhance the consolidation of auditory fear extinction memory, and whether fear extinction augmented by acute exercise is resistant to renewal. In order to explore these questions, male Long Evans rats were familiarized with wheel running by being exposed to either a running wheel or a locked wheel on alternating nights for a total of 6 nights. Forty eight hours after the third wheel running active cycle, rats were exposed to auditory fear conditioning which consisted of 4 pairings of an auditory conditioned stimulus (SC) with an aversive foot shock. The following day at the start of the active (dark) cycle, rats were placed into a novel context and were exposed to the CS tone multiple times in the absence of foot shock in order to extinguish fear. Immediately following fear extinction, rats were placed into either their familiar mobile or locked running wheels for 2 hours. Thus, rats in the acute exercise group were given two consecutive opportunities to run during the consolidation phase of fear extinction memory formation that occurs immediately after fear extinction training. This procedure was repeated the next day, so that rats had a total of two days of exposure to either a locked or mobile running wheel during the fear extinction memory consolidation phase. The morning after the second fear extinction session, rats were placed into either the familiar extinction context or a novel context and the extinguished CS was presented 4 times in order to evaluate fear extinction memory and fear renewal, respectively. Rats were sacrificed 90 minutes after the test session and brain circuits implicated in fear and extinction were processed with immunohistochemistry for the neural activation marker c-Fos. Behavioral and brain data are currently being analyzed

Title: A neural circuit mechanism for calculating prediction errors in amygdala neurons to set adaptive level of fear memory

Authors: *T. OZAWA[1], E. A. YCU[1], T. AHMED[2], A. KUMAR[1,3], L.-F. YEH[1,4], J. KOIVUMAA[1], J. P. JOHANSEN[1,4];

Sch. of Arts and Sci., Univ. of Tokyo, Tokyo, Japan

Abstract: For adaptive behavioral decision making, the strength of aversive learning needs to be appropriate to the level of danger and exaggerated fear learning is characteristic of anxiety disorders. During auditory fear conditioning, animals learn that an auditory tone predicts an aversive outcome (typically electric shock). Learning finally reaches a steady state at a certain memory strength (termed the learning asymptote) beyond which further training is ineffective at producing learning unless the strength of the aversive outcome is increased. We previously found that learning produces a reduction in shock-evoked responding in lateral nucleus of the amygdala (LA) neurons (termed prediction error coding) and that shock-evoked responding in LA neurons is required for fear learning to occur. Prediction error coding also occurs in periaqueductal gray (PAG) neurons which relay aversive shock signals to LA. PAG receives projections from the central nucleus of amygdala (CeA) which is activated by tones after fear learning. Here, we hypothesized that a CeA-PAG pathway provides a feedback signal to down-regulate aversive shock processing resulting in prediction error coding in PAG and LA. Furthermore, we hypothesized that this CeA-PAG pathway, and ultimately prediction error coding in LA, functions to set behavioral fear learning asymptotes. To address these questions, we first developed a 4-day fear conditioning paradigm in which rats were trained (days 1, 3) and tested (days 2, 4) twice. In this paradigm, rats reached learning asymptote after initial training (day 1)

as learning was not enhanced by overtraining (day 3). We found that: (1) optogenetic inactivation of CeA to ventrolateral PAG (vlPAG) afferents at learning asymptote disinhibited predicted shock-evoked responses (i.e. reengaged prediction error coding) in dorsolateral PAG (dlPAG) and LA neurons. (2) optogenetic inactivation of dlPAG cell bodies during the shock period in training impaired acquisition of fear conditioning. (3) optogenetic inactivation of the CeA-vlPAG circuit increased learning levels beyond the original asymptote through activation of LA neurons. These results demonstrate that a CeA-vlPAG pathway generates prediction error coding in dlPAG and LA to set fear learning asymptotes. This suggests a distributed circuit mechanism for setting adaptive levels of fear memory strength and shows that disrupting this circuit produces exaggerated levels of fear.

Title: The functional role of locus coeruleus noradrenaline neurons in fear learning and extinction

Authors: *A. UEMATSU[1], E. YCU[1], J. JOHANSEN[1,2];
[1]RIKEN BSI, Wako-Shi, Japan; [2]Dept. of Life Sciences, Grad. Sch. of Arts and Sci., Univ. of Tokyo, Tokyo, Japan

Abstract: Noradrenaline neurons in the locus coeruleus (LC) play an important role in mood, attention, cognitive processes, and learning through their projections to a diverse set of brain regions. Recently, we showed that noradrenaline in the lateral amygdala modulates Hebbian plasticity mechanisms to facilitate the formation of auditory fear memories. Noradrenaline is also required for the extinction of fear memories, a process which involves the lateral amygdala as well as medial prefrontal cortex regions. While the LC sends projections to these brain areas the

functional role of LC noradrenaline neurons in fear learning and extinction is not clear. To understand these questions we used optogenetic and electrophysiological approaches in a transgenic rat expressing cre-recombinase under the control of the tyrosine hydroxylase promoter (TH-cre rat). We injected the LC of TH-cre rats with adeno-associated virus expressing a cre-dependent light responsive opsin protein archaerhodopsinT (ArchT)-GFP. This produced specific expression of ArchT in noradrenaline neurons (>95% of ArchT-GFP positive cells were TH positive) and could be used to inhibit these cells in response to orange light. This allowed for optogenetic identification and subsequent analysis of task related neuronal coding of LC noradrenergic neurons and an determination of the function role of these neurons in fear and extinction learning. Rats were trained with 3 pairings of an auditory tone (conditioned stimulus, CS) and foot shock (unconditioned stimulus, US) followed by CS alone presentations. We found that inhibition of noradrenaline neurons during the US period of fear conditioning significantly reduced long-term fear memory while inactivation during the CS period had no effect. Consistently, we found that many optogenetically identified LC noradrenaline neurons showed phasic responses to the US during fear conditioning. We next examined the role of LC neurons in fear extinction, where the tone is repeatedly presented without the aversive US following fear learning. Optogenetic inhibition of noradrenaline neurons during the CS period blocked long-term extinction memory, whereas inactivation during the shock US omission period had no effect. In electrophysiological experiments, LC noradrenaline neurons showed CS-evoked responses after fear learning but no change in response to shock omission. These results demonstrate a temporally precise, but differential role for activity in LC noradrenaline neurons during fear memory formation and extinction of these fear memories when they are no longer appropriate. Further results will be discussed in the poster.

Title: Differential effects of allopregnanolone in the basolateral amygdala and bed nucleus of the stria terminalis on Pavlovian fear conditioning in rats

Authors: *G. M. ACCA[1], B. TSAO[2], J. JIN[1], C. FU[2], S. MAREN[1,2], N. NAGAYA[1,2];
[1]Inst. for Neurosci., [2]Psychology, Texas A&M Univ., College Station, TX

Abstract: Considerable evidence indicates that gonadal hormones and their metabolites regulate emotional behavior. We have previously demonstrated that allopregnanolone (ALLO), a progesterone metabolite and $GABA_A$ receptor modulator, inhibits the expression of conditional freezing to an aversive context when infused into the bed nucleus of the stria terminalis (BNST) in rats. Intra-BNST infusions of ALLO did not affect the expression of fear to an auditory conditioned stimulus (CS), consistent with a selective role for the BNST in contextual fear. In addition to the BNST, the basolateral amygdala (BLA) is a potential target for neurosteroid modulation of conditioned fear. Here we compare the effects of ALLO infusions into the BNST (Expt 1) or BLA (Expt 2) on the acquisition and expression of Pavlovian fear conditioning. After cannulae implantation and recovery, adult male rats were given infusions of either ALLO (8 μg/μl) or vehicle (VEH; 30% β-cyclodextrin) into the BNST or BLA before either conditioning or retention testing in a factorial design. Conditioning consisted of 5 CS (2 kHz, 10 s, 80 dB)-footshock (2 s, 1 mA) pairings and the retention test consisted of a context test (10 min) followed by a tone test (4 CS-alone trials) in a novel context. ALLO infused into the BNST disrupted both the acquisition and expression of contextual freezing, however, this effect was entirely state-dependent. That is, rats infused with either VEH or ALLO before both the conditioning and testing sessions exhibited similar and high levels of conditioned freezing. Conditioned freezing to the auditory CS was not affected by intra-BNST ALLO. In contrast, intra-BLA ALLO infusions attenuated the expression of both context and CS freezing, without affecting acquisition. These findings reveal that infusion of ALLO into the BNST modulates conditioned fear in a state-dependent manner, perhaps by altering the animal's representation of interoceptive context. This contrasts with the effects of ALLO in the BLA, which appear to produce a global attenuation in the expression of conditioned fear.

Abstract: There is considerable interest in the role of the infralimbic (IL) region of the medial prefrontal cortex in the regulation of conditioned fear. We have previously shown that infusion of the GABAA receptor antagonist, picrotoxin, into IL impairs the expression of freezing to an auditory conditioned stimulus (CS) (Chang and Maren, 2011). This suggests that GABAergic inhibition in IL is involved in fear regulation and may have a critical role in the regulation of extinguished fear. To examine this issue, we conducted two experiments in which rats received either muscimol (0.2 ug in 0.2 ul) or picrotoxin (10 ng in 0.5 ul) infusions into the IL prior to an extinction recall test or fear renewal test, respectively; freezing served as the index of conditional fear. Rats were implanted with a single guide cannulae targeting IL at the midline. After recovery from surgery, the rats underwent a standard fear conditioning procedure consisting of five tone (2kHz, 10sec, 80dB)-footshock (2s, 1mA) trials. Twenty-four hours later they were returned to either the conditioning context or a novel context and were presented 45 extinction (CS-alone) trials. Twenty-four hours after extinction, the rats were infused with drug or vehicle (0.9% saline) and, 15 minutes after infusion, placed in either the extinction context (Exp 1) or a context different from extinction (Exp 2) where they received 45 CS-alone trials to test retention of fear to the extinguished CS. Infusions of muscimol into the IL impaired the expression of extinction (Exp 1) and resulted in a relapse of conditioned freezing, whereas infusions of picrotoxin into the IL (Exp 2) yielded low levels of conditioned freezing and prevented fear renewal. These data suggest that GABAA receptors in IL bidirectionally regulate the expression of fear after extinction. Importantly, the IL is required for the retrieval of fear and safety memories after extinction. Supported by a grant from the NIH (R01MH065961).

Title: Reversible inactivation of the nucleus reuniens of the midline thalamus disrupts fear suppression after extinction

Authors: *J. JIN[1,2], Q. WANG[3], S. MAREN[1,2];
[1]Inst. for Neurosci., Texas A&M Univ., College Station, TX; [2]Psychology Dept., College Station, TX; [3]Biol. Dept., College Station, TX

Abstract: The extinction of conditioned fear is context-specific: fear to an extinguished conditioned stimulus (CS) is suppressed in the extinction context but 'renews' in any other context. Recent work indicates that projections from the ventral hippocampus (VH) to the medial prefrontal cortex (mPFC) are involved in this process. In addition, indirect projections from the mPFC to the hippocampus via the thalamic nucleus reuniens (RE) have recently been implicated in context processing. As a first step to exploring the contribution of this pathway to contextual memory retrieval, we examined whether pharmacological (muscimol) or chemogenetic ('designer receptors exclusively activated by designer drugs', DREADDs) inactivation of RE would disrupt the context-specific expression of extinction memories. In Experiment 1, rats were implanted with a cannula aimed at RE. Seven days after surgery, rats underwent fear conditioning (5 tone-shock pairings) in context A and, twenty-four hours later, extinction (45 tone-alone) in context B. On days 3 and 4, rats were microinjected with either muscimol or vehicle and immediately placed in either the extinction context (ABB, extinction test) or the conditioning context (ABA, renewal test) and presented with the extinguished CS; drug condition and contexts were counterbalanced. Pharmacological inactivation of RE increased freezing in the extinction context, but did not affect the high levels of freezing expressed during the renewal of fear in a different context. In Experiment 2, rats received unilateral infusions of an adeno-associated virus (AAV) expressing an inhibitory DREADD (AAV5-CaMKIIα-hM4D[Gi]-mCherry) into the RE. Three weeks later, rats underwent conditioning, extinction and retrieval testing in a within-subjects design. Each rat received clozapine N-oxide (CNO, a synthetic DREADD agonist; 1 mg/kg, i.p.) or VEH prior to testing in both the extinction and conditioning contexts (for a total of four tests). CNO administration increased freezing to the extinguished CS in both test contexts. Together, these experiments suggest that RE inactivation impairs the retrieval of extinction memories. The RE may be an essential bridge in mPFC-HPC top-down inhibition of context-dependent fear expression after extinction.

Title: Propranolol modulates medial prefrontal cortical activity and enhances extinction after recent fear

Authors: *T. F. GIUSTINO[1,2], P. J. FITZGERALD[2], S. MAREN[1,2];
[1]Texas A&M Inst. for Neurosci., College Station, TX; [2]Psychology, Texas A&M Univ., College Station, TX

Abstract: It is well known that psychological stress impairs extinction learning. This is exemplified by the immediate extinction deficit, a phenomenon in which extinction trials administered soon after fear conditioning fail to produce long-term fear reduction. We have recently shown that fear conditioning produces dramatic changes in medial prefrontal cortical (mPFC) single-unit firing, including sustained decreases in infralimbic cortical (IL) firing rates, up to an hour after conditioning. Interestingly, this effect was mitigated by systemic administration of propranolol (10 mg/kg, i.p.), a β-adrenergic receptor (β-AR) antagonist. This suggests that propranolol might facilitate extinction under stress by stabilizing shock-induced changes in mPFC firing. To address this question, we examined the consequences of post-conditioning propranolol administration on both mPFC activity and the immediate extinction deficit. On Day 1, rats underwent a standard auditory fear conditioning procedure, immediately followed by vehicle or propranolol administration. Thirty minutes after drug administration, animals received 45 extinction trials. Propranolol treatment reduced freezing throughout the session. Vehicle-treated rats exhibited post-shock increases and decreases in prelimbic (PL) and IL spontaneous single-unit activity, and a decline in conditioned stimulus (CS)-evoked activity throughout the extinction trials. Propranolol treatment counteracted post-shock suppression of spontaneous firing in IL, and suppressed CS-evoked firing in IL during extinction. Drug treatment also rescued shock-induced suppression of IL bursting. Fear conditioning was associated with changes in the local field potential in both IL and PL of vehicle-treated rats, with decreases in both gamma and theta power that persisted through the extinction period. Propranolol administration enhanced PL and IL theta power during the immediate extinction trials. In a drug-free retention test given 48 hours after extinction (Day 2), prior treatment with propranolol reduced freezing and also suppressed CS-induced increases in spontaneous firing rate. Prior drug treatment also enhanced PL gamma power and suppressed CS-evoked IL

responses. Collectively, these data show that systemic β-AR blockade produces marked alterations in mPFC neural activity during and after immediate extinction. Propranolol may be a useful adjunct to therapeutic interventions in recently traumatized individuals and patients suffering from stress- and trauma-related disorders.

Title: Nonassociative inhibition of conditional fear engages the medial prefrontal cortex in rats

Authors: *P. J. FITZGERALD[1], T. GIUSTINO[1,2], S. MAREN[1,2];
[1]Dept. of Psychology, Texas A&M Univ., College Station, TX; [2]Texas A&M Inst. For Neurosci., College Station, TX

Abstract: Considerable evidence suggests the medial prefrontal cortex (mPFC) plays a crucial role in emotional regulation in both rats and humans. For example, the infralimbic (IL) region of the mPFC has an important role in both the acquisition and expression of extinction, a form of learning that results in the inhibition of conditioned fear responses such as freezing. Whether IL plays a specific role in extinction or a more general role in fear inhibition is not known. To investigate this possibility, we examined single-unit activity in the mPFC during the nonassociative inhibition of fear produced by a novel stimulus (i.e., external inhibition). On Day 1, animals received either signaled or unsignaled footshocks in the recording chamber; the conditioned stimulus (CS) (in signaled rats) consisted of a 2 sec, 80 dB, 2 kHz tone and the unconditioned stimulus (US) was a 0.5 s, 1 mA footshock. Twenty-four hours later, the animals were returned to the recording chamber (modified to create a novel context) where they received 5 tone-alone trials (60 sec ISI). During this test session, all rats exhibited a moderate level of generalized fear to the recording chamber. After tone presentation, freezing behavior increased in rats that had received signaled shocks, but decreased in animals in the unsignaled condition. Hence, a novel auditory stimulus caused the external inhibition of freezing behavior. Interestingly, single-unit responses in mPFC mirrored the differential behavioral responses to the auditory stimuli in signaled and unsignaled rats. In particular, the spontaneous firing rate of both

IL and PL neurons in signaled rats was reliably lower than that in unsignaled rats after presentation of the auditory stimuli. These changes in spontaneous firing rate returned to baseline within 4 minutes of the last tone in the unsignaled rats. In contrast to the spontaneous firing rate changes, short-latency tone-evoked responses (<200 ms after onset of the tone) were only observed in signaled rats. Collectively, these data suggest that increases in the spontaneous firing rate of mPFC neurons are associated with the external inhibition of fear to a novel stimulus, whereas decreases in this activity are associated with the expression of fear to a CS. In contrast to other reports, the neural correlates of fear expression and inhibition were similar in PL and IL. These data reveal that the mPFC is involved the regulation of fear by both associative and nonassociative stimuli.

Title: Combinatorial DREADD silencing of ventral hippocampal neurons projecting to infralimbic cortex prevents fear renewal

Authors: *T. D. GOODE[1], J. JIN[1,2], R. HOLEHONNUR[3], J. E. PLOSKI[3], S. MAREN[1,2]; [1]Inst. for Neurosci., [2]Psychology Dept., Texas A&M Univ., College Station, TX; [3]Dept. of Mol. & Cell Biol., Univ. of Texas, Dallas, TX

Abstract: Extinguished fear to a conditioned stimulus (CS) renews outside of the place or context in which extinction training occurred. Here we examined the hypothesis that projections from the ventral hippocampus (VH) to the infralimbic region (IL) of the medial prefrontal cortex mediate fear renewal. In two experiments, we used 'designer receptors exclusively activated by designer drugs' (DREADDs) to either non-selectively inhibit VH neurons (Experiment 1) or selectively silence VH neurons projecting to IL (Experiment 2) during fear renewal. In Experiment 1, rats received bilateral infusions of an adeno-associated virus (AAV) expressing inhibitory DREADDs (AAV-CaMKIIα-hM4D[Gi]-mCherry) or a GFP control (AAV-CaMKIIα-GFP) into the VH. Two weeks later, in a between-subjects design, rats were subjected to an ABA renewal procedure. First, rats were conditioned in Context A, consisting of 5 CS (10 s, 2 kHz, 80

dB tone)-unconditioned stimulus (US; 2 s, 1 mA footshock) pairings. Freezing behavior served as the index of fear. Twenty-four hours later, rats were extinguished to the CS in Context B (45 nonreinforced CS-only presentations). Twenty-four hours after extinction, rats were injected with either clozapine N-oxide (CNO, a synthetic DREADD agonist; 3 mg/kg, i.p.) or vehicle at 30 min prior to a renewal test in Context A. In Experiment 2, the VH was infused with an inhibitory DREADD-expressing virus under the control of Cre (AAV-hSyn-DIO-hM4D[Gi]-mCherry). In these same animals, the IL was infused with a canine adenovirus (CAV) to retrogradely express Cre and inhibitory DREADDs in VH neurons projecting to IL. Four weeks later, rats underwent ABA renewal (as in Exp. 1) in a counterbalanced within-subjects design. Each rat was tested to the CS outside of the extinction context on CNO (1 mg/kg, i.p.) and vehicle. As predicted, DREADD-mediated inactivation of either VH or VH neurons projecting to IL disrupted fear renewal as compared to control animals. The data suggest that VH projections to the infralimbic cortex are necessary for renewal. These data are consistent with the possibility that, during fear renewal, the VH inhibits the IL to limit the suppression of fear to an extinguished CS.

Title: Differential control mechanisms mediating the acquisition and consolidation of cued fear extinction

Authors: *T. N. HUYNH, E. SANTINI, E. KLANN;
Ctr. for Neural Science, New York Univ., New York, NY

Abstract: De novo protein synthesis is required for the extinction of cued fear memory. Central to the regulation of translation is the mammalian target of rapamycin complex 1 (mTORC1) signaling pathway, which stimulates cap-dependent translation through the phosphorylation of two downstream effectors: eIF4E-binding proteins (4E-BPs) and p70 S6 kinase 1 (S6K1).

Phosphorylation of 4E-BPs permits the binding of eIF4E to eIF4G to form eIF4F and phosphorylation of S6K1 leads to the phosphorylation of additional translational control molecules that stimulate protein synthesis. We first sought to determine the role of mTORC1 in the extinction of cued fear memory. We found that rapamycin, an mTORC1 inhibitor, had no effect on the acquisition of extinction, but blocked extinction memory. Similarly, inhibition of eIF4E-eIF4G interactions blocked the consolidation of extinction. We then examined the role of S6K1 in extinction. We found that both pharmacological inhibition and genetic ablation of S6K1 impaired acquisition of extinction. In addition, our biochemical studies indicate that S6K1 is regulated by extracellular signal-regulated kinase (ERK), but not mTORC1, during the acquisition of extinction. Moreover, we found that S6K1, via ERK activation, phosphorylates the GluA1 subunit the AMPA receptor during extinction. Overall, the results of our studies indicate that mTORC1 and its downstream effectors are critically involved in the acquisition and consolidation of cued fear extinction.

Title: Subcellular localization of HDAC4 affects amygdala-dependent fear memory

Authors: *S. A. MADDOX[1], R. D. PENROD[2], C. W. COWAN[2], K. J. RESSLER[1,3,4]; [1]Harvard Med. Sch., McLean Hosp., Belmont, MA; [2]Intergrative Neurobio. Lab., McLean Hospital; Harvard Med. Sch., Belmont, MA; [3]Psychiatry and Behavioral Sci., Emory Univ. Sch. of Med., Atlanta, GA; [4]Howard Hughes Med. Inst., Chevy Chase, MD

Abstract: Epigenetic alterations have recently been implicated in the initial consolidation of amygdala-dependent fear memories. While much work has noted the regulation of histone acetylation in fear memory processes, little is known about the specific role that histone deacetylases (HDACs), which mediate the deacetylation of histone tails, might have in fear memory consolidation. Motivated to understand the epigenetic alterations that may be associated with human clinical PTSD, our group has previously noted that CpG methylation in HDAC4 is associated with PTSD. While much work has examined the role of HDACs in learning and memory employing pan HDAC inhibitors in rodent models, very little is known about the role that specific HDACs play in mediating the initial formation of fear memories. HDAC4 is a class IIa HDAC whose subcellular localization can be cytoplasmic or nuclear and is regulated by Ca2+ and NMDAR-mediated signaling cascades; a level of regulation not yet explored *in vivo* with fear memory formation. Recent work in rodent models has noted that repression of HDAC4 is associated with deficits in spatial learning and hippocampal-dependent contextual fear memory consolidation (Sando et al 2012; Kim et al 2012) suggesting a role for HDAC4 in memory. Despite this progress, the role of HDAC4 in amygdala-dependent auditory fear memory has not been elucidated. Using auditory fear conditioning, we examined the regulation of HDAC4 mRNA in the amygdala 2h following tone-shock pairings and revealed training-related regulation of HDAC4 mRNA. Next, using cytoplasmic or nuclear restricted HDAC4 viral constructs in the amygdala we examined if the subcellular localization of HDAC4 impacts fear memory formation. While we found no difference in freezing during fear acquisition, 24h later mice expressing nuclear-restricted HDAC4 show impaired fear memory consolidation compared to the cytoplasmic-restricted and GFP-control animals. Given the role of HDACs in regulating transcriptional processes we examined how HDAC4 may mediate the transcriptional processes underlying fear learning and memory by examining HDAC4 occupancy at gene loci using ChIP. We found a reduction in HDAC4 occupancy at the BDNF locus following conditioning, at a timepoint when the mRNA expression of BDNF has been shown to increase with fear conditioning. These data suggest that nuclear accumulation of HDAC4 likely functions as a negative regulator of fear memory-related plasticity through impeding training-related transcriptional processes, such as the transcription of BDNF. In sum, these findings strongly suggest that HDAC4 and its subcellular localization impacts fear memory consolidation.

Title: Neuronal activation underlying recent and remote fear extinction memory

Authors: *W. A. SZADZINSKA, J. BUKOWCZAN, M. MIKOSZ, K. ROKOSZ, E. KNAPSKA;
Nencki Inst. of Exptl. Biol., Warszawa, Poland

Abstract: Fear extinction memory is a susceptible memory that becomes weaker with the passage of time and is liable to the environmental changes. To understand the neuronal basis of this phenomenon, we subjected rats to Pavlovian fear conditioning with a tone (CS) co-terminated with a foot-shock (US) on the first day. On the following day rats were subjected to fear extinction - in a changed context. The test of the extinction memory was performed 1 or 28 days after extinction, in the original or changed context. Behavioral results (measured as the levels of freezing during CS) indicated that successful retrieval of extinction memory (low levels of freezing) occurred only in the group tested 1 day after extinction in the extinction context. c-Fos expression analysis in the prefrontal cortex, amygdala and hippocampus revealed distinguishable patterns of activation in different groups. Different patterns of activation of amygdala inhibitory neurons (GAD67 positive) were also observed. 28 days after extinction, we observed different, context-dependent patterns of the activation of prefrontal cortex layers. Further, we investigated active projections from the basolateral amygdala and ventral hippocampus to the prelimbic part of prefrontal cortex with the use of anterograde tracing in a transgenic rat in which neurons express a dendritically-targeted PSD-95:Venus fusion protein under the control of a c-fos promoter. Co-localization of projections and construct-positive neurons revealed that the basolateral inputs are highly activated in the groups expressing high levels of fear. The results show different patterns of brain activation underlying recent and remote fear extinction memory, and suggest that the basolateral inputs to the prelimbic cortex may drive retrieval of fear memory.

Title: Distinct roles of the basolateral amygdala and infralimbic cortex in the extinction of restored fear

Authors: *N. LINGAWI[1], V. LAURENT[2], R. WESTBROOK[1];
[1]Psychology, Univ. of New South Wales, Sydney, Australia; [2]Psychology, Univ. of Sydney, Sydney, Australia

Abstract: The basolateral amygdala (BLA) has been consistently implicated in fear extinction. However, fear spontaneously recovers after extinction with the passage of time, and is renewed by a change in context. Previous research in our lab suggests that the mechanisms underlying initial and subsequent extinction in fact differ. For example, the BLA is not required to re-learn inhibition of fear after reconditioning. It has been proposed that compensatory mechanisms in the infralimbic prefrontal cortex (IL) are recruited to relearn fear inhibition during times when the BLA is inactive. In a series of experiments, we examined the roles of the BLA and IL in extinction of recovered and renewed fear. These behavioral paradigms directly mimic the circumstances under which relapse of anxiety disorders are likely to occur in patient populations. We confirmed that inactivation of the BLA impaired long-term extinction learning. However, inactivation of the BLA during extinction of recovered and renewed fear spared long-term extinction learning. These results suggest that the BLA is not required to learn extinction of recovered fear if initial extinction occurred while the BLA was intact. We also found that pharmacological stimulation of the IL facilitated long-term extinction of renewed fear. Together, these results suggest that the BLA and IL work in concert to learn inhibition of fear after restoration, and provide insight into the neural mechanisms of fear inhibition after relapse.

Title: Small conductance calcium-activated K+ channels in the prelimbic cortex modulate extinction of fear memory in male C57BL/6J mice

Authors: *J. C. LORA, L. SHARVIT, R. W. STACKMAN, Jr.;
Biol. Sci., Florida Atlantic Univ., Jupiter, FL

Abstract: Post-traumatic stress disorder (PTSD) is characterized by the resurgence of a memory of a traumatic event by an external stimulus. Common behavioral symptoms of PTSD are aggressiveness, irritability, and decrease in attention among many others. Understanding the underlying brain mechanisms of PTSD and the ways to attenuate aberrant behavioral manifestations is of great interest. One current project focuses on small conductance calcium-activated potassium (SK) ion channels, which are expressed in brain regions important for long-term memory. SK1, SK2 and SK3 channels limit the development of learning-dependent synaptic plasticity, and memory for spatial, non-spatial and emotional information. We have previously reported that drugs that block SK channels facilitate learning and memory, while drugs that activate SK channels impair learning and memory. In the present fear extinction study, adult male mice received three pairings of a 30-s tone (CS) that co-terminated with a 1-s mild foot-shock (US). Twenty-four hr after training, mice received local bilateral microinfusions of an SK2 channel activator, CyPPA or vehicle control, into the prelimbic cortex, and then were presented with 20 CS-alone extinction trials. Freezing, a measure of fear elicited by the CS, was found to decline significantly in the vehicle control mice over the course of the extinction trials. In contrast, CyPPA-treated mice exhibited a significant impairment in the acquisition of fear extinction. These results indicate that activation of prelimbic SK2 channels delays extinction of fear memory. We are currently testing whether blocking prelimbic SK2 channels can facilitate fear extinction in mice. This work represents a first step in determining the efficacy of SK channels to modulate the manifestation of behaviors that may relate to symptoms expressed in PTSD. SK channels may prove to be an effective target to include in an effort to reduce the PTSD symptomology in order to improve cognitive recovery.

Title: High-affinity α4β2 nicotinic receptors are required for the impairing effects of acute nicotine on contextual fear extinction

Authors: *M. G. KUTLU, E. HOLLIDAY, T. J. GOULD;
Temple Univ., Philadelphia, PA

Abstract: Previously, studies from our lab have shown that while acute nicotine administered prior to training and testing enhances contextual fear conditioning (e.g. Gould & Higgins, 2003), acute nicotine injections prior to extinction sessions impair extinction of contextual fear (Kutlu & Gould, 2014). There is also strong evidence showing that the acute nicotine's enhancing effects on contextual fear conditioning require high-affinity α4β2 nicotinic acetylcholine receptors (nAChRs) but not low-affinity α7 nAChRs (Davis Gould, 2006; Davis et al., 2007; Gould et al., 2012). However, it is unknown which nAChR subtypes are involved in the acute nicotine-induced impairment of contextual fear extinction. In this study, we investigated the effects of acute nicotine administration on contextual fear extinction in knock-out (KO) mice lacking α4, β2 or α7 subtypes of nAChRs and their wild-type (WT) littermates. Both KO and WT mice were first trained and tested for contextual fear conditioning and received a daily contextual extinction session for 4 days. Subjects received intraperitoneal injections of nicotine (0.18 mg/kg) or saline 2-4 mins prior to each extinction session. Our results showed that similar to the acute nicotine's enhancing effects on contextual fear conditioning, the mice lack α4 and β2 subtypes of nAChRs showed normal contextual fear extinction but not the acute nicotine-induced impairment while the mice that lack α7 subtype showed both normal contextual extinction and nicotine-induced impairment of contextual extinction. These results clearly demonstrate that activation of high-affinity α4β2 are necessary for the acute nicotine's impairing effects on contextual fear extinction.

Title: Rescuing impaired fear extinction is associated with the regulation of miRNAs in the amygdala

Authors: *C. MURPHY[1], V. MAURER[1], R. GSTIR[2], S. SCHAFFERER[2], N. WHITTLE[3], A. HÜTTENHOFER[2], N. SINGEWALD[1];
[1]Dept of Pharmacol. and Toxicology, Univ. of Innsbruck, Innsbruck, Austria; [2]Dept of Genomics and Rnomics, Innsbruck medical Univ., Innsbruck, Austria; [3]Friedrich Miescher Inst. for Biomed. Res., Basel, Switzerland

Abstract: A particular challenge in the treatment of anxiety disorders, including exposure-based therapy (EBT), is to obtain long-lasting benefits. Mimicking anxiety patients which show delayed and/or reduced extinction of fear (Duits et al, 2015), 129S1/SvImJ (S1) mice exhibit profound resistance to induce fear extinction. This impaired fear extinction in S1was shown to be rescued by dietary Zn2+ restriction (ZnR), facilitating long-lasting and context-independent fear inhibitory memories. Here we aim to reveal mechanisms involved in the formation of these fear inhibiting memories including the regulation of de novo gene expression by microRNAs (miRNAs) which control gene expression by targeted translational repression and/or mRNA degradation. We assessed the regulation of miRNAs in an extinction relevant brain area, the amygdala (AMY) of S1 mice after ZnR-induced rescue of deficient fear extinction. Microarray-based analysis revealed the regulation of a number of miRNAs after the rescue of impaired fear extinction. Using diverse bioinformatic platforms we identified promising candidate miRNAs for further investigation. We focused on a candidate miRNA that has been previously linked with the positive regulation of the signalling cascades MAPK/ERK and PI3/ARK. MAPK/ERK activation in the basolateral amygdala (BLA) is required for the consolidation of fear extinction. Indeed, fluorescent *in situ* hybridization (FISH) revealed an increased expression of this miRNA in the BLA of S1 mice after rescuing impaired fear extinction. Using Immuno-staining coupled with FISH, we then assessed the role of miRNA mediated activation of the MAPK/ERK signalling cascade by examining the levels of phosphorylation of p44/42 (MAPK(ERK1/2). Understanding the role of miRNAs in the formation of long-lasting fear inhibitory memories could provide novel targets for the treatment of anxiety disorders such as post-traumatic stress disorder. Title: Using measures of transcriptional activity to determine mnemonic processes through which SPS exposure leads to extinction retention deficits

Authors: *D. K. KNOX[1,2], B. R. STANFIELD[2], J. M. STAIB[2], S. M. KELLER[2], S. P. ALBANESE[2];

Abstract: Previous research has demonstrated that single prolonged stress (SPS), a rodent model of post traumatic stress disorder (PTSD), induces deficits in extinction retention (i.e. the ability to inhibit conditioned fear responding to a previously extinguished fear conditioned stimulus (CS)). While this effect has been consistently observed, it is unknown if SPS disrupts extinction retention by enhancing fear memory, disrupting extinction memory, or some combination of both processes. We previously attempted to use behavioral manipulations to address this question, but the results of these experiments were inconclusive. In this study, we examined mnemonic processes through which SPS exposure results in extinction retention deficits by assaying c-Fos levels in fear and extinction circuits after fear conditioning, extinction training, and extinction testing in SPS and non-stressed rats. If SPS disrupts extinction retention by enhancing fear memory or disrupting extinction memory, then relevant memory-specific changes in c-Fos levels should be observed with SPS exposure after fear and/or extinction memory formation. Groups of SPS and non-stressed rats were either fear conditioned (CS-fear) or presented with CSs in the absence of any footshock (CS-only). Subsets of SPS and non-stressed rats were then euthanized after fear conditioning, extinction training, or extinction testing. A separate set of SPS and non-stressed rats were euthanized after removal from their housing colony in order to establish basal levels of c-Fos in each brain region. Semi quantitative measures of c-Fos levels were measured in the medial prefrontal cortex (mPFC), dorsal hippocampus (dHipp), ventral hippocampus (vHipp), lateral amygdala (LA), and basal amygdala (BA). In replication of previous studies, SPS induced extinction retention deficits. Preliminary findings suggest that SPS exposure decreases baseline c-Fos levels in the vHipp, LA, and BA. Furthermore, enhanced c-Fos expression in the mPFC, LA, BA, and vHipp were observed with CS-fear and CS-only presentations in SPS rats during fear conditioning. While the study is ongoing, the results support the hypothesis that SPS-induced changes in transcriptional activity prior to and during CS memory formation contribute to extinction retention deficits in the SPS model.

Title: Altered fear extinction in a rodent model of mild traumatic brain injury and posttraumatic stress disorder

Authors: *J. A. GRECO[1,2], I. LIBERZON[1,2];
[1]Univ. of Michigan, Ann Arbor, MI; [2]VA Ann Arbor Healthcare Syst., Ann Arbor, MI

Abstract: Background: Mild traumatic brain injury (mTBI) and post-traumatic stress disorder (PTSD) are common, debilitating conditions that often co-occur following trauma. Changes in fear-associated learning have been found in rodent models of PTSD and mTBI, and in PTSD patients. However, limited work has explored changes in fear-associated learning following both PTSD and mTBI. In this study, we explored the effect of controlled cortical impact (CCI) and single prolonged stress (SPS), models of mTBI and PTSD, on fear-associated learning and extinction in rodents. Methods: Experiment 1: 12 Sprague-Dawley rats underwent CCI (5 mm impact, 1.5 mm depth, 3.0 m/s velocity, 100 ms dwell time). An additional 12 rats received craniotomies without receiving impact. Seven days after CCI or sham injury, all rats underwent a 3-day fear learning and extinction paradigm in individual observation chambers. Freezing during the acquisition, extinction and extinction recall phase was scored and analyzed. Experiment 2: 24 Sprague-Dawley rats underwent CCI, and 24 rats received craniotomies without receiving impact. Seven days after CCI or sham injury, 12 rats from each group underwent SPS, while another 12 rats from each group remained in their cages. Seven days later, all rats underwent the 3-day fear learning and extinction paradigm. Freezing during all phases was scored and analyzed. Results: No significant results were seen during fear acquisition. During fear extinction, repeated measures ANOVA found a significant interaction of injury x time in both Experiment 1 ($F(8.486, 93.351) = 2.464$, $p = .016$) and Experiment 2 ($F(3.149, 100.756)=3.699$, $p=.013$). During fear extinction recall in Experiment 2, there was an interaction approaching significance of injury x time (Block*Injury: $F(4,128)=2.187$, $p=.074$). Conclusions: These results suggest that the rate of fear extinction is impaired in a model of mTBI in rodents. This impairment was seen in both experiments, with extinction occurring 8 days after CCI in

Experiment 1, and 15 days after CCI in Experiment 2. Immunohistochemistry will characterize the inflammation and damage following the injury to further examine the effect of mTBI and PTSD together on fear learning.

Title: Reconsolidation promotes the strengthening of extinction memory

Authors: *J. HAUBRICH, A. MACHADO, F. ZACOUTEGUY BOOS, A. P. CRESTANI, F. SANTANA, R. ORDONEZ SIERRA, L. DE OLIVEIRA ALVARES, J. A. QUILLFELDT; Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil

Abstract: Brief reactivation of a previously stored memory can render it into a labile state that requires de novo protein synthesis in order to be re-stabilized and persist, a process called reconsolidation. Previous works have shown that this procedure can lead to memory strengthening. On the other hand, when an associative memory is persistently retrieved in the absence of the unconditioned stimulus, the consolidation of an extinction memory takes place. Although effective in suppressing fear at short delays, extinction fails to do so permanently since several relapse processes can take place, such as spontaneous recovery. In this work we evaluated whether the natural decay of an extinction memory can be counteracted by a reconsolidation process able to strengthen the trace. In all experiments, male wistar rats were trained in the contextual fear conditioning task and 24h later were re-exposed to the training context during 30 minutes without the US/footshock (extinction session). On experiment 1, rats were tested on day 3 and retested either on days 10, or 17, or 24, or 31, in order to assess the time-point when fear spontaneous recovery occur. On experiment 2, rats were again re-esposed to the context without the US on day 3, but only for 3 minutes (reactivation session), being injected with the protein synthesis inhibitor cyclohexemide (2 mg/kg i.p.) immediately after; on day 4, test was conducted in order to verify if the extinction memory did undergo reactivation-induced reconsolidation. On experiment 3, rats where tested on day 3 and a spontaneous recovery test was conducted on day 31 in order to confirm if the procedure can strengthen the memory trace; in between these two tests, on days 10, 17 and 24, one group of animals was periodically exposed to 3-min reactivation sessions while controls remained in their homecages.

First, we confirmed that the extinction memory undergoes a time-dependent decay, and spontaneous recovery of fear response is observable already after 21 days. The observed disruptive effect of cyclohexemide shows that, whatever takes place after a brief reactivation session, it requires a de novo protein synthesis in order to persist, suggesting that the extinction memory undergoes a labilization-reconsolidation process. When periodically reactivated, the time-dependent decay of the extinction memory was interrupted and no spontaneous recovery was observed for at least 4 weeks. Taken together, our results show not only that an extinction memory can be modified by reconsolidation, but that this procedure may allow for a long-lasting persistence of fear suppression.

Title: Dnmt3a2 is required for fear memory extinction

Authors: *H. BADING, T. J. HEMSTEDT, A. M. M. OLIVEIRA, H. E. FREITAG;
IZN At the Univ. of Heidelberg, Heidelberg, Germany

Abstract: During the past years, the regulation of epigenetic processes in memory formation and fear extinction have been shown to be crucial in a variety of studies (Oliveira et al., 2012, Bahari-Javan et al.,2012). However, the underlying molecular and cellular mechanisms are far from being understood. The expression level of the de novo DNA methyltransferase Dnmt3a2 has been previously shown to influence memory performance in young and aged mice (Oliveira et al., 2012). Here, we demonstrate that memory formation can be enhanced when Dnmt3a2 is overexpressed in the hippocampus of young adult mice. In addition, by using an inducible CreERT2/loxP system in combination with rAAV-mediated gene transfer, we show that overexpression of Dnmt3a2 leads to facilitated fear memory extinction and is further associated with an increase in expression levels of plasticity-related genes. Conversely, mice show an impairment in fear memory extinction when the level of Dnmt3a2 is decreased. Thus, besides of its impact on memory formation the level of Dnmt3a2 is further critical for fear memory

extinction. Therefore, regulating Dnmt3a2 expression may serve as novel strategy to treat anxiety and fear disorders, such as post-traumatic stress disorder.

Title: Preventing recovery of learned fear: A novel extinction procedure

Authors: *A. M. SCHNEIDER[1], P. E. SIMSON[3], M. LICHTEN[1], J. WALSH[1], D. KALAMARIDES[4], C. EVERBACH[2], L. G. KIRBY[4];

Abstract: Following fear conditioning in a typical extinction experiment, animals are returned to and remain in the apparatus in the absence of shock until fear is extinguished. The effect of extinction is often temporary: with passage of time fear recovers. This recovery is thought to result from an inhibitory memory acquired during extinction that temporarily suppresses the otherwise intact fear memory. In contrast to the typical extinction procedure, we recently used a modified extinction procedure in which animals, following contextual fear conditioning, were exposed to the conditioning apparatus in the absence of shock for a brief period (30-sec); thus, animals were removed from the apparatus before an opportunity developed to recall fear to a significant degree. A retention test the next day revealed that the brief-exposure was effective in weakening retention of fear. What remained to be determined were the endurance of the brief-exposure effect and the degree to which it could be manipulated. To this end, in the present study, male Long-Evans rats underwent contextual fear conditioning followed 24 hr later by the brief-exposure procedure. Fear conditioning consisted of placing rats in a dark compartment for 120 sec followed by a single footshock (0.8 mA, 0.5 sec); the brief-exposure procedure consisted of confining the animals to the dark compartment in the absence of shock for 0 sec, 30 sec, 60 sec or 180 sec or for two 30-sec exposures separated by 10 min (the 30-sec/10 min/30-sec

condition). Level of fear (freezing behavior) was monitored during the exposure conditions and a retention test to assess recovery of fear was administered either 1 or 13 days later. The results indicated that fear increased during exposure in all conditions with one exception: fear decreased in the 30-sec/10 min/30-sec condition. In addition, retention of fear decreased in the short term (retention test 1 day later) and recovered in the long term (retention test 13 days later) in all conditions with one exception: retention of fear did not recover in the 30-sec/10 min/30-sec condition. To account for these results, we propose that learning occurs during the exposure conditions, but the type of learning is dependent on the level of fear during the exposure. If fear is relatively high (as a result of 30, 60 or 180 sec exposure) inhibitory learning (or equivalently prediction error) occurs, the original fear memory is temporarily suppressed and retention of fear recovers. If fear is relatively low (as a result of the 30-sec/10 min/30-sec condition) the animal learns to associate weak fear with the apparatus, the original fear memory is displaced and retention of fear does not recover.

Title: Sub-region specific prefrontal-amygdala interactions during rapid eye movement (REM) sleep underlies consolidation of extinction memory

Authors: *S. DUVARCI[1], D. POPA[2], T. SIGURDSSON[1], D. PARE[3];
[1]Goethe-University Frankfurt, Frankfurt, Germany; [2]IBENS, Paris, France; [3]CMBN, Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Animals must identify and react appropriately to stimuli that signal danger in their environment but they must also adapt their behavior when those stimuli no longer predict danger. A well-studied example of this process is fear extinction, during which animals decrease their

fear responses to a conditioned stimulus (CS) previously associated with an aversive unconditioned stimulus (US). The available evidence suggests that fear extinction represents a new form of learning rather than the erasure of the original CS-US association. There is also evidence to suggest that extinction learning, like other forms of learning, requires consolidation in order to stabilize the extinction memory. Sleep has been shown to play an important role in memory consolidation and REM sleep in particular has recently been shown to be important for the consolidation of extinction learning. However, the neural network mechanisms underlying the consolidation of extinction memories during sleep remain unknown. The prefrontal cortex (PFC) plays a key role in extinction, likely via its interactions with the basolateral amygdala (BLA). Notably, different PFC sub-regions play opposing roles in this process, with the IL mediating fear extinction and the PL promoting fear expression. We therefore recorded neural activity in BLA, PL and IL in rats during sleep after fear extinction learning. We quantified BLA-PFC interactions by measuring correlations in the power of theta oscillations in the two structures, which recent studies have associated with the regulation of fear and anxiety. We found a selective increase in IL-BLA theta power correlations during REM sleep following fear extinction learning. In contrast, PL-BLA theta power correlations did not change. Although all animals displayed extinction learning, freezing levels varied considerably during the extinction recall test the next day, reflecting variability in extinction memory consolidation. Strikingly, theta power correlations between BLA and IL during REM sleep negatively correlated with freezing levels during extinction recall. In contrast, theta power correlations between BLA and PL showed the opposite relationship. Our results suggest that theta coordination in the prefrontal-amygdala circuit during REM sleep underlies consolidation of fear extinction in a prefrontal sub-region specific manner.

Title: Medial prefrontal cortex NMDA and CB1 receptors interaction modulating reconsolidation and extinction contextual fear conditioning memory

Authors: *D. G. REIS, A. FASSINI, D. C. LAGATTA, S. F. LISBOA, L. B. M. RESSTEL; Univ. Sao Paulo, Ribeirao Preto, Brazil

Abstract: Introduction: The ventral portion of medial prefrontal cortex (vMPFC) is involved in the modulation of processes involving learning and memory, especially in processes of expression and extinction of conditioned emotional response (CER). Studies showed that vMPFC NMDA and CB1 receptors present opposing roles on behavioral and autonomic modulation during expression of the CER. However, the precise role of a possible interaction between these receptors on autonomic and behavior responses associated to reconsolidation and extinction of contextual fear memories has not be fully studied. The aim of the present study was to investigate the effect of simultaneous antagonism of NMDA and CB1 receptors in vMPFC on reconsolidation and extinction processes, by CER responses evoked by re-exposure to an aversively conditioned context. Methods: Male Wistar rats (250g) had a radio-telemetry probe implanted for recording autonomic activity and guide cannulas in vMPFC for drug administration. Day 1: Preconditioning started 1 wk after guide cannula implantation and consisted of one 10-min-long pre-exposure (habituation) in the footshock box. After 4h, the animals received 4 electrical footshock (FS) (0.8 mA, 1s). Day 2: Two groups were tested, reconsolidation group (5 min session) or extinction group (30 min session) re-exposure without FS presentation. Each group received two intra vMPFC injections (1st vehicle (V) or CB1 antagonist AM251 30 pmol (AM) / 2nd vehicle or NMDA antagonist LY235959 0.4 nmol (LY) 15 or 10 min before reconsolidation or extinction sessions forming 4 groups (V x V / V x LY / AM x V / AM x LY). Day 3: The test session take place in the next day consisting of a 10-min re-exposure to the FS box without any shock or injection given. Results: Reconsolidation Day 2: No significant differences were observed between all groups on CER (Freezing: $F(3, 19)=0.4$; $P>0.05$ ΔMAP: $F(3, 85) = 1.386$ $P<0.05$ ΔHR: $F(3, 85) = 0.7$ $P<0.05$ ΔCT: $F(3, 85)=22$; $P<0.05$). Day 3: Group AM x V presented an elevated expression of CER compared to all other groups (Freezing: $F(3,19)=8.9$; $P<0.05$ ΔMAP: $F3,85=13$ $P<0.05$ ΔHR: $F3,85=42$; $P<0.05$ ΔCT: $F3,85=22$; P0.05 ΔMAP: $F (3, 102) = 1,1$ $P>0.05$ ΔHR: $F (3, 102) = 0.6$ $P>0.05$ ΔCT: $F (3, 102) = 0.3$ $P>0.05$. Day 3: Group AM x V presented an elevated expression of compared to all other groups (Freezing: $F(3,19)=8.9$; $P<0.05$ ΔMAP: $F3,85=6.37$ $P<0.05$ ΔHR: $F3,85=19$; $P<0.05$ ΔCT: $F3,85=31$; $P<0.05$). Conclusion: The interaction between NMDA and CB1 receptors in vMPFC modulates both reconsolidation and extinction process associated to contextual fear memories.

Title: Pharmacologically-induced grooming behavior: grooming patterning and its relation with fear extinction

Authors: *A. E. REIMER[1,4], A. R. DE OLIVEIRA[5,4], J. B. DINIZ[2], M. Q. HOEXTER[2], S. CHIAVEGATTO[3], R. G. SHAVITT[2], E. C. MIGUEL[2], M. L. BRANDÃO[1,4];

Abstract: Self-grooming consists of complex sequences of movements directed to clean and maintain the fur and skin of the head and body. The complex patterning of grooming in rodents is highly sensitive to stressors, which can alter the quantity, the regional distribution and the transitions between grooming stages. Additionally, grooming behavior can be induced pharmacologically by compounds that alter serotonergic or oxytocinergic neurotransmissions, both supposed to be involved in obsessive-compulsive disorder (OCD) physiopathology. Since recent evidence have indicated that OCD patients show important impairments in fear extinction, in the present study we evaluated pharmacologically-induced grooming patterns and its relation with conditioned fear expression and extinction. For this, male Wistar rats were submitted to a contextual fear conditioning training and re-exposed to the aversive context for three consecutive days (extinction sessions). Before the first extinction session or before each extinction sessions, rats received intra-central amygdala administration of oxytocin (OXT) or intraperitoneal administration of mCPP (a nonspecific serotonergic agonist). Grooming behavior was evaluated before first extinction session, immediately after drug treatments. Freezing behavior was evaluated for 10 min, in each one of the three extinction sessions. Both OXT and mCPP increased grooming expression but, OXT-treated rats presented an altered grooming regional distribution (increased caudal grooming), when compared with control group. When single administered, OXT and mCPP did not produce effects on fear extinction. However, when administered before each extinction session, OXT enhanced fear extinction throughout the sessions while mCPP impaired extinction. Present data indicate that grooming can be modified by different pharmacological approaches and it is possible that these different grooming patterns

could be associated with distinct emotional states. Besides, the grooming induced by OXT, which has been previously proposed as an OCD animal model, seems not to be associated with impaired fear extinction, a deficit observed in OCD patients. Further analyses on grooming syntactic chain could help to examine other possible relations between grooming behavior and anxiety disorders.

Title: Early adversity disrupts the adult use of aversive prediction errors to reduce fear in uncertainty

Authors: *K. M. WRIGHT, A. DILEO, M. MCDANNALD;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Early adversity increases anxiety in adult rodents and primates, and increases the risk for post-traumatic disorder (PTSD) in humans. Long-studied in the context of reward, recent work highlights the role of prediction errors in aversive learning. Increased anxiety in adverse-experienced individuals may partially result from an inability to utilize negative aversive prediction errors (−APEs) to reduce fear. To test this hypothesis, we gave adolescent rats a battery of adverse experiences from postnatal day 26 to 35, then assessed their ability to reduce fear in a probabilistic Pavlovian fear conditioning task during adulthood (beginning postnatal day 75). In the task, rats were confronted with three cues associated with different probabilities of foot shock: one cue (A1) never predicted shock - 0.00, another cue (A2) predicted shock with uncertainty - 0.25, and a final cue (A3) always predicted shock - 1.00. Control rats initially acquired fear to all three cues, but reduced fear to both the A2 and A3 cue halfway through discrimination trials, maintaining these levels for the remainder of the task. Because A2 predicts shock with uncertainty, the use of -APEs is most likely required for A2 fear reduction. The low level of fear to the uncertain cue suggests Controls successfully used -APEs to reduce fear. Adverse-experienced rats (EA) were impaired in the reduction of fear to the uncertain cue and

the cue not predicting shock. While they eventually showed little or no fear to the non-predictive cue, by the end of discrimination trials, EA rats continued to show elevated fear to the uncertain cue. These results suggest early adversity impairs the use of -APEs to reduce fear, especially in situations of uncertainty.

Title: Fear extinction combined with chronic treatment of fluoxetine in pyramidal neuron- and interneuron-specific TrkB heterozygous knockout mice

Authors: *J. UMEMORI[1], F. WINKEL[1,2], C. BUJ[3], E. CASTRÉN[1];
[1]Neurosci. center, Univ. of Helsinki, Helsinki, Finland; [2]Fac. of Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands; [3]Fac. of Sci., Aix Marseille Univ., Marseille, France

Abstract: Major neuronal network plasticity is normally limited to the critical periods of early postnatal life. We have previously reported that antidepressant drug treatment induces a juvenile critical period-like plasticity (iPlasticity) in the adult brain. This process allows brain networks to better adapt to the internal and external milieu (1-3). We hypothesize that, in the context of neuropsychiatric disorders, iPlasticity allows psychotherapy to guide plastic networks resulting in a more effective treatment. In fact, combination of extinction training and chronic fluoxetine (Flx) treatment, but neither treatment alone, was demonstrated to induce an enduring loss of conditioned fear memory in adult mice (2) similar to the permanent fear extinction found in early postnatal mice (4,5). Chronic Flx treatment increases expression levels of Brain-derived neurotrophic factor (BDNF), and our laboratory showed that its expression is necessary and sufficient for iPlasticity in the visual cortex and amygdala (1, 2). BDNF binding to TrkB receptors causes dimerization and autophosphorylation of TrkB and results in transcription of genes that stimulate neuronal survival, outgrowth and neurogenesis (6). However, it is not clear whether TrkB activation is necessary for iPlasticity or in which neuronal subpopulations expression of TrkB is required. In this study, we used mice lacking TrkB in Calcium/Calmodulin-Dependent Protein Kinase II Alpha (aCaMKII) and Parvalbumin (PV)

expressing neurons to test fear extinction with chronic Flx treatment. We used heterozygotes since homozygous aCaMKII- and PV- TrkB KO mice had hyperactive phenotype and vestibular dysfunction respectively (7,8), which disturbs further analysis. Our preliminary experiments show that PV-TrkB KO mice treated with Fluoxetine have lower extinction compared to control mice, suggesting that TrkB expression in PV neurons are involved in erasure of fear memories. We will also discuss the possible roles of TrkB expressed in pyramidal neurons and interneurons for fear extinction. 1. Maya Vetencourt JF et al., *Science* 320, 385 (2008) 2. Title: Fear extinction modulates AMPA receptor expression in the nucleus accumbens

Authors: *A. MCGRATH[1], S. S. CORREIA[2], K. A. GOOSENS[2];
[2]Dept. of Brain and Cognitive Sci. and McGovern Inst. for Brain Res., [1]MIT, Cambridge, MA

Abstract: Fear extinction is a process in which fear responses are weakened through repeated exposure to the fearful stimulus in a safe environment. It has been used in clinical settings to treat fear-based psychiatric illnesses such as phobias, panic disorder, anxiety and post-traumatic stress disorder. The nucleus accumbens (NAc), a striatal region well-known for its involvement in reward processing, is thought to also participate in aversive memory. In addition, the NAc is believed to be important for fear extinction. It has been previously demonstrated that antagonism of the AMPA receptor in the NAc can modulate both appetitive and avoidance behavior, suggesting that AMPA receptors in the NAc are critical for responding to motivational stimuli.

Given that the NAc has been implicated in fear extinction, and that AMPA receptors in the NAc impact emotional behavior, we hypothesized that fear extinction would change the expression of AMPA receptors in the NAc. In this experiment, rats underwent fear conditioning and varying degrees of extinction training. One hour after the final training day, the rostral and caudal NAc were harvested, and Western blot analysis was used to determine the levels of the AMPA receptor subunits GluA1 and GluA2. We found that both fear conditioning and extinction modulate expression of AMPA receptors in the NAc, and that AMPA receptor levels correlated with freezing levels during extinction. A better understanding of the molecular basis of fear extinction can contribute to the improvement of treatments for patients with fear-based psychiatric diseases.

Title: Performance of formal economic coordination and cooperation games by macaques

Authors: *C. R. VAN COEVERDEN[1], W. SCHULTZ[2];
[1]Dept. of Physiology, Develop. and Neurosci., [2]Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Coordination and cooperation are necessary for the survival of social animals. Coordination merely requires the organisation of actions to work together. In addition to this, cooperation also requires an actor to forgo some of her immediate payoff to obtain a later, higher mutual outcome. A well validated economic game for investigating cooperation is the prisoner's dilemma (PD). In PD the highest individual reward can be obtained by defection when the opponent chooses to cooperate. This highest reward is also commonly referred to as the temptation value. Recent studies show that macaques cooperate in a significant proportion of trials when playing an iterated PD. However, it is not clear to what extent the temptation value in otherwise similar games drives differences in levels of coordination and cooperation.

Furthermore, it is currently unclear whether and how the animals use information from other animals' choices to inform their own. In our experiment two macaques indicated choices (cooperation or defection) on a touchscreen to obtain rewards. The reward magnitudes were dependent on the choices of both animals. In different versions of the task we varied the temptation value. This resulted in different games varying from a simple coordination game to more complex prisoner's dilemmas. Analyses of both macaques' choices revealed that there was a significant decline in the amount of coordination as a function of the temptation value (binary logistic regression: b=-.255,Wald=390, $p<0.0001$). In addition, there was an even sharper decline in cooperation in games with higher temptation values (b=-.440,Wald=1162, $p<0.0001$). Even though levels of defection in the prisoner's dilemmas where higher, macaques mutually cooperated on a significant number of trials (26.3%, Z=2.44p=0.0015). Interestingly, there was a significant increase in response time of the second chooser when the first chooser chose the cooperative option across all games. To summarize, our results suggest that macaques can coordinate their actions and cooperate in economic games. However, coordinating on a higher payoff becomes less frequent in prisoner's dilemmas where cooperation is required to overcome temptation. Macaques also seem to use the information from seeing the other's actions to adapt their behaviour when playing social economic games. This suggests that, in our experiment, macaques do not merely make choices based on their trial history but show a social component to their behaviour.

Title: Role of primate amygdala neurons in decision-making

Authors: *F. GRABENHORST, W. SCHULTZ;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The amygdala is considered a key system for reward and emotion with a classic function in fear; however, recent evidence suggests that it also participates in decision-making beyond reward processing. We recently showed that primate amygdala neurons signal economic choices (Grabenhorst et al., 2012) and plans for internal, distant reward goals (Hernadi et al., 2015). Despite these advances, the amygdala's role in decisions is poorly understood. Because the amygdala is implicated in a wide spectrum of behaviors and pathological conditions, it is critical to know whether its neurons express a decision function. Here we recorded the activity of 180 amygdala neurons as a monkey chose between sequentially presented visual objects based on learned reward probability and cued reward magnitude. On each trial, two objects appeared sequentially in a central position, separated by a delay, before reappearing in randomized left-right positions as saccade targets. Object-specific reward probabilities changed over trial blocks and had to be learned through experience; reward magnitudes changed trial-by-trial and were cued sequentially with the objects, thus requiring flexible computation of expected value. Our design separated valuation, decision-making and action planning: the monkey could not make its choice until seeing the second object and could not plan its action until seeing the final object positions. We found evidence for gradually unfolding decisions in amygdala neurons. At first object presentation, a significant number of neurons (18%) encoded object-specific values reflecting both reward probability and magnitude. Such 'object values' seem suited as inputs for a competitive decision process. At second object presentation, neurons encoded the value of the second object relative to the first object (value comparison, 17%) and upcoming choice for first or second object, irrespective of its identity (11%). At left-right object presentation, many neurons encoded the identity of the chosen object (21%), thus signalling the output of an object-based decision process. These results indicate that amygdala neurons encode the principal stages of reward-based decision-making: converting object value input via value comparison to object choice output. The data are consistent with a decision function for this key reward structure.

Title: Utility functions predict skewness preferences in monkeys

Authors: W. GENEST[1], *W. R. STAUFFER[2], W. SCHULTZ[1];
[1]Physiology, Develop. and Neurosci., [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Individuals must often choose between risky alternatives, and it has long been recognized that risk influences subjective value (utility). Risk modulated by the variance of outcome distributions is commonly studied in the lab. However, few real-world gambles are normally distributed, thus variance alone does not provide a full description of the risk for these gambles. Indeed, a large body of evidence suggests that individuals are also sensitive to risk modulated by skewness - the asymmetry of the outcome distribution. Moreover, skewness attitudes and variance attitudes stem from different properties of the utility function. They are therefore formally independent of each other. Here we sought to characterize skewness attitudes and investigate the relationship between skewness attitudes and utility functions. We derived utility functions from the choices two monkeys made between safe rewards and binary, equiprobable gambles. Such gambles are not skewed; hence the risk was modulated solely by the variance. The utility functions obtained from those choices predicted the subject value of eight new binary gambles, providing evidence for their numerical validity (R^2=0.734, P=10^{-12}). Next, we introduced skewness using gambles with three equiprobable outcomes. We measured the subjective values of these gambles and tested how well they could be predicted by our utility functions. Linear regression analysis revealed that these utility functions (derived using only variance) predicted well the subjective value of four skewed gambles (R^2=0.232, P=10^{-8}). The subjective value rankings of the skewed gambles suggested a preference for positively skewed gambles over negatively skewed ones. To test this we presented the animals with choices between positively and negatively skewed three outcome gambles (all with the same expected value and variance). They consistently preferred positively skewed gambles over negatively skewed ones (P = 10^{-6} in both animals). Thus, their choices were consistent with third order stochastic dominance (a measure of risk sensitivity that demonstrates meaningful incorporation of skewness into subjective value). Empirically derived utility functions were therefore useful behavioural measures for inferring risk preferences modulated by both variance and skewness. This lays the foundation for further investigations into the neural origins of risk and skewness attitudes, and the mechanism by which the brain computes economic utility.

Title: Evaluating the neurobiology of strategic coordination in non-human primates

Authors: *W. S. ONG, M. L. PLATT;
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Coordination and cooperation depend on effective social communication. Deciphering the neural basis of social coordination and communication is thus a priority. In humans, brain areas linked to both social behavior and reward are activated by cooperation. The neural processes indexed by these blood flow signals, however, remain unclear. We previously reported neurons in anterior cingulate cortex and amygdala signal vicarious reward in monkeys when they choose to reward another monkey. Such signals may inform computations mediating coordination and cooperation.To test this idea, we developed a new task based on the classic "chicken game." Two monkeys (M1 & M2) face each other across a shared monitor. Two colored annuli framing random dot motion arrays and 4 response targets are presented. Color indicates the annuli and targets belonging to each monkey. On ½ of trials, the larger reward (denoted by visual tokens) lies opposite the controlling monkey behind the opponent's annulus; smaller rewards lie to the left. To obtain the larger reward, M1 goes straight, but if M2 also goes straight the annuli collide and neither monkey gets reward. On some trials, a "cooperation bar" allows both monkeys to obtain larger rewards only if both choose to go left. If only one monkey yields he receives a smaller reward. On some trials, dot motion coherence is randomized to obscure intention signals. When playing a computer opponent, monkeys played the pure Nash equilibrium strategy of maximizing reward by choosing the left target when it offered more reward, regardless of the opponent's choice. When the straight target gave more reward, they played a mixed Nash equilibrium strategy by choosing straight unless the computer opponent signaled it would go straight; then, monkeys chose the left target and obtained less reward.Monkeys' deviated from the Nash equilibrium strategy when playing a live monkey opponent by going straight more often regardless of reward size or the opponent's choice. This behavior depended on both social dominance and information about the opponent's intentions. High-ranking monkeys challenged low-ranking monkeys, who tended to yield. Mid-ranking monkeys switched strategies depending on whether the opponent was higher or lower ranking. When intention signals were obscured, monkeys collided thrice as often as when intentions were

signaled clearly. These findings demonstrate strategic, competitive behavior in monkeys that depends on both social context and communication, thus validating our task as an effective tool to determine the neural basis of social coordination and cooperation.

Title: Pharmacological manipulation of the serotonergic system modulates the value-based decision making in non-human primate

Authors: *G. DRUI[1], Y. SAGA[1], A. RICHARD[1], P. N. TOBLER[2], V. SGAMBATO-FAURE[1], L. TREMBLAY[1];
[1]CNRS UMR5229 - Ctr. of Cognitive Neurosci., BRON, France; [2]Dept. of Econ. - Zurich Univ., Lab. for Social and Neural Systems Res., Zurich, Switzerland

Abstract: Beyond the behaviors associated with positive outcomes (approach towards appetitive stimuli), a lot of stimuli or events are associated with a negative outcome and induce aversive anticipation to produce avoidance or escape behaviors. Previous studies have linked the serotonin system to anxiety and impulsive behaviors and thus to an inappropriate aversive anticipatory process. To study the neurobiological mechanisms involved in such context, we have developed an instrumental delay task with a condition that allows the expression of aversive anticipations and associated behaviors. Four monkeys were trained to recognize conditioned stimuli (CS) associated with appetitive (juice) or aversive (air puff) outcome in two different conditions. In a choice condition, two opposite CS (i.e. appetitive and aversive) were presented simultaneously. After a delay, if the animals choose to select the target positioned where the appetitive CS was previously located, it performed an active avoidance from the aversive

outcome and an approach toward the reward in the same time. In an imperative condition, only one CS was presented, so monkeys must either approach the appetitive stimulus or actively avoid the aversive one. We showed that monkeys did perform approach for appetitive trials and avoidance for aversive trials. Progressively during the daily session, the strategy of the animals toward the aversive stimuli was modified as they produced premature responses and omissions, which could be both interpreted as escape behaviors. Interestingly, systemic fluoxetine, a selective serotonin reuptake inhibitor (SSRI), delayed these escape behaviors for all monkeys. These results suggest that the modulation of the serotonergic tone modifies the appetitive and/or the aversive encoding and thus the decision-making. The characterization of the fluoxetine's effect in the neural encoding of the appetitive and aversive information in cerebral structures which receive large input of serotonin fibers such as the ventral striatum could help to understand the pathophysiology of obsessive compulsive disorders, depression and anxiety related disorders for which SSRI are effective.

Title: Facilitation negative decisions in the non-human primate by stimulating a ventral striato-pallidal pathway linked to the anterior insula

Authors: *Y. SAGA[1,2], G. DRUI[1], V. SGAMBATO-FAURE[1], C. RUFF[3], L. TREMBLAY[1]; [1]Ctr. de Neurosci. Cognitive, Bron Cedex, France; [2]Japan Society for Promotion of Sci., Tokyo, Japan; [3]Dept. of Econ., Lab. for Social and Neural Systems Res., Zurich, Switzerland

Abstract: The limbic territories of the Basal Ganglia (BG) - such as ventral striatum (VS) and ventral Pallidum (VP) - are thought to play important roles in goal-directed behavior by guiding decision to approach rewarding outcomes. However, using neuronal recordings in monkeys

performing a value-based choice task, we have recently identified in these BG structures neurons that selectively respond to negative conditioned stimuli or aversive outcomes (Saga et al. FENS, 2014; Richard et al. SFN, 2014). Recent imaging studies in humans show that negative events or decisions in a negative context lead to active in the anterior insula. Moreover, the anterior insula is known to have a projection to VS (Sgambato-Faure et al. 2014), suggesting that a limbic Cortico-BG circuit may process the negative values of stimuli that can inhibit behavioral approach and facilitate the active avoidance of negative outcomes. The purpose of the present study was to determine the role of the structures in this circuit (VS, VP and Insula) for aversive encoding, decision-making and context-adapted behaviors. For this purpose, we applied micro-stimulation specifically when animals were making value-based decisions. Two monkeys were trained to perform a choice task that involved conditioned stimuli (CS) that were associated with either an appetitive (juice) or aversive (air puff) outcome. When monkeys held the start lever, one or two CSs (single/dual cue conditions) were presented on the screen and were followed after a delay by two targets. Subsequently, monkeys made their choice by touching one of the targets located at the same (approach) or different (avoidance) position from the selected CS. Micro-stimulation (pulse-train of 700 ms with 0,2-0,6 mA as in Worbe et al. 2009) was applied before, during or after CS presentation and induced increases of non-initiated choice (omission) and escape reactions (premature responses) as well as disadvantageous choices (avoidance of positive outcomes or approach to aversive outcomes). Taken together, our micro-stimulation results combined with previous anatomical studies and neural recordings highlight the involvement of a Cortico-BG circuit (passing through the indirect pathway and closely linked to the anterior Insula) in negative value encoding and corresponding choices to escape or avoid disadvantageous outcomes in aversive contexts.

Title: Conflict between different task rules influences the prefrontal neuronal activities during behavioral choice

Authors: M. NEJIME[1], M. INOUE[2], M. SARUWATARI[3], A. MIKAMI[4], *S. MIYACHI[1]; [1]Primate Res. Institute, Kyoto Univ., Inuyama, Japan; [2]Natl. Inst. of Information and Communications Technol., Suita, Japan; [3]Grad. Sch. of Frontier Biosci., Osaka Univ., Suita, Japan; [4]Fac. of Nursing and Rehabil., Chubu Gakuin Univ., Seki, Japan

Abstract: While we often use previously acquired rule to choose our behavior, sometimes we need to choose it based on immediate cue ignoring the acquired rule. How is such a flexible behavior realized? Previously, we have examined the neuronal activities of the medial and dorsolateral prefrontal cortex (MPF and DLPF) while the monkeys were performing a delayed matching-to-sample (DMS) task and a transverse patterning (TP) task, which needs long-term memory of relations between the visual cues. In the present study, we examined how the acquired TP rule influences the neuronal activities during performance of the DMS task. The TP task was a set of three visual discrimination problems, in which two out of the three visual stimuli (A, B, C) were presented simultaneously, and the monkey chose the target based on the rule, which was acquired by long-term practice (A+/B−, B+/C−, C+/A−, where + and − indicate the target and the distractor). In the DMS task, the same three stimuli were used, but the correct target was determined by the immediate sample cue that was randomly chosen in each trial. In a half of the trials (congruent trials), the target was the same as in the TP task (e.g., A+/B−), but in the other half (incongruent trials), the target was opposite (e.g., B+/A−). Both monkeys showed lower percent correct in the incongruent trials than the congruent trials ($P < 0.001$), showing interference from the acquired TP rule. We examined activities of 136 DLPF and 56 MPF neurons in the DMS task. The firing rates were analyzed in 2 task periods: cue period shortly after the presentation of the choice cues, and presaccade period immediately before the saccade onset. We examined the influence of the congruency with the TP rule on the neuronal activities by three-way ANOVA (factors: congruency, target shape, and target location). In the cue period, 5 DLPF (4%) and 1 MPF (2%) neurons showed the main effect of congruency. In the presaccade period, the numbers increased to 16 in DLPF (12%, $P = 0.019$) and 5 in MPF (9%, $P = 0.125$). In either area, the large majority of the congruency-dependent neurons showed higher firing rate in the incongruent trials during the presaccade period (13 out of 16 DLPF neurons, $P = 0.009$; 5 out of 5 MPF neurons, $P = 0.031$). These results suggest that the neuronal activities in both the DLPF and MPF, especially in the presaccade period just before the response execution, are affected by the conflict with the currently irrelevant rules in the process of behavioral choice depending on the immediate cue. Such increased activities in presaccade period may contribute to the execution of the correct behavior against the irrelevant rule(s).

Title: Hierarchical hidden Markov modeling of real time changes in strategic behavior in a game theoretic context

Authors: *D. L. XIE[1,3,4], J. BECK[2,5], J.-F. GARIEPY[3,5,4], M. L. PLATT[3,4,5];
[1]Ctr. for Cognitive Neurosci., Duke Univ., Raleigh, NC; [2]Duke Univ., Durham, NC; [3]Duke Inst. for Brain Sci., Durham, NC; [4]Duke Ctr. for Cognitive Neurosci., Durham, NC; [5]Duke Univ. Dept. of Neurobio., Durham, NC

Abstract: In a dynamic environment in which players are continuously interacting in a competitive game, these players must generate flexible strategies that can adaptively respond to their opponent's actions in real time. For example, consider a simplified two-player soccer match in which a kicker's objective is to dribble a ball into a goal, while a goalie's objective is to block the kicker. A strategy a kicker may consider is feinting to mislead the goalie into moving in the opposite direction of the kicker's intended scoring point. However, given the dynamic nature of this game, if the goalie were to be unaffected by this maneuver, then the kicker should adaptively change strategies in real time. Because strategies are adaptively adjusted in real time, it is difficult to determine precisely which strategy is being utilized at any given time. Indeed, a common approach to identify behavioral strategies is to cluster complete behavioral trajectories through k-means clustering or other clustering algorithms to elucidate behaviors. While useful for identifying games which, in their entirety, are played out in similar fashion, these methods are incapable of identifying particular strategies utilized at any given time. To address this issue, we consider a hierarchical hidden Markov model (HHMM) in which high-level states represent current strategies of the subject and low-level states represent current behavior. Sequences of high-level states are used to identify global patterns that summarize entire gameplay sequences, while low-level behavioral states making up a given sequence can be identified as the strategy the player is currently employing. We applied this approach to the aforementioned two-opponent game played by male rhesus macaques. The HHMM automatically discovered four global

patterns of behavior. More importantly, it also identified when the kicker initiated a change in behavior or adaptively transitioned to another. This approach reveals highly nuanced and sophisticated strategies in interactions between non-human primates in a competitive game setting that require advanced theory of mind capabilities and working memory of the other player's intentions and strategies. Here, we demonstrate a novel application of HHMM that identifies current strategies implemented throughout a continuous sequence of a competitive game. Not only does this analysis provide a concise representation of global patterns of behavior, but it may also serve to generate effective predictors of neural activity in higher-level brain areas, providing a novel paradigm for investigating the neural circuitry underlying real-time behavior and strategies in game theoretic contexts.

Title: Dissociating the functions of the macaque ventrolateral and orbitofrontal cortex

Authors: *P. H. RUDEBECK[1], R. C. SAUNDERS[2], D. LUNDGREN[2], E. A. MURRAY[2]; [1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Orbitofrontal cortex (OFC) has long been associated with the flexible control of choice behavior in general and efficient performance of the object reversal learning task in particular. In large part, this is based on the repeated finding that aspiration lesions of the OFC in humans, monkeys, and rodents - among other mammals - lead to deficits in stimulus-reward reversal learning. Recently we showed that excitotoxic fiber-sparing lesions of macaque OFC do not affect learning and reversing stimulus-reward associations in a deterministic setting (Rudebeck et al., 2013, Nat Neurosci 16:1140). Evidence suggests that impaired performance on reversal tasks following aspiration of OFC is caused by damage to white matter tracts passing nearby OFC, which disrupts the connections and functions of other frontal cortex areas. The lack of effect on a deterministic task also left open the question of OFC contributions to stimulus-reward learning and reversal in probabilistic settings. Here, we set out to determine the role of

both the OFC (Walker's areas 11,13, and 14) and the ventrolateral prefrontal cortex (VLPFC, Walker's area 12), the area laterally adjacent to the OFC, in learning and reversing probabilistic stimulus-reward associations. Macaques (Macaca mulatta) were trained to perform a stimulus-based three-arm bandit task for food rewards. The probability of receiving a reward from any of the stimuli fluctuated over the course of 300-trial testing sessions. Both controls (n=8) and macaques with excitotoxic lesions of the OFC (n=4) were readily able to learn and track which of the three stimuli was associated with the highest probability of reward. In contrast, macaques with excitotoxic lesions of VLPFC (n=4) were severely impaired. Logistic regression analyses indicate that this was because monkeys with VLPFC lesions were unable to form contingent associations between stimuli and rewards. We are currently assessing whether VLPFC lesions affect all types of flexible choice behavior, including the ability to learn and update specific stimulus-outcome associations, a function dependent on OFC. Irrespective of this, our data are consistent with the idea that the deficits in flexible stimulus-reward learning and reversal previously ascribed to OFC are the result of unintentional damage to projections to or from VLPFC. This work was supported by the intramural research program of the NIMH.

Title: Spatial selectivity of neurons in the primate prefrontal and parietal cortices

Authors: *P. VISWANATHAN[1,2], A. NIEDER[1];
[1]Univ. of Tübingen, Tübingen, Germany; [2]IMPRS for Cognitive and Systems Neurosci., Tübingen, Germany

Abstract: Both, the primate prefrontal cortex (Mikami et al., 1982; Suzuki, 1985) and the parietal cortex (Duhamel et al., 1997) are known to be visually and spatially selective. In the prefrontal cortex, neurons have been described as having "memory fields" which circumscribe the area of increased delay period activity of a certain neuron to a preferred object when it is presented in specific part of the visual field (Rainer et al., 1998). Thus, while retaining the representation of an object, they additionally retain its location by having spatial selectivity. Quite remarkably, this spatial selectivity is highly localized and contralateral in many neurons

and not foveal as long believed. Similarly, neurons in the ventral intraparietal area of the posterior parietal cortex have a sophisticated multi-modal representation of objects in space using different reference frames (Avillac et al., 2005; Zhang et al., 2004). These reference frames are sometimes found to shift from eye-centered to head-centered representations, possibly enabling spatial transformations during movement. In short, spatial selectivity in such higher order visual areas appears to subserve the cognitive functions they perform. To address this possibility in another domain, we record single unit responses simultaneously from both areas while monkeys fixate a central spot and a moving bar stimuli is used to scan the visual field for spatial selectivity. Additionally, we record the same units during a delayed match-to-sample task with centrally placed dot array stimuli. We first investigate the spatial selectivity of these cells. We compare the spatially restricted responses during the fixation task to their responses towards numerically rich stimuli during the active matching task. We further test the responses of these cells to varying directions and orientations of the moving bar stimuli.

Title: The neural representation of empty sets in macaque posterior parietal cortex

Authors: *A. RAMIREZ-CARDENAS, A. NIEDER;
Animal Physiol., Univ. of Tübingen, Inst. of Neurobio., Tuebingen, Germany

Abstract: A general magnitude system primarily hosted in the posterior parietal cortex is considered responsible for the representation of quantity in primates. However, in the small extreme of the natural numbers the neuronal correlates of zero remain unexplored, even when behavioral studies have shown that non-human primates do possess a pre-symbolic precursor of zero. We trained 2 rhesus monkeys in a delayed match-to-sample task involving as stimuli sets of black dots (0-4) presented against a gray background. We controlled for total dot area, dot density, background shape and area, and total luminance of the stimuli. Importantly, when empty sets were presented as sample, monkeys mistakenly matched them to numerosity 1 more frequently than to numerosity 2. This pattern in behavior, a ‘distance effect’, suggests empty sets

were ordered in the context of other numerosities and so treated in a quantitative way. Single-cell recordings in VIP (ventral intraparietal area) revealed a significant population of numerosity-responsive neurons (16.3% sample, 23% delay), most of which (77.9% sample, 82.8% delay) did not exhibit interactions between number and other factors in their responses. Just as for other numerosities, a distinct subpopulation of responses having zero as preferred numerosity was identified by tuning-curve clustering. Crucially, the averaged tuning curve of zero-preferring responses showed a graded decay in firing rate with increasing numerosities. Error analysis confirmed the behavioral relevance of such responses. Numerosity-preferring responses included empty sets in their response range as if placed in the numerical continuum. A decoding approach corroborated our findings. When a SVM classifier was trained on the responses of numerosity selective neurons, its performance in numerosity discrimination exhibited a distance effect. Altogether, our data show that single neuron responses in the posterior parietal cortex represent empty sets as endowed with null quantity. Unexpectedly, empty sets are actively encoded in this cortical region and find a place in the neural number line.

Title: Preference judgment of visual items and contribution of the orbitofrontal cortex in monkeys

Authors: ***S. FUNAHASHI**, W. NAKAMOTO;
Kyoto Univ. Kokoro Res. Ctr., Kyoto, Japan

Abstract: Both humans and animals like to watch neutral and biologically insignificant visual stimuli. Behavioral studies have revealed that animals more frequently select stimuli with symmetrical and regular patterns and short movies compared to stimuli with unsymmetrical and irregular patterns and photographs, respectively. Preferred visual stimuli can serve as rewards for

animals performing behavioral tasks. Therefore, preferences for visual stimuli could be related to the magnitude of the pleasant feelings that are experienced when the stimuli are seen. The orbitofrontal cortex is known to participate in the detection and prediction of reward, the estimation of the value of the stimuli as a reward, and positive emotion. Human neuroimaging studies have shown that the magnitude of orbitofrontal responses to the presentation of neutral visual stimuli correlates with the strength of the preference for the stimuli in the behavioral studies. In the present study, to examine whether the magnitude of orbitofrontal single-neuron responses to neutral visual stimuli correlates with the strength of the preference for these stimuli observed in the behavioral study, we first determined two Japanese monkeys' preference for 50 visual stimuli obtained from the FMD database using a simple choice task (select one stimulus from simultaneously presented two stimuli by eye movements) and then examined whether or not the magnitude of orbitofrontal neural responses to these stimuli correlated with the rank order of these stimuli obtained in the behavioral study. The behavioral study showed the rank order of the preference in these 50 stimuli based on the chosen ratio of each stimulus during the simple choice task. Among 188 single-neuron activities recorded from the orbitofrontal cortex, 65 neurons exhibited visual responses to 50 visual stimuli and exhibited stimulus selectivity. One third of these neurons exhibited either positive or negative correlations between the magnitude of visual responses and behaviorally determined preference rank orders of visual stimuli. These results suggest that the orbitofrontal cortex plays an important role in the judgment of the preference for visual stimuli and that the magnitude of orbitofrontal responses to the visual stimuli is related to the strength of the pleasant feelings that are produced by the stimuli.

Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: An influential theoretical framework argues that neural systems capitalise on the statistics of stimulus presentation to actively predict forthcoming sensory information, and optimise perceptual decisions. Human functional neuroimaging studies have provided support for predictive theories of perception, but evidence from single-unit neurophysiology has been conspicuously absent. We recorded from 252 single neurons in inferior temporal cortex (IT) while monkeys judged whether a degraded cue image was a face or a fruit, signalling their decision by responding to a matching image after a variable delay. The probability of each object cue (face vs. fruit) was controlled at 5 levels (0%, 25%, 50%, 75% and 100% face probability) that changed unpredictably over the experiment. Monkeys' choices were determined by the physical stimulus (responding "face" when the cue was a face), but they were also strongly biased by the object probability (i.e. responding "face" when faces were more probable). Changes in probability were not signalled overtly, implying that monkeys were learning the most likely cue from the recent trial history. We identified neurons that were selective for both faces and fruit, but critically, averaging responses over the neuronal population revealed embedded signals related to expectation. Starting at about 150 ms following cue onset, responses to expected cues were attenuated relative to responses to unexpected cues ("expectation suppression"), which is consistent with findings from human neuroimaging studies. Control analyses showed that this effect was not due to adaptation to the cue from the previous trial, and the degree of expectation suppression for a given cue type was negatively correlated with the neuron's selectivity for that cue (i.e., expectation suppression for face cues correlated negatively with face selectivity, and expectation suppression for fruit correlating negatively with fruit selectivity). Fitting a reinforcement-learning model to the data, we further observed temporally dissociable neural responses that encoded both stimulus-specific prediction errors (stronger response for unexpected faces > unexpected fruit, starting at 100 ms) and stimulus-general prediction errors (stronger responses for unexpected > expected cues, starting at 150 ms). Together, these findings suggest that the responses of neurons in IT reflect the probability of occurrence of a stimulus over time, derived from the statistics of stimulus presentation. These findings support the view that neural signals in the mammalian visual system actively encode and update predictions about the local sensory environment.

Title: Representation of reward value by single unit in the monkey orbitofrontal cortex during decision-making

Authors: *T. SETOGAWA[1], T. MIZUHIKI[1,2], F. AKIZAWA[2,3], R. KUBOKI[2], B. J. RICHMOND[4], N. MATSUMOTO[5], M. SHIDARA[1,2];

Abstract: In our daily life, we often choose one item or action from several alternatives by considering their values and efforts to obtain them. To study the neural mechanism of such decision-making process, we developed a decision-making schedule task to obtain a reward and recorded single neurons from monkey orbitofrontal cortex (OFC). Two monkeys were initially trained to perform a reward schedule task. In this task, the monkey had to complete the schedule composed of 1, 2 or 4 trials of visual discriminations to earn 1, 2 or 4 drops of liquid reward. After the monkey learned this task, the decision-making schedule task was introduced. The decision-making schedule task had a decision-making part and a reward schedule part. In the decision-making part, two choice targets (CT), each a bar of light, were presented sequentially at the center of a computer monitor. Brightness and length of the CT were proportional to the amount of liquid reward (1, 2, or 4 drops) and the required number of the visual-discrimination trials (1, 2, or 4 trials) to be performed, respectively. After both first and second CTs had been presented, the same two CTs simultaneously reappeared along side the fixation point. The monkey was required to choose one of the two CTs by touching the corresponding bar in the chair. Then, the chosen reward schedule task was started. We recorded 253 neurons in the monkey OFC during the decision-making schedule task (137 and 116 neurons from each monkey). The CT values were estimated from the monkey's choice behavior by an exponential

discounting model of reward value. Multiple regression analysis after the second CT period revealed that 172/253 neurons had responses correlated with CT values (either one or the other chosen value, 108/253; both chosen value, 64/253). To investigate whether the recoded neurons could be involved in comparing reward values, the trials were divided into 2 groups: trials when monkeys chose the first CT and the trials when they chose the second CT. Multiple regression analysis for the two groups separately showed that 84/253 (33.2%) of the recorded neurons had different signs for the coefficients of 2 CT terms, and 29/253 (11.5%) neurons had coefficients with the same signs. 76/253 (30.0%) neurons coded currently presented CT values. These results suggest that OFC neurons related to both the predicted outcome values, and to the value comparison between the alternatives.

Title: Dopamine D2 receptor stimulation enhances working memory coding in primate prefrontal cortex neurons

Authors: *T. OTT, A. NIEDER;
Inst. of Neurobiology, Univ. of Tübingen, Tübingen, Germany

Abstract: Working memory processing in the prefrontal cortex (PFC) is modulated by dopamine. Manipulation of either dopamine receptor type, the D1 or D2 receptor family, impacts behavioral performance of tasks requiring working memory in humans and animals. However, only D1 receptors modulate the memory fields of single neurons in the PFC during spatial working memory. Despite strong clinical implications of prefrontal D2 receptors, cellular mechanisms by which D2 receptors modulate working memory processing in the PFC remain unknown. Therefore, we trained two macaque monkeys to perform a memory-guided decision-making task. Monkeys had to remember the amount of dots, i.e. the numerosity, of a sample item to decide whether a test item had a larger or smaller numerosity. During the delay between sample and test, no visual information was available. We recorded single units in the PFC while

applying specific dopamine D1 or D2 receptor targeting drugs using micro-iontophoresis. The activity of single units in the PFC was selective for one of the three sample numerosities during the memory period without visual stimulation, i.e. they were tuned to their preferred numerosity. After stimulating D2 receptors with the D2 receptor agonist quinpirole, neuronal responses to the preferred numerosity were increased, thus enhancing their tuning properties. At the population level, D2 receptor stimulation increased the representation of sample numerosities and improved decoding accuracy. In contrast, manipulation of D1 receptors did not strongly affect working memory coding. These results show that prefrontal D2 receptors are involved in working memory processing at the cellular level and serve as a possible basis for cognitive changes observed after D2 receptor manipulation.

Title: Not quite noisy, suboptimal, or wrong: rational process models and strategic decision making

Authors: ***D. L. BARACK**[1], Y. LI[1], M. R. NASSAR[2], J. I. GOLD[1];
[1]Dept of Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Brown Univ., Providence, RI

Abstract: Strategies determine the probability of taking an action given a state of the world. Optimal strategies are those likeliest to achieve particular goals, such as maximizing rewards or minimizing costs. However, agents often seem to behave sub-optimally, such as making more errors than expected. Such sub-optimalities might result from mixed strategies, with contributions from both optimal and suboptimal components. Alternatively, these apparent sub-optimalities might result from rational process models that approximate optimal strategies using simpler but psychologically plausible computations. The goal of this study is to develop a framework for distinguishing between these contributing strategies. We focus on the behavior of monkeys performing a ten-choice saccade task. Monkeys chose one target on each trial, receiving a juice reward for correct choices as well as visual feedback informing them of the rewarding target on that trial. On each trial, the rewarding target was drawn probabilistically

from a distribution centered on a single, best target. From time to time, change-points occurred, when the best target was randomly reselected from the remaining nine possible targets. To maximize rewards, monkeys should identify and always pick the best target, even if that target is not rewarded on a given trial. Monkeys' behavior reflected components of an optimal inference process, including a tendency to choose the best target determined from recent history, and apparently simpler heuristics, including a tendency to choose the previously rewarded target. We develop a three-step framework to decompose the behavior into underlying strategies. First, we represent the behavioral data with a matrix that specifies action probabilities given a set of states. Second, we define how a range of strategies would map onto this matrix, using both a priori selection of strategies ranging from simple (e.g., follow the winner) to complex (fully Bayesian) and more data-driven approaches that extract strategy-like features from the behavioral data. Third, we compare these strategies to a rational process reduction of the Bayes optimal model, a mixture of delta rules model with different learning rate time constants. Preliminary results indicate that the rational process model can recapitulate many different heuristics including the optimal strategy by changing the parameter settings governing its computational complexity. Further work will analyze how time-dependent variability in the parameter settings of these kinds of rational process models can generate complex behavioral patterns that appear to reflect mixtures of optimal and sub-optimal components.

Title: Structural and functional changes in brain circuits associated with learning rules in macaques

Authors: ***J. SALLET**[1], M. P. NOONAN[1], A. THOMAS[1,2], F.-X. NEUBERT[1], B. AHMED[1], J. SMITH[1], A. H. BELL[1,3], M. J. BUCKLEY[1], K. KRUG[1], R. B. MARS[1,4], M. F. S. RUSHWORTH[1];

[1]Univ. of Oxford, Oxford, United Kingdom; [2]NIH, Bethesda, MD; [3]MRC Cognitive and Brain Sci. Unit, Cambridge, United Kingdom; [4]Donders Inst. for Brain, Nijmegen, Netherlands

Abstract: In discrimination reversal (DisRev) learning tasks animals learn that one choice leads to reward while another does not. Animals also learn that when the reward assignments are switched, the previously unrewarded choice has become the one followed by reward. Behavioural flexibility in DisRev has often been thought to rely on a brain circuit centered on the orbitofrontal cortex (OFC). To identify the components of this circuit we sought brain regions where structure and activity changes were associated with DisRev experience in a group of nine macaques: 4 animals choosing between target identities, 5 animals choosing between target locations. We obtained structural and functional MRI (fMRI) measures of activity at two time points while animals were at rest. At time 1 the animals already had learned that pressing a target on a touchscreen, either on a left or a right side of the screen, was associated with a juice reward. At time 2 the animals had negotiated 5 sessions with 5 reversals within a session and with performance above 85% correct Compared with control animals, significant grey matter increases were associated with DisRev experience in amygdala, basal forebrain, and medial thalamus, medial orbitofrontal cortex, anterior cingulate cortex (ACC), and the lateral prefrontal cortex (lPFC). No significant changes were observed in the central OFC (cOFC). As well as structural changes functional coupling changes were also found between the same regions. Second, to examine further whether these areas might constitute the circuit affected by OFC aspiration lesions, we examined the impact of OFC lesions in two macaques on grey matter and activity coupling in and between these same areas. Structural and fMRI data revealed that OFC lesions were associated with significant changes in grey matter in many of the same areas including medial thalamus, lPFC, mOFC, medial forebrain, and amygdala. In most cases the changes were decrements in grey matter but increased grey matter was found in the amygdala and hippocampus Although we failed to identify changes in cOFC associated with DisRev we were able to show that adjacent frontal areas, likely to be disconnected by OFC aspiration lesions, are important in DisRev. The results are consistent with the view that fluent DisRev performance is mediated not just by choice-reward association learning mechanisms linked to OFC, but also by acquisition of a cognitive set or task model, dependent on many interacting brain regions, representing the inter-relationships between the different choice-reward associations active in the task at different times

Title: Irrational decisions? blame your vmpfc

Authors: *G. K. PAPAGEORGIOU[1], J. SALLET[1], M. J. BUCKLEY[1], M. F. S. RUSHWORTH[1,2];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]FMRIB Centre, Univ. of Oxford, John Radcliffe Hosp., Oxford, United Kingdom

Abstract: Aims The medial orbitofrontal cortex (mOFC)/ventromedial prefrontal cortex (vmPFC) has been implicated in decision-making and encoding the value of expected outcomes. Here we investigate its role in valuation and decision-making in the context of multi-faceted outcomes. We report an unusual 'less is more' effect where subjects have the tendency to choose options that are less valuable than others and show the effect is dependent on mOFC/vmPFC. Methods Six adult macaque monkeys (controls: 4, mOFC/vmPFC-lesioned: 2) participated in the experiment. All animals were trained on a 2-choice 6-options behavioural task in which choices of three stimuli led to 3 different types of reward and the other 3 stimuli led to no reward delivery. More specifically, one stimulus led to a highly valued reward ('High option'), a second stimulus led to a low valued reward ('Low option') and a third stimulus could led to the combination of the two ('Compound option'). All possible choice combinations have been used. Once this phase of the experiment was completed, the 4 control animals, executed a modified version of this task inside the fMRI scanner. Results All control animals preferred the high option over the low option and the compound option over the low option. Surprisingly, however, they preferred the high option over the compound option suggesting that the value of the multifaceted compound option was not the sum of the values of its component parts. This unusual choice pattern on high option versus compound was significantly less pronounced in animals with mOFC/vmPFC. Further analyses of the fMRI data at the time of the stimulus presentation showed stronger mOFC/vmPFC activation for the high option in comparison with the compound option. Conclusion Together, lesion and neuroimaging results suggest that mOFC/vmPFC plays an important role in representing values of multi-faceted options.

Title: Neuronal responses of macaque caudate nucleus and frontal eye field during visual perceptual learning

Authors: *T. DOI, J. I. GOLD;
Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Our ability to detect, discriminate, and identity sensory stimuli can improve with training. This phenomenon, called perceptual learning, is observed widely across sensory modalities and is preserved throughout adulthood. Although psychophysical aspects of perceptual learning have been studied extensively, the underlying neural mechanisms are not clear. Our previous work with monkeys suggested that a learning mechanism based on reward feedback—reinforcement learning—can guide perceptual learning on a visual motion direction-discrimination task. The basal ganglia, a set of neural structures implicated in reinforcement learning, along with interconnected regions of prefrontal cortex may together contribute to the training-based perceptual improvements. Here we recorded single- and multi-unit activity from caudate nucleus, the primary input stage of the basal ganglia, and the frontal eye field (FEF) of prefrontal cortex while a monkey was trained to perform the direction-discrimination task. We presented a patch of noisy, moving dots for a fixed duration at the center of the visual field. After a variable delay, the monkey indicated the perceived direction by making a saccade to one of two choice targets located along the axis of motion. Initially, we used only easy stimuli in which all the dots coherently moved in the same direction. After the monkey learned the correct association between motion and saccadic directions, we introduced more difficult stimuli in which varying portions of dots move in random directions. The percentage of coherently moving dots, termed motion coherence, dictated the strength of motion stimulus. As expected, the monkey's sensitivity to weak motion stimuli improved over the course of training. We found that task-driven responses of caudate neurons also changed during training. Most strikingly, the sensitivity to motion coherence increased, with most neurons responding more to lower coherences but some responding more to higher coherences. These changes were observed for neural responses measured during the delay and post-saccadic periods and occurred before FEF neurons began to show coherence selectivity. The coherence-sensitive responses in caudate tended to be similar for trials that resulted in choice saccades contralateral and ipsilateral to the recorded hemisphere and thus did not appear to be related directly to the monkey's decision.

These responses are consistent with a representation of choice-independent value, which could, in principle, be used to guide reinforcement-driven learning of the perceptual discrimination.

Title: Observations from a successful DREADD silencing experiment in non-human primate orbitofrontal cortex

Authors: *W. LERCHNER, M. A. G. ELDRIGE, R. C. SAUNDERS, V. DER MINASSIAN, S. BHAYANA, B. J. RICHMOND;
LN/NIMH, NIH, Bethesda, MD

Abstract: We used the DREADD (Designer Receptors Exclusively Activated by Designer Drugs) technology to reversibly silence virally transduced orbitofrontal cortex (OFC) neurons in two monkeys with contralateral rhinal lesions. On days when hM4Di-DREADD expressing neurons were silenced by systemic injection of the DREADD receptor ligand Clozapine-N-Oxide (CNO), at 10mg/kg, there was a marked reduction in discrimination between expected reward sizes in a simple stimulus-reward association task, and an overall reduction in error rate compared to days without injection of CNO. There was no difference in the total number of trials completed or in the reaction times of the monkeys under these conditions. Therefore the DREADD technology can be used to silence neurons in an extended region of sheet-like structures such as the monkey cortex, to a sufficient degree to induce changes in behavior. In the course of these experiments, we made several observations on the use of virally expressed DREADDs in monkeys: 1) We made 40-70 handheld lentivirus injections into OFC, resulting in dense local expression areas of up to 2000 μm width near the presumed injection tracks, with gaps in between injection sites. The volume coverage of areas with DREADD expressing cells was approximately 7% in Brodmann area 13 and 3.0% in Brodmann region 11. Neuron specific expression, as determined by NeuN overlap, imaged on a confocal microscope, in the 200 x 200 μm center of expression areas, averaged 60% and often reached 100%. Even though it was not possible to cover cortex completely with handheld lentivirus injections, the limited coverage

(<7%) can be enough to change behavior. 2) Dense projections expressing DREADD protein were visible in ventromedial caudate and insular cortex as well as in region TE. Sparser projections were detected in the rhinal cortex. Thus, even with a relatively small percentage of expressing neurons, labeled axons are seen in brain regions previously known to receive projections from the OFC. 3) Time course analysis of CNO levels in cerebrospinal fluid (CSF) showed a peak concentration at 60 minutes after intramuscular injections. Despite concerns of conversion of CNO into clozapine (observed in humans and guinea pigs), only trace amounts of clozapine were detected in the CSF and serum when analyzed in a group of 10 monkeys at the 60-minute time point. 4) Some monkeys showed side effects from 10 mg/kg CNO injections when tested before DREADD virus injections. Side effects included fewer trials completed and lengthened reaction times. Therefore, animals should be screened to know whether they are affected by experimental doses of CNO before virus injection.

Title: Adaptive value coding: Temporal influences on choice mediated by divisive normalization in rhesus monkey

Authors: *J. ZIMMERMANN[1,2], T. LOFARO[3], P. W. GLIMCHER[2], K. LOUIE[2];
[1]Ctr. for Neuroeconomics, [2]New York Univ., New York, NY; [3]Mathematics and Computer Sci., Gustavus Adolphus Col., St. Peter, MN

Abstract: Any organism has to react and adapt to a constantly changing environment. Its neuronal system is thus confronted with the task of encoding a broad range of sensory information efficiently within the finite constraints of its coding capacity. This problem is widely believed to explain temporal adaptation and spatial normalization in sensory systems. Recent work has demonstrated that temporal adaptation occurs in reward-processing and decision-

related brain areas, but the computational mechanisms and behavioral consequences of this temporal adaptation have remained largely unknown. Here, we present data from a saccadic choice task. Trained monkeys were offered a choice between two options differing in reward magnitude and juice type. Block of trials were presented which were composed of a mixture of "adaptor trials" and "measurement trials". In measurement trials, fixed in structure across all blocks, monkey were asked to choose between an unvarying reference reward (fixed reward magnitude and juice type) and one of 5 variable rewards. These responses allowed us to plot the monkey's probability of choosing the reference reward as a function of the magnitude of the variable reward; exposing a "choice curve". What we systematically varied across blocks was the structure of the adaptor trials. We then examined the effects of the standard deviation of adaptor variability on the slopes of these choice curves. We attempted to account for the effects of adaptor variability on choice behavior using a model of adaptive value coding based on the dynamic normalization models we have previously explored. Our current model implements two cascaded divisive-normalization networks which we refer to euphemistically as OFC and LIP. Adaptation is implemented via divisive normalization, a canonical neural computation widely reported in sensory processing, in both networks. The time constants of the networks, however, differ by several orders of magnitude (with OFC being much slower) and allows the OFC network to effectively adapt the sensitivity of the LIP network. Our behavioral and simulation results demonstrate that the temporal value context significantly influences monkey choice behavior and that the temporal dynamics of our model can account for these changes. The findings suggest that divisive normalization, may underlie adaptive value coding in decision-making areas and shape behavioral choices accordingly. Single unit recordings from real monkey OFC will relate neuronal dynamics to behavioral and model dynamics in a future step.

Title: The dynamics of neural population activity during decision-making

Authors: *P. E. CISEK, J.-F. CABANA, D. THURA, A. FEGHALY;
Univ. of Montreal, Montreal, QC, Canada

Abstract: How does the brain make decisions in a dynamic and constantly changing world? We have recently shown (Thura & Cisek, 2014) that when monkeys perform a task in which relevant sensory information for action selection varies over time and they are free to respond at any moment, many neurons in dorsal premotor (PMd) and primary motor cortex (M1) continuously reflect the evolution of sensory information along with a signal related to the growing urgency to respond. Approximately 280ms prior to movement onset, the activity of these cells reveals the resolution of a competition between the choices, implicating them in the process of volitional commitment. The above conclusions were based on analyses of cells that showed statistically significant directional tuning prior to the moment of commitment and comprise about a third of the total PMd/M1 population. The remaining cells include those that only become tuned during or shortly before movement as well as untuned cells whose relation to the task is difficult to quantify. However, it is well-known that cortical populations are highly heterogeneous and do not neatly partition into clear categories such as “decision” or “movement cells”. Thus, inspired by recently developed methods, here we analyze the activity of the entire population by plotting the dynamical state of the system as a trajectory through a high-dimensional neural space. We use Principal Components Analysis to reduce this high-D space into a lower-dimensional projection and examine 1) how neural trajectories evolve in different conditions, and 2) how individual cells contribute to the dimensions identified by PCA. We found that during deliberation, the neural state evolves on a 2-dimensional “decision manifold” defined by orthogonal directions roughly corresponding to sensory evidence and urgency, and then rapidly falls off this surface at the moment of commitment into trajectories specific to each choice. This is consistent with a dynamical attractor network that implements decisions through a winner-take-all process. During blocks in which monkeys were motivated to make hastier decisions, the neural state evolved on the same decision manifold but was shifted closer to the edge where commitment appears to occur. Finally, we found that the “loading matrix”, which quantifies how each cell contributes to individual PCs is a continuous distribution, without distinct clusters. This does not support the idea of separate functional groups but instead suggests that the entire PMd/M1 population works together to govern the dynamics of decision-making.

Title: Rhesus monkeys make probabilistic evaluations of the individual features in compound visual stimuli

Authors: *H. RAO[1], M. RYOO[1], A. TOADER[1], J. BECK[2,3], S. FERRARI[2,4,5], H. OH[2,6], T. EGNER[2,6,7], M. A. SOMMER[1,3,6];
[1]Biomed. Enginnering, [3]Neurobio., [4]Mechanical Engin. and Material Sci., [5]Duke Inst. for Brain Sci., [6]Ctr. for Cognitive Neurosci, [7]Psychology and Neurosci., [2]Duke Univ., Durham, NC

Abstract: Making decisions during real-life analyses of a scene involves the consideration of visual attributes that may be interlinked and probabilistic, such as evaluating apples by virtue of their shape and color. Both feature dimensions provide a probabilistic contribution to the choice of which apple to eat. If time pressures are involved (e.g. someone else may grab the best apple), subjects may use heuristics for expediency rather than a full analysis (e.g. just go for the reddest apple). Prioritization of some sources of information over others in the face of decision pressures is known as satisficing. Here we examine the capacity for rhesus monkeys to evaluate the probabilistic worth of individual features in compound visual objects, to set the stage for neurophysiological investigation of satisficing. Monkeys (and humans for comparison) were presented with two stimuli, each consisting of four "cue dimensions". A stimulus was red or blue (the cue dimension of color), a circle or a square (shape), outlined in white or black (contour), and contained horizontal or vertical stripes (orientation). Within these cue dimensions, each feature carried a differential value, e.g. circle = .8 but square = .2, that contributed to the aggregate conditional probability that selection of the stimulus would result in reward. Subjects selected the "best" stimulus in each trial on that basis. We used Bayesian inference and model comparisons to quantify their decision-making strategies. We found that within a few weeks of training, monkeys learned the differential probabilities associated with each cue dimension. Given ample time to view pairs of stimuli, > 1000ms, the animals based their choices on the 3 most informative cue dimensions. Humans tested in single sessions, in contrast, were adept at using all 4 dimensions. Next steps will impose pressures such as reduced viewing time to determine the satisficing strategies adopted by the monkeys. The overall outcome will be to

establish the parameters under which more naturalistic, information-restricted decision-making may be studied at the single neuron level in the macaque.

Title: The neuronal basis of oxytocin's effect on interactive social behavior

Authors: ***K. HAROUSH**[1], Z. WILLIAMS[2];
[1]Neurosurg., [2]Harvard Med. Sch., Boston, MA

Abstract: Social behaviors such as conspecific bonding, sexual encounters, cooperation and parental care have been shown to be modulated by the neuropeptide oxytocin. However, the mechanisms by which oxytocin affects neuronal activity to mediate these changes in behaving animals remain largely unknown. Building upon our recent findings, that delineate a causal link between neural activity in the dorsal Anterior Cingulate Cortex (dACC) and cooperative behavior in rhesus macaques (Haroush and Williams, 2015), we set to investigate how inhaled oxytocin affects social interactions in behaving individuals and the manifestation of its effect in the dedicated neuronal circuitry underlying this behavior. To this end, we trained pairs of rhesus monkeys on an adapted version of the iterated Prisoner's Dilemma (iPD) game, where the outcome of each monkey depended on the concurrent, joint decision of both animals. On successive trials, each individual could either opt for cooperation which could mutually benefit both individuals, or attempt to maximize personal profit at the other's expense. Each pair of monkeys sat side-by-side facing a screen. The monkeys chose on each trial between two stimuli, representing cooperation and defection, which were operationally defined by the payoff matrix. Neither monkey was aware of the other's choice until both completed their own selection. Since both monkey's decisions influenced their outcome and no one decision could guarantee reward, their choices required an element of trust when making a cooperative decision. While the primates performed the task, we carried out electrophysiological recordings in single cells in the dACC. In the midst of each experimental session we introduced both monkeys with either saline

or a 48IU dose of oxytocin, inhaled via a previously acclimated pediatric nebulizer for a period of 5 minutes, in counterbalanced fashion. Neuronal recordings were continued throughout the session and behavioral paradigm was resumed at the end of inhalation. We found that oxytocin significantly enhanced cooperative social behavior compared to saline inhalation, similar to the previously reported effect of oxytocin in humans. Furthermore, oxytocin effects were dependent on the social context of the task as they were not evident when the monkeys played each other in separate rooms. At the neuronal level, oxytocin significantly affected the computation carried out by the neuronal circuits in the dACC. These results are instrumental in understanding the neural basis by which oxytocin influences interactive social behavior, with implications for the treatment of disorders such as Autism Spectrum Disorder and Schizophrenia.

Title: Effects of choice errors versus response inhibition on response times

Authors: *P. MIDDLEBROOKS[1], J. D. SCHALL[2];
[1]Psychology, [2]Vanderbilt Univ., Nashville, TN

Abstract: Perceptual choice and response inhibition have each been a major focus of decision-making research for decades. During stop-signal tasks, participants tend to respond slower to a go stimulus following a successfully stopped trial. During speeded choice tasks, participants tend to respond slower following choice error trials. To date no studies have examined the relationship between response inhibition and choice-error slowing. The choice stimulus was a

cyan-magenta checkerboard. Saccade choice was specified by the fraction of cyan or magenta in the checkerboard, varied around discrimination threshold. On 25-40% of trials a visual stop signal replaced the central fixation spot after a variable stop-signal delay. On no-stop signal trials reinforcement was earned for a correct choice. On stop signal trials reinforcement was earned for inhibiting the saccade. Previously we reported that performance measures of choice and response inhibition indicate that choosing and stopping are independent cognitive processes (Middlebrooks & Schall 2014 Atten, Percept & Psychophys). Here we investigated further the extent of this independence by examining whether the effects of stopping inhibition and choice errors on the response time in subsequent trials were additive, interfering or independent. Data were analyzed from two perspectives. First we measured no-stop trial response times following trials of each possible pairwise outcome, comparing them to overall mean no-stop response times. Second, we compared no-stop trial response times following trials of each possible outcome to no-stop trial response times preceding trials of each possible outcome in a triplet trial sequence. No-stop responses were faster after successive no-stop trials. Following canceled stop trials, they were slower relative to the preceding no-stop trial, and they did not change much after non-canceled stop trials. These three findings replicate previous work. However, unlike previous observations, no-stop trials after no-stop choice errors were faster than overall no-stop response times. That is, we found post-choice error speeding instead of slowing. The post-choice error speeding may be due to executive processing dominance of inhibition over choice given the task demands. These behavioral results, in conjunction with ongoing stochastic accumulator modeling and electrophysiological recordings, contribute to weave together two major threads of research on decision-making, perceptual choice and response inhibition.

Title: Ventral tegmental dopaminergic stimulation causes preference reversals

Authors: *D. FREESTONE[1], L. GRATTAN[2], R. B. RUTLEDGE[3], K. LOUIE[1], P. W. GLIMCHER[1];

[1]New York Univ., New York, NY; [2]Army Inst. of Publ. Hlth., Aberdeen Proving Grounds, MD; [3]Univ. Col. London, London, United Kingdom

Abstract: In natural environments, animals make foraging decisions based on the values of potential food sources, foraging more at locations associated with high values. But to accomplish this, animals must first learn the values of the available options. The dopaminergic reward prediction error (RPE) hypothesis is the dominant view of how biological reinforcement learning works, proposing that midbrain dopamine neurons encode the difference between actual and predicted rewards. Under this theory, dopaminergic RPEs serve as a teaching signal, with dopamine bursts signaling better-than-expected outcomes that increase the subjective value of associated options. There is an enormous amount of correlational support for this hypothesis, but few studies assess the causal role of dopamine in reinforcement learning. Here, we examine how selective microstimulation of midbrain dopamine neurons impacts reinforcement learning. We trained two rhesus macaques on the matching law foraging task in which two options yielded water rewards with equal probability (25%) but different magnitudes. The reward magnitudes changed abruptly over time, requiring constant updating of subjective value estimates. In select blocks, we stimulated dopaminergic neurons in the ventral tegmental area along with the delivery of the smaller magnitude reward; this stimulation resulted in a preference reversal by which monkeys chose the smaller (but stimulated) option. Consistent with a dopaminergic mechanism, administration of the dopamine D2 receptor antagonist raclopride reduced the size of this effect. Aspects of trial-by-trial choice dynamics following both reward and combined reward-stimulation were captured by standard reinforcement learning models. These results provide causal evidence that midbrain dopamine neurons carry a teaching signal that updates the value estimates that guide value-based decision-making.

Title: Are search strategies a result of adaptation to, or emergence due to, resource distributions?

Authors: *S. SHAH[1], B. HAYDEN[2];
[1]Univ. of Rochester, Rochester, NY; [2]UNIVERSITY OF ROCHESTER, ROCHESTER, NY

Abstract: Animal's evolutionary success depends, in part, on the efficiency with which it can search for prey in its environment. Many animals, indeed, can be said to perform efficient searches. How do animals search efficiently? Such efficiency could be a result of the animal understanding the resource distribution and adopting a suitable strategy or heuristic. Alternatively, the animal could be following an innate process that evolved over millennia to optimize foraging in a naturalistic setting. In most natural foraging environments, resources are patchy and sparsely distributed. Theoretical work has shown that the optimal search strategy in such environments would be to perform a Lévy walk. This comprises of many short steps, and a few long ones. A Lévy walk would increase the probability of encountering new patches, reduce the chances of visiting the same site again, and also allows the animal to explore more distant locations. This theoretical result has been supported by empirical work in diverse species like sharks, bony fishes, sea turtles, spider monkeys and penguins. Is this Levy walk search strategy a result of the animal following an innate strategy (adaptation) or does the search behavior merely appear to be a Levy walk due to the nature of the resource distribution (emergent)? We tackle this question in a computerized search task in a lab setting with rhesus macaques. By varying the resource distribution, we are able to dissociate between a resource distribution influenced behavior and an innate behavior.

Title: Habitual saccades aiming at valuable objects - a role of basal ganglia

Authors: *H. AMITA, O. HIKOSAKA;
Lab. Sensorimotor Research, NEI, NIH, Bethesda, MD

Abstract: Habitual behavior emerges after repetitive learning. After experiencing many fractal objects (n>280), half with a large reward ('good objects') and the other half with a small reward ('bad objects'), for more than 5 days, monkeys freely looked at good objects more frequently, quickly, and intensely than bad objects, even though no reward was given (Hikosaka et al.

Trends Cogn Sci 2013). Is such a habitual behavior useful? To answer this question, we devised a value-biased object saccade task in which the monkey obtained a large or small reward depending on which object (good or bad) was targeted by a saccade, unlike free viewing. On choice trials, two objects (good and bad) were presented at the same eccentric positions (15 deg) as the central fixation point turned off. On forced trials, one object (good or bad) was presented. The objects were seen only in periphery because they changed to white dots as soon as a saccade started. On choice trials, the saccade targeted the good object on most trials (>90%) if the monkey had experienced the objects with a large or small reward for >5days, even when the objects were chosen randomly out of 200 learned objects. On forced trials, the saccade tended to occur earlier to the good than bad object. Interestingly, the good-bad discrimination was absent if the saccade occurred too early. An analysis of cumulative saccade latencies showed that value-biased discrimination started around 150 ms after object presentation. This indicates that neurons responsible for the value-based saccade discrimination must show differential responses to good and bad objects before 150 ms. We hypothesized that neurons in the substantia nigra pars reticulata (SNr) serve this function, since they transmit stable object value signals from the caudate tail (CDt) to the superior colliculus (SC) (Yasuda & Hikosaka, J Neurophysiol 2015). Indeed, the SNr neurons were inhibited by good objects and mostly excited by bad objects, especially when they were presented on the contralateral side, and the discrimination started about 130 ms or less after object presentation. To test the causal role of SNr neurons, we are testing whether the pharmacological manipulations of the CDt-SNr-SC circuit affect the value-biased saccade.

Title: Effects of whole-brain-irradiation (WBI) on primate brain and related cognitive function

Authors: *S. A. DEADWYLER, A. PEIFFER, C. A. SEXTON, J. B. DAUNAIS, D. B. HANBURY, E. L. MITCHELL, K. T. WHEELER, J. D. BOURLAND, J. M. CLINE, R. E. HAMPSON;
Wake Forest Sch. of Med., Winston Salem, NC

Abstract: A recent publication (Hanbury et al. Radiation Res. 2015), has demonstration effects of fWBI on several vascular regions of the brain, and provided a preliminary estimate of the time course of cognitive function decay associated with progressive brain deterioration in a 12 month window. The study described here assesses the same time course and confirms the degree of change in performance and associated functional brain activity, but using a much more detailed analysis of the cognitive changes that progress temporally from the time of WBI treatment. Two cohorts of nonhuman primates (NHPs) were tested for long-term effects on performance of a complex memory task over a 10-12 month time period following fractionated Whole Brain Irradiation on delayed match to sample (DMS) task. fWBI was administered in the same fashion and with the same target parameters used with human cancer patients. Each subject received eight 5-Gray fractions (40 Gy total) delivered by linear accelerator, with a lead block system to limit the exposure to the cranium and shield the eyes and optic chiasm. Fractions were separated by 3 or 4 days each; total elapsed time for the fWBI regimen was 4 weeks. Cognitive performance was assessed using a visual object and position-oriented delayed-match-to-sample (DMS) task (see Hampson et al. poster, this meeting). A major variable associated with performance decay over months was the number of trials that each animal was capable of performing within a daily session. The decline in this factor over time was directly associated with the decrease in performance of two types of trials, spatial and object, which required differential encoding by hippocampal and prefrontal neurons as shown in past research in this laboratory (Hampson et al. J. Neural Eng. 2012). The decline in performance was directly related to 1) the number of distracter images presented in the nonmatch phase of the task, as well as 2) the duration of the delay interval between Sample and Match phase of the same task. Measures of brain imaged activity in MRI and PET scans across the same time period, showed changes in areas normally activated during the task when performance was at pre-WBI levels. The gradual decline in hippocampal and prefrontal cortex activation was related to increased vascular impairment in regions that normally supply those brain areas. Therefore these results indicate that WBI imposes a major disruption in brain function that progresses relatively slowly over time (months and years), likely related to progressive cell loss in critical brain regions as a consequence of vascular impairment induced by radiation exposure to eliminate other types of pathological cells.

Title: The modulating effects of stress, sex and age on early neurogenesis in mouse dentate gyrus

Authors: *H. WU.[1], L. YU[2];
[1]Inst. of Behavioral Med. of NCKU, Tainan, Taiwan, Tainan, Taiwan; [2]Inst. of Behavioral Med. of NCKU, Tainan, Taiwan

Abstract: Unconditioned foot shock followed by restraint in water was used as a stress regimen and the number in cell proliferation and early neurogenesis in mouse dentate gyrus (DG) was counted. This study aimed to assess sex difference and age-related modulating effect on the stressor-altered cell proliferation and early neuronal differentiation. Young (7 to 8-week) of age mice or aged (over 8 months of age) C57BL/6 mice were intraperitoneally injected with a bromodeoxyuridine (BrdU) (100 mg/kg) injection immediately before the stress regimen. Bromodeoxyuridine staining was used to indicate newly mitotic cells and doublecortin co-staining was used to reveal early differentiated neurons. Aged mice had lower baselines in the number of newly proliferated cells and neural progenitors compared to younger mice regardless of sex. Surprisingly, aged female mice exhibit increased numbers in cell differentiation and early neurogenesis in response to our stress regimen. Companions did not seem to prevent the stress-decreased cell proliferation or early neurogenesis in aged male mice.

Title: Sex difference in conformity behavior

Authors: *C.-Y. WANG[1], L. YU[2];
[1]Inst. of Basic Med. Sci., Natl. Cheng Kung Univ., Tainan City, Taiwan; [2]Inst. of Behavioral Med. of NCKU, Tainan, Taiwan

Abstract: Conformity behavior refers to the act of changing one's behavior to match the response of others. Using an approach dilemma paradigm in mice, we attempted to examine whether female mice are more prone to exhibit behavior of conformity than male mice in this study. First, food-deprived experimental mice were trained to obtain a sucrose pellet at the end of the black arm or white arm in a custom-made double J-shaped maze. In contrast, four corresponding food-deprived mice serving as a group of conformity for each experimental mouse were trained to obtain food pellet at the opposite end of the arm. When the correct arm choice was over 70% for both experimental mice and their respective groups, we, then, started the experiment. The experimental mice alone or along with their respective group were re-introduced into the start box of the maze. The correct arm choice was obtained for each experimental mouse. Approximately 24 hours later, the correct arm choice was obtained immediately after the conclusion of five consecutive extinction trials with pellet omission in the arm end. We found that male and female mice' correct arm choice was not affected by the presence of the group. Nonetheless, female, but not male, mice exhibited a significant decrease in correct arm choice after the extinction trials. More surprisingly, the presence of the group produced an obvious decline in the correct choice in male, not female, mice immediately after the extinction trials. Although the dominance indices at fight was used to determine the social hierarchy of each member of a group, the social hierarchy of the experimental mice did not seem to have impact on their correct arm choice.

Title: Social buffering effects prevent the stressor-decreased dendritic length, branching in dentate granule cell and -decreased memory performance

Authors: *W.-Y. TZENG[1,2], L. YU[2];
[1]Inst. of Basic Med. Sci. of NCKU, Tainan, Taiwan; [2]Inst. of Behavioral Med. of NCKU, Tainan, Taiwan

Abstract: A robust stressor regimen can decrease early neurogenesis and BDNF level in the dentate gyrus (DG), while the presence of companions reverses the changes. This study was undertaken to assess whether such stressor regimen may render morphological changes in the

existing DG granule cells and whether the presence of companions can prevent the plausible changes. Moreover, we assessed whether the morphological changes in DG granule cells could be associated with the alterations in local extracellular-regulated kinase (ERK) and cAMP-responsive element binding protein (CREB) phosphorylation as well as the performance of the hippocampus-related memory. Single granule cell in slice containing DG was visualized by lucifer yellow labeling in conjunction with the 2-D imaging techniques. Six hours after the conclusion of the stressor procedure, the morphological indices (including the total length of dendrites, the total number of dendritic branches and Scholl analysis results) of the granule cells along the neuraxis (from Bregma -0.94 to -3.5) of the DG (including the suprapyramidal blade, hilus tip, and infrapyramidal blade division) were obtained in three groups of Balb/C mice, the stressor-free control, stressor, and stressor with company groups. The stressor procedure produced significant decreases in the total length of dendrites, number of dendritic branches, and the size of the dendritic field in granule cells, while the social buffering effects prevented all these changes. The stressor-produced decreases and social buffering effects in these morphological indices of the DG granule cells were correlated positively with local ERK phosphorylation immediately after the stressor regimen and the memory performance in the object recognition and location tasks approximately six hours after the conclusion of the stressor procedure.

Title: Effect of anxiety on learning and memory in mice

Authors: ***T. PARETKAR**[1], E. DIMITROV[2];
[2]Physiol. and Biophysics, [1]Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Norepinephrine and glucocorticoids play an important role in the consolidation of emotionally arousing memories. The neurons of the amygdala express receptors for both, norepinephrine and glucocorticoids, and the amygdala is critical for integrating affect, learning and memory. We tested the hypothesis that increased anxiety will activate locus ceruleus (LC) and hypothalamic-pituitary-adrenal axis (HPA) and will increase norepinephrine and corticosterone signaling in the amygdala, which in turn will negatively affect both working and

long term memory in mice. The anxiety-like behavior of mice was assessed under conditions of low light intensity (6 lux, LLI) and high light intensity (200 lux, HLI). As expected, the different light conditions affected the anxiety-like behavior of tested mice. The mice spent less time in the open arms of Elevated O-maze and took longer time to exit from the dark compartment of the Light/Dark box when tested under HLI as compared to the group tested under LLI. The animals tested under HLI also showed significantly lower number of correct spontaneous alternations in the Y-maze test and significantly lower discrimination index in the Novel Object Recognition test. Furthermore c-Fos expression in basolateral amygdala (BLA), central amygdala (CeA) and LC was significantly higher in HLI group when compared to the LLI group. Next, we injected cre activated adeno-associated virus expressing inhibitory designer receptor exclusively activated by designer drug (AAV/DREADD/Gi) into the CeA of transgenic VGATcre mice. Clozapine N-oxide (CNO) is the only ligand for DREADDs. The inhibition of the CeA GABAergic neurons by an intraperitoneal injection of CNO abolished the effect of HLI on anxiety-like behavior and memory tasks. Pretreatment of VGATcre mice with the beta adrenergic blocker propranolol reversed the effects of CeA inhibition. Next we evaluated the stress response of the experimental animals to different light conditions. The HPA axis activation was assessed by measuring plasma corticosterone levels 30 minutes and c-Fos expression in the PVN one hour after Y-maze test. Surprisingly, plasma corticosterone levels and c-Fos expression in PVN were similar between the HLI and LLI groups.Our investigation showed that HLI activates LC norepinephrine neurons, increases anxiety-like behavior and negatively affects memory. The activation of LC under HLI occurs before the activation of the HPA axis and depends on GABAergic input from CeA. The increased norepinephrine signaling in the amygdala may modulate initial memory processing independently of the HPA axis.

Title: Optogenetic manipulation of theta rhythm reveals sleep-dependent cognitive processing

Authors: *R. BOYCE[1], S. GLASGOW[2], S. WILLIAMS[1], A. ADAMANTIDIS[3];
[1]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [2]McGill Univ., Montreal, QC, Canada;
[3]Univ. of Bern, Bern, Switzerland

Abstract: Rapid-eye-movement (REM) sleep is present in nearly all terrestrial mammals studied to date and has been positively correlated with memory formation. However, identifying a direct causal link between neural activity during REMs and memory has proven difficult due to a sporadic pattern of occurrence in addition to a spectrum of critical caveats associated with REMs deprivation techniques. To overcome these issues we genetically targeted inhibitory archaerhodopsin (ArchT) to GABAergic neurons of the medial septum (MS), a brain region required for generation of *in vivo* theta rhythm, a prominent ~7 Hz oscillation present during active wakefulness and REM sleep that is linked to cognitive processing. We found that green light pulses reliably hyperpolarized ArchT-expressing cells by ~ 40 mV, completely preventing spiking in transfected neurons in MS brain slices *in vitro*. Using a combination of optogenetic and electrophysiological (MS unit recording and dorsal hippocampal CA1 field potential and unit recording) techniques in freely-behaving mice, we further found that green light delivered to the MS could completely and reversibly silence putative MS GABAergic neurons with <1 s temporal resolution. Silencing GABAergic neurons during REMs resulted in a significant (> 60%) and reversible attenuation of theta rhythm power recorded in the dorsal CA1 region of the hippocampus without disturbing the ongoing REMs episode. To determine whether MS GABAergic activity during REMs is involved in memory formation, we tested mice in a novel object place recognition test as well as a fear conditioning task. During the four hour period immediately following the learning phase of each test, MS GABAergic neuronal activity was silenced selectively during REMs. When tested the following day, novel object place recognition and fear-conditioned contextual memory were both found to be significantly impaired relative to controls. Collectively, our results have identified MS GABA neurons as one of the major generators of hippocampal theta rhythm and provide a direct causal link between MS GABAergic neuronal activity during REMs and memory formation.

Title: Deep-brain stimulation of central lateral nucleus of thalamus strengthens striatal-thalamic connectivity and enhances cognitive behavior

Authors: *E. T.-H. SHEN[1], Y.-T. TSAI[2], H.-C. PAN[4], J.-A. CHEN[2], H.-C. LIN[3], Y.-Y. CHEN[2], F.-S. JAW[1];
[1]Inst. of Biomed. Engin., Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. of Biomed. Engin., [3]Dept. and Inst. of Physiol., Natl. Yang-Ming Univ., Taipei, Taiwan; [4]Inst. of Neurosci., Taipei, Taiwan

Abstract: Deep brain stimulation (DBS) is a potent therapeutic approach for several neurological diseases and psychiatry disorders. However, the exact molecular mechanism of DBS remains elusive. Several studies has shown that DBS mediates behavioral improvements and neurological changes, and also indicated that interval stimulation with specific phase and at critical timing of medial temporal lobe, an important region related to memory formation, is dominant for memory processing. Direct hippocampal stimulation may disrupt local neuronal activities and inter-regional connections, thus DBS of central thalamus (CL) may provide more advantages of safety and efficiency for memory enhancement. The CL plays an important role in arousal regulation and awareness. In this study, we demonstrate drastically enhanced learning behavior of water-drinking tasks in rodents, along with reinforced oscillations and connectivity of the central lateral nucleus of thalamus, dorsal striatum, and ventral striatum. Recordings of local field potentials were used to examine memory-related oscillation pattern and behaviors, including theta and alpha oscillation and its spectral density. An increase is shown in the thalamic CL nuclei, along with the ventral and dorsal striatum area following thalamic CL DBS treatment in rodents. The correlation matrices of functional connectivity before and after behavioral training obtained showed a strong bilateral correlation of delta and theta synchronizations in the thalamic CL nuclei, ventral striatum and dorsal striatum, as well as between the thalamic CL nuclei and striatum. The expression of neuronal c-Fos, the proto-oncogene, is a well-known marker of neuronal activity. For comparison of neuronal activation distribution between DBS treated and sham control groups, we investigated c-Fos positive cells in various learning related brain regions and found statistically significant increased expression in DBS treated c-Fos positive neurons relative to the sham controls. The striatal neural circuits are composed of dopaminergic or cholinergic synapses to receive signals from cerebral cortex and propagate to basal ganglia to modulate movement. Thus, we examined the protein level of D2R and nAcha4 of striatum by Western blot analysis, finding statistically significant increases in the level expression for both stratial and hippocampal proteins. We suggest that thalamic CL DBS can strengthen the thalamic-striatal functional connectivity in the brain. The up-regulated

dopaminergic and cholinergic systems by CL DBS-treatment is involved in the water reward learning.

Title: Reverberating cell assemblies formed by axo-axonic GABA neurons in the rodent basal amygdala

Authors: ***M. BHAGAVATHI PERUMAL**, R. SULLIVAN, P. STRATTON, P. SAH; Queensland Brain Insititute, Brisbane, Australia

Abstract: Donald O Hebb's proposal of reverberating cell assembly remains one of the most elegant hypotheses to describe cognitive processes as discrete synchronized neural networks. Many in-vivo field potential studies have provided evidence for existence of these cell assemblies. But the types of neurons and synapses that form a cell assembly, as well as its temporal dynamics remain elusive. A cell assembly should have strong synaptic interconnectivity among its members to generate temporal precision. Axo-axonic neurons (AAC) are a unique subset of GABA neurons that synapse on to the axon initial segment (AIS) of pyramidal neurons. Depolarized GABA-A reversal at the AIS is presumed to enable GABAergic excitation at the pyramidal AIS in a state dependent manner. AAC in the rodent basal amygdala (BA) and cortex, when stimulated to threshold, receive di-synaptic time-locked feedback excitation. Using *in vitro* whole cell patch clamp recordings, we found that AACs in the rodent BA triggered recurrent time-locked feedback excitation that followed the first di-synaptic feedback with a latency of 4.7 ms ±0.3ms (n=7). The reverberating feedback excitation reached maximum amplitude at 18.1±2.4ms (n=9) and triggered multiple action potentials in the AAC in current clamp. The recurrent feedback excitation lasted up to 48.6±10.2ms (n=9) after the initial AAC spike. These oscillations were abolished with GABAA receptor or AMPA receptor antagonists. Therefore we suggest that the AAC driven reverberating microcircuits may form a novel model for cell assembly with axo-axonic synapses, GABAergic excitation and strong reciprocal glutamatergic connections.

Title: LMO4 regulates the excitability of pyramidal neurons in the basolateral amygdala of mice

Authors: *R. A. MANGIERI[1], R. MAIYA[1], R. O. MESSING[1], U. HEBERLEIN[2], R. A. MORRISETT[1];
[1]Pharmacol., Univ. of Texas at Austin, Austin, TX; [2]HHMI, Janelia Res. Campus, Ashburn, VA

Abstract: The transcriptional regulator LMO4 is highly expressed in pyramidal projection neurons of the basolateral complex of the amygdala (BLA), and we previously demonstrated an important role for BLA LMO4 in fear learning. More recently we have examined the role of LMO4 in cue–reward learning using mice that have a genetrap insertion at the *Lmo4* locus (*Lmo4gt/+*), which results in 50% reduction in *Lmo4* expression. We found that *Lmo4gt/+* mice display a selective deficit in conditioned reinforcement that was recapitulated by RNAi-mediated knockdown of LMO4 in the BLA of wild type mice. Thus, given the BLA as a critical structure in which LMO4 influences fear and reward learning, we sought to investigate whether electrophysiological properties of neurons in this region are altered in *Lmo4gt/+* mice. To that end, we performed whole-cell patch-clamp recordings in current clamp mode to measure membrane properties and the excitability of BLA pyramidal neurons *in vitro*. The resting membrane potential and the threshold potential for firing action potentials in response to depolarizing current injection were similar in BLA neurons from WT and *Lmo4gt/+* mice, as were other action potential characteristics. However, BLA neurons from *Lmo4gt/+* mice exhibited several features of increased excitability such as greater input resistance ($p<0.01$) and lower rheobase current (the amplitude of depolarizing current injection necessary to evoke action potential firing) ($p<0.01$). *Lmo4gt/+* BLA neurons also displayed greater spike firing frequencies in comparison with WT BLA neurons in response to increasing steps of depolarizing current injections ($p<0.01$). In light of this difference in intrinsic excitability, we next evaluated whether

Lmo4gt/+ BLA neurons were equally sensitive to the modulatory effects of dopamine on excitability. As expected, brief bath application of dopamine (10 μM) significantly increased the firing frequency of WT BLA pyramidal neurons in response to depolarizing current step ($p<0.01$). Dopamine application also increased the firing of neurons from *Lmo4gt/+* mice ($p<0.01$), but the magnitude of this effect was markedly attenuated relative to WT ($p<0.05$). Thus, the ability of BLA pyramidal neurons to respond dynamically to an increase in extracellular dopamine concentration appears to be compromised in *Lmo4gt/+* mice. Overall, these findings suggest that reduction of LMO4 in the BLA causes changes in pyramidal neuron physiology, which may contribute to the behavioral differences observed between WT and *Lmo4gt/+* mice.

Title: Effect of chronic stress and streptozotocin treatment on choline acetyltransferase and neuronal plasticity in adolescent rats

Authors: K. HERNÁNDEZ-MERCADO[1], L. REYES-CASTRO[2], E. ORTA-SALAZAR[3], *C. PEREZ-CRUZ[1];

Abstract: Chronic stress triggers maladaptive changes altering learning and memory functions. During adolescence some parts of the brain are still under development and exposure to stress events may cause plastic changes in the central nervous system leading to behavioral alterations. Furthermore, metabolic diseases such as diabetes type two, also triggers cognitive decline. Importantly, animal models have shown that chronic stress dampers the development of diabetes after streptozotocin (STZ) administration. Despite the importance of those two factors involved in cognitive functions, there are no reports regarding the effect of chronic stress in development of diabetes in adolescent rats, and its impact in cognitive functions and neuroanatomical alterations. In this study, we hypothesized that chronic restraint stress in adolescent rats will cause neuroplastic changes at structures involved in learning and memory functions and modify

the further effect of STZ injection. Our results showed that stress and STZ causes behavioral alterations, and its effects are related to modifcations in choline acetyltransferase and postsynaptic density protein 95 immunoreativity and number of dendritic spines in CA3 region of hippocampus and prefrontal cortex. These data may offer important information to develop strategies to manage the incidence of stress-related pathologies during the adolescence.

Title: Non-RGD ß1 integrins regulate cytoskeletal reorganization underlying long-term potentiation in the dentate gyrus

Authors: *W. WANG[1], S. KANTOROVICH[1], C. M. GALL[1,2], G. LYNCH[1,3];
[1]Dept. of Anat. and Neurobio., [2]Dept. of Neurobio. and Behavior, [3]Dept. of Psychiatry and Human Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: A now substantial body of evidence indicates that membrane adhesion receptors belonging to the integrin family play a critical role in the consolidation of long-term potentiation (LTP) and memory. Moreover, particular subunits of the integrin alpha/beta dimers have been linked to these physiological and behavioral effects. Studies to date have focused on hippocampal field CA1 or forms of learning dependent upon that field; very little is known about integrins and plasticity at other sites. Here we report that i) integrins are critically involved in LTP in the lateral perforant path (LPP) projections to the dentate gyrus, and ii) the pertinent integrins differ from those involved in plasticity in field CA1. Peptides or toxins (disintegrins) that block the consensus RGD binding site for a large family of integrins block LTP in field CA1 but these reagents had no effect in the LPP. However, neutralizing antisera against the ß1 integrin subunit, which prevents LTP consolidation in CA1, proved to be very effective in the LPP. Moreover, mice with a conditional knockout of the ß1 integrin subunit also had a severe

LTP impairment in the dentate. Two homologous, integrin associated tyrosine kinases (FAK, Pyk2) provide essential links between the adhesion receptors and cytoskeletal reorganization. Studies using Fluorescence Deconvolution Tomography showed that LTP induction is accompanied by FAK activation at LPP synapses, a result that is highly suggestive of integrin activation. Collectively, the results indicate that engagement of non-RGD, ß1 integrins are required for memory-related changes to LPP contacts. The list of such integrins is relatively short, particularly given what is known about integrin subunit expression in the entorhinal-dentate system. Hypotheses about the functional significance of regional differences in integrin driven LTP will be described.

Title: Excitatory and inhibitory disabled-1 knockdown reveals cell-specific role of reelin signaling in adult synaptic plasticity

Authors: *A. L. LUSSIER[1], H. L. MAHONEY[2], J. H. TROTTER[3], A. DODGE[2], B. CAPRARO[2], B. CAPRARO[2], H. SOUEIDAN[2], G. D'ARCANGELO[4], E. J. WEEBER[2]; [1]Mol. Abstract: Disabled-1 (Dab1) is an intracellular adaptor protein that acts downstream of the Reelin signaling pathway to promote neuronal migration in the developing brain. In the adult brain the Reelin signaling pathway is important in dendritic and spine growth, learning and memory, and synaptic plasticity. Using novel Dab1 knockout mice in excitatory (eKO; Camk2 promoter) and inhibitory (iKO; GAD2 promotor) cells, we examined the role of Reelin on cell-specific activation of Dab1 in adult synaptic plasticity. In support of the well characterized role of Reelin signaling in excitatory neurotransmission, our eKO mice revealed a deficit in induction and maintenance of long-term potentiation. Surprisingly, the inhibitory Dab1 knockout mice (iKO) also show a deficit in long-term potentiation induction and maintenance. To examine the

role of Reelin in GABAergic cell activation we injected Reelin into the ventricles of eKO mice which revealed an activation of GABAergic interneurons. These data support a role of the Reelin signaling pathway in GABAergic interneurons and open new avenues for understanding the role of the Reelin signaling pathway in synaptic plasticity and learning and memory. Collectively, these data demonstrate an important new method for examining Reelin-Dab1 signaling in the adult brain, and underscore the importance of this pathway in synaptic plasticity.

Title: Simultaneous and persistent CaMKII, PKC and PKA activation is required for maintaining learning-induced enhancement of AMPAR-mediated synaptic excitation

Authors: *S. GHOSH, E. BARKAI, R. LAMPRECHT;
Univ. of Haifa, Haifa, Israel

Abstract: Learning leads to changes in AMPA receptor (AMPAR) synaptic expression level and conductance. The mechanisms for maintaining such alterations needed for memory formation remain to be clarified. Here we report a novel molecular mechanism needed for maintaining high-skill learning-induced AMPAR-mediated enhancement of synaptic excitation. We show that training rats in a complex olfactory discrimination task, such that requires rule learning, leads to the enhancement of averaged amplitude of AMPAR-mediated miniature excitatory post-synaptic currents (mEPSCs) in piriform cortex pyramidal neurons for days after learning. Inhibiting calcium/calmodulin-dependent kinase II (CaMKII) or protein kinase C (PKC), days after learning, reduced the averaged mEPSC amplitude in neurons from the trained rats to the level where they are not significantly different from mEPSC of control animals. Inhibition of protein kinase A (PKA), days after learning, reduced the averaged mEPSC amplitude in trained rats significantly but not to the level of the control rats. Concomitant inhibition of CaMKII, PKC and PKA activities abolished the learning-induced enhancement of mEPSC in a non-additive

manner. We conclude that the maintenance of learning-induced enhancement of AMPAR-mediated synaptic excitation requires the persistent and simultaneous activation of CaMKII, PKC and PKA.

Title: Changes in brain structure volume following training depend on long term memory formation and CREB

Authors: ***D. A. VOUSDEN**[1,3], M. VAN EEDE[2], A. YIU[2], L. SPENCER NOAKES[2], B. J. NIEMAN[2,3], M. HENKELMAN[2,3], S. A. JOSSELYN[2,4], P. W. FRANKLAND[2,4], J. P. LERCH[2]; [1]Neurosci. & Mental Hlth., [2]Hosp. For Sick Children, Toronto, ON, Canada; [3]Dept. of Med. Biophysics, [4]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Recent human imaging studies show that learning can change the brain at a scale detectable with MRI. For instance, learning to juggle or navigate a complex environment alters the volume of task-specific brain areas [1]. These findings have been recapitulated in rodent studies, which show spatial training increases the volume of the hippocampus, a critical area for spatial memory [2]. However, the cellular mechanisms and signaling pathways underlying these volume changes remain unknown. . It is well established that learning and memory formation require cellular changes in the brain. Initially, learning depends on changes in synaptic strength; long-term memory (LTM) formation, however, requires protein synthesis, which enables structural alterations to neurons and surrounding glia. We hypothesize that the training-associated neuroanatomical changes seen with MRI are due to neuronal and glia remodelling associated with LTM formation. Accordingly, we hypothesize that volume changes can be blocked by targeting the signaling pathways implicated in LTM. . CREB is a transcription factor that is critical for LTM. It regulates the transcription of many genes whose products are involved in LTM, and also modulates dendritic growth. Here, we used CREB mutant mice to ask whether changes in brain structure volume following training depend on CREB-dependent signaling and LTM formation. . Methods: CREB mutant mice (CREB -/-, CREB +/- & CREB +/+) were

trained on either the spatial or non-spatial Morris water maze for 6 days (N=20/group). A probe trial was performed 24 hours after training. Eight days after training mice were sacrificed and brains were imaged with high-field MRI. Automated image processing algorithms were used to detect volumetric brain changes associated with training. . Results: All mice learned the platform location, but CREB -/- mice had significant deficits in LTM on the probe. Preliminary results suggest that consistent with prior studies, hippocampal volume is larger in spatially trained wildtype mice than in untrained controls. Conversely, there was little effect of spatial training on hippocampal volume in the CREB -/- mice. This suggests that volume changes following maze training depend on LTM formation and CREB-dependent signaling, and that CREB-dependent cellular remodelling may underlie the neuroanatomical changes seen with MRI. Intriguingly, CREB +/- mice trained on the spatial water maze had normal LTM, but there was no effect of training on hippocampal volume. This suggests both LTM formation and CREB dosage underlie the volume changes seen with maze training. . **References** 1. Zatorre et al Nat Neurosci 2012 2. Lerch et al NeuroImage 2011

Title: Role of voltage-gated potassium channel Kv1.5 in CNS-based behavior

Authors: *S. BHATTA[1], C. PATEL[2], H. MCGEE[2], W. CHILIAN[3], G. CASADESUS SMITH[2,1];
[1]Biomed. Sci., [2]Biol. Sci., Kent State Univ., Kent, OH; [3]Physiol., Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Voltage-gated potassium channels, such as the Kv1 family, are responsible for maintaining membrane potential and are capable of modulating electrical excitability in excitable tissues. Previous studies have shown that loss of the Kv1.5 channel in the heart causes atrial fibrillation. Accumulating evidence suggests Kv1.5 is present in the brain, however its role in CNS function is unknown. As maintenance of neuronal excitability is essential for synaptic transmission, we proposed that genotypic loss of Kv1.5 channel would induce changes in CNS

associated behaviors. To address this, we carried out a full phenotyping battery to determine whether CNS functions including locomotor, emotion, and learning and memory would be altered in the Kv1.5 knockout mouse. Our results demonstrate that Kv 1.5 knockout shows impairments in learning and memory function in addition to habituation and anxiety processes when compared to wild-type littermate controls. Taken together, our work suggests Kv1.5 channel is crucial for functionality of the brain in addition to its known role in the heart and provides potential mechanisms of through which changes have occurred.

Title: Circadian levels of serotonin in plasma following a mild traumatic brain injury in rats

Authors: *C. C. TENN, N. CADDY, M. GARRETT;
DRDC Suffield Res. Ctr., Medicine Hat, AB, Canada

Abstract: Introduction There has been a lot of interest especially among the military population, in the role blast exposure plays in traumatic brain injuries (TBI) and how this may link to the clinical features of the injury. The mechanism by which exposure to a shockwave can affect memory, concentration, balance, sleep and other neurobehavioral functions is still unknown. Previous studies have shown that various neurotransmitter systems including serotonin (5-HT) are affected following brain injury. Moreover, 5-HT has been suggested as one of several biomarkers associated with the cognitive dysfunction following TBI. Understanding the serotonin responses following brain injury could aid in predicting cognitive outcomes of TBI patients. In this study, we assessed the circadian levels of 5-HT in plasma using a brain injury model previously shown to induce cognitive impairment. **Methods** Rats were housed under controlled environmental conditions of light (12h light/dark cycles) and temperature. A mild brain injury was induced in anaesthetized animals by exposure to a single shockwave intensity of 140 kPa for 7.1ms duration. Control animals underwent the same treatment except for the shockwave exposure. Blood samples were taken at various times during the light and dark periods within a 24h period. All handling during the dark period was done under a dim red light. Sampling was done several days prior to the shockwave exposure (baseline), 24h and 7d

following exposure. Serotonin levels were determined by means of a commercially available enzyme immunoassay kit. **Results** Baseline data revealed a circadian variability in plasma levels of 5-HT during the 24h test period. The highest level of 5-HT was measured at 2h after lights-off with the lowest levels occurring late in the dark period. Twenty-four hours after shockwave exposure, 5-HT levels were significantly elevated in brain injured animals and the circadian pattern was altered when compared to controls. One week following the exposure, the levels of 5-HT were similar between the two groups of animals during the day. Although the neurotransmitter levels remained higher during the dark period for the head-injured animals, the circadian pattern returned to that of controls. **Conclusion** The findings from this study demonstrate that exposure to mild blast resulted in transient changes in the circadian levels of serotonin in blood. These changes in 5-HT levels in the acute phase following a mild brain injury may play an important role in the pathophysiology of blast-induced neurotrauma.

Title: The cognitive and neural impact of recurrent hypoglycemia is mediated by glucocorticoids in the hippocampus

Authors: *E. C. MCNAY, D. M. OSBORNE;
Behavioural Neurosci., Univ. At Albany, Albany, NY

Abstract: Recurrent hypoglycemia (RH) is primarily caused by repeated over-administration of insulin. This occurs most commonly among patients with Type I Diabetes; however, it is increasingly common in Type 2 diabetes also. Although acute hypoglycemia impairs cognitive and neural function, the long-term effects of RH are more complex: during subsequent euglycemia, both humans and animals show enhanced hippocampal memory following RH along with altered hippocampal metabolism and activity. Hypoglycemia causes systemic elevation of counter-regulatory hormones including glucocorticoids (GCs), and RH alters this secretion profile. Because GCs modulate cognitive performance and modulate the hippocampus, we investigated whether the impact of RH on the hippocampus might be mediated, at least in part,

by GCs. Using our previously-validated rat model of RH, hypoglycemia was induced once a day for three consecutive days, with or without an infusion of GC antagonists to the hippocampus. Following the final RH bout, rats were trained and 24 hours later tested in contextual fear. Hippocampal tissue was immediately extracted following tested for analysis by western blot. RH increased fear memory, and this effect was completely attenuated by hippocampal GC blockade during the RH episodes. Additionally, the improved cognitive performance in RH rats was accompanied by increased hippocampal expression of glucocorticoid receptor, SGK1, pCREB, as well as plasma membrane levels of AMPA and NMDA receptors; ALL of these effects were regulated by GC activity. These results indicate that RH produces several physiological changes in the dorsal hippocampus that are conducive to enhanced memory, and support the hypothesis that GCs are responsible for mediating the impact of RH on hippocampal function. Moreover, changes induced by RH are adaptive, indicating a response that would reduce physiological damage which could otherwise arise following repeated exposure to hypoglycemia.

Sci., Federal Univ. of Rio De Janeiro, Rio de Janeiro, Brazil; [6]Ctr. for Biol. Sci., Federal Univ. of Santa Catarina, Santa Catarina, Brazil

Abstract: Substantial improvements have been achieved in recent years in the treatment of sepsis and its sequelae. However, a large portion of sepsis patients develops long-term cognitive impairment, and the underlying causes of such a devastating symptom remain to be established. Here, we subjected mice to sepsis induced by cecal ligation and puncture (CLP) to examine the possibility that brain insulin signaling might be dysregulated and associated with cognitive impairment in post-septic mice, similarly to what has been described in Alzheimer's disease (AD) brains. Mice underwent CLP or sham-operation and were treated with antibiotic therapy. Thirty days thereafter, mice were tested in the novel object recognition (OR) paradigm, followed by molecular analysis to evaluate possible impairment in hippocampal insulin signaling. Sepsis-surviving mice (30 days after surgery) failed to acquire the OR memory, but exhibited normal performance when re-evaluated 45 days after surgery. Increased tumor necrosis factor (TNF- α) and decreased cAMP response element-binding protein (CREB) mRNA levels were found in hippocampal extracts from post-septic animals (30 days after CLP). Significantly, CLP impaired brain IRS-1 signaling, indicated by increased hippocampal IRS-1 phosphorylation at serine residue 636 (IRS- 1pSer636) and decreased phosphorylation at tyrosine residue 465 (IRS-1pTyr465). We also found that phosphorylation of Akt at serine residue 473 (AktpSer473) and phosphorylation of GSK3 5; at serine residue 9 (GSK3βpSer9) were decreased in hippocampi of post-septic animals, supporting the notion that, as in AD, brain IRS-1 inhibition and increased GSK3β activity are linked to long-term memory impairment in sepsis. Conclusions: By establishing that disrupted insulin signaling is a common denominator between post-septic and AD brains, results improve our understanding of the pathophysiology of sepsis-associated encephalopathy and cognitive impairment, and open new avenues for therapeutic approaches targeting this condition.

Abstract: Paracetamol, commonly known as tylenol, is the most commonly used over-the-counter pain and fever medication. However, there has been little investigation into its cognitive effects. Recent evidence suggests that the analgesic effects of paracetamol may be due, in part, to its actions as a cannabinoid reuptake inhibitor. Cannabinoids can interfere with memory consolidation through CB1 receptors in the hippocampus. Thus, paracetamol may interfere with memory consolidation through its interactions with cannabinoids. In this study, 24 male C57Bl/6 mice were tested on the object recognition (OR) task, which is dependent on the dorsal hippocampus. Following training, mice were assigned to receive regular drinking water or one of two doses of paracetamol (200 mg/ml or 400 mg/ml) suspended in drinking water for 12 hours. No group demonstrated an object or side preference during training. Mice receiving regular drinking water showed a preference for the novel object during testing, indicating intact memory for the familiar object. Mice in the 200 mg/ml and 400 mg/ml groups did not show a preference for the novel object during testing, suggesting no memory for the familiar object. Based on these results, it appears that 12 hours of paracetamol exposure interferes with OR memory in mice.

Title: Chronic nicotine treatment normalizes hypothyriodism induced suppression of camkii pathway during learning and memory processes

Authors: *K. H. ALZOUBI[1], K. ALKADHI[2];
[1]Jordan Univ. of Sci. & Technol., Irbid, Jordan; [2]Univ. of Houston, Houston, TX

Abstract: Calcium/calmodulin protein kinase II (CaMKII) is a crucial molecule for hippocampus-dependent learning and memory. Activation of CaMKII is triggered by an increase in intracellular calcium concentration, which will activate PKCγ. This will release calmodulin

that will activate CaMKII forming phosphorylated (P-) CaMKII. Recently, we have shown that hypothyroidism impairs hippocampus-dependent learning and memory in adult rats. Nicotine, on the other hand, alleviates cognitive deficits during hypothyroidism. In this study, we investigated the interactive effect of nicotine and hypothyroidism on the CaMKII pathway during learning and memory processes. To locate a hidden (2cm under water) platform, each rat was trained in the radial arm water maze (RAWM) for 8 consecutive trials. Thirty minutes later, a memory test was done, and immediately after that hippocampi were dissected out, and CA1 areas were removed for determination of P-CaMKII, total CaMKII, PKCγ and calmodulin protein levels. RAWM trained rats were compared with age-matched controls, nicotine-treated, hypothyroid and nicotine treated/hypothyroid animals that underwent the same number and duration of swimming trials, but to locate a clearly visible (2cm above water) platform in an open (no radial arms) swim field. Western blot analysis revealed a significant increase in P-CaMKII, total CaMKII and PKCγ in the CA1 region of the hippocampus in RAWM-trained control, nicotine-treated, and nicotine treated/hypothyroid groups, but not in the hypothyroid group. However, no significant increase was found in the level of calmodulin in CA1 area of the hippocampus of all RAWM trained rats. Therefore, our study shows that chronic nicotine treatment normalizes hypothyroidism induced suppression of P-CaMKII, total CaMKII and PKCγ levels during hippocampus dependent learning and memory.

Abstract: An epileptic seizure is a brief episode of abnormal electrical activity in the brain that manifests as behavioral or sensory changes. While the episodes are transient, patients with epilepsy are at an increased risk for developing lasting deficits to cognitive function and/ or behavioral abnormalities. Choline alfoscerate (α-GPC) is a natural choline compound found in the brain. It is also a parasympathomimetic acetylcholine precursor that has been shown to be effective in the treatment of Alzheimer's disease and dementia. α-GPC is used to enhance memory and cognition for stroke and Alzheimer's patients but currently remains untested in patients suffering from epilepsy. This study aimed to evaluate whether α-GPC treatment after seizure can ameliorate seizure-induced cognitive impairment and neural injury. The potential therapeutic effects of α-GPC on seizure-induced cognitive impairment were tested in an animal model of pilocarpine-induced epilepsy. Seizure was induced by intraperitoneal (i.p) injection of pilocarpine (25 mg/kg) in adult male rats. α-GPC (250 mg/kg) was injected into the intramuscular (i.m) space three weeks after seizure onset for three weeks once-daily administration. To evaluate if treatment with α-GPC provides protection to hippocampal-dependent cognitive abilities following seizure we analyzed subject performance using a standard water maze test protocol and brain NeuN immunohistochemistry to determine hippocampal neuronal survival. All groups were sacrificed at 6 weeks post-seizure. In the present study, we observed enhanced survival of hippocampal neurons and improved cognitive function in animals receiving α-GPC injection after pilocarpine-induced seizure. Therefore, choline alfoscerate (α-GPC) injection may serve as a beneficial treatment for improvement of cognitive function in epilepsy patients.

Abstract: Recently, the importance of the quality of life and mental condition of patients being treated for cancer has become recognized. Anxiety and depression are the most common mental disorders among all cancer patients. In addition, it was reported that cancer patients receiving chemotherapy experienced some degree of cognitive impairment. Previously, we examined that doxorubicin and cyclophosphamide led to anhedonia-like, anxiety-like, and spatial cognitive impairment in rats. The chronic administration of doxorubicin and cyclophosphamide decreased serum brain-derived neurotrophic factor (BDNF) protein levels and BrdU-positive cells in the dentate gyrus of the hippocampus. These behavioral changes may be attributed, in part, to decreased hippocampal neurogenesis, and chemotherapy may lead to these impairments by altering neurogenesis. In this study, we determined the effect of doxorubicin and cyclophosphamide treatment on neurochemical mechanisms in rats. [METHODS] Male Wistar rats were administered doxorubicin (2 mg/kg, i.p.) and cyclophosphamide (50 mg/kg, i.p.) once per week for 4 weeks. [RESULTS] Hippocampal BDNF and Bdnf mRNA levels were not decreased by treatment with doxorubicin and cyclophosphamide. However, hippocampal Cyclin D1 levels were significantly decreased by chemotherapy. [DISCUSSION and CONCLUSION] These results suggest that doxorubicin and cyclophosphamide induce anhedonia, anxiety, and spatial cognitive impairment, in addition to negatively affecting hippocampal neurogenesis, which may be related to hippocampal cyclin D1 levels but not hippocampal BDNF levels.

Abstract: Many patients who receive chemotherapy to treat cancer experience depressive- and anxiety-like symptoms or cognitive impairment. However, irrespective of the evidence for anxiety, depressive impairment, and cognitive impairment due to chemotherapy, the underlying mechanisms are still not understood. Previously, we examined that doxorubicin and cyclophosphamide led to anhedonia-like, anxiety-like, and spatial cognitive impairment in rats. On the other hand, nicotine, an agonist for nicotinic acetylcholine receptors, is well-known to have cognitive and anxiolytic effects in both animals as well as humans. This study was undertaken to determine the effect of nicotine on doxorubicin and cyclophosphamide-induced anhedonia-like, anxiety-like, and spatial cognitive impairment in rats. [METHODS] Doxorubicin (2 mg/kg) and cyclophosphamide (50 mg/kg) were injected intraperitoneally once per week for 4 weeks. Nicotine (2 mg/kg, s.c.) was administered daily. We performed sucrose preference and novel location recognition tests. [RESULTS] Doxorubicin and cyclophosphamide led to anhedonia-like and spatial cognitive impairment in rats. The spatial cognitive impairment was reversed by nicotine treatment. [DISCUSSION and CONCLUSION] These results suggest that nicotine can reverse anticancer drug-induced spatial cognitive impairment. Studies are underway to clarify the subtypes of nicotine receptor mediating nicotine's improvement of spatial cognition impairment and mechanism of neurogenesis in rats repeatedly treated with doxorubicin and cyclophosphamide.

Title: Evaluation of chronic treatment with quetiapine on executive function and prefrontal cortex volume, perfusion and ERK/MAPK signaling in rats

Authors: *I. PODDAR[1], C. M. HERNANDEZ[1], P. M. CALLAHAN[1], L. VANDENHUERK[2], M. G. BARTLETT[3], X. YANG[3], A. V. TERRY, Jr.[1];

[1]Pharmacol. and Toxicology, [2]Small Animal Behavior Core, Georgia Regents Univ., Augusta, GA; [3]Dept. of Pharmaceut. and Biomed. Sci., Col. of Pharmacy, The Univ. of Georgia, Athens, GA

Abstract: Cognitive dysfunction is considered one of the most debilitating symptoms of schizophrenia, however, our current understanding of how the primary treatments of this disease, antipsychotics (APs) affect cognition remains inadequate. Our previous work in animals has established that some APs can negatively affect several domains of cognition including attention, spatial learning, and memory as well as some neurobiological substrates of cognition (e.g., growth factors, cholinergic receptors). Here, we were interested in extending these studies to the commonly prescribed AP, quetiapine. The first objective was to determine a clinically-relevant dosing approach for quetiapine, in rats, by measuring plasma and brain levels over several chronic time points. Rats were thus treated with Quetiapine (25 mg/kg/day) orally in drinking water and plasma and brain quetiapine levels were measured after 15, 30, 60 and 120 days of exposure. In parallel groups, the effects of chronic quetiapine treatment on executive function was assessed using a set-shifting task and as an additional measure of cognition (also known to rely in part on the prefrontal cortex-PFC) extinction of fear memory was assessed. No changes were associated with shorter delays (i.e., 24 hours) and analyses are in progress to assess longer delays: 4, 7, 14, and 21 days following an unconditioned stimulus. Test subjects were also evaluated for extrapyramidal side effects using standard catalepsy tests: bar, grid and paw tests. Quetiapine treatment was not associated with any signs of catalepsy after any period of exposure that might have influenced performance in set-shifting or fear memory tasks. To correlate any structural changes in the PFC with quetiapine treatment, we utilized magnetic resonance imaging (MRI) to measure both perfusion and volume between 30 and 120 days exposure. No notable changes in PFC volume were associated with 30 days of quetiapine treatment. Analyses are underway to determine if quetiapine treatment is associated with time-dependent changes in PFC volumetric and/or intraflow rate. To supplement the MRI studies, multiple signaling molecules are being assessed after 30 and 120 days of treatment (ERK/MAPK, Akt/PKB, CREB and histone H3 motifs) to gain insight into molecular mechanisms that may underlie altered memory function. To date, we have observed significant alterations in Akt phospho-signaling after 30 days of treatment. In future experiments we will continue evaluating the chronic effects of quetiapine on additional domains of cognition, the integrity of the PFC, relevant signaling proteins, and we will make comparisons to other commonly prescribed APs.

Title: Comparison of chronic treatment with quetiapine to risperidone on hippocampal-dependent memory function, volume and ERK/MAPK signaling in rats

Authors: *C. M. HERNANDEZ[1], I. PODDAR[1], P. CALLAHAN[1], S. SINHA[1], X. YANG[2], M. BARTLETT[2], A. V. TERRY, Jr[1];

Abstract: Cognitive dysfunction is considered one of the most debilitating symptoms of schizophrenia. However, our current understanding of how antipsychotics (AP), the primary treatment of this disease, affect cognitive function remains inadequate. Not only does this lack of knowledge extend to how APs affect the neurobiological processes that support cognitive function but also the development of therapeutic interventions to improve cognition in schizophrenia. Our previous work in animals has established that both representative typical and atypical APs can negatively affect attention, spatial learning, and memory if administered chronically, however, the mechanism for these adverse effects have not been clearly elucidated. In this study, male Wistar rats were dosed daily in drinking water up to 120 days, in mg/kg: Quetiapine (QUE, 10 or 25) or Risperidone (RISP, 2.5). Hippocampal (HIP)-dependent memory function was assessed after 30 days treatment using both an object recognition task (delay intervals: 4-, 6- and 48-hours) and water maze (spatial acquisition test). In a parallel cohort, brain AP levels were measured after 30, 60 and 120 days of exposure periods. After 30 days treatment, QUE treatment was associated with impaired recognition memory after an intermediate 6-hour delay compared to vehicle-treated controls. After 60 days treatment, no spatial learning deficits were associated with either AP. Locomotor activity was assessed in all rats and no AP-associated motor deficits were observed. To identify potential HIP structural changes associated with memory deficits, we utilized magnetic resonance imaging (MRI) to measure HIP volume and perfusion rate after 30 and 120 days treatment. To date, no notable volumetric changes were measured after 30 days treatment and analyses are in progress in the same cohort following an additional 90 days treatment. To supplement these structural and functional analyses, multiple signaling molecules (ERK/MAPK, Akt/PKB, CREB and histone H3 motifs) are being assessed in hippocampal extracts harvested after 30 and 120 days exposure to gain insight into potential molecular mechanisms that may underlie altered memory functions but also differ between QUE and RISP. In the future it is our objective to compare QUE and RISP (and other APs) and measure the timeline for these APs on cognition and HIP structural integrity.

Title: Regulation of a cerebellar voltage-gated potassium channels and cerebellum-dependent learning and memory

Authors: *J. R. FUCHS[1], A. D. MORIELLI[2], J. T. GREEN[3];
[1]Psychology, [2]Pharmacol., Univ. of Vermont, Burlington, VT; [3]Psychological Sci., Univ. of Vermont, Bulington, VT

Abstract: Eyeblink conditioning (EBC) is governed by sites of plasticity in the cerebellar cortex and the interpositus nucleus. However, the cellular mechanisms supporting EBC are poorly understood. The voltage-gated potassium channel alpha-subunit Kv1.2 is densely expressed at basket cell (BC) axon terminals (Koch et al., 1997) where they form inhibitory synapses with Purkinje cells (PCs). Kv1.2 is also expressed on PC dendrites (Koch et al., 1997). Our previous work showed that intra-cerebellar blockade of Kv1.2 facilitated EBC (Williams et al., 2012) and manipulations to trafficking mechanisms associated with Kv1.2 endocytosis lead to impairments or enhancement during delay EBC (Fuchs et al., 2014; Williams et al., 2012). In the current work, we addressed the question of whether EBC regulates surface expression of Kv1.2 in cerebellar cortex. Rats underwent three days of training, and training consisted of either delay EBC, explicitly unpaired stimulus presentations, or no stimuli. Following the last trial, cerebellar tissue surrounding the primary fissure and ipsilateral to the conditioned eye was fixed, harvested, and analyzed via biotinylation/western blot (WB) and multiphoton microscopy (MP) techniques. These two techniques offer a global and quantitative measure of Kv1.2 surface expression, and a region-specific level of analysis, respectively. After three days of training, the Unpaired group showed significantly less surface Kv1.2 at BC axon terminals as measured by MP and a trend towards greater surface Kv1.2 at BC axon terminals and PC dendrites as measured by WB. We hypothesized that inhibition of the inferior olive by the interpositus nucleus resulting from the generation of conditioned eyeblink responses contributed to differences observed between the Paired and Unpaired groups following three days of training. Thus, if we measure surface Kv1.2 expression earlier in training, we hypothesized that the Paired group and Unpaired group would appear similar, showing reduced surface Kv1.2 expression at BC axon terminals (MP) and increased surface Kv1.2 expression across the entire section (WB). This hypothesis is currently

being tested by repeating the experiment with only a half-day of EBC training. Overall, these data suggest that regulation of surface Kv1.2 in cerebellar cortex may be involved in acquisition but not expression or maintenance of the learned response during cerebellar-dependent EBC.

Title: Cerebellar mGluR1 modulates cerebellar-dependent learning

Authors: *M. SHIPMAN[1], S. C. MADASU[2], A. D. MORIELLI[3], J. T. GREEN[4];
[1]Neurosci. Grad. Program, [2]Cellular, Molecular, and Biomed. Sci. Grad. Program, [3]Pharmacol., [4]Psychological Sci., Univ. of Vermont, Burlington, VT

Abstract: Eyeblink conditioning (EBC), a type of cerebellar-dependent learning, is an ideal model for studying learning because its neural circuitry is well characterized and behavior is easily quantifiable. In EBC paradigms, rats receive training sessions that consist of many trials of conditioned stimulus (CS) and unconditioned stimulus (US) pairings. In these trials, a tone (CS) predicts a periorbital shock (US) and rats learn to blink to the tone (CS) in anticipation of shock (US). This learned, anticipatory eye blink is the CR. Input from the CS and US are relayed separately through the brainstem onto both Purkinje cells in cerebellar cortex and to one of the deep cerebellar nuclei, the interpositus nucleus. CRs occur following disinhibition of the tonically inhibited interpositus nucleus. Mice lacking metabotropic glutamate 1 receptors (mGluR1) show impairments in EBC as well as parallel fiber (PF)-Purkinje cell (PC) long-term depression (LTD) (Kishimoto et al., 2002; Aiba et al., 1994; Ohtani et al., 2014); restoration of the mGluR1a splice variant in PCs restores both EBC and PF-PC LTD (Kishimoto et al., 2002; Ohtani et al., 2014). To examine the consequences of mGluR1 stimulation in cerebellar cortex on cerebellar-dependent learning, we infused 0.5 uL of the mGluR1 agonist DHPG (1 uM) into the lobulus simplex prior to training sessions 1 and 2 of delay EBC. Rats received 6 training sessions across 6 days, with 80 paired trials intermixed with 10 CS-alone and 10 US- alone trials per session. We found that mGluR1 stimulation enhances delay EBC. We then utilized the same experimental design to determine the effects of an mGluR1 antagonist in cerebellar cortex on

EBC using the mGluR1 antagonist YM-298198 (50 uM). Data collection for this second experiment is ongoing. Our results might be explained by drug effects on PF-PC LTD, although one study found that mice with mutations that prevent internalization of GluR2 AMPA receptors, a process necessary for expression of LTD, showed normal EBC (Schonewille et al., 2011). Other work from our lab has shown that blockade of the voltage gated potassium channel alpha-subunit Kv1.2, which is densely expressed at basket cell (BC)-PC synapses, enhances EBC and that DHPG reduces surface expression of Kv1.2. Reduction in surface Kv1.2 at BC-PC synapses could also explain how mGluR1 stimulation enhances EBC.

Title: PKM-ζ is involved in cerebellar-dependent learning and memory

Authors: *K. CHIHABI[1], J. T. GREEN[2], A. D. MORIELLI[3];
[2]Psychological Sci., [3]Pharmacol., [1]Univ. of Vermont, Burlington, VT

Abstract: PKM-ζ has long been implicated in a hippocampal cellular correlate of learning, long-term potentiation (LTP), through its regulation of hippocampal AMPA receptors (Ling et al., 2002; Yao et al., 2008). Disruption of PKM-ζ with Zeta-inhibitory peptide (ZIP) can irreversibly disrupt hippocampal memory that has been maintained for many weeks (Hernandez et al., 2003). Despite being highly expressed in the cerebellum (Oster et al., 2004), no studies have examined how regulation of cerebellar PKM-ζ may affect cerebellar-dependent learning and memory. We have shown for the first time that infusion of ZIP in the lobulus simplex of the cerebellum can significantly disrupt delay eye-blink conditioning (EBC) in rats, a form of cerebellar-dependent learning. Infusion of 0.50 µl 20 mM ZIP or 0.50 µl PBS vehicle occurred 2 hours prior to the first acquisition session of EBC, ipsilateral to the conditioned eye; rats underwent a total of 6

daily sessions of 350-ms delay EBC. We hypothesized that PKM-ζ may have regulatory effects on voltage-gated potassium channel alpha-subunit 1.2 (Kv1.2). Several studies have shown that PKC-ζ can co-immunoprecipitate with and phosphorylate a β subunit that associates with cerebellar Kv1.2 (Gong et al., 1999; Croci et al., 2003). Kv1.2 is highly expressed in cerebellar basket cell axon terminals and Purkinje cell dendrites and our lab has shown that Kv1.2 is important for cerebellar EBC in rats (Williams et al., 2012). Here we demonstrate that PKM-ζ can significantly reduce Kv1.2 surface expression in HEK 293 cells.

Title: Sleep deprivation and voluntary alcohol consumption: the neuroplasticity of chronic behaviors

Authors: *J. DYCHE[1], K. PONDER[2];
[1]Psychology, [2]James Madison Univ., Harrisonburg, VA

Abstract: Alcohol is one of the most common psychoactive drugs, and has been used by humans for thousands of years. Research has focused on the effects of alcohol on sleep, however recent trends in the literature have taken a more bidirectional approach to the relationship between alcohol and sleep. Research on transcription factors involved in the drugs of abuse, including alcohol, suggests a maladaptive alteration of these proteins in the presence of chronic use. The research on transcription factors and chronic sleep deprivation has been sparse. The present study extends the results of previous research on sleep and alcohol to voluntary alcohol consumption and the subsequent buildup of addiction related transcription factors. This research investigates the effects of chronic, partial sleep deprivation on alcohol consumption. Twelve Sprague Dawley rats had free access to two bottles at all times, one containing water and one containing a 7% alcohol and water solution. Five rats had no access to alcohol. Sleep deprivation was achieved by using a forced exercise wheel. All rats were sleep restricted every day for 7 days in one week. There were three total weeks of chronic partial sleep deprivation that were interspersed with a week for recovery. Three rats experienced an alcohol only condition, and three rats were purely

control rats with no exposure to sleep deprivation or alcohol. There was a significant effect of sleep condition on voluntary alcohol consumption, $F(4, 44) = 9.191$, $p < .001$, partial $\eta 2 = .455$. The partial eta squared showed a large effect, 45.5% of the variance in error associated with alcohol consumption can be explained by sleep condition. It was found that sleep deprivation increased alcohol consumption. Histology was performed on all rats to stain for differences in Delta Fos B levels in areas involved with reward and sleep.

Abstract: Energy drinks contain caffeine and taurine, among other compounds, which have been associated with improved cognitive performance. In the last 8 years, increased sales of drinks like Red Bull and Monster reflect an increase in energy drink consumption among the general

population. Few studies have directly compared the effects of these compounds on cognitive function during different developmental stages. Adolescence is a critical period of development when significant brain maturation occurs with varying rates of growth between sexes, in comparison to the adult brain. The objective of this study was to determine whether caffeine and taurine differentially effect cognition in adolescent and adult male and female rodents. Sixty-four Sprague Dawley rats of each sex were randomly divided into four groups (1) caffeine (n=8; 20mg/kg; ip), (2) taurine (n=8; 100mg/kg; ip), (3) caffeine and taurine (n=8; cocktail) or (4) saline. Adolescent rats began treatment on postnatal (P) day 33 and adults began treatment on P68. Animals were pre-treated for one week before beginning consecutive behavioral assessment for working, visual and spatial memory. Treatment was continued throughout the days of testing. Females were the least affected by compounds found in energy drinks, showing no effects on visual or working memory. However, a repeated measures three way ANOVA revealed a main effect of treatment ($p = 0.0075$) and age ($p=0.0016$) on the spatial memory task. Specifically, adolescent females showed impaired spatial memory, while taurine improved memory. Interestingly, adolescent males treated with taurine displayed improved working memory ($p = 0.05$) when compared to the saline controls. Nevertheless, they showed impairments in the visual and spatial memory tasks when exposed to caffeine, taurine and the cocktail. Adult males exhibit impairments only on the spatial memory task when exposed to caffeine and the cocktail. Three way repeated measures ANOVA revealed a significant interaction of age by treatment ($p = 0.0071$) in the spatial memory tasks, highlighting how compounds found in energy drinks can differentially effect adolescent and adult animals. Our findings suggest that males are more vulnerable to the separate and combined effects of caffeine and taurine when compared their female counterparts both adolescence and adulthood. In addition, these studies also underscore that the adolescent brain is more susceptible to the effects of exogenous compounds and their impact on behavior. Further studies will investigate the mechanisms by which these compounds differentially affect the cognitive behaviors.

Title: Self-administration of caffeine in rats

Authors: *C. A. BRADLEY, A. M. BROWN, E. A. WILLIAMS, C. N. SWYMER, M. I. PALMATIER;
East Tennessee State Univ., Johnson City, TN

Abstract: Caffeine is the most consumed psychoactive drug in the world and functions as a reinforcer in participants who are low to moderate consumers of caffeine. However, no study has effectively established caffeine as a reinforcer in pre-clinical paradigms. In humans, the relationship between caffeine and operant behavior includes salient orosensory stimuli that could moderate the reinforcing effects of the drug (e.g., coffee, energy drinks, etc.). Therefore, we hypothesized that adding a salient gustatory reinforcer (saccharin) to a rodent caffeine self-administration paradigm would result in higher levels of operant responding. In Experiment 1, thirty rats were instrumented for intravenous self-administration and assigned to one of three groups: saccharin only (SACC, 0.2% w/v), caffeine only(CAFF, 0.5 mg/kg/inf.), and caffeine+saccharin (CAFF+SACC). The oral reinforcer (saccharin) was delivered in a liquid dipper cup, caffeine was delivered intravenously. Rats were tested in 1-hr sessions and their assigned reinforcer was available under a Progressive Ratio (PR) reinforcement schedule. This schedule measures motivation by increasing the number of responses required to earn each reinforcer (saccharin and/or caffeine). Lever pressing in the CAFF group declined across sessions, confirming previous studies showing that caffeine is not a reliable reinforcer. Saccharin maintained moderate levels of responding for rats in the SACC group. However, responding increased in the CAFF+SACC group and was significantly higher than both control groups by the end of testing, confirming our hypothesis that caffeine would increase operant behavior if it was delivered with a salient orosensory stimulus. In Experiment 2 we investigated whether this same approach would result in oral caffeine self-administration. Rats from CAFF+SACC and CAFF groups were combined into a control group that could earn dipper presentations of a vehicle solution (0.5% decaffeinated coffee and 0.2% saccharin). For the SACC group, the same vehicle was available but was spiked with different caffeine concentrations (0.5, 1.8, 2.5, 3.5, 5.0 mg/ml) in a pseudo-random order. The oral reinforcers were presented under the same PR schedule as Experiment 1. Oral caffeine dose-dependently increased responding for the vehicle solution, with the peak concentration between 1.8 and 2.5 mg/ml. These findings indicate that caffeine interacts with non-drug gustatory reinforcers to increase a well-defined operant response and are the first demonstration of reliable and repeatable caffeine self-administration in non-human subjects.

Title: Aspartame consumption affects hippocampus, memory and anxiety in mice

Authors: *P. U. NWOHA[1], A. Y. ONAOLAPO[1,2];
[1]Obafemi Awolowo Univ., Ile-Ife, Nigeria; [2]Human Anat., Ladoke Akintola Univ. of Technol., Ogbomoso, Nigeria

Abstract: Aspartame is a widely used sweetener and food additive. Yet nothing is known about its effect on the hippocampus and memory. In the present study, 30 adult male albino mice weighing, 20-22g were used. The mice were divided into five groups of six mice each. Group A is control and received distilled water. Groups B, C, D, and E were experimental and received 20, 40, 80, and 160mg/kg body weight respectively of aspartame dissolved in distilled water. Administration of distilled water or aspartame was daily by oral intubation for 28 days. Spatial memory was measured by recording sponataneous alternation behaviour in Y-maze, and anxiety was measured by noting open arm entries in elevated plus maze. Behavioural tests were conducted before and at end of the treatment period. After 28 days, the mice were anaesthetised by ketamin, brains removed processed for routine histology, sectioned at 5μ, and stained with H & E, Cresyl violet, and Bielschowsky's silver. Under the microscope the morphology and stereology of the hippocampi were studied. Values obtained were analysed statistically by ANOVA and Tukey's test. Results of the H & E, and cresyl violet methods showed extensive degeneration of pyramidal cells of CA1, CA2, CA3 and CA4 layers of the hippocampus, and granule cells of dentate gyrus. On Y-maze there was significant increase in % alternation at 20mg/kg, but significant decrease at dose 160mg/kg aspartame compared to control ($p<0.05$). Elevated plus maze showed significant increase in % time spent in the open arms ($F=26.6$) for all doses of aspartame compared to control ($p<0.05$). These suggest that aspartame consumption for such long period and for the doses affect the morphology of the hippocampus, reducing spatial memory and increasing anxiety in mice.

Title: Involvement of endogenous opioid system in sucrose-induced analgesia during infancy and long-term effects on learning and memory during adulthood in rats

Authors: *K. NUSEIR, K. ALZOUBI, A. BAWAANE;
Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: Premature human infants and newborns are often exposed to painful procedures. Several studies show that early pain experiences may have long-term consequences such as altered neurobehavioral development, and long-term changes in responsiveness of the neuroendocrine and immune systems to stress at maturity. Impairment in memory and learning process could be a long-term consequence of pain at early life. Pain is difficult to assess especially in neonates and young infants. Studies show that fear of adverse reactions and long-term effects often lead to inadequate use of analgesics in neonates. This leads to inadequate pain management in this group of patients. We have shown previously that orally administered sucrose solution given to rat pups exposed to painful stimuli during early life protected against short-term memory impairment. Sucrose induced analgesia is thought to be mediated, at least in part, via endogenous opioid system. Opioid antagonists inhibit sweet substances induces antinociception, and sweet solutions given orally augment morphine analgesia. In this study we will examine the involvement of the endogenous opioid system in sucrose-induced analgesia during infancy by using the orally effective pure opioid receptor antagonist naltrexone. We also will study the long-term effect of this treatment on learning and memory formation during adulthood in the rat. As well as examine the ability of sucrose solution for analgesia to reverse pain-induced learning and memory impairment. And weather this is mediated via endogenous opioid system.

Title: Effect of Local Kappa Opioid modulation on forebrain dependent trace associative learning: An eyeblink conditioning analysis

Authors: *R. LOH, S. SHAH, R. GALVEZ;
Univ. of Illinois: Urbana-Champaign, Urbana, IL

Abstract: There have been several findings indicating a primary role for the opioid receptor system in the modulation of learning and memory. Spatial tasks, fear conditioning, and y-maze spontaneous alternation have all demonstrated that opioid modulation can impair task acquisition. Much of the current literature investigating opioid effects in learning and memory have focused on the mu opioid receptor; however, several reports have indicated that there is a likely role for the kappa opioid receptor in various behavioral learning paradigms. We have recently demonstrated that systemic administration of the kappa specific opioid antagonist, NorBNI, prior to training also delays acquisition for whisker-trace eyeblink (WTEB) associations in mice. In investigating the specific brain region mediating this effect, it is well known that primary somatosensory neocortex (S1) is required for the acquisition as well as consolidation of the trace association. The following study utilized intra-S1 injections of NorBNI with the behavioral paradigm WTEB to determine if the kappa opioid receptor is mediating its learning induced effect through primary somatosensory cortex. In WTEB, animals are trained to associate whisker stimulation (CS) with a salient unconditioned stimulus (US) that causes an unconditioned response. After several trials in which the CS is paired with the US, the animal begins to exhibit a conditioned response in anticipation of the US. Separating the CS and US with a stimulus free trace interval makes this paradigm forebrain dependent by recruiting higher brain structures such as the hippocampus and most importantly, the neocortex. The current study utilized localized primary somatosensory injections of 10μg of NorBNI paired with WTEB behavioral training. We found that local injections of NorBNI significantly retarded learning relative to saline controls, suggesting that the kappa opioid receptor is neocortically involved in the acquisition of forebrain-dependent trace associative learning. Further research will focus on determining the specific downstream effects of the kappa opioid receptor that is mediating this effect in learning.

Title: Grape powder supplementation prevents cognitive, behavioral and biochemical impairments in rat model of social defeat

Authors: ***N. SOLANKI**[1], G. PATKI[2], F. ATROOZ[2], S. SALIM[2];
[1]Col. of Pharm. Univ. of Houston, Houston, TX; [2]Univ. of Houston, Houston, TX

Abstract: Psychological stress has been known to cause behavioral and cognitive impairments. In our previous study we used the modified version of the resident-intruder rat model of social defeat (SD) to induce stress. In the same study we have reported that SD-induced psychological stress is associated with increased oxidative stress, anxiety and depression-like behavior and cognitive deficits. Furthermore, we have reported protective effects of grape powder (GP) on behavioral impairments in pharmacologically-induced oxidative stress. However, the protective effect of GP treatment in SD-induced behavioral and cognitive deficits is unknown. Therefore, in the present study using the rat model of SD, we examined the protective effect of GP on SD-induced cognitive, behavioral and biochemical impairments. Male Sprague Dawley rats were randomly assigned into five groups: Naïve control, Naïve control treated with GP, Social defeat, control exposure, social defeat treated with GP. Anxiety-like behavior tests (open-field, light-dark and elevated plus maze) and forced swim test data suggested that GP treatment prevented SD-induced anxiety and depression-like behavior of rats. Moreover, GP also improved SD-induced impairment of memory function of rats, when examined using radial arm water maze test. Results suggest that GP ameliorates SD-induced behavioral and cognitive deficits possibly via reducing oxidative stress in rats.

Title: Glucocorticoids enhance emotional memory consolidation via recruitment of striatal endocannabinoids

Authors: C. SILLER PÉREZ[1], E. SOTELO BARRERA[1], N. SERAFÍN[1], R. PRADO-ALCALÁ[1], P. CAMPOLONGO[2], B. ROOZENDAAL[3], *G. L. QUIRARTE[1];

Abstract: After a stressful experience, glucocorticoid hormones target brain structures that regulate the stress response as well as memory processes. One such structure is the dorsal striatum, which integrates different types of information associated to context, procedures, and arousal. Administration of corticosterone into the dorsal striatum enhances memory consolidation of an inhibitory avoidance task. Additionally, glucocorticoids in association with acetylcholine enhance memory consolidation. However, it is unknown if different neuromodulators interact with glucocorticoids to store a memory. Our objective was to asses if glucocorticoids interact with striatal endocannabinoids to consolidate a memory trace. Male Wistar rats were implanted bilaterally with cannulae into the anterodorsal striatum and were trained on an inhibitory avoidance task. In Experiment 1, the CB1 cannabinoid receptor antagonist AM251 (0.28 or 0.56 ng/µl) or its vehicle was administered intra-striatally immediately after training with a higher foot-shock intensity (0.6 mA, 1 s), and memory retention was evaluated 48 h later. In Experiment 2, rats were trained with a lower foot-shock intensity (0.45 mA, 1 s) and immediately after training they received 0.56 ng/µl of AM251 or its vehicle, followed by a systemic administration of corticosterone (3 mg/kg, i. p.) or its vehicle; a retention test was performed 48 h after training. We found in Experiment 1 that AM251 administration (0.56 ng/µl) caused a significant impairment in retention. In Experiment 2, systemic administration of corticosterone enhanced memory consolidation; importantly this effect was blocked by the prior intra-striatal administration of AM251 (0.56 ng/µl). Our findings provide evidence of the interaction of endocannabinoids and glucocorticoids in the modulation of emotional memory, suggesting that the endocannabinoid system needs to be active up-stream for glucocorticoids to enhance memory consolidation of an emotional training experience. Title: Basolateral amygdala-striatal interactions regulating glucocorticoid effects on memory retrieval of a cued water-maze task

Authors: *J. PARGA-MARTÍNEZ[1], S. N[1], A. P[2], P.-A. RA[1], R. B[2], Q. GL[1];

Abstract: Evidence indicates that glucocorticoid hormones, released after a stressful experience, impair the retrieval of hippocampus-dependent spatial/contextual memory in rats and declarative memory in humans. Recent findings suggest that glucocorticoids also act in the dorsal striatum to impair the retrieval of procedural memory. The present experiments investigated whether these effects depend on noradrenergic activity within the basolateral amygdala (BLA). Adult male Wistar rats were trained on a session of eight trials in a water maze to find a platform that was marked with a visual cue. The platform position and rat´s starting position were repositioned randomly on each trial. Retention of the training was tested 48 h later. In the first experiment, rats received infusions of either vehicle or corticosterone (5, 10 or 20 ng) into the dorsal striatum 30 min before the retention test. Corticosterone (10 ng) significantly impaired escape latencies to find the platform. In the second experiment, rats received corticosterone (10 ng) or vehicle into the dorsal striatum and the β1-adrenoceptor antagonist atenolol (0.5 μg) or β2−adrenoceptor antagonist zinterol (0.5 μg) or saline into the BLA 30 min before the retention trial. A blockade of noradrenergic activity (β1 and β2 receptors) in the BLA prevented the impairing effect of corticosterone on memory retrieval. These findings indicate that the BLA interacts with the striatum in mediating the impairing effects of glucocorticoids on retrieval of procedural memory.

Title: Chronic resveratrol treatment ameliorates cognitive deficits associated with a high fat diet

Authors: *K. O'LEARY, R. ANKAWA, E. C. MCNAY;
Behavioral Neurosci., Univ. At Albany, Albany, NY

Abstract: Resveratrol is a polyphenol antioxidant, found in red wine and known to have anti-aging, anti-cancer, and anti-obesity effects in both humans and other animals. Resveratrol's primary biological action is as an antioxidant, causing a reduction in reactive oxygen species (ROS). ROS become abnormally elevated in individuals who consume a high fat diet (HFD) or who have metabolic conditions like Type II Diabetes Mellitus (T2DM); in these circumstances, elevated ROS lead to cellular damage and cell death. Another common effect of a diet high in fat and calories is cognitive impairment, and specifically impaired memory. Here, we investigated whether resveratrol administration would attenuate or reverse cognitive impairment caused by the ingestion of a high fat diet. Rats on either a control (chow) diet or high fat diet (60% kcal fat) were treated with resveratrol (or vehicle) once weekly for 20 weeks. Unexpectedly, no metabolic effect of resveratrol were seen: treatment did not affect body mass or fat level. However, resveratrol treatment reversed cognitive deficits seen in high-fat-fed rats, indicating a possible role of resveratrol as a therapeutic intervention to improve memory in individuals with metabolic dysregulation. Intriguingly, resveratrol treatment of control animals impaired, rather than enhancing, cognition, suggesting a possible inverted-U dose-response curve. Post-mortem measurement of molecular markers linked to memory formation, insulin signaling, and oxidative stress, and results suggested that resveratrol's impact may be mediated at least in part through regulation of AMPK activity. Our data suggest a possible role for resveratrol in preventative care for individuals prone to metabolic disease and related cognitive dysfunction.

Title: Do estrogen and progesterone act synergistically to accentuate the cognitive effects of a serotonergic antagonist in female rats?

Authors: ***S. S. MASWOOD**, J. HASSELL;
Biol., Millersville Univ., Millersville, PA

Abstract: The neurotransmitter serotonin (5-HT) is involved in the modulation of cognitive functions. Although the precise mechanism of action of the 5-HT system in the facilitation of cognitive functions has not been clearly identified, compounds such as tropisetron that act as 5-HT3 receptor antagonist enhance cognition. Similar to the cognitive enhancing effects of tropisetron, female gonadal hormones such as estrogen and or progesterone also improve cognitive behavior in rodents. Interestingly, both estrogen and progesterone inhibit the function of the 5-HT3 receptors. The objective of our study is to evaluate the cognitive effects of tropisetron in rats primed with both estrogen + progesterone. Since tropisetron, estrogen and progesterone all act as antagonists at the 5-HT3 receptors we are expecting to see an accentuation of tropisetron's effect on cognition in rats primed with both estrogen + progesterone. We are evaluating the effects of these compounds in ovariectomized Sprague-Dawley female rats using the object recognition task. The object recognition task is a model of cognition in rodents in which the natural tendency of rats to explore novel aspects of the environment is utilized. Rats spend more time exploring the novel object, suggesting that rats recognize previously explored objects. Our preliminary data are in agreement with earlier studies

and show that in comparison to rats receiving no estrogen, rats primed with 20 µg of estrogen (subcutaneous) show an increase in cognition by spending greater percentage of time with the novel object. Furthermore, tropisetron's (2.5 mg/Kg, intraperitoneal) effect on cognition is further accentuated in rats primed with 20 µg of estrogen. Ongoing studies evaluating the combined effects of both estrogen + progesterone (250 µg) priming in rats are expected to show the greatest increase in cognition in response to tropisetron.

Title: Oxytocin (OT) and arginine-vasopressin (AVP) act on OT receptors (OTRs) to influence social but not non-social recognition in Syrian hamsters (mesocricetus auratus)

Authors: *Z. E. SONG, T. E. LARKIN, M. O'MALLEY, H. ALBERS;
Neurosci. Institute, Ctr. for Behavioral Neurosci., Georgia State Univ., Atlanta, GA

Abstract: OT and AVP play essential roles in a variety of social behaviors through their actions in the central nervous system. Here we report effects of intracerebroventricular (ICV) injection of OT and AVP on social versus non-social recognition. Because OT and AVP can activate each other's receptors due to structural similarities in both the peptides and their receptors, we determined whether OT and AVP influence social recognition by acting on OT or AVP V1a receptors. A two-trial discrimination test was used to measure social recognition. During the social recognition test, male hamsters were first exposed to a flank gland odor of another male adult conspecific for 3min and subsequently exposed to a flank gland odor of that same individual together with a flank gland odor from a novel individual for another 3min. Hamsters discriminated between the pre-exposed and novel odors by spending more time on the latter for 20min and 24h, but not 48h or 7 days. Twenty minutes, 24h, 48h, and 7d after the pre-exposure, hamsters spent 71.6% ± 6.7%, 65.5% ± 5.0%, 58.0% ± 10.6%l, and 46.5% ± 11.9% of total sniffing time, respectively, on the novel odor. ICV injections of OT and AVP, but not saline, prolonged the recognition of the previously encountered odor up to 48h. OT and AVP injected hamsters spent 63.0% ± 3.1% and 67.0% ± 3.5% of total sniffing time, respectively, on the novel

odor tested 48h after the pre-exposure, while saline hamsters spent 51.3% ± 4.3% of sniffing time on the novel. This enhancement of recognition after OT or AVP injections was mimicked by injection of highly selective OTR but not V1aR agonists. Furthermore, the selective OTR antagonist but not the V1aR antagonist blocked recognition of the odor 20min after the pre-exposure. In the non-social recognition test, hamsters were pre-exposed to a lemon scent and subsequently exposed to a cocktail of lemon and vanilla. Control hamsters were not pre-exposed to either lemon or the cocktail and were directly tested with the two scents. Hamsters discriminated the lemon scent from the cocktail scent by spending more time on the novel scent for 20min, 60min, but not 24h. They spent 64.5% ± 11.4%, 67.8% ± 7.5%, and 42.0% ± 11.7% of total sniffing time on the cocktail with ITIs of 20min, 60min, and 24h, respectively. Neither the selective OTR nor V1aR antagonist blocked the recognition of the scents, they spent 71.1% ± 3.8% and 67.0% ± 2.8% of total sniffing on the cocktail. Our results suggest both OT and AVP enhance social recognition by acting on OTRs and the recognition enhancing effects of OT and AVP may be limited to social stimuli.

Title: Melatonin prevents memory impairment induced by chronic sleep deprivation

Authors: ***O. F. KHABOUR**, K. ALZOUBI, F. MAYYAS, F. BANI SALAMEH, N. MHAIDAT;
Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: Sleep deprivation (SD) has been associated with memory impairment through induction of oxidative stress. Melatonin, which promotes the metabolism of many reactive oxygen species (ROS), has antioxidant and neuroprotective effects that attenuate oxidative stress related risks. In this study, the effect of melatonin on memory impairment induced by 4 weeks of sleep deprivation was investigated using rat animal model. Animals were sleep deprived using modified multiple platform model. Melatonin was administered via oral gavage (100mg/kg/day). Spatial learning and memory were assessed using the radial arm water maze (RAWM). Changes

in oxidative stress biomarkers in the hippocampus following treatments were measured using ELISA procedure The result revealed that SD impaired both short and long term memory ($P<0.05$). Use of melatonin prevented memory impairment induced by SD. Furthermore, melatonin normalized SD induced reduction in the hippocampus activity of catalase, glutathione peroxidase (GPx), and superoxide dismutase (SOD). In addition, melatonin enhanced the ratio of glutathione GSH/GSSG ratio in sleep deprived rats ($P<0.05$) without affecting TBARS levels ($P>0.05$). In conclusion, SD induced memory impairment, whereas melatonin prevented this impairment probably through normalizing antioxidant mechanisms in the hippocampus.

Abstract: A major barrier to deployment of NMDAR receptor antagonists as pharmacotherapies is the fact that they exhibit poor therapeutic ratios and produce debilitating cognitive impairments. Thus, NMDARs are largely considered therapeutically untargetable because blockade of these receptors produces memory as well as motor impairment. Consequently, drug discovery efforts have been directed toward the development of small molecules that interrupt the signaling cascades downstream of NMDARs by targeting protein-protein interactions. The

scaffolding protein postsynaptic density 95kDA (PSD95) tethers the enzyme neuronal nitric oxide synthase (nNOS) to NMDAR. Thus, the PSD95-nNOS protein-protein interface represents a therapeutic target due to its role linking excessive NMDAR activity to nitric oxide (NO) production. One of us (Lai) developed IC87201, the first in class small molecule inhibitor of PSD95-nNOS protein-protein interactions (Florio et al. (2009) British Journal of Pharmacology 158: 494-506). Because PSD95-nNOS inhibitors such as IC87201 and ZL006 act downstream of NMDARs, they may lack cognitive impairment associated with NMDAR antagonists. We used a source-memory preparation (Crystal et al. (2013) Current Biology 23:1-5) we developed for use in rats to evaluate possible impairments of both spatial memory and higher order memory functions in the same task. Source memory is a representation of the origin (i.e. source) of information. We compared the cognitive profiles of an NMDAR antagonist (i.e. MK801) with that induced by PSD95-nNOS inhibitors (i.e. IC87201 and ZL006) in this source memory task. MK801, at doses that did not impair motor function, preferentially impaired source memory under conditions in which spatial memory was spared. These observations suggest that source memory is more vulnerable than spatial memory to impairment. By contrast, IC87201 and ZL006, administered at doses that are effective in suppressing pain behavior in rats, spared source memory, spatial memory, and motor function. Thus, PSD95-nNOS inhibitors are likely to exhibit favorable therapeutic ratios compared to NMDAR antagonists. These results lend support to the translational value of animal models of episodic memory for validation of pharmacotherapies with limited cognitive side effects.

Title: Enhanced object recognition memory following inhibition of cyclic nucleotide phosphodiesterase 2 (PDE2): role of NOS/cGMP pathway

Authors: *L. M. LUEPTOW[1], Y. XU[2], J. M. O'DONNELL[2];
[1]Neurobio. and Anat., West Virginia Univ., Morgantown, WV; [2]The State Univ. of New York at Buffalo, Buffalo, NY

Abstract: Cyclic nucleotide phosphodiesterases (PDEs) are critical regulators of second messenger cAMP and cGMP signaling. PDE2 is of special interest due to its significant level of expression in forebrain regions, which are highly implicated in learning and memory. In order to examine the role of PDE2 in the early memory consolidation, we trained mice in the object recognition test (ORT). Immediately following exposure to two identical objects, mice were injected with a PDE2 inhibitor, Bay60-7550 (3 mg/kg) or ND7001 (3 mg/kg). Twenty-four hours later, mice were exposed to the familiar object and a novel object. Mice injected with either Bay60-7550 or ND7001 spent significantly more time exploring the novel object, indicating PDE2 inhibition enhanced ORT memory. Next, we pre-treated mice with inhibitors of various molecules in the cGMP pathway, to better understand the underlying signaling that mediates the memory enhancing effects of PDE2 inhibition. When given 30 minutes prior to either Bay60-7550 or ND7001, the nitric oxide synthase (NOS) inhibitor L-NAME (20 mg/kg) and the soluble guanylyl cyclase inhibitor ODQ (20 mg/kg) prevent both Bay60-7550 and ND7001 mediated enhanced ORT memory. This indicates that the memory enhancing properties of PDE2 inhibition during early consolidation are likely mediated via the NOS/cGMP pathway. Ongoing research will continue to investigate other potential molecules in this pathway and the cAMP pathway, to further elucidate the role of PDE2 in ORT memory. Developing a greater understanding of the role of PDE2 in these memory processes will allow for potential drug development for the intervention of a variety of human diseases related to cognitive decline and memory impairment, which plague millions of individuals each year.

Title: A mechanistic study of the effects of nitrous oxide on spatial working memory in mice

Authors: *E. KLEIN[1], D. EMMANOUIL[3], Y. ZHANG[2], D. Y. SHIRACHI[4], R. M. QUOCK[1]; [1]Psychology, [2]Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA; [3]Pediatric Dent., Univ. of Athens, Athens, Greece; [4]Physiol. and Pharmacol., Univ. of the Pacific, Stockton, CA

Abstract: Nitrous oxide (N_2O) is a safe, fast-acting psychoactive drug, and it is the most popular sedative in the field of pediatric dentistry. A recent clinical study demonstrated that in combination with propofol, N_2O potentiated amnesia in patients during dental procedures [Yokoe *et al., J Oral Maxillofac Surg* 73:P402-409, 2015]. Other studies have indicated that prolonged exposure to high concentrations of N_2O (70%) in oxygen affected spatial learning memory in rodents [Culley *et al., Anesth Analg* 105:83-88, 2007]. Therefore, the aim of the study was to explore potential mechanisms of N_2O in reducing spatial working memory in mice. Studies have shown that flumazenil reversed N_2O-induced anxiolysis in mice [Emmanouil *et al., Psychopharmacol* 115:167-172, 1994]. Furthermore, there has been evidence indicating that hyperbaric oxygen (HBO_2) improved cognitive functions in both humans and mice that have suffered brain injury [Boussi-Gross *et al., Neuropsychology,* Nov 10, 2014, doi.org/10.1037/neu0000149; Liu *et al., Neural Regen Res* 8:3334-3343, 2013]. Therefore, flumazenil and hyperbaric oxygen (HBO_2) were used to study potential mechanisms of N_2O-induced spatial working memory dysfunction. The T-Maze Spontaneous Alternation Task (T-SAT) has been utilized for decades to test spontaneous alternation behavior (SAB) and, therefore, spatial working memory in mice in this study. It was found that mice exposed to 70% N_2O (in O_2) exhibited severely reduced alternation behavior in the T-SAT. Mice in this environment alternated their route only 33.04% of the time, in comparison to the control (room air) rate of alternation at 62.81%. Three groups of mice received intraperitoneal injections of flumazenil (0.1, 1.0 or 10 mg/kg) and demonstrated a dose-dependent restoration of spatial working memory under 70% N_2O in the T-SAT. Lastly, mice pretreated for 60 min with HBO_2 at 3.5 atmospheres absolute demonstrated 47.32% alternation under 70% N_2O in the T-SAT. This study verified that 70% N_2O reduced spatial working memory in mice, which can be improved independently by flumazenil and HBO_2. Further, this study implied that N_2O possibly affect the $GABA_A$ receptor complex in inhibiting spatial working memory. The mechanism of HBO_2 has not been elucidated, though this study introduced that HBO_2 might share a similar mechanism with flumazenil in restoring spatial working memory.

Title: Understanding behavioral networks: A novel, scalable microscope designed to enable whole brain imaging of behavior-driven circuits with subcellular resolution

Authors: R. LIANG[1], C. WANG[1], S. PACHECO[1], B. K. BAGGETT[2], M. K. CHAWLA[3,4], D. T. GRAY[3,4], U. UTZINGER[2], *C. A. BARNES[3,4,5];

Abstract: One impediment to progress in understanding the critical differences between brains of normal versus diseased individuals is the difficulty of reconstructing, from sectioned tissue, wiring diagrams that reveal structural or molecular circuit differences. This will be a fundamental requirement for a deeper understanding of how electrical and chemical signals code information in neural circuits and give rise to sensations, thoughts, emotions and actions. With recent advances in whole brain clarification methods (i.e., CLARITY [Chung et al., Nature, 2013, 497:332] and CUBIC [Susaki et al., 2014, Cell, 157:726]), the ability to identify cells, their long-range projections as well as protein and RNA composition of neural networks is a reasonable goal. The physical sectioning required for standard confocal microscopes, however, is not optimal for whole brain imaging because of low imaging speed, layer misalignment and surface mismatching. A number of approaches have been developed (such as the light-sheet microscope) to address fundamental requirements of resolution and speed; however no approach has addressed speed, resolution, working distance and field-of-view simultaneously. We are developing a novel, scalable **h**igh speed, **h**igh resolution, **l**ong working distance, **l**arge field of view **c**onfocal **f**luorescence **m**icroscope ("**H^2L^2-CFM**") that overcomes key limitations of standard single scanning point microscopes, to meet all of these four needs for whole-brain imaging. The novelty of our H^2L^2-CFM approach is that it divides the field of view of the objective (that can scale to the size of an entire mouse or rat brain) into subregions (3x3, 5x5, etc.) with each region having its own multifocal scanning channel. This multi-region, multifocal scanning configuration compensates the remaining aberrations of the objective in each subregion with a collimating lens for each channel. The outcome, once scaled, will be a more than 200x

increase in imaging speed compared to the conventional fluorescence microscope. This novel confocal fluorescence microscope design should overcome the major impediments in current technologies to realize single-cell imaging of large-scale brain networks, and allow for large volumes of brain tissue to be studied on a timescale of weeks to months instead of years. Such an increase in the speed of anatomical data acquisition will enable highly significant experimental questions to be answered including how brain networks change during development, aging or in models of disease.

Title: Is Arc mRNA expression regulated by the threshold for dendritic Ca++ plateau potentials generated from integration of entorhinal cortical inputs to granule cells?

Authors: *M. K. CHAWLA[1,2], D. T. GRAY[1,2], M. J. HUENTELMAN[1,4], C. A. BARNES[1,2,3];

Abstract: Immediate-early genes (IEGs) are rapidly and transiently induced following excitatory neuronal activity including maximal electroconvulsive shock treatment. The rapid RNA response can be blocked by the sodium channel antagonist tetrodotoxin, without blocking seizures, indicating a role for electrical excitation in induced mRNA responses (Cole et al., 1990). Using the IEG *Arc* (Lyford et al., 1995) that is selectively synthesized at active synapses, we examined whether lowering the current used to elicit seizures reduces the numbers of *Arc*-positive granule cells in rat hippocampus. F344 rats (5-6 mo old) were divided into 4 groups. Three groups received electroconvulsive shock treatment (20, 40 and 85 mA), and a fourth group did not receive shock. The electrically-induced seizures were produced following attachment of saline-

soaked earclips, using a UGO Basile ECT unit (1sec, 100Hz, 0.5ms square wave pulse) at the three stimulus intensity levels. Five minutes following treatment, brains were rapidly extracted and quick frozen. Twenty micron thick sections were cut and thaw-mounted on frosted slides. Fluorescence *in situ* hybridization was performed as described previously (Chawla et al., 2005) using the full length *Arc* cDNA. Confocal images were acquired using a Leica SP5 microscope equipped with 405 nm and 543 nm lasers, with a 20x dry lens. Overlapping images were obtained of entire dentate gyrus, and *Arc* mRNA-positive granule cells were counted. An estimate of total number of granule cells was used to obtain the percentage of total *Arc*-positive cells in the 0, 20 and 40 mA stimulus conditions. For the 85 mA condition, negative cells were counted to derive the percentage of *Arc* expression. Although seizures were induced by the 20 and 40 mA conditions, these currents resulted in very low *Arc* mRNA expression (20 mA = ~4% +/- 0.4; 40 mA = ~6.0 +/- 0.6 *Arc*, 0 mA ~1% +/- 0.3 mRNA positive cells). Excitation at 85 mA resulted in *Arc* mRNA expression in ~ 93% of granule cells. The minimal expression observed in the lower current conditions may reflect a threshold effect for granule cell burst spiking activity. Indeed, recent observations in CA1 pyramidal neurons suggest that a supralinear summation of electrical activity occurs when entorhinal layer III input to distal CA1 dendrites crosses a threshold to produce a Ca^{++} plateau potential. These plateau potentials appear to drive burst firing, characteristic of CA1 place cell discharge (Milstein and Magee, SfN Abstr, 2014). Our data suggest the possibility that similar plateau potential processes may regulate both the *in vivo* patterned firing that occurs when granule cells express place fields and when granule cells express *Arc* mRNA.

Title: Enhanced single unit firing to unexpected large rewards in aged amygdala neurons

Authors: *R. D. SAMSON[1,2], L. DUARTE[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory and Aging,
[3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: With aging, changes in emotional regulation can lead to biases in decision making towards certain or safe options. In fact, we found that aged rats are more risk averse and will more readily select a small certain reward over a larger probabilistic one. The activity of neurons in the basolateral complex of the amygdala (BLA) was examined in young and aged rats during rest and while acquiring and performing a probabilistic decision making task. The greatest modulation in firing rate occurred following reward, with the largest change occurring after uncertain large rewards, a modest change in firing rate following small/certain rewards and no change when rewards were not delivered. When all neurons that fired at or above 0.1 Hz were analyzed, the variability and amplitude of change following rewards was much larger in old than in young rats. When neurons with a firing rate below 1Hz were excluded from analysis in both age groups, the young and aged rats did not differ in the amplitude of change of their firing rates in response to uncertain/large rewards. To better characterize how BLA neurons change their firing rate to uncertain rewards, BLA cells were separated into four categories: regular, irregular, irregular/bursty and bursty, based on their local variance, which is a measure of the variability between adjacent inter-spike intervals (ISI). Regular firing neurons accounted for only 1-2% of the 10,000 BLA neurons recorded, and had high firing rates at rest, which were reduced following reward delivery in aged rats. In contrast, irregular neurons accounted 20% of the BLA neural population, and showed the greatest increase in firing rate following large rewards, in both age groups. The vast majority of neurons (60%) had a local variance around 1.5 and an ISI distribution indicating that these cells alternated between irregular and burst firing modes. Following rewards, some of these cells displayed increases and others decreases in firing rates. This effect was consistent across age groups. Finally, bursty neurons accounted for the remaining 20% of the BLA population and only in aged rats did these cells show an increase in firing rate following uncertain/large reward delivery. Thus the change in firing rates of BLA neurons to unexpected rewards appears to be mediated by neurons from all categories, but aging appears to selectively impact low firing rate BLA neurons in a way that allows the aged network to be more responsive to rewards. This effect may contribute to the age-related increases in risk aversion found during probabilistic decision making tasks.

Title: Enhanced beta band activity in the aged amygdala during probabilistic decision making

Authors: *L. DUARTE[1,2], R. D. SAMSON[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory and Aging,
[3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: With aging, older adults tend to use strategies that differ from those used by young adults to solve decision making tasks. When compared to young adults, older adults perform better in tasks that are best solved with a win-stay-lose-shift strategy. The amygdala is known to be involved in both the acquisition and maintenance of optimal probabilistic decision making strategies. We recorded single units and local field potentials from this structure in young and aged rats for up to fifty days as they learned three versions of a decision making task. Two versions were discrimination tasks in which either the reward magnitude (reward magnitude discrimination) or the probability of receiving a reward (probability discrimination) was manipulated. The third version was a probability discounting task in which rats had a choice between a small/certain reward and a large/uncertain reward (probability discounting). In aged rats, we found increased oscillatory power in the beta range (20-40Hz, peak ~24 Hz) in the basolateral complex of the amygdala (BLA). These increases occurred in the delay between the chosen lever presses and resulting outcomes, and lasted for ~1 second. Beta band oscillations were not observed in the younger rats. This effect was not present immediately, but developed after an acquisition period of ~ 6 days in aged rats. Furthermore, the effect was only present in the reward magnitude discrimination and probability discounting tasks. It was of higher amplitude during free choice trials, for both tasks. While beta band activity increased in all aged rats, some showed a stronger increase after choosing the uncertain/large reward, while others showed greater increases in beta power after choosing the certain/small reward. This effect was present in spite of the consistent finding that the old animals all became more risk averse over training compared to the younger animals. Beta power did not increase during the probability discrimination task. One possible explanation for this observation is that this task was only administered for 6 days. This may have been too brief a period for the increased beta band power to emerge. Since behavioral performance on the reward magnitude discrimination version of the task was similar between age groups, this suggests the possibility that aging, rather than differences in behavior, impacts BLA networks in a way that promotes the emergence of beta band activity. Because beta oscillation increases occur in associative learning and motor function, it is possible that our findings reflect a compensatory mechanism in the amygdala of

aged rats, which supports the instrumental associations formed during probabilistic decision making.

Title: Age-related changes in external cue-based navigation in the medial entorhinal-hippocampal network

Authors: *A. W. LESTER[1,2], A. J. KOUTIA[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: The hippocampus and entorhinal cortex are critical for spatial navigation and are highly susceptible to age-associated brain changes. As with older adults, aged rats are impaired in many spatial navigation tasks. These impairments are accompanied by changes in the degree to which the spatial tuning properties of hippocampal place fields are influenced by external visual cues in an environment. Such alterations may arise from circuit disruptions caused by known age-related functional and anatomical changes in the hippocampal processing pathway, which could have the effect of either slowing external cue processing or weakening the ability of these cues to influence firing field alignment. To address these possibilities, a novel behavioral apparatus has been developed that allows for complete and immediate control of all visual cues in the environment. The apparatus is composed of a 1.4 m diameter circular track. Projectors arranged around the outside of the apparatus project a 360 degree panorama of visual cues on 68 cm tall cylindrical walls that enclose the track. There are 36 identical feeders evenly spaced along the perimeter of the track and animals learn to run to only one of them for food reward. The projected cues around the rewarded feeder are identical for 50 degrees to either side which eliminates any local visual cue information, forcing the rat to use the full panorama of cues to navigate to the rewarded feeder. By instantaneously rotating the cues we can precisely

characterize when and to what degree animals update their internal representation of space to realign to the rotated external cues. In this context, we can: 1) investigate how spatial representations are updated both at very short time-scales of tens of milliseconds and over longer time intervals of seconds to minutes; 2) identify how different processing stages within the hippocampal formation are affected by age. Behavioral pilot data collected from three young (9 – 13 months old) and two aged (24 month old) animals show that immediately following a 40 degree rotation of the projected cues, animals typically visited feeders that were offset from the learned feeder by a comparable distance (i.e., 20 – 40 degrees). These findings suggest that rats rapidly update their behavior to maintain alignment with the orienting cues in an environment. The next step of the study will be to perform simultaneous high density recordings from both medial entorhinal cortex and the CA1 region of the hippocampus as rats perform the task. With these measurements we hope to more precisely characterize the loci, timing and effect of age-related functional changes within the medial entorhinal-hippocampal network.

Title: Time-dependent decrease in the peak frequency and power of hippocampal sharp-wave ripples and high-gamma events during post-behavior sleep in aged and young rats

Authors: ***J.-P. WIEGAND**[1,2], D. T. GRAY[1,2], L. A. SCHIMANSKI[1,2], P. LIPA[1,2], C. A. BARNES[1,2,3,4], S. L. COWEN[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory and Aging, [3]Dept. of Psychology, [4]Departments of Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Sharp-wave ripples (SPW-Rs) are brief (20-150 ms), high-frequency (130-180 Hz) oscillations in the hippocampus (Buzsaki et al., 1992) linked to the process of memory consolidation. Previous work has demonstrated that neural activity associated with recent experience is reactivated during SPW-Rs (e.g., Wilson and McNaughton, 1994) and that the

strength of this reactivation decreases to approximately 20% of original levels within 30 minutes after behavior (Kudrimoti et al., 1998). We investigated the general hypothesis that the rapid decrease in reactivation strength is correlated with a time-dependent reduction in frequency and power of the ripple oscillation. Given the association between age and memory decline, we also investigated whether the time course of such change differs between aged and young animals. CA1 local field potentials (LFPs) were recorded in aged (n = 5) and young (n = 6) male F344 rats during rest periods following a place-dependent eyeblink-conditioning task. To examine the time course of the probability of occurrence of high frequency LFP events during the 20 minutes following the behavior experience, we bandpass filtered between 80-300Hz, rectified the data, set a power threshold, and then found the onset and offset of these events throughout this time period. Peak frequency and power at higher frequencies were reduced in aged rats compared to young, and both frequency and power decreased gradually during the first 20 minutes to ~90% of initial levels in both age groups (unpaired t-test, $p < 0.05$). In the older animals, the entire probability distribution of peak frequency oscillatory events was significantly shifted downward. This reduction could reflect an increase in the proportion of fast gamma to ripple events, or age-associated changes in the CA1 network that limit the maintenance of high-frequency oscillatory activity. Given that high gamma activity is associated with increased entorhinal input to CA1 (Colgin et al., 2009), these results suggest that CA1 may receive increasing input from entorhinal cortex throughout the course of sleep, and that this effect may be particularly strong in aged animals.

Title: Behavioral evidence for enhanced interference during working memory and associative learning tasks in aged macaques

Authors: *D. T. GRAY[1,2], S. L. ASHFORD[1,2], W. PYON[1,2], S. N. BURKE[4], A. C. SMITH[1], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ; [4]Evelyn F. McKnight Brain Institute, Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: The ability to protect ongoing cognitive processes from distracting stimuli is known as interference control. Human studies investigating this phenomenon have revealed that despite impressive flexibility in most cognitive domains, there is a severe capacity limitation in the ability to perform multiple tasks simultaneously. Efforts to develop behavioral paradigms for animal models to study interference control at the single-neuron level have recently led to insights into the neuronal mechanisms behind these limitations. For example, Wantanabe and Funahashi (2014) demonstrated that during a spatial attention task, neurons in the lateral prefrontal cortex show a decreased ability to represent task-relevant information proportional to the cognitive demand of a competing task. During normal aging this capacity limit is further reduced, but our understanding of the neural basis underlying these age-related declines is minimal. To this end, a computer-controlled associative learning task with varying levels of interference is described. Learning of this task is characterized using a state-space modeling algorithm (Smith et al., 2004). The ability of monkeys to form associations with reward between images in novel object pairs was significantly reduced as the number of object pairs to simultaneously learn increased. This interference effect was proportionally greater in aged than in young monkeys. Additionally, behavioral data demonstrating age-related increases in the susceptibility to interference during a manually-presented working memory interference task (adapted from Clapp et al., 2009) are described here (and in Plange et al., 2011). In this task, distractors are presented in the delay period of a delayed nonmatching-to-sample task, which decreases the performance of aged monkeys significantly more so than young monkeys. Together these data support the observation that older macaque monkeys exhibit age-related deficits in interference control. As with the first associative learning paradigm described above, this second task is currently being implemented under computer control to facilitate the temporal precision required to monitor behavior in relation to electrophysiological recordings, which will provide a novel opportunity to study these aging deficits at the single-neuron level.

Title: Species- and age-related differences in learning and performance on working memory tasks in two species of macaque monkeys

Authors: *A. COMRIE[1,2], D. T. GRAY[1,2], S. N. BURKE[4], A. C. SMITH[1], C. A. BARNES[1,2,3]; [1]Evelyn F. McKnight Brain Institute, Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Deficits in executive function, such as working memory, are characteristic of human aging. Because of similar aging phenotypes and homology in the organization of the lateral prefrontal cortex, nonhuman primate research continues to be especially informative for understanding the underlying mechanisms of normal cognitive brain aging. Two nonhuman primate models that have been used for studying such age-related changes include the rhesus macaque (*Macaca mulatta*) and the bonnet macaque (*Macaca radiata*). It is unknown how these two macaque species compare in their abilities to learn and perform working memory tasks, and how these skills change throughout healthy aging. We employed state-space modeling algorithms (Smith et al., 2004) to analyze behavioral data from young and aged rhesus and bonnet macaques from two separate colonies in order to characterize any possible species or age-related differences in task acquisition and levels of performance. The macaques were trained on two behavioral tasks that engage working memory systems for optimal performance. These tasks include the delayed response (DR) and delayed nonmatching-to-sample (DNMS) tests, which have been shown to be dependent on different association areas of the brain, including the hippocampus and prefrontal cortex. The data suggest that, although performance on the tasks after reaching criterion is comparable across age and species, bonnet macaques appear to learn working memory tasks faster than do rhesus macaques and also show smaller age-related differences in performance than do rhesus. This finding occurred even though the ages at which the animals were tested were comparable between the two species (i.e., mean rhesus old = 24 years, bonnet old = 25 years; mean rhesus young = 11 years, bonnet young = 11 years). To obtain human equivalent ages from macaque ages, Tigges et al. (1988) have suggested that the

age conversion of 3 human years for every one macaque year is a good approximation. Thus these data reflect animals that range in age from 21 to 90 human equivalent years - a significant portion of the lifespan. An understanding of the differences in cognitive aging between these species may inform future choices in selecting models of normal aging for experiments, and should help to connect respective bodies of primate literature using each species.

Title: Behavioral impact of long-term chronic implantation of neural recording devices in the rhesus macaque

Authors: *C. KYLE[1], M. R. PERMENTER[4], J. A. VOGT[4], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]ARL Div. of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ; [4]Univ. of California, Davis, California Natl. Primate Res. Ctr., Davis, CA

Abstract: Although ensemble recording methods are pervasive throughout neuroscience, little is known about how chronic electrode implants affect behavioral performance. Here we investigate the effect of chronic hippocampal tetrode array implants on behavioral performance in a delayed nonmatching-to-sample (DNMS) task. Five female rhesus macaques were tested (mean age: 16 yrs (+/-) 7.7, ranging 7 – 26 yrs) prior to implant, and re-tested (mean age: 21 yrs (+/-) 6.9, ranging 15-31 yrs) after implant (mean elapsed time between tests: 5.1 yrs (+/-) 1.5). DNMS testing was conducted at delay intervals of 10, 15, 60, and 120 seconds using the Wisconsin general testing apparatus. A 4x2 (delay interval by test session) repeated measures ANOVA revealed a main effect of retention interval ($F(3,12) = 9.02$, $p=.002$), and a trending delay by test session (pre vs post implant) interaction ($F(3,12) = 2.8$, $p=.08$) on accuracy. While the main

effect of delay interval confirms typical DNMS findings that performance decreases as delay interval increases, the lack of a significant main effect of test session (pre- vs post-implant) suggests that the cumulative impact of aging between tests and the effect of the implant did not significantly affect performance for all delay periods. Rather, the trending interaction may reflect that the cumulative effects of the implant and aging affect different delay periods differentially. Future analysis will seek to compare our results to typical age related declines in DNMS to better assess the effects of aging versus the effects of the implant.

Title: Age-associated regional network pattern of MRI gray matter in the bonnet macaque

Authors: *P. K. BHARADWAJ[1], S. N. BURKE[7], T. P. TROUARD[2,3], K. CHEN[8], J. R. MOELLER[9], C. A. BARNES[3,4,5], G. E. ALEXANDER[1,3,6];

Abstract: Studies of healthy aging in humans have consistently observed brain atrophy, often preferentially involving frontal and selective temporal brain regions, which is associated with cognitive aging. We have previously reported regionally distributed patterns of magnetic resonance imaging (MRI) gray matter in healthy aging in humans and a nonhuman primate (rhesus macaque) model of aging (Alexander et al., 2006; 2008) using multivariate network

analysis with the scaled subprofile model (SSM; Alexander and Moeller, 1994) and voxel-based morphometry (VBM). In this study we investigated the effects of aging on the regional pattern of MRI gray matter in a group of 13 healthy adult female bonnet macaques (BM) with ages ranging from 10.2 to 30.8 years (human equivalent age range of 31-92 years). Volumetric T1 MRI scans were acquired on a GE 3T Signa scanner with 600 micron isotropic voxel resolution. Image processing for VBM included brain extraction, inhomogeneity correction, and tissue segmentation with high dimensional warping and smoothing using Statistical Parametric Mapping (SPM12; Wellcome Department of Imaging Neuroscience, London, UK) to produce smoothed gray matter maps. Regional network analysis was performed on the gray matter maps with the SSM using Akaike information criterion with small sample correction, which identified a linear combination of three component patterns that was associated with age in the BM (R^2 = 0.66, $p \leq 0.017$). This pattern was characterized by reductions in prefrontal and bilateral posterior temporal/visual association regions with increasing age in the group, as well as with areas of relative increase in the bilateral primary motor/somatosensory regions. These findings indicate that aging in BM is associated with a regionally distributed pattern of MRI gray matter reduction involving selective frontal and temporal brain regions that are generally consistent with previous findings of structural covariance in human and other non-human primate models of aging. This work provides further support for the application of multivariate network analysis methods on a voxel basis, to investigate gray matter integrity in the context of healthy aging and its potential relation to the effects of cognitive aging.

Title: Synaptic GPER1 distribution in the monkey prefrontal cortex is altered with aging, modulated by estrogen, and correlated with working memory

Authors: *J. L. CRIMINS[1], A. C. WANG[2], F. YUK[1], R. PURI[1], W. G. JANSSEN[1], Y. HARA[1], P. R. RAPP[3], J. H. MORRISON[1];
[1]Neurosciences, Mount Sinai Sch. of Med., New York, NY; [2]Univ. of Colorado Sch. of Med., Aurora, CO; [3]Natl. Inst. on Aging, Baltimore, MD

Abstract: Humans and nonhuman primates are vulnerable to age- and menopause-related deficits in working memory, an executive function mediated by layer III neurons of the dorsolateral prefrontal cortex (dlPFC). Long-term cyclic estrogen replacement therapy rescues cognitive deficits in aged rhesus monkeys that have undergone surgical menopause by ovariectomy, in part through the restoration of thin dendritic spines on dlPFC neurons. However, relatively little is known about how the distribution of an estrogen receptor(s) within synapses might contribute to the procognitive effects of estrogen treatment. Here, young and aged vehicle- and estrogen-treated ovariectomized (OVX) rhesus monkeys were first tested on a delayed response (DR) test of spatial working memory. Then, quantitative immunoelectron microscopy was used to evaluate the effects of age and estrogen treatment on the distribution of G protein-coupled estrogen receptor 1 (GPER1) in layer III dlPFC synapses, and its potential relationship to working memory performance. Our data indicated that aged OVX monkeys had a lower density of GPER1-containing synapses than did young OVX monkeys due to the specific loss of synapses with non-perforated postsynaptic densities (PSDs); importantly, this synaptic subclass was partially restored with estrogen treatment. The majority of axon terminals (93%) and dendritic spines (81%) expressed GPER1, but the abundance of GPER1 did not differ across age or treatment groups for either synaptic specialization. GPER1 was predominately localized to mitochondria in axon terminals, and was also highly expressed in the plasmalemmal and cytoplasmic domains of both terminals and spines, as well as at the PSD. There was an age-dependent reduction in the percentage of GPER1 gold particles subjacent to the PSD, which was a strong positive correlate of synaptic density. Intriguingly, working memory performance (average DR accuracy) inversely correlated with the density of GPER1 in the presynaptic active zone across all monkeys. Taken together, these data suggest that GPER1 is strategically positioned to perform diverse estrogen-dependent functions key to the modulation of synaptic plasticity, and ultimately to the functional integrity of dlPFC.

Title: Differential expression of phosphorylated LIM kinase in non-human primate prefrontal cortex correlates with working memory

Authors: F. J. YUK[1], E. BLOSS[1], R. PURI[1], J. L. CRIMINS[1], *W. G. JANSSEN[1], Y. HARA[1], P. R. RAPP[2], J. H. MORRISON[1];

Abstract: Pyramidal neurons in layer III of the dorsolateral prefrontal cortex (dlPFC) play a critically important role in working memory and goal-directed behaviors in non-human primates (NHP). These executive functions are highly vulnerable to aging, and age-related cognitive impairments have been associated with a loss of thin, highly plastic spines. The spine actin cytoskeleton is directly linked to its stability and phosphorylated LIM kinase (pLIMK) is thought to contribute to this stability by phosphorylating cofilin and inhibiting its actin severing activity within the spine. In the current study, young and aged NHP were first tested on a delayed response task, a well-characterized measure of working memory. Using post-embed immunogold electron microscopy and subsequent three-dimensional reconstruction of axospinous synapses in layer III of dlPFC, we asked if pLIMK expression is related to promoting spine stability with aging in NHP dlPFC. Consistent with previous studies, we found an age related 36% decrease in synaptic density, specifically due to a loss of synapses on thin spines. pLIMK immunogold count per synapse was significantly increased with aging in the postsynaptic density (PSD) as previously reported by our group in rats. However, when immunogold density measures were derived by normalizing for area and volume, this significant difference in PSD label was diminished and instead, significant age-related losses in the densities of spine cytoplasmic and subsynaptic pLIMK gold particles emerged. A cluster analysis by spine size and synaptic type revealed that this cytoplasmic decrease selectively occurred in perforated synapse spines, while the subsynaptic decrease was localized exclusively to small non-perforated synapse spines. Furthermore, the decrease in subsynaptic label was inversely correlated with performance on the delayed response task (average accuracy) across all age groups. These data support our hypothesis that age-related alterations in proteins mediating spine dynamics associated with plasticity are associated with age-related cognitive deficits.

Title: Effect of androgen supplementation on cognitive performance in old male rhesus macaques

Authors: *H. F. URBANSKI[1], K. G. SORWELL[1], A. MARQUEZ LOZA[1], D. I. BROWN[2], L. RENNER[1], M. NEURINGER[1], S. G. KOHAMA[1];

Abstract: Cognitive decline in the elderly appears to be causally related to the marked age-related decline in circulating levels of several hormones, including estradiol (E2), testosterone (T), and the adrenal androgen dehydroepiandrosterone (DHEA). We have previously demonstrated beneficial effects of E2 replacement on cognitive function in aged female rhesus macaques, as determined by performance in a delayed response (DR) task, and wondered if androgen supplementation in aged male rhesus macaques would result in similar cognitive benefits. We developed a physiological replacement paradigm for old males, involving daily T and DHEA supplementation, which resulted in circulating E2 and 5α-dihydrotestosterone levels similar to those of young adults - both in terms of magnitude and in terms of circadian profile. As expected, ~6 months of combined androgen supplementation resulted in a slight decrease in the size of the testes, but they were approximately the same size as those of young adults, with no obvious pathology. In the DR memory test, both the young and old androgen-supplemented animals showed improvement with practice. In contrast, the old untreated controls showed no improvement. Consequently, after ~6 months their performance in moderately difficult (15-s delay) DR tasks was significantly worse than in the young animals, whereas the performance in

old androgen-supplemented animals was similar. In a delayed matching-to-sample (DMS) memory test, all of the animals showed improvement in performance with time, but no obvious beneficial effect of androgen supplementation was observed even after ~6 months. Taken together, the data suggest that physiological hormone supplementation paradigms have the potential to alleviate some of the cognitive deficits associated with aging in elderly men, without negatively impacting the neuroendocrine reproductive axis, but significant benefits on cognitive function may require longer periods of treatment.

Title: Intrahippocampal blockade of L-type calcium channels increases unit activity in dorsal CA1 of aged rats

Authors: *D. M. CURLIK, II, X.-W. YU, M. M. OH, J. F. DISTERHOFT;
Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The calcium (Ca2+) hypothesis of aging predicts that age-related cognitive impairments result from disruption of Ca2+ homeostasis. In aged animals Ca2+ influx is increased in CA1 pyramidal neurons, resulting in a decrease in the intrinsic excitability of those cells. A common measure of intrinsic excitability, the post-burst afterhyperpolarization (AHP), is increased in CA1 pyramidal neurons from aged-cognitively impaired animals, resulting in impaired neuronal function and plasticity in those animals. Increased intracellular Ca2+ is believed to underlie these age-related biophysical deficits, as bath application of L-type voltage-gated Ca2+ channel (LVGCC) antagonists reduces Ca2+ influx and the amplitude of AHP *in vitro*. Additionally, systemic intravenous administration of these antagonists increases hippocampal activity *in vivo*, and ameliorates age-related learning impairments. Moreover, we have recently reported strong correlations between expression of Cav1.2 protein in dorsal CA1 and age-related cognitive impairments. That is to say, aged rats with the greatest expression of Cav1.2 protein in area CA1 were the most cognitively impaired. Together, these results suggest

that an age-related increase in the number, and/or function, of LVGCCs in CA1 pyramidal neurons mediates age-related cognitive deficits. However, to date no experiments have directly demonstrated whether intrahippocampal blockade of LVGCCs is sufficient to ameliorate age-related biophysical and behavioral deficits *in vivo*. To determine whether dorsal CA1 is a therapeutic site for ameliorating age-related deficits through intrahippocampal blockade of LVGCCs we measured activity of dorsal CA1 neurons before and after direct intrahippocampal infusion of varying concentrations of the LVGCC antagonist nimodipine (100nM through 10uM). Results revealed that 100nM nimodipine was sufficient to increase activity in dorsal CA1 of aged rats. However, the maximal increase in unit activity was observed following infusion of 10uM nimodipine. These results suggest that intrahippocampal infusion of nimodipine will ameliorate age-related cognitive deficits. To test this hypothesis we will infuse nimodipine or vehicle into dorsal CA1 of aged rats every day before training with trace and delay eyeblink conditioning.

Title: Assessment of neuronal function during normal aging in male sprague dawley rats

Authors: *A. J. IDOWU[1], I. I. OLATUNJI-BELLO[2];
[2]Physiol., [1]Lagos State Univ. Col. of Med., Ikeja, Lagos, Nigeria

Abstract: During normal aging, there are physiological changes especially in high energy demanding tissues including the brain and skeletal muscles. Aging may disrupt homeostasis and allow tissue vulnerability to disease. To establish an appropriate animal model which is readily available and will be useful to test therapeutic strategies during normal aging, we applied behavioral approaches to study age-related changes in memory and motor function as a basis for neuronal function in ageing in male Sprague Dawley rats. 3 months, n=5; 6 months, n=5 and 18 months, n=5 male Sprague Dawley Rats were tested using the Novel Object Recognition Task (NORT) and the Elevated plus Maze (EPM) Test. The results showed a gradual decline in exploratory behavior, locomotor activity and memory function. Importantly, we established a novel finding that the minimum distance from the novel object was statistically significant and may be an index for age-related memory impairment in the NORT. Altogether, we conclude that

the male Sprague Dawley rat show age-related changes in neuronal function and is a useful model for carrying out investigations into the mechanisms involved in normal ageing or possible therapeutic strategies.

Title: Increased basal levels of NFκBp65 in the nucleus of hippocampal cells is related to maintenance of hippocampus-dependent spatial memory in aged rats

Authors: *A. F. JONES[1], N. R. PILGERAM[2], P. J. COLOMBO[3];
[1]Ctr. for Aging, [2]Neurosci. Dept., [3]Psychology Dept., Tulane Univ., New Orleans, LA

Abstract: While the association between aging and inflammation is well known, the cellular mechanisms by which inflammation could influence age-related memory impairment are not well understood. One point of convergence between aging and inflammation is the 65 kDa subunit of the transcription factor Nuclear Factor-κB (NFκBp65) which, unlike other subunits, contains a transactivation domain (Schmitz & Baeuerle, 1991). It is sequestered in the cytoplasm as a hetero- or homodimer until its inhibitor, IκB, is phosphorylated, releasing IκB from NFκBp65 and allowing it to translocate to the nucleus (Brown et al., 1993). Once in the nucleus, NFκBp65 activates transcription of genes related to pro-inflammatory cytokines, growth factors, cell adhesion molecules, and apoptosis (Salminen & Kaarniranta, 2009). Aged rats demonstrated increased nuclear NFκBp65 (Toliver-Kinsky et al., 1996), increased levels and activity of pro-inflammatory cytokines (Coppe et al., 2010) and enhanced reactivity to inflammatory signaling (Krabbe et al., 2001). Additionally, experiments that induce inflammation via endotoxins demonstrated impaired spatial memory in young animals which was exacerbated in aged animals (Chen et al., 2008). However, research into the role of basal levels of NFκBp65 and spatial memory during aging is lacking. To test the hypothesis that increased basal levels of NFκBp65 in the nucleus of hippocampal cells during aging is related to impaired spatial memory, 3- and 20-month-old male Brown Norway rats were tested on a spatial water maze task, and basal levels of NFκBp65 were measured in hippocampal nuclear and cytoplasmic fractions using quantitative

western blotting. Aged rats demonstrated increased levels of nuclear NFκBp65 and worse spatial memory in comparisons to young rats. Elevated levels of NFκBp65 in the nucleus were measured in aged rats that had spatial memory within the range of the young, but not in those with spatial memory impairment. Given that 20 months is approximately middle-aged in the Brown Norway strain, the results suggest that increased NFκBp65 is a compensatory mechanism which benefits spatial memory. In a future experiment, we will test this hypothesis by determining if nuclear NFκBp65 is still related to maintenance of spatial memory in a group of rats aged 30 months, which is the approximate average lifespan for the Brown Norway strain.

Title: Effects of prior distracter exposure on learning in aged rats

Authors: C. T. KOZIKOWSKI, A. TAPP, C. LEONG, *J. A. BURK;
Psychology, Col. of William & Mary, Williamsburg, VA

Abstract: Previous research in our lab showed that the addition of a visual distracter during a two choice sustained attention task enhances young adult rats' acquisition of a novel discrimination task when compared to animals that were not exposed to the distracter. The present study was designed to investigate if similar results were observed in aged animals. FBNF1 hybriderats (N = 20) were trained on two choice sustained attention task, that required discrimination of a variable duration visual signal (illumination of a panel light for 500, 100 or 25 ms) from trials when the panel light was not illuminated, until 20 months of age. Rats then continued in a non-distracter condition in which they performed the same attention task with a stable house light (n = 10) or began a distracter condition where a flashing house light was introduced while performing the attention task for 20 sessions (n = 10). After the addition of the distracter there was a significant session block x signal duration x condition interaction. Subsequent analyses revealed that the basis for this interaction was a significantly lower hit rate by the distracter animals compared to rats that were not exposed to the distracter for the 100ms signal duration trials during block 1 (sessions 1-5) and for the 500ms trials and 100ms trials

during block 2 (sessions 6-10). There were no significant differences in hits between the two groups during block 3 (sessions 11-15) or block 4 (sessions 15-20). After these testing sessions, novel visual discrimination task trials were intersperse with trials of the sustained attention task for both groups for 20 sessions. The new visual discrimination task required animals to press a lever under either an illuminated left or right light. Initially, 40% of the trials contained the novel signal discrimination task. For the next 20 sessions 70% of the trials contained the novel visual discrimination task. During the 70% novel signal discrimination sessions, there was a significant signal duration x condition interaction when assessing accuracy of signal detection on the sustained attention task. Follow up analyses revealed a significant difference in performance of the between the two groups for the 25ms trials with the distracter-exposed animals showing higher accuracy levels compared to rats that were not exposed to the distracter. There were no differences in performance between the groups when evaluating correct rejections, omissions or performance on the novel signal discrimination task for the 40% or 70% sessions. The present results suggest that aged animals can still benefit from distracter exposure, but the extent of the beneficial effects is weaker compared with young adult animals.

Title: Ghrelin agonist as an aging modifying peptide

Authors: *I. KADISH[1], M. SHARPE[1], T. VAN GROEN[1], K. L. GAMBLE[2], M. E. YOUNG[3], D. B. ALLISON[4];
[1]Dept Cell, Developmental and Integrative Bio, [2]Dept. of Psychiatry, [3]Dept. of Med., [4]Sch. of Publ. Health, Office of Energetics, Nutr. Obesity Res. Ctr., Univ. Alabama Birmingham, Birmingham, AL

Abstract: Caloric restriction (CR) is a long established paradigm which extends longevity and slows signs of aging through mechanisms which have yet to be clearly elucidated. Ghrelin is a hunger-inducing gut peptide, and the interoceptive cues caused by ghrelin are likely similar to those produced by CR. In this long term treatment study we tested the novel hypothesis that a ghrelin agonist attenuates behavioral and cognitive decline, and also changes energy metabolism and glucose tolerance in aged C57BL/6J mice and that these changes involve interoceptive cues, rather than reduced energy intake per se. Two groups of C57BL/6J male 2 month old mice were used in this study. One group (control) had ad libitum access to food, while the second group (ghrelin) received the mean amount of diet consumed by the control group and a ghrelin agonist (LY444711; 30 mg/kg of LY in a 45 mg sucrose pellet) daily for 10 or 22 months. At the end of the experimental feeding protocol all mice were analyzed for body composition using quantitative magnetic resonance (QMR). A battery of behavioral and cognitive tests was carried out to analyze behavioral/cognitive differences. All animals were also assessed in CLAMS cages for energy expenditure. Glucose tolerance test was performed for both time points. Biochemistry and immunohistochemistry analysis were carried out to assess the changes in brain tissue and plasma. Ghrelin agonist treatment did not alter the body composition of either group. Cognition was significantly improved in ghrelin group of 24 month old mice compared to control group, but did not significantly influenced the cognitive outcome of 12 month old mice. In a 12:12 light-dark cycle, both control and ghrelin agonist treated mice exhibited typical 24-hour rhythmicity in general cage activity, respiratory exchange ratio (RER), and energy expenditure. Ghrelin agonist treatment improved glucose tolerance in 24 month old mice. In conclusion, “hunger” without caloric restriction has similar cognitive and glucose handling benefits to caloric restriction, without the potential problem of weight loss in aging individuals.

Abstract: Aging is a complex biological process characterized by a marked decrease on the cognitive skills of all organisms. Stress is also an important regulator of cognition. Effects of stress on learning and memory have been demonstrated on developing, mature, and aged subjects. In this experiment, a group of aged rats were exposed to chronic stress and their MWM execution profiles were compared as a function of whether or not they experienced stress at early stages of live. To this end, we exposed male Wistar rats to chronic noise stress when juveniles, and then, they were re-exposed to chronic variable stress when reached the age of 18 months. We found an improving effect of stress in senile rats that also experienced stress when juveniles. So, early stressful experiences may become beneficial for aged subjects when new aversive conditions demand cognitive adaptation.

Title: Effects of testosterone and age on spatial memory and BDNF in male rats

Authors: *M. D. SPRITZER, C. E. SUPER;
Dept. of Biol. and Program in Neurosci., Middlebury Col., Middlebury, VT

Abstract: Spatial memory, the ability to remember spatial aspects of one's environment or one's own position in space, has been shown to have a positive correlation with circulating testosterone levels. In men, testosterone levels decline due to a number of reasons, including treatments for prostate cancer and the natural process of aging. Interestingly, some studies have demonstrated

that low testosterone levels lead to an increased risk of age-related memory loss. Furthermore, brain-derived neurotrophic factor (BDNF) may be the mechanism by which testosterone influences memory. To investigate this connection, we tested young (2 month old) and old (20-21 month old), Fisher 344 castrated and sham-castrated male rats over a period of 25 days for working and reference memory on an eight-arm radial maze. All rats showed a significant reduction in working memory errors over the course of testing, demonstrating learning. Importantly, old rats showed significant impairments in spatial working memory compared to young rats. Contrary to previous results, the young rats showed no differences in working memory between castrated and intact individuals. Among aged rats, however, the castrated group performed significantly more working memory errors than did the intact group during the later days of testing. This suggests that castration exacerbated an age-related impairment in working memory. There was no significant change in the number of reference memory errors overall across the 25 days of testing, suggesting minimal learning on this component of the task. Interestingly, young rats performed significantly more reference memory errors than did the aged rats. This may be due to more use of a response strategy by the young rats compared to the old rats. There were no effects of castration on number of reference memory errors. Testosterone ELISA revealed that old, intact rats had significantly lower testosterone levels than young, intact rats, which indicates that age-related memory loss is associated with decreased testosterone levels. Preliminary ELISA's indicate that old rats had higher BDNF levels in the hippocampus while young rats had comparatively higher BDNF levels in the cortex and striatum. Castrated rats had higher BDNF levels in the hippocampus and cortex while intact rats had comparatively higher BDNF levels in the striatum. Thus, both age and castration seem to impact BDNF levels in different brain regions. Overall, our results suggest that age-related deficits in spatial working memory may be due to decreased testosterone levels, and testosterone may have this effect by influencing BDNF levels in specific brain regions.

Title: Aging in rats leads to task-dependent impairments and improvements in learning that are accompanied by changes in markers of brain energetics

Authors: *L. A. NEWMAN, R. S. GARDNER, B. V. HAMLING, D. L. KOROL, P. E. GOLD; Biol., Syracuse Univ., Syracuse, NY

Abstract: We found that while aged rats are impaired on hippocampus-sensitive tasks compared to young rats, aged rats are superior to young rats when trained on striatum-sensitive tasks. Thus, cognitive decline is not a universal age-related change in brain function. In the current study we examined whether changes in markers of brain energetics might accompany changes in learning. Young adult (3-mo-old) and aged (24-mo-old) male Fischer-344 rats were trained on two versions of the same maze: a place version that is hippocampus-sensitive and a response version that is striatum-sensitive. These mazes have the same motivational (food) and locomotor (arm entry) requirements yet differ in the rule used to solve the maze: after leaving the start arm a) go to a location in the room for place learning (hippocampus) or b) turn in a specific direction for response learning (striatum). In comparison to young rats, aged rats were impaired in learning the spatial version of the task but better at learning the response version. During training, extracellular lactate levels increased in both the hippocampus and striatum at both ages and for both tasks. However, when trained on either task, aged rats had lower lactate release in the hippocampus than did young rats; the lowest training-related increases were seen during place learning in aged rats. The results were somewhat different for striatal measures of lactate release. Surprisingly, increases in striatal lactate levels were substantially higher in young rats during place learning than during response training. Moreover, striatal lactate levels increased less in old than in young rats during place training. In contrast, the striatal lactate increases were similar in old and young rats trained on the response task. To obtain clarification about metabolic processes that may produce this pattern of results, we are currently examining age-related differences in other metabolic markers such as extracellular glucose levels during and tissue glycogen levels before and after place and response training. The data collected thus far suggest that during place learning, lactate production is decreased in both the hippocampus and striatum of aged rats. However, lactate production during response learning is not depressed in the striatum of aged rats, though it is in the hippocampus. These changes in extracellular lactate may reflect altered metabolic responses to training in aged vs. young rats, perhaps contributing to an age-related shift from hippocampus- toward striatum-based strategies in learning.

Title: Influence of chronic restraint (psychosocial stress) on young and aged rats

Authors: *K. STAGGS, J. POPOVIC, S. QUTUBUDDIN, E. M. BLALOCK;
Pharmacol., Univ. of Kentucky, Lexington, KY

Abstract: Psychosocial stress is a non-painful stimulus associated in humans with major life changes, such as loss of a job or spouse or social isolation, and strongly influences multiple systems (e.g., corticosterone level, body temperature regulation, sleep and cognition). There is an increased likelihood of experiencing chronic psychosocial stress with age, and the negative consequences to that exposure are more severe. Despite this, little work has investigated mechanistic changes with age in the chronic psychosocial stress response. We hypothesize that, compared to young, aged subjects' initially blunted psychosocial stress response will be followed by chronically worsened outcomes. To test this, young (3 mos) and aged (19 mos) male Fischer 344 rats were assigned to control or psychosocial stress groups and implanted with wireless telemetry from DSI (Data Sciences International) to monitor sleep architecture and body temperature. Chronic psychosocial stress (restraint, 3 h/ day, 4 days/ week, 4 weeks) effects on Morris water maze and body temperature were collected (sleep architecture, blood corticosterone, and transcriptome-level data are being reserved for future analysis). Aged animals showed significant deficits in water maze while hyperthermic responses were conditional on stress exposure.

Title: Effects of the calcium-binding protein apoaequorin on acquisition of trace fear conditioning in adult and aging rats

Authors: *V. L. EHLERS[1], K. L. FELDMANN[1], J. R. MOYER, Jr.[1,2];
[1]Psychology, [2]Biol. Sci., Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Normal aging is associated with an increased susceptibility to cognitive impairment. Of great importance is the ability to develop neurotherapeutic tools that can mitigate cognitive decline and ultimately enhance the quality of life in old age. The hippocampus is widely implicated in learning and memory, and many forms of learning that are hippocampus-dependent are impaired in aging animals, including trace fear conditioning (Moyer & Brown, 2006). A proposed contributor to aging-related cognitive impairment is aging-related calcium (Ca2+) dysregulation. Normally involved in the regulation of Ca2+ transients, Ca2+-binding proteins (CaBPs) are reduced with advancing age, and evidence suggests that this reduction is associated with aging-related cognitive impairments (Soontornniyomkij et al., 2012). Previous data from our lab indicate that a single hippocampal infusion of the CaBP apoaequorin (AQ) is neuroprotective in the event of an ischemic insult (Detert et al., 2013), however, the effect of AQ on cognitive function in aging rats has yet to be investigated. Briefly, adult (3 mo.) and aged (22 mo.) F344 rats received bilateral dorsal hippocampal infusions of either AQ or vehicle. Twenty-four hours following infusion, rats underwent trace fear conditioning, and were tested the following day. Consistent with prior reports, aged vehicle-treated rats demonstrated a significant impairment in trace fear conditioning as evidenced by a reduction in freezing following CS presentation during the test relative to adult vehicle-treated rats ($p < .05$). In adult rats, both vehicle- and AQ-treated animals demonstrated similar freezing during the test (79% and 75%, respectively), suggesting that a single infusion of AQ into the dorsal hippocampus had no adverse effects on trace fear learning. Similarly, a single infusion of AQ did not significantly improve trace fear conditioning in aged rats ($p = .12$). These data demonstrate that although a single intra-hippocampal infusion of AQ is neuroprotective, this treatment did not improve memory in adult or aged rats. However, it is possible that a chronic treatment regimen may be required to observe improvements in aging-related behavioral deficits. Thus, to further determine the effectiveness of AQ in mitigating aging related-cognitive decline, the effect of multiple infusions of AQ on trace fear memory will also be investigated. These studies may shed new light on the role of AQ in trace fear conditioning in adult and aging rats, and will address its value not only in neuroprotection, but also as a potential neurotherapeutic tool for mitigating aging-related cognitive decline.

Title: Nucleus accumbens core muscarinic and nicotinic acetylcholine receptors differentially modulate phasic dopamine release and mediate cue-induced incentive motivation

Authors: *A. L. COLLINS[1], V. GREENFIELD[1], I. XU[1], S. OSTLUND[2], K. WASSUM[1]; [1]UCLA, Los Angeles, CA; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Recent primarily *in vitro* data has demonstrated that within the striatum muscarinic and nicotinic acetylcholine receptors differentially modulate dopamine signaling. The working hypothesis is that striatal acetylcholine levels acting at nicotinic receptors on dopamine terminals act as a low-pass filter on phasic dopamine signaling, attenuating release when acetylcholine levels are high, and facilitating release when levels are low. Muscarinic receptors located on striatal cholinergic interneurons regulate acetylcholine release and therefore regulate this terminal modulation of dopamine release. Whether this occurs in awake, behaving animals and, vitally, whether such modulation has functional consequences related to motivated behaviors is currently unknown. Phasic dopamine is robustly released in the nucleus accumbens core (NAc) in response to reward-paired cues and such release tracks the incentive motivational impact of these cues- their ability to elicit excitation/arousal and to enhance a non-selective range of reward-seeking actions. Therefore, here we used the Pavlovian-instrumental transfer (PIT) task to evaluate the hypothesis that activity at NAc acetylcholine receptors terminally modulates the phasic release of dopamine to mediate the ability of reward-paired cues to invigorate reward-seeking actions. First, we evaluated the role of NAc muscarinic and nicotinic acetylcholine receptors in PIT and found opposite contributions. Blockade of NAc nicotinic receptors (with intra-NAc mecamylamine) enhanced the invigorating influence of a reward-paired cue over reward-seeking actions, while blockade of muscarinic receptors (with intra-NAc scopolamine) selectively attenuated this effect. To determine if these effects were mediated through modulation of dopamine release, in a second experiment we monitored phasic NAc dopamine concentration changes with fast-scan cyclic voltammetry in rats behaving in the PIT task following unilateral infusion of either mecamylamine, scopolamine or ACSF vehicle directly into the recording zone. Early results suggest that local blockade of NAc nicotinic receptors accentuates and blockade of NAc muscarinic receptors attenuates cue-induced phasic dopamine release during PIT. These preliminary data support the hypotheses from *in vitro* data and provide

a potential functional role for acetylcholine modulation of dopamine release in mediating the excitatory influence of reward-paired cues over reward-seeking actions.

Title: Arithmetic and local circuitry underlying dopamine prediction errors

Authors: ***N. ESHEL**[1,2], M. BUKWICH[2], V. RAO[2,3], V. HEMMELDER[2], J. TIAN[2], N. UCHIDA[2];

Abstract: As we encounter stimuli in the environment, we make predictions about their value. When outcomes match our predictions, learning is not required. When outcomes are unexpected, however, we update our predictions to reflect our experience. This learning process is thought to involve midbrain dopamine neurons, which encode prediction errors, or the difference between actual and expected value. Although dopamine prediction errors have been extensively characterized, little is known about how dopamine neurons calculate these responses. In particular, how are predictions conveyed? Recently, *in vivo* recordings from GABAergic neurons in the ventral tegmental area (VTA) revealed that these neurons signal the predicted value of cues (Cohen et al., 2012). Given known connectivity between VTA GABA and dopamine

neurons, these findings suggest that VTA GABA neurons could provide dopamine neurons with information they need to calculate prediction errors. We combined optogenetic manipulations with extracellular recordings in behaving mice to test this hypothesis. First, we recorded from light-identified dopamine neurons (n = 40 neurons in 5 mice) while mice received rewards of various sizes. On some trials, an odor cue predicted the timing of reward delivery, while on other trials, reward was delivered unexpectedly. By comparing dopamine response functions to various sizes of reward in these two trial types, we found that expectation suppresses dopamine firing (P < 0.001, t-test), and that this suppression was identical regardless of reward size. In other words, dopamine neurons perform subtraction, a computation that is ideal for reinforcement learning but rarely observed in the brain. Next, we used optogenetics to selectively stimulate or inhibit VTA GABA neurons while simultaneously recording from putative dopamine neurons (n =119 neurons in 12 mice). We found that stimulating VTA GABA neurons subtracts from dopamine reward responses (P < 0.001, t-test), as if reward is more expected, and that inhibiting VTA GABA neurons increases dopamine reward responses (P < 0.001, t-test), as if reward is less expected. Thus, VTA GABA neurons causally contribute to prediction error calculations. Finally, we tested the behavioral relevance of VTA GABA activity by bilaterally stimulating these neurons during a classical conditioning task (n = 12 mice). We found that VTA GABA stimulation dramatically reduced anticipatory licking to conditioned odours (P < 0.001, mixed effects linear model), consistent with an important role for these neurons in reinforcement learning. Together, our results uncover the arithmetic and local circuitry underlying dopamine prediction errors.

Title: Habenula lesions reveal that multiple mechanisms underlie dopamine prediction errors

Authors: *J. TIAN[1], N. UCHIDA[2];
[2]MCB, [1]Harvard Univ., Cambridge, MA

Abstract: Dopamine neurons are thought to facilitate learning by signaling reward prediction errors (RPEs), or the discrepancy between actual and expected reward. However, how RPEs are calculated remains unknown. Recent studies have found that neurons in the lateral habenula also encode RPEs, but with the opposite sign compared to dopamine neurons. Therefore, it has been hypothesized that dopamine neurons receive RPE signals from the lateral habenula. Here, we tested how lesions of the habenular complex (including media and lateral habenula) affect the response of optogenetically-identified dopamine neurons in mice. Mice were trained in an odor based classical conditioning task. After >10 days training, animals were randomly assigned into control (n=7) or lesion group (n=5). Dopamine neurons (control: n=45; lesion: n=44) were identified based on their responses to light and were recorded while mice performing the conditioning task. We found that habenula lesion impaired specific aspects of RPE signaling in dopamine neurons. In control animals, most of the dopamine neurons showed a significant dip in activity (86.7%; $P < 0.05$, Wilcoxon rank sum test). In lesion animals, however, a much smaller fraction of dopamine neurons showed a dip during the omission of predicted reward (47.7%, $P < 0.05$,). The magnitude of the dip was also reduced in lesion animals (control: -2.6 ± 0.2, spikes/s; lesion: -1.5 ± 0.2, spikes/s; mean ± s.e.m; $P < 0.0001$, Wilcoxon rank sum test). In contrast, inhibitory responses to aversive stimuli, such as air puff-predictive cues or air puff, remained unimpaired. Furthermore, we found that after habenula lesions, dopamine neurons' ability to signal graded levels of positive RPEs became unreliable, yet significant excitatory responses still remained. At the behavioral level, we observed a phenotype that is consistent with a relative reduction of negative, over positive, RPEs. These results demonstrate that the habenula plays a critical role in dopamine RPE signaling but suggest that it is not the exclusive source of RPE signals.

Title: Electrophysiological activity mapping of neurons presynaptic to dopamine neurons

Authors: *M. WATABE-UCHIDA[1], J. TIAN[1], J. Y. COHEN[2], F. OSAKADA[3], E. M. CALLAWAY[4], N. UCHIDA[1];
[1]Ctr. for Brain Science, BL4005, Harvard Univ., Cambridge, MA; [2]Johns Hopkins Univ., Baltimore, MD; [3]Nagoya Univ., Nagoya, Japan; [4]Salk Inst., La Jolla, CA

Abstract: Midbrain dopamine neurons play important roles in learning and motivation but how their activity is regulated remains unclear. In a previous study, we performed whole-brain mapping of neurons presynaptic to dopamine neurons ("input neurons") using modified rabies virus (Watabe-Uchida et al., 2012). However, to understand the role of specific inputs, it is essential to know when and how a population of input neurons modulates their activity in a behavioral context. In the present study, we recorded the activity of input neurons in behaving mice using a modified rabies virus coding channelrhodopsin-2 (ChR2) (Osakada et al., 2011). AAVs were injected to express TVA (receptor for modified rabies virus) and RG (rabies glycoprotein necessary for trans-synaptic spread) in dopamine neurons in the ventral tegmental area (VTA). After recovery, mice were trained in an odor-based classical conditioning task. We then injected modified rabies virus with ChR2 into the VTA, and implanted an optetrode (tetrodes and optic fiber) into one of the input areas. Five to 16 days after rabies injection, we examined the activity of optogenetically-identified input neurons from the major presynaptic areas such as the rostromedial tegmental area, the pedunculo pontine tegmental area, the ventral pallidum, the striatum and the lateral hypothalamus (n = 30 mice in total). We found that input neurons in most of these areas showed task-related activities, such as value-dependent responses to outcome-predictive cues and/or outcome, or sustained responses modulated by reward expectation. In contrast to the prevalent theories of prediction error computations, we found most task-responsive input neurons showed a mixed coding of reward and reward expectation signals in diverse and complicated ways. Furthermore, a small fraction of input neurons already showed relatively intact prediction error coding. New models are needed to explain how dopamine neurons filter complicated inputs to extract robust reward prediction error signals.

Title: A set of projection-specific circuit maps for midbrain dopamine neurons

Authors: *W. MENEGAS[1], J. BERGAN[2], S. K. OGAWA[3], Y. ISOGAI[1], N. UCHIDA[1], M. WATABE-UCHIDA[1];
[1]Harvard Univ., Cambridge, MA; [2]Univ. of Massachusetts, Amherst, MA; [3]MIT, Cambridge, MA

Abstract: Midbrain dopamine (DA) neurons are involved in a diverse set of processes such as learning, motivation, and motor control. Although these neurons are known to project widely throughout the forebrain, the functional differences between populations of DA neurons with distinct projection targets are still unknown. We reasoned that DA populations with unique functions are likely to have unique distributions of inputs. Furthermore, inputs common to all populations of DA neurons are likely to be involved in computations that might be performed by all DA neurons, such as reward prediction error (RPE) calculation. Therefore, we infected populations of midbrain DA neurons with rabies-GFP based on their projection target, so that we could compare the inputs of DA neurons that project to the dorsal striatum, ventral striatum, medial prelimbic cortex, lateral orbitofrontal cortex, central amygdala, lateral habenula, and globus pallidus. In order to to compare a large number of total brains (n=81) with high accuracy, we developed a high-throughput pipeline for whole brain image acquisition and analysis. First, we used CLARITY to make brains optically transparent and imaged them at 1um x 1um x 5um resolution using a light-sheet microscope. Then, we aligned these images to a “reference space” and made a 3 dimensional map of this space in order to compare the number of labeled cells (as determined by automated cell counting) in each region. Employing these methods to compare many brains in a single reference space allowed us to identify differences in the distribution of inputs to DA neurons with distinct projection targets.

Title: Dopamine neurons code reward and aversion in a context-dependent manner

Authors: *H. MATSUMOTO, J. TIAN, N. UCHIDA, M. WATABE-UCHIDA;
Dept. of Mol. and Cell. Biology, Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Dopamine is thought to be a key regulator of learning from reward and punishment. It has been proposed that dopamine neurons signal value prediction error (VPE, often referred to as reward prediction error), that is, the difference between the values of actual and predicted outcomes. However, how dopamine neurons integrate information about aversive events remains controversial. Some studies have shown that aversive stimuli inhibit dopamine neurons, while others have suggested that aversive events activate at least some dopamine neurons. One recent study postulated that dopamine neurons largely ignore aversive events (Fiorillo, 2013). In the present study, we performed a series of experiments to resolve these issues. First, we recorded the activity of optogenetically-identified dopamine neurons in the ventral tegmental area in a "mixed-prediction" task in which a single odor predicted both reward and punishment in a complementary and probabilistic manner. We found that dopamine neurons' response to the odor predicting both reward and punishment was larger than their response to the odor predicting only punishment ($n = 26$, $P < 0.05$, paired-sample t test) while smaller than that to the odor predicting only reward ($P < 0.001$). We also found that a vast majority of dopamine neurons were exclusively inhibited by aversive events, and their responses to reward and punishment were reduced when these outcomes were predicted ($P < 0.001$ and $P < 0.05$, respectively). These results demonstrate that dopamine neurons signal VPEs integrating information about both reward and punishment in a common currency. In different experimental contexts, however, many dopamine neurons acquired short-latency excitations that are consistent with "salience prediction error". Furthermore, their responses to air puff-predictive cues were indistinguishable to the responses to nothing-predicting cues, suggesting that the short latency excitations mask inhibitions by aversive events. Together, these results reconcile recent controversies in the field, and demonstrate that dopamine neurons have different modes of signaling, each of which may be adaptive for different environments.

Title: Sex-specific lateralization of mesocorticolimbic dopamine receptor mRNAs in adolescent mice

Authors: R. L. MURPHY, *K. J. FRYXELL;
Sch. of Systems Biol., George Mason Univ., Manassas, VA

Abstract: Lateralization of the mesocorticolimbic system plays fundamental roles in motivation and emotion. For example, Davidson and colleagues have shown that left/right asymmetries in D2 dopamine receptors in the striatum and prefrontal cortex (PFC) are correlated with the relative sensitivity of human subjects to positive (attractive) vs. negative (aversive) stimuli. Mesocorticolimbic responses to stress are also lateralized, for example Gratton and colleagues have shown that the right medial PFC (mPFC) of rats plays a predominant role in stimulating the emotional and endocrine responses to stress. Dopamine receptor gene expression in the mesocorticolimbic system undergoes dramatic increases during early to middle adolescence (Teicher and colleagues). Thus adolescent emotional behavior and vulnerability to drug abuse may also be influenced by changes in the levels and lateralization of dopamine receptor expression. Here we show that mice during early adolescence (postnatal day 33) show dramatic and sex-specific lateralization of dopamine receptor gene expression. We used qRT-PCR to measure D1, D2L, and D2S mRNA levels on the left vs. right sides of the mPFC, the ventral striatum (VS), and the ventral tegmentum (VT) of male vs. female mice on postnatal day 33 (p33). We found that p33 female mice tended to have dramatically higher dopamine receptor gene expression (than p33 males), as well as higher lateral differences in all three dopamine receptors, and in all three brain areas examined. Female mice had higher levels of D1, D2L, and D2S mRNAs on the right sides of the mPFC and VS, by 1.9-fold to 5.4-fold (in comparison to the same brain area on the left side). Female mice also had higher levels of D1 mRNA on the right side of the VT by 2.3-fold (in comparison to the same brain area on the left side). Male mice were less asymmetric in their expression of these mRNAs, with significant asymmetries only in D1. Males had a 4.0-fold excess of D1 in the right mPFC, but a 1.9-fold excess of D1 in the left VS (in comparison to the same brain area on the other side). These differences in dopamine receptor levels and lateralization hint at fundamental sex differences in the

development of dopamine signaling in the mesocorticolimbic system, which may be involved in sex differences in emotional behavior, as well as age differences in drug abuse. The response of these genes to nicotine stimulation will be reported elsewhere.

Title: Individual variability in dopamine transporter regulation of neurotransmission and incentive motivation

Authors: *B. F. SINGER[1], B. GUPTAROY[2], C. J. AUSTIN[1], M. E. GNEGY[2], T. E. ROBINSON[1], B. J. ARAGONA[1];
[1]Biopsychology, [2]Pharmacol., Univ. of Michigan, Ann Arbor, MI

Abstract: Conditioned stimuli (CSs) have the capacity to powerfully motivate behavior by producing conditioned responses (CRs). There is considerable individual variation in the degree to which a CS exerts motivational control over behavior. For example, in an autoshaping animal model, a lever CS that predicts food reward (unconditioned stimulus, US) becomes attractive, wanted, and elicits an approach CR in a subset of outbred rats termed “sign-trackers” (ST), whereas “goal-tracker” (GT) rats exhibit a CR toward the location where the reward is delivered. Dopamine (DA) neurotransmission in the nucleus accumbens (NAc) core mediates the attribution of motivational meaning to the CS: it is required for lever-directed approach in ST rats, but not conditioned responding in GTs, even though all rats learn the stimulus-reward relationship equally well. Using *in vivo* fast-scan cyclic voltammetry (FSCV) recordings of DA release in the NAc core, we first replicated earlier studies (Flagel et. al. 2011) demonstrating CS-evoked DA responses during lever approach in STs. In contrast to STs, GTs displayed both CS-

and US-evoked DA release during approach to the food-receptacle. A series of experiments were then conducted to better understand what mechanisms may account for differences in DA signaling in the NAc core. It was found that injection of AMPH directly into the NAc core selectively enhanced lever-directed approach in STs, amplifying the incentive value of the CS. This was hypothesized to result from increased DA transporter (DAT) binding of AMPH in STs, as STs showed elevated ventral striatal DAT surface expression compared to GTs. DAT regulation over DA was further investigated using *ex vivo* FSCV recordings of electrically-evoked DA release. STs showed more rapid DA uptake compared to GTs, supporting enhanced DAT function in STs. We propose that greater DAT surface expression in STs increases control over synaptic DA, enhancing the ability of phasic DA to induce plasticity that underlies the encoding of attraction to a reward paired cue (incentive motivation).

Title: *In vivo* optogenetic manipulation of dopamine neurons in a novel behavioral economics based food-seeking task

Authors: *S. SCHELP, G. KRZYSTYNIAK, J. GAGE, D. RAKOWSKI, R. DAS, E. OLESON;
Univ. of Colorado, Denver, Denver, CO

Abstract: The mesolimbic dopamine system is strongly implicated in motivational processes. Currently accepted theories suggest that transient mesolimbic dopamine release events are involved in assessing the value of reward predictive stimuli and/or in generating motivated action sequences directed toward obtaining reward. During the pursuit of reward, critical associations are formed between the reward and otherwise neutral stimuli that begin to predict reward availability. Through these experiences, dopamine neurons, which initially represent the receipt of reward, begin to represent its earliest conditioned predictor (i.e., cue). The resulting concentration of dopamine release scales proportionally to the magnitude of reward predicted.

Here, we are investigating the role of cue- and reward-evoked dopamine release on cue-motivated food seeking. To address this research question we developed a novel behavioral economics food-seeking task. In this task, food is provided to rats across 10 different unit-prices (i.e., response requirement/reward magnitude). Importantly, in this task, multiple pairings (>10/price/session; unlike with progressive ratio schedule) occur between each unit-price, reward and its predictive cue. Using fast-scan cyclic voltammetry we first determined that the concentration of accumbal dopamine time-locked to cue presentation decreases as a function of unit-price in this task. We next sought to assess the effect of optically augmenting release both at reward delivery and cue presentation. We selectively activated channelrhodopsin-2 expressing dopamine neurons within the ventral tegmentum during either cue or reward presentation (order counter balanced across animals). Preliminary data reveal that optically facilitating dopamine release at the cue decreases motivation for food; whereas, facilitating release at reward delivery increases motivation for food. Interestingly, optically augmenting release at both cue presentation and reward delivery decreased response latency, consistent with an invigoration of responding that might be dissociable from value-based changes in motivation. It is possible that augmenting cue-evoked dopamine release decreases motivation in our task because we are violating the animal's expectation (i.e., the animal receives less than expected) and vice versa. Together these findings suggest that cue- and reward-evoked dopamine release play a causal role in action initiation, yet oppositely influence motivation in value-based behavioral economics based tasks.

Title: The role of NMDA receptor-dependent burst activity of dopamine neurons in reinforcement-learning and depressive-like behaviors

Authors: *K. LOPATA[1], M. WALCZAK[2], P. E. CIESLAK[1], &. SZUMIEC[1], M. TURBASA[1], T. BLASIAK[2], J. RODRIGUEZ PARKITNA[1];

[1]Inst. of Pharmacol. of the PAS, Krakow, Poland; [2]Inst. of Zoology, Jagiellonian Univ., Krakow, Poland

Abstract: Phasic activity of the midbrain dopamine neurons encodes a temporal prediction error and thus underlies reinforcement learning and signaling of incentive salience. Here, we use a transgenic mouse model with inducible deletion of NMDA receptors in dopamine neurons (NR1DATCreERT2 mice) to reduce the burst activity and observe behavioral consequences. As anticipated, iontophoretic application of NMDA had no effect on the activity of dopamine neurons in the ventral midbrain of mutant mice, while it robustly induced bursting in controls. Conversely, the cholinergic agonist, carbachol, had similar effects on neuronal activity in both control and mutant mice, including induction of bursts in subpopulation of dopamine neurons. Thus, the NR1DATCreERT2 mice lack of NMDA receptor-dependent phasic activity of dopamine neurons. We started behavioral experiments from a classic Pavlovian training in which mutant mice correctly associated cue with reward and decreased the time to approach food magazine, however they were impaired in a subsequent conditioned reinforcement test. A second cohort was tested for instrumental responding for food, which was not affected by the mutation, although mutant animals were slower in acquiring this behavior. Moreover, no differences were observed between animals under complex reinforcement schedules. Only under random interval procedure and in instrumental responding for sensory stimuli mutant mice showed deficits. Mutant mice were tested for saccharine preference in an IntelliCage system. While in two cohorts a clear reduction in saccharine preference under FR3 was observed, other experiments have shown normal preference under free access and under gradual increase in FR schedules. To further explore the ability to exert effort to obtain a reward, T-maze test with increasing difficulty to obtain chocolate food pellets was conducted and no changes between mutant and control mice were observed. Finally, based on previous results and literature reports, animals were tested for a depressive-like phenotype. It was shown that mutation reduced the frequency of social interactions as well as increased the time of immobility in the forced swim test, indicating the importance of disrupted phasic DA activity in a negative affect. In summary, the loss of NMDAR-dependent bursting activity in dopamine neurons caused specific impairments in reinforcement learning, with most appreciable changes in cases where rewards were not essential for survival (saccharine, sensory stimuli or conditioned cues) and furthermore, induced depression-related behaviors such as learned helplessness and reduction in social interactions.

Title: Investigating contributions of dopamine D2 and D3 receptors to Pavlovian conditioned approach behaviors

Authors: *K. M. FRASER[1,2,3], J. L. HAIGHT[4], E. L. GARDNER[6], S. B. FLAGEL[2,5,4,3]; [2]Psychiatry, [3]Undergraduate Program in Neurosci., [4]Neurosci. Grad. Program, [5]Mol. and Behavioral Neurosci. Inst., [1]Univ. of Michigan, Ann Arbor, MI; [6]Intramural Res. Program, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Environmental cues that are repeatedly paired with reward can guide behavior in an adaptive manner, bringing one in close proximity to valuable resources (e.g. food, water, sex). However, cues can also acquire incentive motivational value (i.e. incentive salience) and come to control behavior to the point that it becomes maladaptive. Importantly, individuals differ in the extent to which incentive salience is attributed to reward-paired cues. These individual differences can be captured using a Pavlovian conditioned approach (PCA) paradigm. When a discrete cue (lever) is repeatedly paired with delivery of a food reward, some rats, termed sign-trackers attribute incentive salience to the cue; whereas others, termed goal-trackers, treat the cue only as a predictor of reward. This model, therefore, allows us to parse the incentive from the predictive properties of reward cues. Previous studies utilizing this model have shown that dopamine is critical for the attribution of incentive salience to both food- and drug-associated cues. However, the receptors involved in this form of stimulus-reward learning have yet to be identified. Here we examined the effects of dopamine D2 and D3 receptor antagonism on the expression of sign- and goal-tracking behaviors. Following PCA training, sign- and goal-tracking rats were treated with the D2/D3 antagonist raclopride (0.1 mg/kg), or the selective D3 antagonist, SB-277011A (6 or 24 mg/kg). Non-selective antagonism of D2/D3 receptors attenuated the performance sign-tracking behavior for rats that were previously classified as sign-trackers, and attenuated goal-tracking behavior in rats previously classified as goal-trackers. Interestingly, these effects were specific to the previously acquired conditioned response. In contrast, selective antagonism of D3 receptors had no effect on the expression of either the sign- or goal-tracking conditioned response for either phenotype. The present findings suggest that signaling at the dopamine D2 receptor, or perhaps some combination of synergistic activity at D2/D3 receptors, is critical for the expression of Pavlovian conditioned approach behaviors. Although previous studies demonstrated a specific role for dopamine in learning the sign-tracking response (i.e. the attribution of incentive salience to reward cues), the current findings suggest that the expression of both sign- and goal-tracking behavior can be affected when specific dopamine receptor subtypes are targeted.

Title: Chemogenetic inhibition of mesolimbic dopamine reveals excitability-dependent amphetamine action for behavior

Authors: *S. M. CONWAY[1], M. S. MCMURRAY[1], P. A. GARRIS[2], E. H. CHARTOFF[3], R. A. WHEELER[4], J. D. ROITMAN[1], M. F. ROITMAN[1];

Abstract: Amphetamine (AMPH) is characterized as a dopamine 'releaser' as it not only blocks dopamine uptake by the dopamine transporter but also enters the presynaptic terminal, causing vesicular depletion and reverse transport of dopamine. These mechanisms are thought to be action potential-independent. Recent work using intact rats has shown that AMPH increases the frequency of phasic dopamine release events, which, in turn, is thought to be action potential-dependent and thus raises questions about the mechanisms of AMPH action. To further probe the dependency of AMPH on dopamine neuron excitability, we injected virus to deliver the Cre-dependent inhibitory (hM4D-Gi) designer receptor exclusively activated by designer drug (DREADD) into the ventral tegmental area (VTA) of transgenic rats expressing Cre recombinase under the control of the tyrosine hydroxlyase promoter (TH:Cre+) and wildtype littermates (TH:Cre-). Following transfection, systemic administration of the hM4D-Gi ligand, clozapine-N-oxide (CNO), should hyperpolarize VTA dopamine neurons, suppress excitability, and attenuate dopamine release in the NAc of TH:Cre+ but not TH:Cre- rats. Using fast-scan cyclic voltammetry we found that CNO suppressed evoked dopamine release in TH:Cre+ but not TH:Cre- rats thus validating our chemogenetic approach. Next, we evaluated the effect of decreased VTA dopamine excitability on AMPH-induced behavior. TH:Cre+ and TH:Cre-, virus-injected rats received were pretreated with either CNO or saline and tested for AMPH-induced locomotion. A second such session was conducted with the other pretreatment in counter-balanced order. Only TH:Cre+ rats exhibited significantly lower AMPH-induced locomotion following pretreatment with CNO versus saline. A separate set of locomotor tests

indicated no effect of CNO on spontaneous locomotion. To examine the effects of AMPH and CNO on a reward-directed behavior, TH:Cre+ and TH:Cre- rats performed a rate-frequency intracranial self-stimulation task. In line with previous work, AMPH decreased the frequency threshold for self-stimulation in all animals while CNO increased threshold only in TH:Cre+ rats. Both AMPH and CNO showed dose-dependency. Furthermore, pretreatment of CNO in TH:Cre+ rats prevented AMPH-induced reductions in threshold. Taken together, these results demonstrate dopamine excitability-dependent behavioral actions of AMPH using a chemogenetic approach validated by electrochemical recordings thus further highlighting the importance of action potential-dependent mechanisms of this psychostimulant.

Title: Contrasting effects of rewarding electrical and optical stimulation

Authors: *M.-P. COSSETTE, P. SHIZGAL;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Studies of intracranial self-stimulation (ICSS) point to midbrain dopamine (DA) neurons as a critical component of the circuitry underlying reward seeking. Electrical stimulation

of the medial forebrain bundle (MFB) has long been used in ICSS studies. Although such stimulation ultimately excites midbrain DA neurons, the directly stimulated neurons subserving the rewarding effect of MFB stimulation are primarily non-DAergic. Neither the identity of these non-DAergic MFB neurons nor the manner in which they are connected to the DA neurons has been established firmly. As a step towards achieving these goals, we used fast-scan cyclic voltammetry to monitor release of DA in the nucleus accumbens (NAc) in response to electrical MFB stimulation at the level of the lateral hypothalamus (LH) or optical stimulation of neurons in the ventral tegmental area (VTA) that express tyrosine hydroxylase (TH). To render VTA DA neurons optically excitable, we used viral transfection and Cre-Lox recombination to express channelrhodopsin2, tagged with enhanced yellow fluorescent protein (eYFP); an optical fiber was aimed at the viral injection site. To visualize LH to VTA projections, eYFP was expressed in LH neurons under the control of the promoter for the calcium/calmodulin-dependent protein kinase IIa. Whereas unilateral electrical MFB stimulation triggered DA transients in both hemispheres, DA release in the NAc was ipsilateral to the optical fiber when the virus injection had been restricted carefully to one hemisphere. Upon inspection of the VTA to NAc projections via epifluorescence microscopy, we saw no evidence that DAergic fibers cross the midline before terminating in the ventral striatum. In contrast, inspection of LH toVTA projections revealed both fibers confined to the hemisphere ipsilateral to the injection site and fibers that cross the midline en route to the VTA. The latter fibers could have contributed to the observed DA release in the contralateral NAc, as could disynaptic relays via the laterodorsal tegmental and rostromedial tegmental nuclei and pathways that lead to excitation or disinhibition of tonically active, cholinergic interneurons in the ventral striatum. The behavioral consequences of direct optical activation of VTA DA neurons or trans-synaptic activation by electrical MFB stimulation have yet to be worked out.

Title: Repetitive tms of the insula modulates dopaminergic activity: a phno-pet study in healthy subjects

Authors: *S. MALIK[1], M. JACOBS[1], S. CHO[1], I. BOILEAU[1], D. BLUMBERGER[1], A. WILSON[1], Z. J. DASKALAKIS[1], A. STRAFELLA[1], A. ZANGEN[2], B. LE FOLL[1]; [1]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [2]Ben Gurion Univ., Beer-Sheva, Israel

Abstract: Purpose: Modulating the function of the insular cortex could be a novel therapeutic strategy to treat addiction to a variety of drugs of abuse as this region has been implicated in mediating drug reward and addictive processes. The objective of this work was to selectively and bilaterally target the insula with repetitive Transcranial Magnetic Stimulation (rTMS) and subsequently infer changes in dopamine levels using Positron Emission Tomography (PET) with [11C]-(+)-propyl-hexahydro-naphtho-oxazin (PHNO). Methods: This was a within-subject, blinded and sham-controlled pilot study. Seven healthy, right-handed subjects, aged 19-45, underwent 3 PHNO-PET scans preceded by rTMS (sham, 1Hz or 10Hz), on 3 separate days. Sham stimulation (mimicking 1Hz (n=4) or 10Hz (n=4)) was performed on Day 1 followed by real rTMS (1Hz/10Hz, counterbalanced) on Days 2 and 3. PET image analysis was region of interest (ROI)-based. PHNO-specific binding (BPND) was estimated in each ROI using the simplified reference tissue model with the cerebellum as reference region. Statistical comparisons between BPND across conditions in each ROI were done using repeated-measures ANOVA. Tukey post-hoc tests examined differences between paired conditions. Results: Preliminary analysis revealed significant differences in BPND between sham, 1Hz and 10Hz conditions in the substantia nigra, dorsal putamen, dorsal striatum, somatosensory striatum and full striatum (all $P \leq 0.05$). Post-hoc tests primarily showed differences between sham and 1Hz conditions, associated with increases in BPND following 1Hz stimulation. Discussion: Low frequency rTMS (1Hz) targeting the insular cortex significantly decreased dopamine levels in the substantia nigra and striatum relative to the sham condition. Changes in dopamine levels following high frequency stimulation did not appear to statistically differ from the other 2 conditions. Replicating this study in tobacco smokers or alcoholics would be a logical follow-up to assess whether rTMS of the insula can be employed as a treatment option for addiction.

Title: Past exposure to L-dopa accelerates habitual responding in rats

Authors: *T. M. FURLONG[1], A. M. GIBSON[2], K. A. KEEFE[1,2];
[1]Dept. of Pharmacol. & Toxicology, [2]Interdepartmental Program in Neurosci., The Univ. of Utah, Salt Lake City, UT

Abstract: Exposure to amphetamine and cocaine alters the brain and cognition to promote further drug-use. Specifically, these dopamine agonists have been shown to accelerate habitual responding in animals in situations unrelated to obtaining drugs. Recent studies show that these drugs have the ability to increase phasic dopamine signaling, and that phasic dopamine signaling is necessary for forming associations underlying reward-based learning. L-dopa is also a dopamine agonist that can increase phasic dopamine signaling by augmenting vesicular dopamine content. However, the impact of L-dopa on behavioral control has yet to be established. Hence, we sought to determine whether L-dopa accelerates habitual responding in animals, similar to drugs of abuse. Initially, we trained rats to press a lever for food-outcome under the influence of L-dopa (25 mg/kg or 50mg/kg, i.p.). We then tested the knowledge of this response-outcome relationship using an outcome-devaluation task, where the food-outcome was devalued by free-feeding it to satiety before testing responding on the lever. Animals that were trained under L-dopa adjusted their behavior according to the current value of the outcome, and, like control animals, reduced responding on the lever when the associated outcome was devalued. Thus, goal-directed responding was not impacted by L-dopa exposure during training. However, when the same animals were then trained to press a different lever for a different outcome without L-dopa administration, goal-directed responding was reduced at test. That is, lever response rates for the animals that had previously received L-dopa were not significantly different between the lever associated with the devalued outcome and the lever associated with the still valued outcome. Further testing also revealed that the L-dopa exposed animals were able to update the response-outcome contingency when it was reversed or degraded, demonstrating that some aspects of flexible behavior were intact. Our findings suggest that deficits in behavioral control associated with the use of L-dopa may result from accelerated habitual responding similar to that seen following exposure to drugs of abuse, and hence L-dopa exposure may also cause similar neuroadaptations to these other dopamine agonists.

Title: Different routes of cocaine administration resolve multiple mechanisms of action to increase phasic dopamine release in the nucleus accumbens

Authors: *A. I. GERTH[1], A. ALHADEFF[2], S. FORTIN[3], H. GRILL[2], M. ROITMAN[3]; [1]Psychology, Univ. of Illinois At Chicago Dept of Psych, Chicago, IL; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Psychostimulants increase dopamine concentration in the nucleus accumbens through the blockade of the dopamine transporter (DAT). However, they also increase the frequency of dopamine release events, a finding that cannot be explained by reuptake blockade alone. Rather, this effect may be mediated by systemic cocaine-induced increases in neural activity in brain regions that project to dopamine cell bodies resulting in increases in dopamine cell excitability. To further explore regionally selective actions of cocaine on phasic dopamine signaling, we administered cocaine into the lateral or fourth ventricles and compared the dopamine response to that of systemically delivered cocaine. Dopamine release in the nucleus accumbens was evoked by electrical stimulation of the ventral tegmental area and measured using fast-scan cyclic voltammetry in urethane anesthetized rats. Stimulation trains were delivered once every 3 minutes and each train resulted in a rapid and pronounced rise in dopamine followed by a rapid decay due to dopamine clearance via the DAT. The magnitude of dopamine release ([DA]max) by each stimulation train as well as the latency to decay to fifty percent of the maximum (t(1/2); index of DAT activity) were recorded. Following stable [DA]max (3 stimulations differing by less than 10%; baseline), rats received an injection of cocaine [systemic: 2.5mg/kg; lateral and fourth ventricle: 50ug in 1ul) or an equal volume of vehicle. All routes of cocaine delivery caused an increase in [DA]max. However, only systemic cocaine caused an increase in t(1/2). That hindbrain-delivered (fourth ventricle) cocaine caused an increase in [DA]max is novel. Thus, we further explored hindbrain sites that may contribute to an increase in dopamine cell excitability by using c-fos immunohistochemistry. Preliminary data suggest that fourth ventricular cocaine delivery caused a robust increase in c-fos immunoreactivity in the nucleus of the solitary tract, a region that has recently been shown to send direct projections to dopamine cell bodies. Together, the data show that cocaine induced effects on phasic dopamine signaling are mediated via actions throughout the brain including the caudal brainstem.

Title: Collective activity of ventral tegmental area neurons encodes information about ongoing actions

Authors: ***J. WOOD**[1], N. W. SIMON[1], S. KOERNER[2], R. E. KASS[2], B. MOGHADDAM[1]; [1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Statistics, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In order to plan, organize, and flexibly update behavior, it is necessary to continually monitor actions and feedback. The dopamine systems, and the ventral tegmental area (VTA) are implicated in several processes related to these forms of cognition. Most studies of the VTA or dopamine system focus on how these neurons encode information about reward prediction errors, novelty, and salience during tasks requiring very actions. We were interested in how the collective activity of dopamine and non-dopamine VTA neurons might encode information about repetitive series of instrumental actions performed to earn reward. We performed ensemble recordings while rats executed repetitive actions which were randomly rewarded. Different actions activated different neurons. Some neurons fired predominantly during low numbered actions in a trial, whereas others fired during the medium or high numbered actions. Neural activity was thus, diversely tuned to action execution. The number of actions performed in a trial could reflect effort expenditure, progress toward a goal, or other information necessary for behavioral organization, which is closely linked to dopamine function. Because population averaged neuronal activity did not vary with action number, and owing to the diversity of neuronal tunings to action execution, action number could be encoded via the combined activity of the entire ensemble of neurons. To quantify this, we used linear discriminant analysis (LDA) to classify actions as low (actions 1-7), medium (actions 8-14), or high (15-21). We decoded both population averaged activity, and the collective activity of the entire ensemble of neurons (without averaging or otherwise combining activity across neurons). This analysis revealed that decoding of population averaged activity correctly classified binned action number at chance levels (approximately 33% accuracy). In contrast, the ensemble activity was correctly classified

at approximately 85% accuracy, which was significantly greater than population averaged activity or chance levels. There was no effect of session number, neuron type, or action number bin, demonstrating that this pattern did not significantly differ across sessions, between dopamine and non-dopamine neurons, or between high, medium, and low numbered actions. These results suggest that both dopamine and non-dopamine VTA neurons encode an ensemble signal that provides real-time information about serial action execution. Our data demonstrate a previously unreported ensemble code in the VTA, which encodes novel types of information, which could be used for behavioral organization.

Abstract: Depression is one of the most common and debilitating non-motor symptoms of Parkinson's disease (PD). Yet, the underlying neurobiological mechanisms are still unclear and treatment is often suboptimal. Affective processing biases characterize depression and presumably contribute to the development of depressed mood. Affective biases have been linked to attenuated striatal function across various tasks. Specifically during reversal learning, depressed individuals demonstrate enhanced punishment and impaired reward learning alongside attenuated striatal responses. Striatal dopamine levels modulate the balance between learning from reward and punishment. Specifically, decreases in dopamine shift the balance to enhanced punishment relative to reward learning, a profile resembling that of depression. Parkinson's disease is characterized by striatal dopamine depletion. However, it is unknown whether

decreases in striatal dopamine and attenuated striatal function contribute to affective processing biases in reversal learning in depression in PD. Here we used functional MRI to compare striatal responses during reward and punishment reversal learning between PD patients without and with (a history of) PD related depression, most not currently depressed. Patients were tested ON and OFF their dopaminergic medication to assess the potential influence of striatal dopamine levels. Irrespective of drug, patients with PD-related depression exhibited impaired reward (but not punishment) reversal learning alongside attenuated valence-dependent striatal BOLD signal. Specifically, whereas unexpected reward elicited significantly greater increases in striatal BOLD signal than unexpected punishment in non-depressed PD patients, this was not observed in depressed PD patients. Furthermore, attenuations in valence-dependent striatal BOLD signal correlated with impairments in reward reversal learning. These findings suggest that attenuated striatal signalling might underlie affective processing biases in reversal learning that putatively contribute to PD-related depressive symptoms.

Title: Midbrain dopamine neurons signal whether planned eye movements are successfully cancelled during a saccadic stop-signal task

Authors: T. OGASAWARA[1,2], M. TAKADA[1], *M. MATSUMOTO[3];
[1]Systems neuroscience section, Primate research institute, Kyoto Univ., Inuyama, Japan; [2]Grad. Sch. of Comprehensive Human Sci., Univ. of Tsukuba, Tsukuba, Japan; [3]Univ. of Tsukuba, Tsukuba, Ibaraki, Japan

Abstract: In daily life, we are often required to inhibit planned or ongoing motor actions that would result in unwanted consequences. This ability, called response inhibition, is impaired in patients with damage to the dopamine (DA) system, as well as in pharmacologically DA-disrupted rodents. Although several lines of evidence suggest the DA contribution to response inhibition, it remains unclear what signals DA neurons transmit to attain this ability. To address this issue, we recorded single-unit activity from DA neurons in the substantia nigra pars compacta (SNc) and the ventral tegmental area (VTA) while a monkey was performing a saccadic stop-signal task. Trials began with the appearance of a central fixation point, and the monkey was required to fixate the point. After 1000 ms, the fixation point disappeared, and a saccadic target was presented on the right or left side of the point. In 70% of the trials, the monkey was required to make a saccade to the target. In the remaining 30%, on the other hand, the fixation point reappeared as a "stop signal" with a random delay (stop-signal delay) after the onset of the saccadic target. The monkey was then required to cancel the planned saccade. When the stop-signal delay was short, the monkey easily cancelled planned saccades. As the stop-signal delay was extended, the monkey increasingly failed to cancel the saccades. We recorded the activity of 40 DA neurons. Of these, 16 neurons (40%) exhibited a significant excitation that was aligned at the onset of the stop signal (Wilcoxon signed-rank test, $P < 0.05$). This excitatory response decreased when the monkey failed to cancel planned saccades, and increased as the stop-signal delay was extended (i.e., as the task became more demanding). Notably, the DA neurons activated with the stop signal were distributed dorsolaterally in the ventral midbrain, corresponding probably to the SNc rather than the VTA. In order to investigate the causal relationship between DA signals and response inhibition, we next pharmacologically disrupted DA signals with intramuscular administration of haloperidol, a D2 receptor antagonist, while the monkey was performing the stop-signal task. We found that the pharmacological disruption impaired the ability to cancel planned saccades. Our data suggest that DA neurons transmit a signal that is necessary to achieve response inhibition, and that these neurons are located in a particular area of the ventral midbrain.

Title: Real-time dopamine release during discrimination and reversal learning in mice

Authors: *A. K. RADKE[1], Y. MATEO[2], A. KOCHARIAN[1], D. M. LOVINGER[2], A. HOLMES[1];
[1]Lab. of Behavioral and Genomic Neurosci., [2]Lab. of Integrative Neurosci., Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: The dopamine system is well known for its role in goal-directed behavior. Phasic dopamine release has been observed in response to novel stimuli as well as to unexpected presentation of rewards, yet few studies have monitored dopamine release over the course of multiple stages of learning and as reward contingencies change. To address this gap, we used fast-scan cyclic voltammetry with chronically implanted electrodes to measure sub-second dopamine release in the nucleus accumbens during a touchscreen-based visual discrimination and reversal learning task in C57BL/6J mice. During initial discrimination learning, we detected significant increases in dopamine release after mice made a correct choice, and dopamine decreases following an error. Interestingly, the increase on correct trials was dependent on the outcome of the previous trial, such that dopamine release was only increased when a correct choice followed an error. These signals abated as discrimination learning progressed to criterion levels of performance. When stimulus-reward contingencies were reversed, such that the previous incorrect choice was now unexpectedly rewarded, a large dopamine signal in the nucleus accumbens re-emerged in response to the unexpected reward. As in discrimination, this response diminished as the new contingences were relearned to criterion. These results support theoretical models that dynamic changes in striatal dopamine signaling guide successful learning.

Title: Repeated exposure to uncertain rewards induces sensitization and increases risky decision-making: implications for modelling gambling disorder in rats

Authors: *F. D. ZEEB[1], Z. LI[1], D. C. FISHER[1], M. H. ZACK[1,2], P. J. FLETCHER[1,3,4];
[1]Biopsychology, CAMH, Toronto, ON, Canada; [2]Pharmacol. and Toxicology, [3]Psychology, [4]Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract: Gambling opportunities are increasing and gambling disorder (GD) is a growing public health concern. An animal model could advance our understanding of GD and aid in the development of effective treatment strategies. Pathological gamblers, compared to healthy controls, demonstrate greater dopamine (DA) release in the striatum and midbrain in response to amphetamine. We hypothesize that repeated exposure to gambling scenarios induces sensitization of the DA system, similar to chronic exposure to drugs of abuse. Here, male rats responded for saccharin reward on a predictable fixed ratio (FR, n=8) or unpredictable variable ratio (VR, n=8) schedule of reinforcement. Rats yoked to receive unpredictable reward according to the FR or VR group were also included (Y, n=16). Animals were trained twice daily for 28 days, beginning with a FR/VR1 schedule which increased to a FR/VR20 schedule. Locomotor activity following an injection of saline or amphetamine (AMPH; 0.5 mg/kg) was then assessed. There was no significant difference between the two yoked groups. Compared to the FR group, rats in the VR and Y groups demonstrated increased hyperactivity following AMPH. Therefore, similar to Singer et al (2012), animals exposed to an uncertain reward schedule demonstrate increased sensitivity of the DA system. Rats were then tested on the rat gambling task (rGT), a rodent analogue of the Iowa Gambling Task (IGT). Risky decision-making may be a hallmark feature of GD and pathological gamblers choose disadvantageously on the IGT. During the rGT rats have 30 min to maximize gains. Animals choose among four options, each associated with the delivery of a different number of rewarding pellets and a different frequency and duration of timeout periods during which reward cannot be earned. These frustrating timeouts decrease long-term gains, equivalent to losses in the IGT. Like the IGT, the optimal strategy is to favour options that yield smaller immediate reward but less loss and avoid risky options associated with greater rewards, but greater long-term loss. All groups learned which options were advantageous and animals in the FR group and Y groups significantly preferred the advantageous options over the disadvantageous options. However, rats in the VR group did not show a significant preference for the advantageous options. Locomotor activity following an injection of saline or AMPH (0.5 mg/kg) was again assessed following rGT training. Compared to the FR group, only the VR group showed greater hyperactivity following AMPH. In sum, actively responding for uncertain reward sensitizes the DA system and impairs the ability to make optimal decisions, possibly similar to patients with GD.

Title: Fast dopamine transients in the medial prefrontal cortex enhance stimulus discrimination

Authors: *A. T. POPESCU, M.-M. POO;
MCB, UC Berkeley, Berkeley, CA

Abstract: Phasic dopamine (DA) release is believed to guide associative learning. Although extensively studied in the ventral tegmental area (VTA) to striatum pathway, the precise action of DA in other target regions remains unclear. We examined DA function in the medial prefrontal cortex (mPFC), and found that mice receiving repetitive temporal pairing of an auditory conditioned stimulus (CS) with optogenetically-induced DA release in mPFC learned faster a subsequent task involving the same CS. During and after CS-DA pairing, mPFC neurons increased firing in response to CS, and blocking DA receptors in mPFC during learning impaired stimulus discrimination. Furthermore, endogenous DA transients in mPFC showed a gradual shift towards the onset of reward-predicting stimuli during learning, in correlation with anticipatory behavior. Thus, DA transients tune mPFC neurons for the recognition of behaviorally relevant events during learning.

Abstract: In the socially monogamous prairie vole (Microtus orchrogaster), activation of D2-like dopamine (DA) receptors results in the development of a selective social attachment, known as a 'pair bond'. However, the specific receptor subtype(s) (i.e. D2 or D3) responsible for this are currently not known. Because of the high density of D2 and D3 receptors within the nucleus accumbens (NAc) shell, we tested the involvement of these receptors in partner preference formation in male prairie voles. Here, we replicate findings showing that quinpirole, a mixed D2/D3 agonist, when infused into the NAc shell, induces a robust partner preference. We then tested whether selective activation of D2 or D3 receptors in the NAcc shell, via infusions of the D2R selective agonist 5,6,7,8-Tetrahydro-6-(2-propenyl)-4H-thiazolo[4,5-d]azepine-2-amine dihydrochloride (BHT-920; 1.5ng, 3ng) or the specific D3R agonist R(+)-2-Dipropylamino-7-hydroxy-1,2,3,4-tetrahydronaphthalene hydrobromide (7-OH-DPAT; 1.5ng, 3ng), influenced the development of partner preferences. Preliminary data suggest that activation of both receptors is involved in partner preference formation. In addition to its initial regulation of pair bond formation, DA transmission within the NAc shell is also substantially altered in voles with fully formed pair bonds. Specifically, pre-synaptic DA release is robustly enhanced and D1Rs are upregulated. However, nothing is known about the regulation of DA transmission in pair bonded voles. We are, therefore, investigating DA autoregulation and uptake in discrete regions of the NAc shell in bonded and non-pair bonded voles using fast scan cyclic voltammetry. Together, these studies will significantly extend our understanding of DA regulation of prairie vole pair bonding.

Title: Sexual experience results in morphological changes in ventral tegmental area dopamine neurons that project to nucleus accumbens and not medial prefrontal cortex

Authors: *L. N. BELOATE[1], L. M. COOLEN[2];
[1]Univ. of Mississippi Med. Center, Program In Neurosci., Jackson, MS; [2]Dept. of Neurobio. & Anatom. Sciences, Physiol. & Biophysics, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Sexual experience in male rats causes neural alterations in the nucleus accumbens (NAc) and ventral tegmental area (VTA) that change d-amphetamine and morphine reward. Specifically, sexual experience reduces soma size of VTA dopamine neurons, which is dependent on mu opioid receptor activation in the VTA, is transient, and is essential for long term maintenance of memory for sexual incentive salience. VTA dopamine neurons project to numerous brain areas, including NAc and medial prefrontal cortex (mPFC). However, it is unknown if sexual experience alters dopamine neurons projecting to each of these brain areas. In the current study we tested the hypothesis that sexual experience causes soma size reduction in specific subpopulations of VTA dopamine neurons with projections to the NAc or PFC. Adult male Sprague Dawley rats received unilateral cholera toxin b (Ctb) in NAc and Fluorogold (FG) injections in ventral mPFC, followed by 5 consecutive days of mating (sexually experienced) or handling (sexually naïve). One week later, males were perfused following either mating behavior or exposure to the mating or handling environment. Brains were sectioned, and VTA sections were immunoprocessed for tyrosine hydroxylase (TH), Ctb and FG using triple immunofluorescence. Injection sites for Ctb and FG were verified. Ctb and FG were found throughout the VTA, with approximately 28% of Ctb and 27% of FG cells co-expressing TH. No colocalization of Ctb and FG was detected. Area and perimeter for Ctb/TH+ and FG/TH+ neurons in the VTA were analyzed based on TH immunoreactivity and averaged per animal. Sexually experienced males had decreased cell body area and perimeter in Ctb/TH+ cells (n=5) but not FG/TH+ cells (n=7), compared to sexually naïve rats (n=4, n=7, resp). In addition, VTA sections were stained for mating-induced cFos and Ctb. Animals that received mating or mating-associated cues had a higher number of cFos/Ctb+ neurons, suggesting that NAc-projecting neurons were activated by mating or exposure to mating cues. In conclusion, sexual experience reduced soma size of TH neurons that project to the NAc, but not the ventral mPFC. Since VTA dopamine soma size reduction has been associated with reduction in trafficking and release of dopamine, sexual experience may thus influence dopamine release in the NAc, but not mPFC. The mechanism by which sexual behavior can result in selective effects on NAc-projecting dopamine neurons is unclear but these results suggest that mu opioid receptor activation during sexual reward may preferentially influence NAc projecting neurons in the VTA.

Title: Correlation of conditioned place preference to high fat/sugar food with nucleus accumbens c-Fos and p-DARPP-32 protein expression

Authors: *G. C. LOPEZ, L. PEREZ, T. SONGTACHALERT, L. MININBERG, S. PIERCE, J. SCHROEDER;
Connecticut Col., New London, CT

Abstract: We have previously demonstrated that conditioned place preference to high fat/sugar food (Oreos) is comparable to conditioned reward behavior associated with cocaine or morphine. Exposure to drugs of abuse and other rewarding stimuli is associated with nucleus accumbens neuronal activation. The current study was an attempt to correlate reward behavior measured using conditioned place preference with c-Fos and p-DARPP-32 protein expression in the nucleus accumbens. An 8-day biased CPP paradigm was used to assess reward behavior in response to high fat/sugar food (Oreo cookies) consumption. Behavioral assessment was followed by immunohistochemical assessment of c-Fos and p-DARPP-32 expression. Results indicate that the reward behavior associated with consuming Oreos is equivalent to previous studies that measured conditioned place preference to cocaine or morphine. The magnitude of conditioned place preference to cocaine and high fat/sugar food was positively correlated with nucleus accumbens c-Fos expression. Immunohistochemcial evaluation of p-DARPP-32 expression is ongoing. These findings suggest that high fat/sugar foods and drugs of abuse trigger similar behavioral and neurobiological brain addictive processes and lend support to the hypothesis that maladaptive eating behaviors contributing to obesity can be compared to drug addiction.

Title: Cannabinoid type 1 receptors facilitate conditioned reinforcement evoked by optogenetic stimulation of dopamine release

Authors: *J. F. CHEER[1,2], D. P. COVEY[1];
[1]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Psychiatry, Univ. of Maryland, Baltimore, MD

Abstract: An ability to predict and exploit one's environment supports the rational and efficient pursuit of rewards and therefore survival. While the goals differ, reward seeking behaviors are all powerfully driven by reward-predicting cues. Mesolimbic dopamine projections from the ventral tegmental area (VTA) to nucleus accumbens (NAc) play a fundamental role in cue-directed reward seeking. Accordingly, dysregulation of this circuit is thought to promote aberrant modes of reinforcement, such as substance abuse and addictions. Alterations in cannabinoid type 1 (CB1) receptor signaling potently regulate conditioned reinforcement, such that increasing or decreasing CB1 signaling potentiates or curtails cue-directed reward seeking, respectively. While this is thought to arise from altered CB1-mediated regulation of VTA to NAc dopamine release, a direct and causal link has not been determined. We first confirmed that VTA-evoked NAc dopamine release supports positive reinforcement by demonstrating that optogenetic activation of channelrhodopsin 2 (ChR2)-expressing dopamine neurons in the VTA of DAT-Cre mice promotes vigorous intracranial self-stimulation (ICSS). Fast-scan cyclic voltammetry recordings demonstrated consistent NAc dopamine release time-locked to dopamine neuron self-stimulation. Additionally, when a predictive cue signaling reward availability was introduced, latency to lever press decreased over consecutive trials while cue-elicited NAc dopamine release increased. Thus, VTA dopamine neuronal firing sufficiently supports NAc dopamine release accompanying reward prediction. Systemic administration of the indirect CB1 receptor agonist JZL-184, which inhibits degradation of the endocannabinoid 2-arachidonoylglycerol (2AG), facilitated cue-directed ICSS as evidenced by a decrease in cue-response latency. Therefore, raising tissue levels of 2AG facilitates behaviors reinforced exclusively by VTA-evoked dopamine release. In separate experiments, we confirmed that blocking CB1 receptors with AM-251 inhibited cue-evoked NAc dopamine release and reward seeking in a food-reinforced task. Importantly, pairing cue presentation with optical stimulation of VTA dopamine neurons reversed the effects CB1 blockade, suggesting that deficits in cue-directed reward seeking arise exclusively from CB1 receptor antagonists suppressing VTA-evoked dopamine release. Collectively, this work confirms and refines current understanding of the canonical role of CB1 receptor signaling in VTA-evoked NAc dopamine release and conditioned reinforcement.

Title: Enhanced extinction of cocaine conditioned place preference via glutamate transporter activation is associated with reduced nucleus accumbens c-Fos expression

Authors: *J. W. PICKEL[1], V. SVYSTUN[1], T. HAVICAN[1], L. MININBERG[1], L. PEREZ[1], S. PIERCE[1], A. DILISIO[1], M. REILLY[1], J. A. SCHROEDER[1], S. M. RAWLS[2];
[1]Connecticut Col., New London, CT; [2]Pharmacol., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Ceftriaxone is a β-lactam antibiotic that activates glutamate transporter subtype 1 (GLT-1), Clavulanic acid is a structurally-related β-lactamase inhibitor that retains the β-lactam core required for glutamate transporter activity but displays more patient-friendly characteristics such as enhanced brain penetrability, minimal antibacterial activity, and oral activity. We have previously shown that both drugs attenuate the rewarding aspects of cocaine by enhancing extinction from cocaine conditioned place preference (CPP). C-Fos is a proto-oncogene that is expressed within neurons following depolarization. The current study was an attempt to correlate these behavioral effects with neurochemical changes by evaluating nucleus accumbens c-Fos protein expression. Animals that underwent a 5-day extinction period following cocaine CPP during which ceftriaxone, clavulanic acid or saline was administered daily were challenged with a final cocaine exposure in their drug-paired environment before being euthanized. Brains were sectioned and processed for c-Fos immunohistochemistry. Results indicate that c-Fos expression in the shell and the core of the nucleus accumbens was reduced significantly in animals that received either ceftriaxone or clavulanic acid during extinction from cocaine CPP. These findings suggest that pharmacologic enhancement of glutamate clearance disrupts the *in vivo* actions of cocaine which are correlated with reduced expression of a proto-oncogene marker of neuronal activity.

Abstract: The courtship song of the zebra finch is a well-studied learned complex behavior that has yielded important insights concerning the mechanisms of vertebrate skill learning and motor performance. The forebrain regions that are necessary for singing are clearly defined and several lines of evidence suggest that a single premotor region called HVC (proper name) plays an important role in the production of song. Indeed, early lesion studies demonstrated that this region is necessary for song production, and focal cooling of HVC results in the stretching of the song without affecting its structure suggesting that this region contains the motor program for the song. Electrophysiological recordings during singing reveal that single HVC premotor neurons exhibit a high-frequency firing pattern at a precise and specific moment during the song, but the representation of the song at the network level is still unclear. Optical methods can enable large scale recordings of neuronal circuits and *in vivo* 2-photon imaging combined with fluorescent activity indicators has been used in the anesthetized zebra finch to study auditory responses to song playback (Graber et al., 2013; Peh et al., 2015). Here we introduce a novel head-fixed singing preparation that has enabled us to study the motor representation of singing behavior at an ensemble level within HVC. Projection neurons exhibited calcium transients that reflected the song-related spiking activity previously observed with electrophysiology. To better understand the contribution of individual neurons to this behavior, we developed an analytical approach that

could integrate information across multiple trials to increase our temporal resolution and to more precisely estimate the onset of HVC neurons. We fitted the calcium trace corresponding to each burst as a double-exponential with additive noise that was matched to our electrophysiological calibration curves. We used a Markov chain Monte Carlo inference method, and then we inverted this generative model to estimate the onset times for each trial. In many cases, we were able to establish a posterior uncertainty that was less than the duration of a single song-related burst event (~10 ms), suggesting that this approach can be used to resolve circuit dynamics related to premotor sequences.

Title: Connectomic analysis of local HVC circuitry in the zebra finch

Authors: *S. BENEZRA[1], J. KORNFELD[2], R. T. NARAYANAN[3], M. OBERLAENDER[3], W. DENK[2], M. LONG[4];
[1]Neurosci., NYU Sch. of Medicine, Dept. of Physiol. and Neurosci., New York, NY; [2]Max Planck Inst. for Neurobio., Martinsried, Germany; [3]Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany; [4]Neurosci. and Physiol., NYU Sch. of Med., New York, NY

Abstract: The zebra finch song is a complex motor sequence with important parallels to human skilled behavior, such as speech and musical performance. Lesions to the cortical nucleus HVC abolish singing behavior, suggesting that this region plays a critical role in the production of song (Nottebohm et al., 1976). Single premotor neurons in HVC exhibit a high frequency burst of action potentials at one time point during singing, and different cells are often active at different moments in the song (Hahnloser et al., 2002; Long et al., 2010; Vallentin and Long, 2015). Cooling HVC slows song speed across all timescales, suggesting that connectivity within HVC is important for generating these premotor sequences (Long and Fee, 2008). Despite

previous electrophysiological studies (Mooney and Prather, 2005; Kosche et al. 2015), we know very little about the local wiring rules within that nucleus, in part because of an almost total lack of knowledge concerning the fine structure of single HVC premotor neurons (Gurney and Katz, 1981; Mooney, 2000). To address this, we conducted an anatomical study of these cells using a strategy that combines light (LM) and electron microscopy (EM) approaches. We filled 15 premotor neurons *in vivo* with single-cell Neurobiotin injections and reconstructed the entirety of these processes throughout the nucleus. We also used serial block-face EM to examine the synaptic properties of labeled premotor neurons within a 150x150x60 μm volume. Together, these reconstructions enabled us to quantify the distribution and identity of presynaptic inputs along the dendrites and to estimate the total number of synapses received by single premotor neurons. To examine the number of postsynaptic targets for each HVC premotor neuron, we quantified bouton distribution along axon collaterals in LM. EM reconstructions were used to assess the extent to which boutons reflect the presence of a synapse. Furthermore, we were able to distinguish the cell identity of many confirmed postsynaptic targets. Because a prominent model of HVC sequence generation relies upon strong feedforward monosynaptic connections between premotor neurons to form a 'synaptic chain' (Long et al., 2010), we were especially interested in examining synapses of this nature. Our approach enabled us to identify a large number of premotor-premotor contacts and to characterize their distribution along various dendritic branches. Taken together, these data will inform computational models of information flow within HVC and help to establish a mechanistic understanding of the circuitry underlying other forebrain sequence generating circuits.

Title: Stability and drift of motor sequencing in the songbird HVC

Authors: *W. A. LIBERTI, III[1], D. C. LIBERTI[2], J. E. MARKOWITZ[1], T. GARDNER[1]; [1]Biol., [2]Ctr. for Regenerative Med. (CReM),, Boston Univ., Boston, MA

Abstract: Nearly all living creatures maintain learned motor skills over long timescales- for days, years or even decades. However, little is known about the mechanistic basis of this stability. Some propose that while motor skills can remain stable for years, the individual neurons controlling them may significantly change their firing properties over the course of hours. Others contend the tuning of individual neurons is as stable as the motor skill itself. Merging these two viewpoints, the central hypothesis of this presentation is that the brain encodes learned behaviors on two distinct levels - a mesoscopic level that is highly stable, and a microscopic level in which single neurons can be influenced by a recent history of reward or punishment. In other words, the stability of a memory is rooted not in single neuron stability, but in the stability of network patterns that persist in spite of drifting individual neuron dynamics. Here, we examine the question of motor coding stability in one of the most stable of all animal behaviors: birdsong. The neural circuits that underlie song are well defined, extensively studied, and in key respects homologous to the cortico-basal ganglia circuits underlying sensory-motor learning in mammals. The extreme precision of vocal behavior in zebra finches, coupled with the long-term stability of song structure, presents a unique opportunity to observe how motor memories are maintained at the network level. A zebra finch will sing the same learned song with great precision for years. Indeed, we observe that both inhibitory interneuron firing patterns and local field potentials in premotor cortical area HVC persist for weeks to months. However, the story appears to be different for at least one class of projection neuron in HVC. Here we use genetically encoded calcium indicators and miniature head-mounted microscopes, to longitudinally track the activity of HVC projection neurons in the freely behaving zebra finch. In contrast to stable LFPs and inhibitory neuron activity, preliminary data indicates that individual projection neurons in HVC can shift their tuning properties over time-scales of days. We discuss these results in light of various models for the maintenance of stable motor actions.

Title: Left and right HVC independently control song respiratory amplitude

Authors: *C. M. URBANO[1], B. G. COOPER[2];
[1]Dept. of Psychology, [2]Texas Christian Univ., Fort Worth, TX

Abstract: Birdsong is a learned vocal behavior, like human speech, that requires formation of long-term auditory memory and precise coordination between the respiratory and syringeal (vocal organ) motor systems to reproduce learned song. In songbirds, HVC (proper name) is critically important for auditory-motor integration. Bilateral HVC ablation in Waterslager canaries (*Serinus canaria*) leads to a complete loss sound production, yet males still assume a singing posture. Subsyringeal air sac pressure measures the combined effects of respiratory muscle activity and syringeal gating of airflow. The respiratory pattern of subsongs produced by in juvenile zebra finches (*Taeniopygia guttata*) have demonstrated the importance of coordinated motor output and suggest that acoustic characteristics of song are refined by improving respiratory and syringeal motor coordination. This refinement can be disrupted in juvenile songbirds through HVC inactivation, which causes young birds to return to producing subsong. In a juvenile zebra finch housed adjacent to a live tutor, we recorded air sac pressure during the development of the bird's song (phd 65-85). In an adult zebra finch, we temporarily inactivated HVC using reverse dialysis of tetrodotoxin and recorded changes in subsyringeal air sac pressure. These replications of previous work (Aronov, et al., 2008; Veit, et al., 2011) confirm that the respiratory pattern produced by juveniles is similar to adult song during HVC inactivation. These results are consistent with the view that HVC enables the coordination of respiratory and syringeal gating of airflow during song. To further study the role of HVC in regulating air pressure during song, we used electrolytic lesions to perform a unilateral, followed by bilateral, HVC ablation. We studied Bengalese finches (*Lonchura striata domestica*) because sound production in Bengalese finches is lateralized at the level of the syrinx but respiratory activity is symmetrical. In three male Bengalese finches, bilateral lesion electrodes were implanted in HVC. Air sac pressure and song were recorded, and then either left (n=2) or right (n=1) electrolytic HVC lesion was performed. The resultant changes in air pressure were measured after each lesion. We found that the sequential lesion procedure resulted in an approximately linear decline in air sac pressure amplitude of song syllables ($p = 0.01$) and strongly suggests that the two HVC nuclei independently contribute to song respiratory control. The emerging view from this research is that HVC is critical for generating the driving air pressure amplitude necessary for phonation via coordinating respiratory and syringeal motor systems.

Title: A computational model that can reproduce the effects of partial HVC ablation on the zebra finch song

Authors: *D. GALVIS[1], D. FLORES[1], M. BASISTA[2,3], W. WU[3,4], R. HYSON[2,3], F. JOHNSON[2,3], R. BERTRAM[1,3];
[1]Mathematics Dept., [2]Psychology Dept., [3]Program in Neurosci., [4]Statistics Dept., Florida State Univ., Tallahassee, FL

Abstract: The temporal ordering of acoustic elements in zebra finch song is controlled by the pre-motor nucleus HVC. Recently, we have shown that bilateral ablation or silencing (TTX) of distinct regions in HVC have differing effects on adult song. Lateral HVC ablation results in syllable omission, but the ordering of the remaining syllables is consistent with the song prior to ablation. Medial HVC ablation, on the other hand, results in misordered song sequences interspersed with bouts of the normal sequence. We present a computational neural network model that can account for these ablation effects. In this model, the "medial" neural population determines note sequence and consists of co-existing chains of neurons coupled by inhibition so that not all chains can fire. The "lateral" neural population is divided into subpopulations that must fire for a specific syllable to be produced. Output from the two populations comes together at a layer of RA (robust nucleus of the arcopallium) neurons. Medial ablation, modeled as the removal of a subset of the medial chains, reduces the inhibition on other chains, allowing them to fire. Lateral ablation, modeled as a reduction in the number of syllable-specific neurons, effectively eliminates the RA firing pattern representative of a specific syllable, while having no effect on the ordering of other syllables. While this model is preliminary, it demonstrates one possible network structure that can account for general features of the ablation data, and uncovers challenges in constructing networks that are consistent with the data.

Title: Using dynamic clamp to explore the current properties of HVC neurons in the zebra finch

Authors: *D. FLORES, M. T. ROSS, J. TABAK, R. L. HYSON, F. JOHNSON, R. BERTRAM;
Florida State Univ., Tallahassee, FL

Abstract: The dynamic clamp technique has become a widely used tool for the study of neural systems at the cellular and circuit levels. One of the many applications of this technique is to evaluate the influence of various ionic currents by injecting channel conductances into neurons that are based on mathematical models (Prinz et al., 2004). From previous current clamp experiments, we developed conductance-based models for the different neurons in the HVC (Daou et al., 2013), an area that is known to have a central role in controlling the remarkable temporal structure of birdsong (Long et al., 2010). Using our mathematical models and a pharmacological approach we were able to determine the contribution of the Ih and ICa-T currents in the production of the sag and the rebound firing respectively, features that are present in the interneurons and X-projecting neurons. Also, we found that the IA current is responsible for the long delay to spiking in one of the two RA-projecting neuron types (Daou et al., 2013). Here, we use dynamic clamp to manipulate these three specific ionic currents in the living cell in real-time without the use of any drug. Subtracting these currents confirmed their contribution to the firing patterns and the accuracy of our models. Unlike the purely subtractive effects of pharmacological manipulations, dynamic clamp also gives us the ability to add currents to neurons to test hypotheses about their contributions to the firing pattern. For example, adding T-type Ca2+ current to an RA-projection neuron produced rebound action potentials following a hyperpolarizing current pulse. This behavior is not typically seen in these neurons. Dynamic clamp also allowed us to test more subtle aspects of our models, such as the effects of varying the activation and inactivation time constants of the currents. This combined approach of modeling and hypothesis-testing using dynamic clamp is leading to a more detailed understanding of the biophysical properties of HVC neurons, overcoming the limitations of pharmacological manipulations.

Title: Chronical electrophysiological recordings using carbon fiber microarrays in a songbird premotor brain region

Authors: *S. MOORMAN, T. J. GARDNER;
Biol., Boston Univ., Boston, MA

Abstract: Many studies, conducted in a range of different species, indicate that motor skills improve when the subjects are allowed to sleep after learning the task. However, the mechanisms that underlie this effect remain largely unclear. To investigate the role of sleep in motor performance, activity patterns need to be tracked in the same group of cells across several days and nights. Prevailing electrophysiological methods cannot track the same neuron over a timescale of several days or longer in freely behaving animals. The major limitation of chronic recording is an immune response that encapsulates conventional electrodes and kills nearby neurons or attenuates their electrical signals. The problem is particularly acute for small, densely packed neurons found in small animals such as mice and birds. Here, we use minimally invasive electrode arrays that were recently developed in the Gardner lab to record neural activity in singing zebra finches over long timescales. The arrays consist of 5 μm diameter, flexible carbon fibers arranged in a bundle, such that they splay apart when inserted in the brain. Using these arrays, we were able to stably record from single neurons in a premotor brain region of freely behaving adult male zebra finches across multiple sleep wake-cycles.

Title: A role for the Ih current in the production of song in zebra finches

Authors: *M. T. ROSS, D. FLORES, R. BERTRAM, F. JOHNSON, R. L. HYSON; Neurosci., Florida State Univ., Tallahassee, FL

Abstract: The I_h current is important in many neuronal systems requiring precise timing of firing. We have previously shown the existence of the I_h current in nucleus HVC (proper name) of adult zebra finches (Daou et al. 2013). The HVC is critical in the learning and production of vocalization as it is thought to be responsible for the timing of the vocal pattern (Roberts et al. 2012, Long et al. 2010). The I_h current has a major role in shaping the physiology of the three main classes of HVC neurons. Here, we use *in vitro* patch clamp electrophysiology to record from cells in the HVC across stages of vocal development and use our biophysical models to identify changes in a variety of ionic currents. We see an increase in the rectifying response to hyperpolarizing currents as the bird ages, implicating a possible role of the I_h current in the development of vocal behavior. Interestingly, the interneurons have adult-like physiology earlier than the projection neurons but show increased variability in the magnitude of the rectifying response across cells in earlier stages of development. Given that the changes in I_h seemed to be linked to the development of the singing behavior we then explored the role the I_h current has in the production of song in the adult bird by infusing the I_h channel blocker, ZD7288, into selective subregions of HVC in awake singing animals and monitoring singing behavior. The application of the drug either selectively deleted notes or altered note timing depending on the location of infusion. The magnitude of the effects gradually decay throughout the day as the drug's effect weakens. Together, the results suggest that changes in I_h across development may represent a form of nonsynaptic plasticity that is required for the emergence of the adult song pattern. The results allow for a greater understanding of the interplay between cell physiology and the process of learning.

Abstract: Many motor actions that animals perform consist of a learned series of movements. How the brain generates these movements and imposes a sequence on them is one of the fundamental unanswered questions of neuroscience. Recent ablation studies in the zebra finch have shown that the avian premotor nucleus HVC (proper name) can be divided along at least two anatomically adjacent and functionally parallel pathways, one that encodes syllable repertoire and another that encodes syllable sequence. It was also found that these pathways converge at the avian vocal-motor cortex, the robust nucleus of the arcopallium (RA). To further explore this parallel organization we developed a surgical technique to bilaterally target infusion cannulae to each parallel pathway within HVC. By systematically varying cannula position between birds as well as the volume of tetrodotoxin (TTX) infused within birds we will test how vocal elements in the repertoire- and sequence-encoding regions of HVC are mapped. Preliminary results demonstrate the reversibility of TTX infusion effects (normal song within hours) and replicate previous ablation findings - inactivation of the repertoire-encoding portion of HVC results in wholesale omission of syllables while inactivation of the sequence-encoding portion of HVC elicits atypical transitions between syllables. Additionally, the physiology of cells within the two parallel pathways is being investigated using patch-clamp recordings. Current experiments are aimed at determining how the outputs from the parallel pathways of HVC interact at the level of RA.

Title: Zebra finch song phonology and structure across populations and continents - a computational comparison

Authors: *S. M. TER HAAR[1,2,3,4], R. LACHLAN[5], C. A. A. VAN HEIJNINGEN[2,3], C. TEN CATE, senior[3,2];

Abstract: Birdsong is a widely used model for behavioral and neural research on vocal learning. Learned bird songs are often characterized by variation between individuals and sometimes populations, while at the same time maintaining species specificity. The evolution of such songs will depend on the balance between plasticity and constraints. Captive populations provide an opportunity to examine signal variation and differentiation in detail. Zebra finches (*Taeniopygia guttata*) are commonly used by many songbird scientists as a model species. Surprisingly, only few attempts have been made to quantitatively study the variation of sounds across populations. Here, we analyzed adult male zebra finch songs recorded from 13 populations across the world, including one sample of songs from wild-caught males in their native Australia. Cluster analyses were performed on both element and syllable level. Element analysis suggests that zebra finch song units broadly belong to universal categories, probably linked to constraints in vocal production and non-song parts of the vocal repertoire. The strongest clustering indicates two universal clusters: high frequency element versus all other elements. There is also slightly weaker evidence for element clustering at 10 element types and 7 syllables types. Across populations, songs also show some similarity in syntactical structure; although any song unit can be placed anywhere within the song, some combinations are more likely to occur than others. Differentiation between populations is statistically significant, but the effect size is very small, and its communicative significance dubious. Probably, duration of isolation for each population is not enough for strong divergence in constraints. In addition to duration of isolation, the weak cultural divergence in zebra finches might be explained by relatively weak song imitation, creating strong within population variation. Zebra finches therefore serve as an example of a system where frequent learning errors may rapidly create within-population diversity, within broad phonological and syntactical constraints. This may prevent the formation of long-term cultural traditions that allow populations to diverge.

Title: Factors determining the degeneracy of the relationship between the parameters and dynamics of conductance model neurons

Authors: ***P. MALONIS**[1], A. DAOU[1], N. KADAKIA[2], U. MORONE[2], H. ABARBANEL[2,3], D. MARGOLIASH[1];
[1]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Physics, Univ. of California at San Diego, La Jolla, CA; [3]Scripps Inst. of Oceanography, La Jolla, CA

Abstract: Conductance models are powerful tools for qualitatively characterizing the mechanisms of electrical activity in single neurons. However, using these models to estimate biological parameters is complicated by the fact that a range of parameters can appear to reproduce the measured behavior of a neuron. Here, we investigate the degree to which this degeneracy in the relationship between model parameters and model fit is an artifact of the method used to compare the model output to recorded biological activity, as well as the type of activity that is compared. We are modeling the responses to somatic current injection in whole-cell voltage patch recordings of Area-X projecting neurons in a brain slice preparation of the forebrain nucleus HVC of zebra finches (see Daou, Malonis, Margoliash abstr). In that study, the magnitude of the principle intrinsic ionic conductances in a previously derived, pharmacologically verified Hodgkin-Huxley model of HVC(X) (see Daou et al., J.Neurophys, 2013) were manually fit by one of us (AD), while holding all other parameters at fixed, biologically plausible values determined from the literature. This resulted in excellent fit to the neuron's response to the injected current, and - importantly - excellent prediction of other injected currents, both step functions and chaotic currents. It is of biological importance to determine whether the maximal conductances for each neuron, and observed similar conductances for some sets of neurons, arise because the manually-derived estimates are indeed near to global best fit to the data. Our strategy for addressing this question involves using a comparison function that takes into account spike timing, subthreshold activity, and several

features of the spike shape. We are investigating the sensitivity of model fit to the features of the comparison function. In order to identify best-fitting parameter sets we employ variational data assimilation methods. Moreover, since the number of principal ionic conductances being varied is small (5), we are able to visualize the entire error function using brute-force searches on a supercomputer. Using these approaches, we are also investigating techniques to eliminate spurious minima of the error function that yield good fits but poor predictions. The results will enhance the ability to use conductance models to make predictions and characterize physiological differences between different classes of neurons.

Title: Premotor population dynamics predict muscle activity in zebra finch song

Authors: ***K. J. BROWN**[1], D. MARGOLIASH[1,2];
[1]Committee on Computat. Neurosci., [2]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Song control requires rapid and precise transitions in motor state, which has been termed vocal gestures. Gesture transitions occur non-uniformly and are necessarily unique for each song. We hypothesize that the timing of gesture transitions is causally related to song production, and therefore the encoding of these times is over-represented in the activity of neurons in cortical areas such as sensorimotor area HVC. Here, we are studying singing in zebra finches. We are using a mathematical model of vocal production, which creates artificial song using physiological parameters pressure and tension. By inverting the model, we can predict pressure and tension from recorded birdsong. Previously, gesture transitions identified using this model were found to predict the timing of activity in HVC. While some gesture transitions are clear from the acoustic features of recorded song as assessed by spectrographic analysis, such as

onsets and offsets of phonation, other gesture transitions may be less apparent. In this work, we record from the syringeal (vocal) muscles directly to 1) evaluate and extend the model of vocal production and 2) provide a model-independent test of HVC gesture transition coding by simultaneously recording from HVC and the vocal muscles. In sleeping birds, song is spontaneously replayed throughout the motor system, from bursting in HVC to activation of the vocal muscles. We find that multi-unit population activity collected with silicon arrays from sleeping birds in HVC is correlated with ventral syringeal muscle (vS) EMG activity with short latency, which is consistent with state-dependent coding in HVC (μ=18.5ms, σ=8ms, units=150). Summed multi-unit activity across recording shanks was significantly correlated with sleeping spontaneous muscle activity, with a mean Pearson's R value of 0.17 (σ=0.2, N=24, $p<.001$). Our current data is likely to be primarily interneurons, as our recorded neurons tend to have a high spontaneous firing rate. We believe this correlation should exist in downstream projecting neurons due to the strong interactions between the interneuron and projection neuron populations. These results are consistent with HVC encoding the timing of gesture transitions in the syringeal muscles. While this data has been collected during sleep, we are currently testing these results in singing birds.

Title: A comparison of vocal organ morphology between Bengalese finches and white-rumped munias

Authors: C. M. URBANO[1], K. OKANOYA[2], *B. G. COOPER[1];
[1]Psychology, Texas Christian Univ., Fort Worth, TX; [2]Univ. of Tokyo, Tokyo, Japan

Abstract: Song learning and sound production in oscine birds is constrained by the central nervous system and the anatomy of the vocal organ (syrinx). Fundamental frequency is controlled by the vibratory characteristics of the sound generating tissues in the syrinx, and the

left and right sides of the oscine vocal organ differentially contribute to the fundamental frequency range. Across several songbird species, the morphologic asymmetry in the size and number of cellular layers of the vibratory tissues is a significant predictor of fundamental frequency range. We sought to explore the role of peripheral versus neural constraints in song learning in Bengalese finches (*Lonchura striata domestica*) because cross-fostering studies have revealed that white-rumped munias (*Lonchura striata*) are less likely to imitate higher frequency, tonal syllables sung by Bengalese finch tutors, whereas Bengalese finches are able to imitate the syllable phonology of adult munia tutors. We predicted that if peripheral constraints restrict learning acoustic features of song, then Bengalese finches should have a greater degree of morphological vocal tissue asymmetry compared to white-rumped munias. Whereas, if neural constraints limit song learning, then munias should show a similar morphologic asymmetry in their vocal tissues as compared to Bengalese finches. We measured the surface area and volume of syringeal structures relevant to sound production (labial tissue, bronchial cartilage, muscle) in both species. We found that the right lateral labium in both Bengalese finches (n=6) and white-rumped munias (n=4) is at least twice as large as the left (BF: $p < 0.001$; WRM: $p < 0.05$, paired t-test). Bronchial semi-rings, A1 and A2, are also larger in the right sound source for the Bengalese finch, but not in white-rumped munias. The right medial labium approached a significant surface area difference compared to the left ($p = 0.06$), in white-rumped munias; no differences in medial labia length in Bengalese finches were found. Muscle volume and area were not lateralized in either species. These results suggest that white-rumped munias do not have a significant anatomic constraint that limits the copying of acoustic features of the song. Instead, these data are consistent with the interpretation that neural constraints limit the acquisition of tonal song syllables in white-rumped munias.

Title: Modulation Dynamics of the Syringeal Skeleton *in vitro* and *ex vivo*

Authors: D. N. DÜRING[1], *C. P. ELEMANS[2];
[1]Biol., Univ. of Southern Denmark, Odense, Denmark; [2]Univ. of Southern Denmark, Odense M, Denmark

Abstract: Birdsong is an important neuroethological model system for understanding learned vocal behavior. Although many components of the involved neural circuitry have been identified, we lack mechanistic insights into the function of the motor circuits that generate song. The small size and inaccessibility of the avian vocal organ, the syrinx, make it difficult to investigate how its structure relates to function in freely singing birds. We currently lack biomechanical insights how the musculature actuates the syringeal skeleton and sound producing structures to generate vocalizations. Here we use combined *in vitro* (excised) and *ex vivo* (perfused organ) paradigms to study motor control of the syringeal skeleton and sound producing structures. The setup enables high-speed imaging of labial and skeletal motion under controlled pressure conditions combined with direct actuation of muscle attachment sites or muscle stimulation. These data allow for the quantification of 3D motion of syringeal elements, estimates of the forces required for modulating syringeal elements, and effects of individual muscle recruitment on mechanical properties of sound producing structures.

Title: Small perturbation of subglottal pressure affect call types differently

Authors: *T. RIEDE;
Midwestern Univ., Glendale, AZ

Abstract: The coordination between breathing and motor control of a sound source is critical for normal vocal production. In most mammals it is the fine-tuned integration between sufficient lung pressure, appropriate glottal opening and vocal fold tension which produces different vocal types. Studies in laboratory rats had demonstrated flexibility in the laryngeal-respiratory motor coordination producing ultrasonic calls. In order to elucidate the source of this flexibility, I tested

if small pertubations of subglottal pressure affect call production. Awake and spontaneously vocalizing male Sprague-Dawley rats were tested while interacting with an estrous female. Subglottal pressure was measured under normal and under experimental conditions during which subglottal pressure was raised by 0.5 kPa by injecting a small amount of compressed air into the trachea through a custom-built implant. One calltype (22 kHz calls) was associated with a large increase in call duration when the subglottal pressure was raised. This effect was not observed or only mildly present in another calltype (50kHz calls). The experimental manipulation of lung pressure did not cause an earlier inspiratory termination but an expiratory prolongation. The call-type specific response could be caused by different laryngeal-respiratory control mechanisms paralleling different brain areas implicated in the generation of the two call types.

Title: Creation of a neuroscience toolbox: neuron-specific Cre and conditional fluorescent protein and opsin rat lines

Authors: *Z. LIU, G. ZHAO, X. CUI;
Horizon Discovery, Saint Louis, MO

Abstract: The Cre-LoxP system has been widely applied in the mouse, providing spatiotemporal control of gene expression. However, its adoption in the rat has been hindered by technical challenges until the recent development of nuclease-mediated genome editing technologies, such as zinc finger nucleases and CRISPR/Cas9, which allow site-specific insertion of Cre expression cassette and loxP sites in rat genome (Brown et al., 2013). We have previously created two dopaminergic neuron-specific Cre lines, tyrosine hydroxylase-Cre (Th-cre) and dopamine active transporter-Cre (DAT-Cre), by inserting an IRES-Cre cassette directly in front of the stop codon of Th and DAT gene, respectively, with zinc finger nuclease technology and shown that the expression of Cre recombinase reflects that of the endogenous Th and DAT gene. Here we report that by employing CRISPR/Cas9 technology, we have created additional neuron-specific rat Cre lines, including Tph2-Cre (Tryptophan hydroxylase 2, serotonergic neurons), Sst-Cre (Somatostatin, somatostatin-expressing neurons), Slc32a1-Cre (VGAT or VIAAT, GABAergic neurons), Calb2-Cre (Calbindin 2 or calretinin, calbindin 2-expressing interneurons), VIP-Cre

(Vasoactive intestinal polypeptide, VIP-expressing GABAergic interneurons) and HTR3A-Cre (5-hydroxytryptamine receptor 3A, serotonergic neurons), CamK2a-Cre (Calcium/Calmodulin-dependent protein kinase II alpha), Pvalb-Cre (Parvalbumin, GABAergic interneurons). Furthermore, we created a fluorescent reporter line and two conditional opsin lines, where the expression of the reporter or opsins relies on the excision of an upstream floxed stop sequence by Cre. We will report the preliminary characterization of these lines as well. We believe these rat lines will not only provide the research community useful tools but also encourage researchers to join force to make more Cre rats.

Title: Neuroprotective efficacy of a calpain-dependent gene regulation system expressing X-linked Inhibitor of Apoptosis Protein in a model of Parkinson's disease

Authors: *J. NAIDOO, D. FONG, A. MURAVLEV, D. YOUNG;
Univ. of Auckland, Auckland, New Zealand

Abstract: Unregulated gene expression is a key issue limiting clinical translation of promising gene therapies. We have developed a novel bicistronic autoregulatory gene expression system that relies on cell stress-induced activation of calpain to drive transgene expression. We have compared the therapeutic efficacy of constitutive expression of the anti-apoptotic gene X-linked Inhibitor of Apoptosis Protein (XIAP) under the control of the chicken beta-actin/CMV hybrid promoter (CBA) to XIAP expression under the control of our regulatory sytem in a neurotoxin based model of Parkinson's disease. Regulated plasmids (Calpain-XIAP, a control Calpain-GFP) and constitutive plasmids (CBA-XIAP and CBA-GFP) were packaged into AAV vectors and injected into the SNc of male Sprague Dawley rats (200-300g). Subgroups of rats (n=6 per vector

per treatment) received a unilateral intrastriatal injection of 20µg 6-hydroxydopamine (6-OHDA) to induce calpain activation or PBS 3 weeks later. Amphetamine-induced rotation and cylinder testing were performed 4 and 8 weeks later followed by euthanasia and removal of brains for immunohistochemical (IHC) analysis. 6-OHDA lesioned animals did not display a significant difference in mean ipsilateral rotational bias or forepaw preference across treatment groups. Lower transgene expression levels were observed in Calpain-XIAP and Calpain-GFP rats compared with CBA-XIAP and CBA-GFP rats, as assessed by IHC against a C-terminal myc tag on XIAP and GFP, respectively. Unbiased stereological counting of tyrosine hydroxylase immunoreactive cells (TH-ir) spaced 240µm apart revealed that compared to the contralateral hemisphere, rats injected with Calpain-XIAP vector had 50.4% TH-ir cells remaining compared with only 18.8, 29.6 and 27.0% in rats injected with the CBA-GFP, CBA-XIAP and Calpain-GFP vectors, respectively ($P<0.05$). No significant differences in TH cell number were observed between vector treatments in PBS rats. Immunostaining for the neuronal marker, HuC/D reflected the extent of cell loss. Calpain-XIAP rats displayed less of an inflammatory response following 6-OHDA challenge compared to CBA-GFP, CBA-XIAP and Calpain-GFP rats, as assessed by changes in glial fibrillary acidic protein and CD11b expression, indicators of astrogliosis and microglial activation, respectively. Our analyses suggest that expressing XIAP under the control of our calpain-regulated system provides superior protection of cell bodies and reduces inflammation in comparison to constitutive transgene expression in the 6-OHDA model of Parkinson's disease. Title: Step-function luminopsin for prolonged activation of neurons by bioluminescence

Authors: *K. BERGLUND[1], C.-A. GUTEKUNST[2], J. TUNG[2], U. HOCHGESCHWENDER[3], R. E. GROSS[2];

Abstract: Over the past decade, optical tools for controlling neuronal activity have vastly expanded. However, there are still unmet needs which require development and refinement of optogenetic probes. For example, light delivery into the brain is still a major practical challenge that hinders potential translation of optogenetics in human patients. In addition, it would be advantageous to manipulate neuronal activity acutely and precisely as well as chronically and non-invasively, using the same genetic construct in animal models. We have addressed these challenges by employing bioluminescence as a light source for optogenetic activation. Luminopsin was created by fusing a light-sensing channelrhodopsin with a light-emitting *Gaussia* luciferase (*PLoS ONE* e59759). To expand applications of luminopsins, we incorporated *Chlamydomonas* channelrhodopsin 2 with step-function mutations (SFLMO). Bioluminescence-induced depolarization in transfected neurons in culture lasted longer than the bioluminescence signal due to very slow inactivation of the channel. In addition, bioluminescence was able to activate almost all the channels on the cell surface due to extremely high sensitivity of the channel to light. As a result, SFLMO unilaterally transduced by a viral vector into neurons of the substantia nigra was able to induce circling behaviors in rats *in vivo* upon intravenous injection of the luciferase substrate. Thus, step-function luminopsin expands the current approaches for manipulation of neuronal activity in the brain and adds more versatility and practicality of optogenetics in freely behaving animals.

Title: Luminopsins allow neuronal activation over a range of spatial and temporal scales

Authors: L. WEN[1], S. PARK[1], K. A. CLISSOLD[2], K. BERGLUND[3], H. H. YIN[2], G. J. AUGUSTINE[1], *U. HOCHGESCHWENDER[4];

Abstract: Luminopsins, LMOs, are fusions of a luciferase, which emits biological light in the presence of a small molecule substrate, and an optogenetic actuator, which translates the light into neuronal activation or silencing (PLoS ONE 8: e59759). LMOs take advantage of the superior versatility of opsins as current conductors and preserve their functionality, while adding chemical genetic access to the entire arsenal of optogenetic elements. By matching the light source - physical or biological - to the experimental question, LMOs allow interrogation of neuronal circuits at different temporal and spatial resolutions in the same experimental animal. Here we applied this approach to analysis of mouse neurons and circuits. An AAV vector containing a human Synapsin promoter-driven Gaussia luciferase fused to Volvox channelrhodopsin 1 (VChR1) was unilaterally injected into the substantia nigra pars reticulata (SNr). The luciferase substrate coelenterazine (CTZ) was injected peripherally into a tail vein. Activation of SNr neurons by bioluminescence caused mice to make ipsilateral turns, consistent with the expected motor effects of unilateral activation of the SNr. Using whole-cell patch clamp in brain slice preparations we recorded responses in individual cells to activation of afferents of these neurons. Small regions were illuminated by a laser light spot in a random fashion to activate local excitatory synapses onto the neurons, assembling a photostimulation map (PNAS 104: 8143). These experiments demonstrate the flexibility of using LMOs to interrogate neuronal circuits by complementing behavioral testing at the macrocircuit level with photostimulation mapping at the local microcircuit level.

Title: Inhibitory luminopsins: genetically encoded bioluminescent opsins for versatile, scalable, and hardware independent optogenetic inhibition

Authors: *J. K. TUNG[1,2], C.-A. GUTEKUNST[2], K. BERGLUND[2], R. E. GROSS[2,1];
[1]Georgia Inst. of Technol., Atlanta, GA; [2]Emory Univ., Atlanta, GA

Abstract: Optogenetic techniques have become mainstream in the neuroscience community because they offer scientists an unprecedented ability to precisely manipulate neural activity in the context of complex neural circuitry. Although the toolbox of optogenetic probes continues to expand at a rapid pace with more efficient and responsive reagents, light delivery into the brain is still a major practical challenge that needs to be addressed. We have bypassed the challenges of external light delivery by directly coupling a bioluminescent light source (a genetically encoded Renilla luciferase) to an inhibitory opsin (Natronomonas halorhodopsin) as a single fusion protein, which we term an inhibitory luminopsin (iLMO). iLMO was shown to suppress action potential firing and synchronous bursting activity *in vitro* in response to both physical light and luciferase substrate. iLMO was further shown to suppress single-unit firing rate and local field potentials in the hippocampus of anesthetized animals. Finally, expression of iLMO was scaled up to multiple structures of the basal ganglia to modulate rotational behavior of freely moving animals in a hardware-independent fashion. This novel class of optogenetic probes demonstrates how conventional opsins can be converted to luminopsins to achieve non-invasive inhibition of neural activity, adding to the versatility, scalability, and practicality of optogenetic applications in freely behaving animals.

Title: Multi-timescale *in vivo* regulation of the thalamic reticular nucleus using bioluminescent optogenetics (BL-OG)

Authors: *B. HIGASHIKUBO[1], E. MCDONNELL[2], U. HOCHGESCHWENDER[3], C. MOORE[2];
[1]Moore Lab, Brown Univ., Providence, RI; [2]Neurosci., Brown Univ., Providence, RI; [3]Neurosci., Central Michigan Univ., Mt Pleasant, MI

Abstract: The thalamic reticular nucleus (TRN) provides inhibitory input to thalamic relay nuclei and is thus poised to gate the transmission of sensory information and to modulate activity in the thalamocortical circuit. The involvement of the TRN in diverse processes like sleep and epilepsy makes it an attractive target for modulation in experimental and clinical contexts. In order to combine the cell-type specificity of optogenetics with the systemic administration associated with pharmacology, we developed a novel approach that uses bioluminescence to drive light-sensitive molecules. Using Luminopsin 3, a fusion of Gaussia luciferase and VChR1, we demonstrated the ability to modulate TRN firing and rhythmicity on the order of seconds to ~45 minutes with a single peripheral injection. Intravenous delivery of the luciferase substrate coelenterazine caused a short-lasting increase in spike rate within seconds, while intraperitoneal delivery drove a more subtle effect lasting 30-60 minutes post injection.

Title: PV inhibitory neuron subtype specificity in cortex from low titer adeno-associated virus (AAV) containing a Fugu parvalbumin promoter

Authors: Y. LIU[1], H. SHAO[1], R. JAPPELLI[2], *D. C. LYON[1];
[1]Anat. & Neurobio., Univ. of California, Irvine, CA; [2]Lab. of Genet., Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: In the visual cortex of transgenic mice, several recent studies have established that the somatic-targeting parvalbumin (PV) positive inhibitory neuron subtype has a distinct role in

shaping visual responses. However, investigation of the roles of any inhibitory neuron subtype in non-transgenic mammals with more complex visual systems remains elusive. An earlier attempt to target PV interneurons with viral vectors, used AAV 2/1 and a 'short' (2.4 Kb) Fugu rubripes (pufferfish) PV promoter fragment driving EGFP, but expression was not restricted to PV neurons (Nathanson et al 2009, Front Neural Circuits 3:19). Promoter size was kept short to stay under the 5.2 Kb packaging capacity of AAV. However, studies have shown that AAV can effectively package larger gene constructs (up to 8.7 Kb) with only a moderate reduction in gene expression (Hirsch et al 2010, Mol Ther 18:6-8). In support of this, we found previously that AAV 9 with a 3.1 Kb GAD1 promoter and a total gene construct of 7.4 Kb selectively transduced GABAergic neurons while yielding high gene expression (Liu et al 2013 Curr Biol 23, 1746-1755). In this same vector backbone, we have now cloned a longer (2.9 Kb) version of the PV promoter in place of GAD1 to make AAV 9 at a titer of 1.33E+11. To test for cell type specificity we made 0.6 µl injections at 2-3 depths in visual cortex of mouse and cat. On average, transduced cells were found over a 500 µm radius from the injection center. Nearer the injection track, <350 µm, PV selectivity was not high (55% were PV+; with ~10% of PV- cells showing pyramidal morphology). However, beyond 350 µm PV selectivity was dramatically higher, ranging from 80-92%, with 0 pyramidal neurons identified. Furthermore, at this distance the number of transduced neurons was still high, so that for example in a single section 360 µm from the injection track in one mouse there were 95 transduced neurons, 84 of which (88%) were PV+. We next tested for PV selectivity at lower titer and found 75-90% selectivity for concentrations reduced to 33% and below, with only 2 pyramidal cells identified out of hundreds. Further investigation is needed to determine whether the PV- transduced neurons represent other inhibitory neuron subtypes or whether this is due to incomplete PV antibody penetration. Either way, this approach using low titer AAV9 with a 'long' PV promoter shows promising specificity for PV inhibitory neurons in non-transgenic animals, and because our AAV construct includes genes necessary for infection and spread of a modified rabies virus this will provide a unique opportunity for targeted circuit tracing of an inhibitory neuron subtype.

Title: Development of CRISPR toolkit for knock-in transgene targeting to the rat rosa26 locus

Authors: *B. K. HARVEY[1], L. FORTUNO[1], Y. ZHANG[1], J. PICKEL[2], C. RICHIE[1];
[1]NPR Section, NIDA - NIH, Baltimore, MD; [2]NIMH - NIH, Bethesda, MD

Abstract: The advent of CRISPR-based genome modification has lowered the investment cost required for the creation of highly-customized model organisms. Here we describe the development of a Cas9-based genetic toolkit for the rat, which streamlines the targeted insertion of transgenes into the Rosa26 locus. We have constructed a set of plasmids which express the Cas9(D10A) nickase (Cas9n) and a pair of rat Rosa26-targeting guide RNAs (gRNAs) along with a selectable marker. When transfected into rat adrenal gland pheochromocytoma (PC-12) cells, these plasmids induce the formation of double-strand breaks and thereby lead to the accumulation of small insertion/deletions (InDels) between the gRNA binding sites. These plasmids also increase the efficiency of homology-directed insertion of a transgene (donor template) when delivered by cotransfection. The verified Rosa26-targeting gRNAs were transcribed and purified *in vitro*, and microinjected alongside Cas9n mRNA into Long-Evans rat embryos. InDel frequency at the Rosa26 locus in the resulting pups was assessed using a T7 endonuclease assay. For three rounds of injections, the frequency of InDels detected was (2 out of 16), (7 out of 12), and (10 out of 15). The ability to enhance homology-directed insertions *in vivo* was also validated by coinjecting these gRNAs with single-stranded oligonucleotides (ssODN) containing a novel loxP site flanked on each side by 72 basepairs of Rosa26 sequence. A single round of injections produced 15 pups, 4 of which carried the loxP allele. Next, a single round of injections employing a plasmid-based donor template with 1 kilobase homologous arms produced 7 pups, 1 of which carried the transgene. The use of this rat Rosa26 CRISPR toolkit will simplify the creation of "defined" transgenic rat models and should reduce the inconsistencies attributed to copy number- and position-effects when dealing with randomly integrated transgenes.

Title: Nanowire transgene injector arrays

Authors: ***Y. KUBOTA**, A. GORYU, R. NUMANO, M. ISHIDA, T. KAWANO;
Toyohashi Univ. of Technol., Toyohashi Aichi, Japan

Abstract: It is possible to modify the function of cells by transferring the DNA into the cells. As the DNA injection into the cells, nanoscale probes such as carbon nanotubes (CNT) and atomic force microscopy (AFM) are powerful methodologies, in terms of multisite and pinpoint DNA injections into cells. However, the cell injecting deep within a brain tissue is still problematic because of the short length of the nanowire/tube devices (< 10 μm in length). To realize multisite and deep area injections, here we propose the injection using an array of vertically aligned nanoscale-tipped wire (NTW) arrays. An array of NTWs with a high aspect ratio is fabricated by vapor-liquid-solid (VLS) growth of silicon-microwire and the nanotiop formation. The length of the NTW varies from 25 μm to 100 μm, depending on the injection applications (cultured cells, brain tissue with a thickness). As DNA trapping sites, these NTWs are metalized with 100 nm-thick gold layer by sputtering, while the sidewalls of the NTWs are covered with 1-μm-thick parylene insulator. Transgene plasmid DNA encoding an FP (Venus: mutant Yellow FP) was injected into HEK293 cells and a fibroblast cell lines using a 20 × 20 NTW-array (wire length = 25 μm, gap = 100 μm). Cells containing yellow fluorescent signals were separated by a gap, which was consistent with the layout of the NTW array. The observation indicated that plasmid DNA containing the FP transgene were transfected into the multiple-cells by the NTW-array injection, without damage to the cells. With 100-μm long NTW array, a plasmid containing a gene encoding the FP (Venus with a negative charge) was injected into cells within a ~400-μm-thick brain slice of mouse suprachiasmatic nucleus (SCN). After slice incubation up to 4 days, confocal microscope observation of the slice confirmed that the FP signals were located at sites of NTWs in a deep area of the brain slice.

Title: New nsc-derived motor neuron model for als generated using crispr/cas9 reveals involvement of dna damage response

Authors: *J. MITRA[1], V. M. VASQUEZ[2], M. L. HEGDE[2];
[1]Radiation Oncology, Houston Methodist Res. Inst., The Houston Methodist Hosp., Houston, TX; [2]Dept. of Radiation Oncology and Neurology,, Houston Methodist Res. Inst., Houston, TX

Abstract: The recent breakthrough of creating patient-derived induced pluripotent stem cells (iPSC) has allowed researchers to study disease mechanism, therapeutic development and patient-specific drug screening in the context of identical genetic information. Particularly in the perspective of neuroscience, these iPSC lines are invaluable resources for scientists. At the same time, challenges exist with regard to transfections and generating disease-linked mutant cell lines. In case of a progressive motor neurodegenerative disease, called Amyotrophic Lateral Sclerosis (ALS), several mutations in the RNA/DNA binding Tar DNA Binding protein 43 (TDP-43) has been implicated in disease development and progression. Till date no such patient-derived iPSC lines are available carrying etiologically linked mutant TDP-43 protein for studying the disease mechanism and therapeutic approach. Here, utilized the recently developed gene editing technology (CRISPR/Cas9 technique) to establish TDP-43 knock-out iPSC - derived neural progenitor stem cells (NSCs). We also generated Q331K mutant TDP-43 carrying progenitor neuronal cells. These two cell models provided tools for proof-of-principle in-depth mechanistic study of TDP-43 - associated ALS pathology mimicking identical genetic background. To reduce the off-target hitting of CRISPR/Cas, we have employed cell penetrating peptide (CPP) tagged Cas9 protein and packaged the sgRNA with a highly cationic CPP, along with a short single-strand DNA as a template for gene editing. Moreover, we have created a cellular condition where homologous recombination would over-weigh non-homologous end joining after CRISPR/Cas mediated double-strand break generation enhancing the possibilities of "clean" gene editing in neural stem cells. Finally, these novel ALS cell models reveal that genome damage and DNA damage response (DDR) are not only involved in TDP-43 pathology-mediated cell death, but could also be potential therapeutic targets.

Title: Dried blood spot RNA sequencing (DBS-RNA-Seq): A novel approach for the identification of circulating biomarkers

Authors: *A. WOLFE[1], A. SINIARD[2], R. RICHHOLT[2], I. SCHRAUWEN[2], M. HUENTELMAN[2];
[1]Tgen, Phoenix, AZ; [2]TGen, Phoenix, AZ

Abstract: There is growing interest in the use of cross sectional RNA biomarkers to determine personalized risk for the development of disease, yet many of these biomarker panels are still in need of independent validation. Typical biospecimens used for neurological disease are either peripheral blood or more frequently, cerebrospinal fluid. Due to the invasiveness of collecting these biospecimens, most research using them is limited to the investigation of a single time point. It is likely that the statistical power of novel biomarker assessment would be improved through the use of longitudinally collected samples. To collect biospecimens with higher frequency and use them during longitudinal analysis, we developed a dried blood spot based (DBS) next generation RNA sequencing approach (DBS-RNA-Seq). Single drops of blood (~30ul) were collected onto RNA-stabilizing filter papers (RNASound) and allowed to dry. We demonstrated the ability to isolate on average 10ng of total RNA from one DBS. This RNA was of sufficient quality and quantity to generate Illumina transcriptome and miRNA-Seq libraries, resulting in the assay of 35,000 transcripts and ~500 miRNAs when sequenced to a depth of ~2 million or 650,000 counts, respectively. RNA-Seq analysis of DBS that were stored for 1, 7, 30, and 60 days demonstrated the presence of no significantly differentially expressed transcripts, suggesting that RNA species collected in this fashion are stable for long periods of time. In summary, these studies demonstrated the feasibility and appropriate performance of the DBS-RNA-Seq approach. As proof of concept, we attempted to utilize the DBS-RNA-Seq to develop a biomarker panel associated with 1 hour of aerobic exercise. Each Monday for 4 consecutive weeks, DBS were collected from one study participant at the following time points: 5am (first wake), 9:30am, every 10 minutes during exercise for a total of 6 collections, and then 1, 2, 3, and 4 hours following exercise. Exercise consisted of a 17-mile road cycling ride (165W average power) on the exact same route. Total RNA was isolated from each DBS and utilized for Illumina transcriptome. Surprisingly, analysis demonstrated no significantly differentially expressed transcripts between 5am and 9:30am. However, several transcripts known to be induced by exercise, and many new transcripts, were identified during exercise as well as during

the hours immediately following exercise. In total, this demonstrated the utility of DBS-RNA-Seq to identify biomarkers associated with a "condition." Therefore, we propose that this approach could be utilized to characterize longitudinal RNA biomarkers in larger cohorts of disease cases and controls.

Institute, Saitama Univ., Saitama, Japan; [6]Dept. of Neurophysiology, Univ. of Yamanashi, Yamanashi, Japan

Abstract: Fluorescent Ca2+ reporters are widely used as readouts of neuronal activities. We recently developed R-CaMP2, a high-affinity red genetically encoded calcium indicator (GECI) with a Kd for Ca2+ < 70 nM and a Hill coefficient near 1. One major breakthrough was the successful use of a mutated Ca2+/CaM-sensing domain of CaMKK-α/β (ckkap sequence) to replace the calmodulin-binding sequence of M13 sequence which was previously used in all G-CaMP derivatives and their color variants. Thus, R-CaMP2 resulted in three-fold faster rise and decay times of Ca2+ transients than R-CaMP1.07. These features allowed resolving single action potentials (APs) and recording fast AP trains in the 20-40 Hz range, with similar efficacy as with previously reported sensitive green GECIs in acute cortical slices and *in vivo*. Here, we show improvement of R-CaMP performance, based on rational mutagenesis of the ckkap sequence of R-CaMP2. Through screening *in vitro* and in acute cortical slices, we identified R-CaMP variant with a further two-fold on-rate amelioration (time-to-peak around 30 msec) while maintaining a relatively high Ca2+ affinity (Kd ~ 100 nM). In acute cortical slices, spike trains over 50 Hz were resolved, consistent with improved linear response properties as compared with R-CaMP2. The characteristics of these next generation red GECIs will provide enormous advantage in measuring activities of fast-spiking neurons that critically regulate cortical local circuits.

Title: A novel plasmid, NASTIE, for distinguishing neurons and astrocytes during calcium imaging experiments in rat hippocampus

Authors: *M. GIBBONS[1,2], S. W. A. TITEN[3], P. TVRDIK[3], M. R. CAPECCHI[3], J. A. WHITE[5], K. S. WILCOX[2,4];
[2]Interdepartmental Program in Neurosci., [3]Dept. of Human Genet., [4]Dept. of Pharmacol. and Toxicology, [1]Univ. of Utah, Salt Lake City, UT; [5]Dept. of Biomed. Engin., Boston Univ., Boston, MA

Abstract: Astrocytes are now recognized to be active participants in neurotransmission. Deciphering their importance in this role is integral to an in-depth understanding of signaling in the healthy and diseased brain. The recent availability of genetically encoded calcium indicators, such as the GCaMP family of proteins, have made it possible to monitor the activity of neurons and astrocytes in large brain networks. However, no genetically encoded tool exists to selectively distinguish astrocyte processes from neuronal processes in a single animal, seriously limiting our ability to assess local interactions between these cells. We recently developed a novel transgene dubbed Neuron Astrocyte Specified Targeting with *In utero* Electroporation (NASTIE). This transgene encodes the ubiquitous CAG promoter driving expression of the newest membrane tethered calcium indicator, Lck-GCaMP6f, followed by the red fluorescent protein, tdTomato, flanked by lox2272 sites, and then followed by the blue fluorescent protein, Cerulean. It also encodes the neuron-specific promoter, synapsin, driving expression of the site-specific recombinase Cre. By placing Cre expression under the control of synapsin, Cre mediates the excision of the lox2272-flanked tdTomato only in synapsin-expressing cells, leaving these cells to fluoresce blue. To obtain functional and stable transfection of the adult rat brain, we used *in utero* electroporation (IUE) to introduce the NASTIE piggyBac transposon and a plasmid carrying the transposase source into the brains of embryonic day 14 rats. To characterize NASTIE transgene functionality in juvenile and adult rat brains, we dissected and post-fixed brains from postnatal day 9 and 35 rats that had previously undergone IUE. Immunohistochemistry was performed on the tissue to label NeuN (neuronal marker), GFAP (astrocyte marker), and GFP (GCaMP marker). Future directions for this project include investigating calcium activity in reactive astrocytes in acute brain slices prepared from adult rats treated with kainic acid in order to evaluate neuronal-glial signaling in the epileptogenic brain.

Title: Establishing the genetic background of marmosets for transgenic production

Authors: A. DALLSTREAM[1,2], B. GOLD[3], B. KOLACHANA[4], *J. PICKEL[1];
[1]Natl. Insitutes of Mental Hlth. / Transgenics, NIH, Bethesda, MD; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Ctr. for Cancer Research, Human Genet. Section, Natl. Inst. of Hlth. - Natl. Cancer Inst., Frederick, MD; [4]HBCC, Natl. Inst. of Hlth. - Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Transgenic primate models offer new insights into the study of inherited complex behavior and neurophysiology. Researchers have produced primate models in rhesus macaque, cynomolgus monkeys, and marmosets. Our laboratory has generated a transgenic marmoset using a lentiviral construct and used CRISPR/Cas9 genome engineering to target genes in marmoset embryos. As the demand for transgenic marmoset models of cognitive, behavioral, and social phenomenon grows, it becomes imperative to establish a thorough genetic background of marmosets used in research. In this study, we have begun to characterize the genetic background of marmosets used in our colony for breeding and production of transgenic animals. DNA was extracted from different tissue and bodily fluid sources. Chimerism poses a unique challenge in genetic studies of marmosets. Due to the fusion of placental tissue and shared circulation in gestation, chimerism has been shown to be present in the hematopoietic tissue of marmosets. Chimerism was also observed in buccal swab samples in this study. More reliable and less invasive DNA extraction methods are needed in order to accrue better data in the future. Published microsatellite markers were used to establish a preliminary genetic background and determine relatedness in the colony. The established microsatellites used in our study are reproducible in our colony. However, our results show that some microsatellites have a greater range of alleles in our population creating an overlap in sizes and that a change of parameters in PCR reactions using multiple primers is necessary. Microsatellite analysis reveals the distribution of alleles among family groups and these results will help guide breeding strategies. This preliminary genotyping data serves as a foundation to future studies to characterize marmosets using clinically relevant genetic markers. Establishing a genetic background of the marmosets in research colonies is imperative for any future studies of marmosets that study behavior in family or social settings as well as any transgenic studies that manipulate social behavior.

Title: Survival of corticostriatal neurons by rho gtpase signaling pathway

Authors: *K. KOBAYASHI[1], H. SANO[2], S. KATO[3], K. KAIBUCHI[4], K. KOBAYASHI[3]; [2]Div. of Syst. Neurophysiol, [1]Natl. Inst. For Physiological Sci., Okazaki, Japan; [3]Dept of Mol Genet, Fukushima Med. Univ., Fukushima, Japan; [4]Dept of Cell Pharmacol, Nagoya Univ., Nagoya, Japan

Abstract: Corticostriatal neurons are widely distributed in the cortex and play an essential role in various higher brain functions. However, the molecular mechanism underlying the survival of corticostriatal neurons remains unknown. The small GTPase Rho is well known to control various cellular functions. In this study, we investigated the role of Rho in the survival of corticostriatal neurons using newly developed gene transfer system combined neuron-specific retrograde gene transfer lentiviral (NeuRet) vector and adeno-associated virus (AAV) vector. We injected NeuRet vector carrying Cre recombinase gene into the striatum in mice to induce the gene expression in neuronal populations innervating the striatum. AAV vector containing a double-floxed inverted open reading frame encoding a gene of C3 transferase, which is known as a general Rho inhibitor, was injected into the cerebral cortex of NeuRet vector injected mice to suppress the activity of Rho specifically in corticostriatal neurons. Expression of C3 transferase caused the remarkable decrease in the number of corticostriatal neurons. These results indicate that Rho signaling pathway plays a crucial role in the survival of corticostriatal neurons.

Title: RNA-lipid nanoparticles: a robust and potent tool for gene knockdown and expression in primary neurons

Authors: A. S. ANSARI[1], D. ZWAENEPOEL[1], A. K. WHITE[2], C. L. WALSH[1], A. THOMAS[1], T. LEAVER[1], A. WILD[1], Y. LI[3], Y. WANG[3], J. R. TAYLOR[1], *E. RAMSAY[1], C. HANSEN[4],

P. CULLIS[5];

Abstract: There is an unmet need for an efficient delivery tool to facilitate the use of RNA to manipulate gene expression in the mammalian central nervous system. Here, we describe a solid-core lipid nanoparticle (LNP) system, developed by employing the microfluidics-based NanoAssemblr platform, capable of delivering RNA into neurons *in vitro* and *in vivo* with high efficiency and low toxicity. The lipid nanoparticles are taken up by 96% of primary neurons within the first 4 hours of treatment. This rapid uptake provides flexibility in experimental design and downstream procedures. Primary neurons exhibit > 85% gene knockdown, which is sustained for 21 days after LNP administration, even at a dose as low as 100 ng/ml of siRNA-LNP. When exposed to mRNA-LNP, primary neurons exhibit > 80% reporter gene expression. A single treatment of 500 ng/ml of mRNA-LNP results in sustained expression of the reporter gene for 7 days post transfection. Investigation of mRNA-LNP induced protein expression at various timepoints with different particle exposure times showed expression of the protein after just 4 hours of LNP administration. This allows for the integration of this system with other procedures in time-sensitive studies. The performance of these RNA-LNP systems is further characterized by looking at their effect on individual cells, in order to gain insight into the response seen in a bulk population. This is facilitated by the use of a microfluidic device capable of carrying out high-throughput single-cell digital PCR and hence precise quantification of RNA levels in hundreds of individual cells. A 9.8-fold mean reduction in mRNA abundance was observed, when the number of GAPDH mRNA transcripts were measured at the single cell level, in response to treatment with GAPDH siRNA-LNP. Single-cell digital PCR also confirmed the presence of reporter gene mRNA in >99% of cells 24 hours after mRNA-LNP administration. These single-cell studies are important to understand cell-to-cell heterogeneity in terms of quantity of delivered RNA, and its correlation within a cell to changes in gene expression. Examination of cell-to-cell variability, kinetics, and efficiency of using this lipid nanoparticle technology for nucleic acid delivery, demonstrates the potency of the developed RNA-LNP system as well as provides an informed basis for optimizing the manipulation of gene expression in neuronal cells. This technology, thereby, offers a simple and versatile solution to enable loss- and gain-of-function studies in difficult-to-transfect primary neurons.

Title: Generation of region-specific induced neural precursors following SOX2/PAX6 transfection of adult human fibroblasts

Authors: *R. LIU, E. FIRMIN, K. JONES, B. CONNOR;
Univ. of Auckland, auckland, New Zealand

Abstract: Somatic cell reprogramming is an innovative field with considerable potential to enhance our understanding of developmental processes. We previously demonstrated that adult human dermal fibroblasts (aHDFs) can be directly converted to neural precursors by over-expression of the transcription factors SOX2 and PAX6, using non-viral plasmid transfection1. Induced neural precursors (iNPs) express a wide range of neural stem/precursor and pro-neural genes and upon differentiation give rise to GFAP+ astrocytes and functionally mature neurons expressing TUJ1, MAP2, NSE, and subtype specific markers TH, calbindin, DARRP32 and GAD65/67. The aim of the current study was to investigate the temporal profile of neural stem and pro-neural gene expression during the conversion of aHDFs to iNPs to determine whether reprogrammed iNPs express the same sequential gene profile as per human neural development, or if they represent defined regions of the developing brain. Expression of genes controlling neural induction, forebrain, midbrain and hindbrain specification were examined through qPCR at weekly time points throughout iNP reprogramming. During early expansion (days 38-45 post transfection), iNPs predominantly expressed the anterior forebrain marker LHX2 and the LGE markers GSH2 and DLX2. The iNPs from late expansion (days 52-66 post transfection) expressed the forebrain markers LHX2, FOXG1, SIX3, and the LGE marker GSH2. The MGE markers NKX2.1 and ASCL1, and the midbrain/hindbrain markers OTX2 and GBX2 were not expressed at any stages of reprogramming. This demonstrates that aHDF-derived iNPs do not express the gene expression profile observed in hESCs or iPSCs, possibly due to the stochastic process of direct reprogramming of iNPs. However, iNPs do exhibit gene expression representative of anterior neuroectoderm initially, and then a telencephalic glutamatergic and GABAergic phenotype with preference for ventral LGE fate. To support this, we observed that differentiation of iNPs retained their transcriptional identity and generated a population of neurons expressing the subtype specific markers GAD65/67, DARRP32 and vGLUT. Overall, these results indicate that direct reprogramming of aHDFs to iNPs by plasmid transfection of SOX2 and PAX6 generates a heterogeneous population of neural precursor cells. 1.Maucksch,

Title: Rapid block of unaltered endogenous receptors *in vivo* with a genetically-targeted drug

Authors: P. F. APOSTOLIDES, C. KIM, B. C. SHIELDS, J. BROWN, E. KAHUNO, S. VAIDYA, J. T. DUDMAN, J. C. MAGEE, L. D. LAVIS, *M. R. TADROSS;

Abstract: Drugs are fundamental to molecular neuroscience and neurotherapeutics. Because drugs act broadly within a tissue, their cell-type-specific mechanisms of action have been elusive−a limitation exaggerated by the enormous diversity of cell types in the brain. Here, we describe a straightforward approach to restrict a broadly-active drug to genetically-specified cells in awake-behaving mice. The technique manipulates unaltered endogenous receptors within minutes, affording a combination of protein specificity, cell-type specificity, and speed of onset not previously achieved. In healthy mice, targeting the same drug to spiny projection neurons of the direct (dSPN) versus indirect (iSPN) class yields opposing effects on locomotion. In hemiparkinsonian mice, dSPN drug targeting has remarkably little behavioral consequence, whereas iSPN targeting yields substantial therapeutic benefit−findings relevant both to the molecular etiology and treatment of the disorder. The approach is modular, and may generalize to many drugs with significance to neural circuits and therapeutics.

Title: Highly restricted mouse driver strains via transposon-based enhancer trapping

Authors: *Y. SHIMA[1], C. HEMPEL[1], K. SUGINO[1], P. TANEJA[1], J. BULLIS[1], C. LOIS[2], S. NELSON[1];
[1]Biol., Brandeis Univ., Waltham, MA; [2]Biol., Caltech, Pasadena, CA

Abstract: There is a continuing need for driver strains to enable cell type-specific manipulation in the nervous systems. Establishing transgenic lines has been the most reliable method to access restricted neuronal populations. However, most current mouse transgenic strategies are designed to copy endogenous gene's expression patterns (promoter-based methods). These methods, such as BAC transgenesis and homologous recombination, have successfully generated many useful lines using specific marker genes associated with specific neurotransmitters and brain regions. However, for many cell types, specific markers are not known, while for others the available markers label a very large number of populations in the brain limiting usefulness for some applications. . Here we explore the alternative method of enhancer trapping. This has been widely used in model animals such as fly and zebrafish but few large-scale enhancer trap screens have been performed in mice, in part because of the low efficiency of traditional methods of transgenesis. We developed an efficient enhancer trapping method using the PiggyBac transposon. Each cross between an animal carrying a single-copy PiggyBac transposon and an animal carrying the transposase can generate new transgenic lines with novel PiggyBac insertion sites. Our enhancer trap probes contain tet-transactivator and a tet-dependent fluorescent reporter to enable expression screening without crossing with reporter lines. Through our screening over 200 founders have been established and most had expression in brain. We have obtained various lines with restricted labeling such as specific cell types in cerebellum, sublayers of cerebral cortex, and thalamic nuclei. We have confirmed most of our lines keep stable expression patterns over many generations. Tet-dependent AAV can drive cell-type specific expression of genes of interest. Images and data of our lines can be browsed at our web site (http://enhancertrap.bio.brandeis.edu/).

Title: Generation of transgenic marmosets expressing genetically encoded calcium indicator GCaMP

Authors: ***J. PARK**[1], X. ZHANG[1], S.-H. CHOI[1], J. PICKEL[2], J. OKAHARA[3], E. SASAKI[3], A. C. SILVA[1];
[1]CMS, LFMI, NINDS, NIH, Bethesda, MD; [2]NIMH, NIH, Bethesda, MD; [3]Dept. of Applied Developmental Biol., Central Inst. for Exptl. Animals, Kawasaki, Japan

Abstract: The chronic monitoring of neuronal activity in the living brain has become feasible as a result of continued development of optical imaging techniques and genetically encoded calcium indicators (GECIs). The green fluorescent protein based GECIs, GCaMPs, have been considered a visible marker of neural activity as these molecules fluoresce upon calcium binding. They can be targeted to specific cell types when used in combination with cell type-specific promoters and can be delivered through transgenic techniques. The common marmoset (Callithrix jacchus) is an important nonhuman primate model in neurophysiological research.

Recently, the successful demonstration of germline transmission confirmed transgenic marmoset has brought greater interest in this species. Here we report the generation of transgenic marmosets that express GCaMPs under the control of either CMV or hSyn promoter. High-titer lentiviral vectors expressing GCaMP under the control of the CMV or hSyn promoter were produced and injected into marmoset embryos that were collected by nonsurgical uterine flushing or laparotomic follicular aspiration followed by *in vitro* maturation and fertilization. Single cell to morula stage embryos injected with lentiviruses encoding CMV-GCaMP5G, CMV or hSyn-mKO-GCaMP6S were transferred to 14, 10 and 20 surrogate mothers, respectively. Twelve of them (three CMV-GCaMP5G, three CMV-mKO-GCaMP6S, and six hSyn-mKO-GCaMP6S) became pregnant and 6 transgenic babies were born. The transgene was detected by PCR using genomic DNA extracted from the mouth swabs and hair roots of six babies. Flow cytometric analysis of peripheral blood samples showed GCaMP positive cells in transgenic marmosets with CMV promoter. The spinal cord tissue was collected from one transgenic marmoset with neuron specific promoter that survived for less than a day, and neuronal GCaMP expression was detected via immunohistochemical image analysis. These results are important steps in developing transgenic marmosets that robustly express calcium sensors for functional optical imaging of neural activity.

Title: MicroRNA-guided neuron tags (mAGNETs) exploit a novel framework for genetically targeting neural subtypes in the mammalian brain

Authors: *M. K. SAYEG, B. H. WEINBERG, S. S. CHA, M. GOODLOE, S. SHAIKH, W. W. WONG, X. HAN;
Biomed. Engin., Boston Univ., Boston, MA

Abstract: The ability to genetically modify specific neural subsets is essential in elucidating their contributions to brain computation and disease. Recently, we developed a novel strategy for targeting transgene expression to neuronal subtypes by exploiting endogenous microRNA (miRNA) regulation, which we call miRNA-guided neuron tags (mAGNETs). miRNAs are small (~20 nt), non-coding RNAs that inhibit gene expression by hybridizing to complementary recognition sites within mRNA transcripts. Because different miRNAs are upregulated in specific cell types, we are able to target gene expression by including “signature” miRNA recognition sites at the end of mAGNET transcripts. Exploiting miRNA regulation to target gene expression is an attractive technique for brain research due to the small footprint of miRNA sites (which facilitates viral packaging), the potential to engineer combinations of miRNA sites to tune selectivity, and the possibility of targeting the many neuron types in the brain for which no cell type specific promoters have been identified. As a proof of principle demonstration, we designed and tested mAGNETs that target EGFP expression to cortical inhibitory neurons in the mouse brain.

Title: *In vivo* photoacoustic imaging of cerebrospinal fluid spaces in mice

Authors: *E. MATHIEU[1,2,3], M. FIRAS[3,4], C. HUPPLE[5], Y. YUCEL[1,2,3,4];
[2]Ophthalmology & Vision Sciences, Lab. Med. & Pathobiology, [1]Univ. of Toronto, Toronto, ON, Canada; [3]Keenan Res. Ctr. for Biomed. Science, St Michael's Hosp., Toronto, ON, Canada; [4]Med. Physics, Fac. of Sci., Ryerson Univ., Toronto, ON, Canada; [5]iThera Med. GmbH, Munich, Germany

Abstract: Introduction: Cerebrospinal fluid (CSF) fulfills various roles in the central nervous system and its improper drainage is implicated in a number of neurological disorders. At present, there is a lack of available *in vivo* techniques for studying CSF flow in mice, a particularly useful species due to the availability of transgenic animals. The purpose of this study was to establish a novel *in vivo* assay for detection of CSF spaces and clearance in mice using a near-infrared fluorescent tracer and multispectral photoacoustic (optoacoustic) imaging. **Methods**: Male CD1 mice (n=4) received CSF injections of IRDye800CW (LI-COR Biosciences, NE, USA) conjugated to 7.5 kDa polyethylene glycol, followed by photoacoustic imaging of the head with a Multispectral Optoacoustic Tomography system (MSOT, iThera Medical, Germany). Under general isoflurane anesthesia (2% in O_2), the head and neck were shaved and hair was removed with depilatory cream. Mice were positioned in a stereotaxic frame and 3 μL of tracer was injected into the CSF of the cisterna magna through a suboccipital incision. The injection site was closed with cyanoacrylate tissue glue, the head and neck were coated in a thin layer of ultrasound gel, and mice were placed in a dorsal recumbent position in the scanning chamber. A 13 mm scan region was defined between the posterior orbits and start of the spinal cord. Mice were scanned prior to CSF injection and then continuously every 2.5 minutes after injection for 28 (n=2), 35 (n=1), or 40 (n=1) minutes. Multispectral photoacoustic data was reconstructed (ViewMSOT, iThera Medical, Germany) and linear regression was used for unmixing spectral components to visualize IRDye 800 signal distribution. Tracer signal was quantified over time in a region of interest corresponding to the subarachnoid space (SAS) of the hindbrain. **Results**: The photoacoustic signal of near-infrared tracer was readily identified in the cerebral subarachnoid space, ventricles and basal cistern. Time-course quantification of the IRDye 800 signal in the hindbrain SAS showed an initial increase in signal with a plateau 15-20 minutes after injection, followed by a steady decrease until imaging was discontinued. **Conclusions**: These preliminary results provide the first evidence that multispectral photoacoustic tomography can be used as a novel *in vivo* assay to qualitatively and quantitatively assess CSF spaces in mice. This technique may be a valuable tool for the study of cerebrospinal fluid clearance in the healthy mouse and in various models of neurological disorders.

Title: Cell-specific optical perturbation of electrical activity *in vivo*

Authors: A. FORLI, C. MORETTI, S. BOVETTI, *T. FELLIN;
Inst. Italiano di Tecnologia, Genova, Italy

Abstract: The ability to determine the spatial and temporal patterns of neuronal activation in response to external sensory stimuli using well-established tools as *in vivo* two-photon microscopy is revolutionizing our understanding of how sensory inputs are processed at the cellular level. However, to causally investigate how these spatial and temporal patterns of neuronal activity encode information about the external stimulus, we lack a complementary method that makes it possible to perturb the activity of many neurons with cellular resolution. To achieve this goal, we combined two-photon patterned illumination to control the size and shape of the two-photon focal volume with photostimulation experiments to perturb the spiking activity of single neurons expressing the excitatory opsin channelrhodopsin-2 (ChR2). Patterned illumination was obtained using a commercial liquid crystal spatial light modulator which was placed in a plane optically conjugated to the objective back aperture. In simultaneous photostimulation and two-photon-guided juxtasomal recordings from ChR2-positive cells in the neocortex of anesthetized mice, we found reliable increase in the firing rate of recorded neurons upon patterned two-photon (λ = 920 nm) illumination with extended shapes. Cellular response increased with light intensity (average power, 10-50 mW) and ChR2-positive neurons up to a maximal depth of 150-200 μm could be reliably photostimulated within this power range. The spatial resolution of photostimulation was ~ 30 μm in the radial direction and ~ 40 μm in the axial direction. Experiments are currently ongoing to investigate the effects of illumination with

different shapes on the suprathreshold response of individual neurons and to characterize these different stimulation protocols in terms of efficiency and spatial resolution. By precisely manipulating the activity of neuronal networks in space and time, this technique provides the basis for the investigation of how neuronal patterns of activation can encode information.

Abstract: Accurate detection of action potentials is key to the study of neuronal networks. Intracellular free calcium concentration is a reliable indicator of neuronal activity, and calcium-sensitive fluorescent indicators have proven useful tools. Indeed, detecting action potentials using 2-photon calcium transient imaging offers advantages over standard electrophysiological approaches as it enables up to thousands of spatially and immunohistochemically defined neurons to be recorded from simultaneously. Recently, we introduced a novel approach to calcium transient detection by making use of finite rate of innovation (FRI) theory (Vetterli et al 2002 IEEE Trans. Signal Process. 50:1417-28). This method enabled us to retrieve the timing of action potentials from calcium transient time series using both surrogate data and real data (obtained by simultaneous electrophysiology and 2-photon imaging of calcium dye signals in cerebellar Purkinje cell dendrites) (Oñativia et al 2014 J. Neural Eng. 50:046017). We have now extended and optimised this algorithm to detect calcium transients with kinetics corresponding to the genetically encoded calcium indicators GCaMP6s and GCaMP6f and the calcium-sensitive fluorescent dye Oregon Green BAPTA (OGB). Upon performing test simulations using surrogate data, the FRI algorithm was able to achieve a high spike detection rate for each fluorescent

indicator, regularly detecting above 90% of spikes. No false positives were produced in 81% of surrogate data (for a spike rate of 0.25Hz, false positive rates were OGB: 8.7x10-3Hz; GCaMP6S: 7.1x10-3Hz; GCaMP6f: 3.4x10-4Hz). The temporal location of GCaMP6s spikes is estimated with the highest accuracy, which can be attributed to its comparatively high signal-to-noise ratio. However, if the comparison of spike detection performance is made linear in terms of signal-to-noise ratio, the fastest decaying pulse, that of GCaMP6f, outperforms both OGB and GCaMP6s (by average spike detection rate margins of 2.1% and 4.3%, respectively). We are now introducing real data from single-neuron and population responses to vibrissae deflection in Layer 2/3 of identified columns in mouse somatosensory (barrel) cortex, using *in vivo* 2-photon imaging to validate the algorithm. Implementation of this algorithm will prove a useful tool for analysis of neuronal network dynamics both within the somatosensory cortex, and across additional cortical areas associated with other sensory modalities (eg. vision, audition, proprioception).

Title: Toward voltage imaging in the live mouse brain with enhanced Rhodopsin based voltage sensors

Authors: *Y. ADAM[1], Y. ZHAO[2], M. A. MOSTAJO-RADJI[1], P. ARLOTTA[1], R. E. CAMPBEL[2], A. E. COHEN[1];

Abstract: Optical detection of action potentials in the intact mammalian brain will open new frontiers in neuroscience research. Archaerhodopsin-based voltage sensors exhibit voltage-sensitive fluorescence, with a sensitivity and speed of response far greater than any other protein- or dye-based voltage indicator. Although they perform well in cultured cells, these indicators are difficult to implement *in vivo* due to their dim fluorescence and poor membrane trafficking. To address these limitations, we designed a series of modified sensors, based on the QuasAr backbone previously developed by our lab. Our panel of constructs included chimeras with other rhodopsins, different fluorescent fusion proteins and linkers, additional signal peptides as well as

rational point mutations. These constructs were then expressed in primary hippocampal neurons and evaluated by measuring their brightness and their signal to noise ratio (SNR) for optically induced action potentials. Constructs that showed significant improvement were then expressed *in vivo* using *in utero* electroporation and tested in acute brain slices. Our screen resulted in new variants of QuasAr, which show significantly improved membrane trafficking as well as brighter fluorescence. These constructs allow high fidelity recording of single spikes in acute brain slices at single cell resolution, and they are currently under evaluation in the live mouse brain.

Title: *In vivo* chronic macroimaging of sensory representation in marmosets

Authors: *Y. MATSUMOTO[1,2], Y. YAMADA[1,2], K. MIKOSHIBA[1,2];
[1]Brain Sci. Institute(bsi), RIKEN, Saitama, Japan; [2]Central institute for Exptl. Animal, Kawasaki, Japan

Abstract: Marmosets represent an attractive primate species for neuroscience research due to 1) ease of handling with the small body size; 2) high reproductive rate and short gestational period; 3) applicability of transgenesis technology. Based on these advantages, several neurological disorder models (e.g. Parkinson's disease, Alzheimer's disease and amyotrophic lateral sclerosis (ALS)) have been recently established with marmosets. To understand the underlying neuronal mechanism of these models, the experimental technique to chronically track the neuronal ensemble activity has been required. Here we established epifluorescent macroimaging of flavoptotein as well as genetically encoded Ca^{2+} indicator GCaMP in marmosets. We have successfully revealed a somatotopic map in the primary somatosensory cortex (area 3b) using electrical stimulation applied to contralateral body parts. Similar activation patterns were

observed with flavoprotein and GCaMP, the latter displaying better signal to noise ratio. The somatotopic map could be stably recorded up to 8 weeks. The responsiveness to sensory stimuli and spontaneous activity rate were found to be much higher under awake state than under anesthetized state. Our experimental system can be applied to other cortical areas, and will be useful for studying the evolution of brain dysfunction underlying neurological disorder.

Title: Visualizing neuronal activities of the deep brain in a freely-moving mouse by using implantable micro imaging devices

Authors: ***Y. OHTA**, M. MOTOYAMA, M. HARUTA, H. TAKEHARA, T. NODA, K. SASAGAWA, T. TOKUDA, J. OHTA;
Grad. Sch. of Materials Sci., Nara Institue of Sci. and Technol., Nara, Japan

Abstract: The mesolimbic dopamine system concerning reward pathway like VTA-NAc circuit has been studied with interest, but few studies have reported direct visualization of neuronal activities. Imaging neuronal activities in a mouse deep brain area such as VTA or NAc is, however, extremely difficult without disturbing behavior of an awake mouse. In order to address this issue, we have developed an implantable micro imaging device [1]. We have successfully visualized activities of GFP-labeled dopamine neurons and GABAergic neurons in the deep brain region of a mouse which was administrated with ethanol acutely. Our device has micro needle shape (width: 0.7mm, thickness: 0.2mm) so as to be suitable for the implantation into deep brain with minimal invasiveness. The device consist of a dedicated CMOS (Complementary Metal Oxide Semiconductor) image sensor and one or two blue LEDs (center wavelength: 460nm) placed on the sides of the sensor to excite GFP. The sensor has 40 x 90 or 40 x 120 pixels with the pixel size of 7.5 μm square. The sensor surface is covered with a filter to cut off the excitation light and to pass the fluorescence of GFP (center wavelength: 520nm). In the experiment, we visualized activity of DP neurons in freely moving TH (tyrosine hydroxylase) transgenic mice expressing GFP in the majority of midbrain dopamine neurons [2]. We

anesthetized a TH-GFP mouse and implanted our device into VTA, in the depth of 4.5mm from the brain surface. In the next day of the implantation, we have demonstrated to visualize the activities of somas of DP neurons in VTA for six hours after oral alcohol administration and successfully measured the intensity change of the GFP luminescence. Since the device is small and light, it can be applied to a multi-point measurement. We have visualized the activity of the GABAergic neurons by a similar method to observe the network of the nerve of the reward system. Two devices were implanted into both NAc shell region and lateral part of the central nucleus of the amygdala in GAD67 (glutamic acid decarboxylase 67) -GFP transgenic mice [3] and successfully visualized network of brain functions at the same time under freely behaving. Since our device has already been confirmed operation in a mouse brain over three months, we are planning an experiment to observe the long term change of neuronal activities in the same mouse. Title: Temperature changes in the brain slice by NIR optical stimulation

Authors: ***S. MIN**, M. YOO, S. KIM;
Gwangju Inst. of Sci. and Technol. (GIST), Gwangju, Korea, Republic of

Abstract: For more than a decade, optical stimulation has been studied as a new tool that can replace the conventional electrical stimulation method to modify neuronal activities. Since temperature increases by optical stimulation have been proven to be the main reason for neuronal modulation, how the optical stimulation parameters would control temperature increases and heat distribution in the brain tissue needs to be investigated to utilize optical stimulation as an efficient tool to stimulate only targeted neurons. In the present study, we studied thermal changes in brain slices by applying various modes of optical stimulation. A male C57BL/6 mouse was decapitated and the brain was extracted. Brain slices were prepared by dissecting the brain with a thickness of 400 μm using a vibratome (VF-200, Precision Instruments). Optical stimulation

using near infrared laser with a wavelength of 808nm and intensities from 1.72 to 35.4 ㎽ was applied to the brain slices in continuous and pulsed modes. The core diameter of the optical fiber was 62.5 μm. The temperature change in the brain slice under laser illumination was measured using an infrared camera (FLIR SC5000, FLIR Systems, Boston, MA). Using continuous waves with intensities of 35.4 and 1.72 mW, the temperature in the brain tissue increased by 1.42℃ and 0.1℃, respectively. The size of the heated area was observed to be around 2.08 mm with the stimulation power of 35.4 ㎽. On the other hand, when pulsed laser with the width of 5 ㎳ and the pulse train duration of 100 ㎳ at the repetition rate of 5 Hz was applied, the affected area was observed to be about 180.2 μm at the same stimulation power of 35.4 mW, and the temperature increased by 1.8℃. This result suggests that pulsed waves provided a better spatial resolution by limiting heat transfer within the restricted area. It is concluded that pulsed laser stimulation affects a significantly smaller area thermally, suggesting that it would provide a better thermal spatial selectivity than that of continuous wave and the possibility that the size of affected areas could be controlled by controlling the pulse width. Also, we found that as the power of optical stimulation increased, larger temperature increases were observed, implicating that the degree of neuronal modulation would be controllable by controlling the laser power level. As further study, we will measure the changes in neural activity by using simultaneous electrophysiological recording and calcium imaging that would provide both detailed temporal and spatial information while optical stimulation is applied.

Abstract: The combination of two-photon microscopy with genetically-encoded calcium indicators enabled researches to chronically monitor neuronal population activity in behaving animals, opening up an avenue to investigating the organization of neural circuits and its plasticity. This technique has been successfully applied to a variety of invertebrates and vertebrates including flies, fish, and rodents. However, thus far, the application of this technique to the primate brain has had severe limitations in terms of the number of simultaneously imaged neurons and its ability to follow the same neuron population over a long time period. One reason of this difficulty is that stronger fluorescent signals are required for clear visualization of calcium signals, because primate brains are less transparent than rodent brains. Here, we present a novel system to chronically image the activity of cortical neurons of the adult marmoset (Callithrix jacchus), a small New World primate. In this system, the subject is head fixed under a two-photon microscope in anesthetized state. A chronically implanted optical window provides access to the cortical surface. The activities of cortical neurons are monitored by GCaMP6f, expressed from an AAV vector-based high expression system. Using this system, we succeeded in monitoring spontaneous neuronal activities of cortical neurons up to 3 months. Importantly we were able to simultaneously image more than a hundred of neurons three dimensionally at high speed, which proved the effectiveness of our system. In conclusion, our system has made it possible to monitor neuronal population activities from primate neocortex with unprecedented quality, and it will be applicable to functional analysis of neuronal population activity in behaving marmosets.

Title: Light-controlled activation of neurons via a graphene-based biocompatible optoelectronic interface

Authors: E. MOLOKANOVA[1], G. B. BRAUN[2], A. ALMENAR-QUERALT[3], A. ZARETSKI[4], L. S. B. GOLDSTEIN[3], M. MERCOLA[5], *A. SAVTCHENKO[5];

Abstract: A light signal is the perfect trigger to reversibly control functional activity of a neuron in a spatially resolved and temporally precise manner. Optogenetics uses genetically encoded light-sensitive proteins to achieve this goal, but in certain cell systems (e.g., stem cell-derived neurons), it is not desirable to express exogenous proteins due to potential side effects. Thus, there is a need for an external light-controlled triggering platform for remote activation of intact non-modified neurons. Considered “the wonder material of the 21st century”, graphene has a unique combination of properties - broadband absorption, high electrical conductivity, high charge carrier mobility, and high transparency, making it very attractive for the proposed graphene-based biointerface for neuronal activation. By rapid generation of free charge carriers under light illumination, we expect a capacitive coupling effect to occur between the neuronal membrane and the local graphene surface resulting in membrane depolarization and subsequent action potential generation. Here we developed a novel graphene-based biointerface and studied its effect on human iPSC-derived neurons. First, using fluorescent and scanning electron microscopy, we confirmed exceptional compatibility of these biointerfaces with long-term cell culture. Then we demonstrated the ability of the graphene-based biointerface to activate neurons by intermittently illuminating them with light while performing electrophysiological recordings. Lastly, taking into account high transparency of the graphene-based biointerface, we explored its utility for all-optical electrophysiology that combines light-controlled activation with optical recording methods. Indeed, in our experiments, we were able to trigger action potentials in

neurons by light illumination of the graphene-based biointerface, and simultaneously monitor the resulting changes in intracellular calcium concentrations using fluorescent calcium indicators. In summary, we present a novel graphene-based optoelectrical biointerface for activation of neurons via external light-controlled electric field. This biointerface is expected to be beneficial for studies of activity-driven neuronal maturation, long-term effects of environmental, pharmacological or genetic factors, and activity-driven corrections in "disease-in-a-dish" models.

Title: A compact multifunctional laser scanning imaging system developed on open source hardware

Authors: *X. LI, K. BORGES, G. M. G. SHEPHERD;
Physiol., Northwestern Univ., Chicago, IL

Abstract: To investigate the functions of neural circuits in the mouse motor system, we are developing an economical, compact, multifunctional 2-photon laser scanning imaging system combined with a portable behavioral task monitoring system. The microscope is developed on optical, mechanical, and electronic parts available as stock items from commercial suppliers, with a small number of custom-made components. The frame of the microscope is built around a horizontal platform. A rotating head allows *in vivo* imaging off the vertical axis, a useful feature for imaging more laterally located cortical areas such as auditory cortex. The beam path can be switched between two different laser scanning modules: (1) a pair of mirror galvanometers (G-G scanner; Cambridge Technology), or (2) a resonant-galvanometer (R-G) scanner (Sutter). Switching is executed by an Arduino based remote control motorized switch. An optogenetic laser scanning photostimulation module can be added in parallel with the 2P imaging modules. The structure of the microscope is very flexible and expandable, new 2D photostimulation

modules such as a digital mirror device (DMD) and spatial light modulator (SLM) can easily be attached. An electrically focus-tunable lens can be attached to the objective to enable fast 3D imaging and photostimulation. The hardware is operated by ScanImage software, and interfaced via National Instrument DAQ boards. In the portable behavior rig, a mouse's locomotion drives a trackball or treadmill, which in turn is interfaced with an Arduino that is programmed with the task paradigm. This Arduino also does basic real time data analysis and triggers the imaging and/or photostimulation from the microscope. A single-board computer (e.g. Raspberry Pi, BeagleBone) as the host controller sets the parameters of the behavior paradigm, and collects, stores, and visualizes the mouse behavioral data streamed from the behavior Arduino. The software is developed in Labview, Matlab, Arduino (and AVR C), and Python.

Title: *In vivo* three-photon excited fluorescence imaging of neural activity in the spinal cord of awake mice

Authors: ***Y.-T. CHENG**[1], I. M. BASTILLE[2], J. CRUZ HERNANDEZ[2], D. G. OUZOUNOV[3], T. WANG[3], X. LI[2], N. NISHIMURA[2], J. R. FETCHO[1], C. XU[3], C. B. SCHAFFER[2]; [1]Neurobio. and Behavior, [2]Biomed. Engin., [3]Applied and Engin. Physics, Cornell Univ., Ithaca, NY

Abstract: Imaging of calcium-sensitive indicators using nonlinear microscopy enables minimally-invasive studies of neuronal activity and circuit dynamics at high spatial and temporal resolution. Due to strong optical scattering from myelinated axons in the dorsal spinal cord, traditional two-photon excited fluorescence (2PEF) imaging is able to visualize cell structure or neural activity only in superficial regions. Current approaches to investigate neuronal circuits in deeper mid/ventral regions of the spinal cord rely primarily on explanted spinal cord preparations, so are unable to capture the full complexity of the system. We recently showed that three-photon excited fluorescence (3PEF) microscopy enables significantly increased penetration into scattering samples as compared to 2PEF imaging (Horton NG, et al; 2013 Nat Photonics).

Here, we demonstrate 3PEF imaging deep into the spinal cord of mice using both 1300 and 1700-nm excitation wavelengths. We implanted the long-term spinal cord imaging chamber we previously developed (Farrar MJ, et al; 2012 Nat Methods) into C57Bl/6 mice. In some mice, the vasculature was labeled with intravenous injections of Fluorescein- (1300 nm excitation) or Texas Red-dextran (1700 nm excitation) and we were able to visualize vascular structure and quantify blood flow in individual vessels at depths of up to 500 μm, or about 50% of the way through the spinal cord. In other mice, we injected adeno-associated viral vectors to drive expression of the genetically encoded calcium sensitive fluorescent protein, GCaMP6, in spinal cord neurons. We delivered electric stimulation to the hind paw while the animals were anesthetized and observed robust neuronal responses (normalized change in fluorescence > 50%) in dorsal horn neurons at a depth of ~200 μm. Finally, we developed a spinning disk treadmill that enables awake mice to be held fixed under the microscope by the spinal cord chamber while able to walk and run on the treadmill. When combined with quantitative tracking of limb motion, this capability for 3PEF imaging of cell-resolved neuronal firing in the spinal cord of awake, moving mice could enable detailed studies of, for example, the patterns of neural activity in central pattern generator circuits that underlie locomotor function.

Title: Mapping large-scale functional connections with chr2-evoked hemodynamic signals

Authors: *A. Q. BAUER[1], G. BAXTER[2], A. KRAFT[3], M. BRUCHAS[4], J.-M. LEE[3], J. CULVER[2];

[1]Radiology, Washington Univ. In St. Louis, Saint Louis, MO; [2]Radiology, [3]Neurol., [4]Anesthesiol., Washington Univ. in St. Louis, Saint Louis, MO

Abstract: A major goal of neuroscience is the development of a connectome for understanding structural and functional connections of the brain. Resting-state functional connectivity (RS-FC) analysis using fMRI has been important for mapping the brain's functional architecture through analysis of spontaneous hemodynamic fluctuations. However, because these oscillations reflect meso-scale activity from ensembles of different types of neurons, FC mapping with fMRI lacks the specificity for measuring how FC within a subpopulation of neurons contributes to the entire network. Optogenetic methods are a natural approach for probing local and global brain circuitry. But, mapping the entire cortex with fMRI optogenetically is challenging due to space constraints, and signal to noise limitations prevent linking these functional subcurcuits to RS-FC patterns. To satisfy this need, we combined optogenetic mapping with optical intrinsic signal imaging in 5 awake Thy1-ChR2 mice. (Fig.1A). We first established that we could elicit hemodynamic responses (HRs) in these mice (Fig. 1B, C), and then titrated optical stimuli to define a regime over which stimulated circuits produce linear HRs (Fig. 1D). These optical stimuli were then scanned over the left hemisphere to generate a functional connectome for Thy1-based circuits (Fig. 1E). Photostimulation of left barrel cortex (S1BC) produces hemodynamic responses in S1BC as well as highly correlated activity in motor cortex (M1) (Fig. 1F, Barrel) that agrees with anatomy (Fig. 1G). Interestingly, while stimulation of M1 evokes a reciprocal connection with S1BC (Fig. 1F, Motor), the time course of S1BC activity to M1 stimulation is less coherent. Further, RS-FC maps of S1BC or of M1 exhibit less specific FC patterns, and do not show the same functional topography as ChR2-based fc maps (Fig. 1F bottom). Understanding how neurons integrate multiple inputs, and the function of coordinated population activity within the larger scope of a functional circuit may help deduce impaired functional relationships between cortical areas in disease models.

Title: High-resolution recording of neural activity by transforming intrinsic optical signals

Authors: ***M. J. WALL**, M. J. E. RICHARDSON, M. G. THOMAS, J. A. COVINGTON, M. S. TURNER;
Univ. of Warwick, Coventry, United Kingdom

Abstract: Understanding functional network dynamics in brain tissue requires chronic recording at high spatial and temporal densities, potentially across large areas of tissue. Existing experimental tools afford either a small number of high temporal-density channels at the cellular level which become overly invasive at high density or instead have recording durations limited by dye bleaching. It has long been known that the intrinsic optical properties of neural tissue are activity-dependent and thus have formed the basis of a non-invasive imaging technique. However, slow temporal dynamics and lack of correspondence with on going network activity, have limited their usefulness. A detailed quantitative analysis of this intrinsic optical signal (IOS) using a high frame rate camera (250 fps) has allowed us to develop a mathematical model that accurately reproduces the IOS from network activity for a range of network activities including: field EPSPs, population spikes, seizure-like bursts and spreading depression. Inversion of this forward model provides a simple procedure for converting IOS imaging data into a transformed IOS (tIOS) that mimics the local-field potential (LFP). This approach markedly increased the temporal resolution of IOS imaging from a timescale of minutes down to tens of milliseconds and also radically improved upon the spatial resolution. Using a standard camera (25 fps) the tIOS was used to characterise seizure-like activity in the neocortex and made it possible to localise the seizure onset zone for infrequent events within ~20 um. This would be very difficult to achieve using dye-imaging techniques because of their limited recording duration. Using tIOS requires little modification of standard electrophysiological imaging hardware, can be carried out with transmitted or reflected light and can be used on-line during experiments, thus has the potential for widespread adoption as an efficient method for monitoring network activity.

Title: Non-invasive functional neuroimaging in the mouse using diffuse optical tomography

Authors: *M. REISMAN, A. BAUER, Z. MARKOW, G. BAXTER, J. CULVER;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: The study of correlated spontaneous activity in functionally related brain regions using functional connectivity magnetic resonance imaging (fcMRI) has allowed comprehensive mapping of distributed brain networks in humans. Extending fcMRI to the mouse has been challenging due to necessary trade-offs between high resolution and high signal-to-noise in the small mouse brain volume. Instead, optical intrinsic signal (OIS) techniques have provided most of the observations of fc in the mouse brain. While effective, OIS requires scalp retraction and is limited to superficial cortical tissues. Diffuse Optical Tomography (DOT) provides non-invasive imaging, but current DOT systems are either too sparsely sampling to match the cortical resolution of OIS or are too slow for capturing functional response in the mouse brain. Here we develop a DOT system that combines the spatial sampling of camera-based systems with the rapid-imaging of structured light illumination to map brain activity in the mouse. The DOT system is comprised of a sCMOS camera and a digital micromirror device (Fig 1A) that produce ~10^6 source-detector pair measurements with 0.15mm spacing at a speed of ~10Hz. This system increases the spatial sampling by >10x over existing human functional neuroimaging DOT and increases the speed by >10x over previous CCD-based mouse DOT. Activations in the somatosensory cortex upon electrical stimulation of the forepaw are seen non-invasively, through the intact scalp (Fig 1B). Extending the technique to imaging spontaneous activity reveals the expected resting state fc maps within the cortex as previously observed using OIS, but with improved depth sensitivity (Fig 1C). Establishing analogous functional imaging in both mouse and man is one of the most promising strategies for providing clinical translation. We have developed a method for optical imaging of the mouse brain using DOT with structured light source patterns. This method extends our previous mouse neuroimaging techniques to image through the scalp and with increased sensitivity to deeper regions of the mouse cortex.

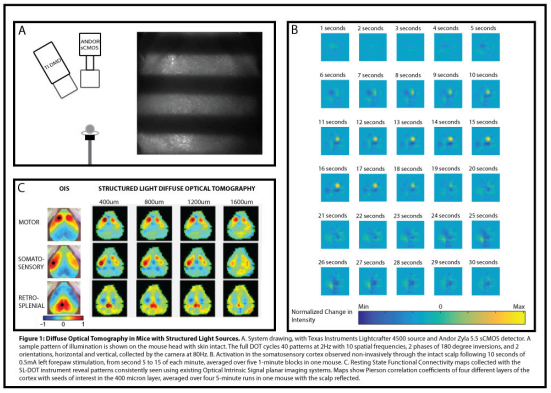

Figure 1: Diffuse Optical Tomography in Mice with Structured Light Sources. A. System drawing, with Texas Instruments Lightcrafter 4500 source and Andor Zyla 5.5 sCMOS detector. A sample pattern of illumination is shown on the mouse head with skin intact. The full DOT cycles 40 patterns at 2Hz with 10 spatial frequencies, 2 phases of 180 degree inversions, and 2 orientations, horizontal and vertical, collected by the camera at 80Hz. B. Activation in the somatosensory cortex observed non-invasively through the intact scalp following 10 seconds of 0.5mA left forepaw stimulation, from second 5 to 15 of each minute, averaged over five 1-minute blocks in one mouse. C. Resting State Functional Connectivity maps collected with the SL-DOT instrument reveal patterns consistently seen using existing Optical Intrinsic Signal planar imaging systems. Maps show Pierson correlation coefficients of four different layers of the cortex with seeds of interest in the 400 micron layer, averaged over four 5-minute runs in one mouse with the scalp reflected.

Title: Sparse MAP inference of cell shapes and spike trains from calcium imaging data with non-negative constraints

Authors: ***T. TAKEKAWA**[1], M. SATO[2], N. OHKAWA[3], K. INOKUCHI[3], Y. HAYASHI[2], T. FUKAI[2];
[1]Fac. of Informatics, Kogakuin Univ., Tokyo, Japan; [2]RIKEN BSI, Wako, Japan; [3]Dept. of Biochem., Univ. of Toyama, Toyama, Japan

Abstract: Calcium imaging technique is a powerful method for simultaneous recording the activity of large number of neurons. However, inferring the spike trains of neurons from calcium imaging movie data is often difficult, due to the noise, the low temporal resolution, unknown biophysical mechanism and parameters of calcium dynamics. Moreover we need further consideration of overlaps of cell position in the frames and signal crosstalks between these neurons especially in analysis of spike coincidence. Therefore many algorithms using different

approaches have been proposed to infer the approximately most likely spike train of each neuron from calcium imaging data. Recently, Vogelstein et al. (2010) propose an idea to sort calcium imaging data based on a simple outer product model of cell shape and fluorescence intensity change. However, their formulation had some problems about stability and convergence of algorithm. In this paper, we proposed a improved statistical model with prior of cell shape and spike frequency and a efficient implementation of the MAP inference algorithm to the model. The model assumes that calcium imaging movies can be reconstituted to the sum of fluorescence intensity of individual cells using a modified non-negative matrix factorization algorithm. Fluorescence intensities of each cell can be also assumed to be deconvoluted to spatial filter that represent the position and shape of cell and time variation derived from spiking activities. Each spike derives transient elevation of fluorescence intensity with double-exponential shape. Spatial filters and spike timings are estimated by two iterative steps. In first step of the algorithm, we prepare tentative spatial filters and estimate spike trains corresponding to respective filters by least-square approach with non-negative restraint condition. Consequently, spacial filters are also estimated using least-square method on condition that estimated spike trains are feasible. In addition, we introduced L1 sparse regularization derived from priors which represent typical cell size and spike frequency. Lastly we evaluated the method using both simulated data and actual calcium imaging data.

Title: Basic principle of Near Infrared Spectroscopy: Application in monitoring cerebral oxygenation and neuronal energy metabolism

Authors: K. SANNAGOWDARA[1], M. RANJI[3], *H. T. WHELAN[2];
[1]Pediatric Neurol., [2]Bleser Professor of Neurol., Med. Col. of Wisconsin, Milwaukee, WI; [3]Univ. of Wisconsin- Milwaukee, Milwaukee, WI

Abstract: We are exploring the possibility of combining regional cerebral oxygen saturation with neuronal energy metabolism utilizing near-infrared spectroscopy (NIRS) in conditions such as epilepsy, migraine, stroke and postural orthostatic tachycardia syndrome. Cytochrome c oxidase, also known as cytochrome aa3, is the final electron transporter enzyme in the mitochondrial respiratory chain. The redox state of cerebral mitochondrial cytochrome c oxidase (CCO) monitored with near-infrared spectroscopy (Δ[oxCCO]) is a signal with potential as a bedside biomarker of cerebral metabolic status. The relevant light wavelengths for Cytochrome c oxidase at approximately one microMolar brain tissue concentration is 600 nm for reduced-CCO, 650nm for oxidized-CCO as 620 nm serves as isosbestic point. The cyto-oximeter is a NIRS device, that will be used to detect cytochrome c oxidase redox state as well as regional cerebral oxygen saturation in-vivo and non-invasively. The oximeter uses light at multiple wavelengths to determine the relative changes in tissue oxygenation and blood volume. Near infrared (NIR) light is used for oximetry measurements because if its ability to penetrate tissues. For a 2-wavelength calculation, one below (short- 735 nm for deoxy-Hb) and one above (long- 850 nm for oxy-Hb) the isosbestic wavelength (805 nm) are used to calculate reduced and oxygenated hemoglobin. The short wavelength is attenuated more by reduced hemoglobin and the long by oxygenated hemoglobin. Measurements in absorption units (ΔOD) can be used to calculate the relative changes in the concentrations of reduced and oxygenated hemoglobin. The probe head contains a dual wavelength LED (light source) and four photodiodes (detectors). The detectors are arranged in a circle, each 2 cm from the LED and separated by 90° The LED and detectors are contained in a molded rubber probe head, which will be affixed to the patient. A daqboard will control the swithcing of the LED's and synchronize the readings from the multi-pixel photon counters (MPPC's). A software (labview) program will record the data generated by the sensors and perform basic signal processing to display the data in real time. The realtive optical densities of each of the wavelengths will be used to estimate the concentrations of oxidized & reduced cytochrome c oxidase (CCO). Available in two or four data channels, clinicians can conveniently monitor multiple brain and body areas Supported by Bleser Endowed Chair of Neurology (HTW) & Baumann Research Endowment (HTW)

Title: Simultaneous high speed, sensitive, sodium and calcium imaging from dendrites

Authors: *W. N. ROSS, K. MIYAZAKI;
New York Med. Col., Valhalla, NY

Abstract: High speed calcium imaging has been an important tool in examining synaptic events in dendrites. It can reveal information about events at locations in the dendrites that cannot be reached by patch electrodes and can aggregate information from many sites in the arborization. Sodium imaging can, in principle, reveal complementary information about dynamic processes that involve [Na+]i changes. However, there are far fewer studies using this technique, possibly because the fluorescence changes using currently available indicators are harder to detect than the [Ca2+]i changes. To take advantage of the potential information that sodium imaging can reveal we designed a system (a) with greater sensitivity than previous systems, (b) that can detect these signals at high speed (250 Hz or faster), and (c) can detect these changes at the same time as [Ca2+]i changes at the same locations. With this system we could simultaneously detect localized subthreshold synaptically activated [Na+]i and [Ca2+]i changes at multiples locations in the dendrites. In some cases these locations could be as small as individual dendritic spines. To achieve high speed and sensitivity we used a microscope with an Olympus 60X, 1.1 NA lens and a RedShirtImaging NeuroCCD 80x80 camera operated at 500 Hz. To detect [Na+]i and [Ca2+]i changes we injected cells with combinations of indicators that have separated excitation bands (either SBFI and OGB-1, or Bis-fura-2 and ANG-2 (a newly developed Na+ indicator from Teflabs)). High intensity LEDs, with excitation bands sharpened with narrow filters, provided illumination at the appropriate wavelengths. The LEDs we used had approximately 10X the intensity at key wavelengths as 75W Xenon lamps often used in similar experiments. Custom designed dichroic and emission filters inserted in a single filter cube allowed alternate detection of fluorescence from the two indicators when the LED source was changed. Quasi-simultaneous illumination was achieved by switching between LEDs every 2 ms with light pulse durations of about 1.8 ms. Alternate camera frames, synchronized with the switching of the LEDs, detected emission separately from each indicator. Control experiments showed that this switching protocol did not introduce additional noise into the system. Noise in each channel was dominated by the shot noise of the detected light. Software then separated the signals into two streams that were displayed along with simultaneously recorded membrane potential from the patch electrode. Localized responses from a single synaptic stimulus were often detected. The main limitation in the experiments was photodynamic damage from the high intensity illumination.

Abstract: Over the past decade, advancements in optical sensors and Genetically Encoded Calcium Indicators (GECIs) have led to new developments in optical recording techniques. These developments include wide-field and two photon head mounted miniaturized microscopes. Miniaturized microscopes have the potential to open up new avenues of research in neuroscience, but the specialized skills required to design and fabricate them and the high cost of purchasing them commercially has thus far limited their use. Here, we present an open-source, low cost, miniaturized wide-field microscopy system which includes all the necessary hardware, electronics, software, and analyses needed to record large-scale neural activity in freely behaving animals. The custom data acquisition (DAQ) hardware and software simultaneously records behavioral and neural video streams and syncs external devices through digital input/output connections. The DAQ software, which is multithreaded and built with Open Computer Vision (OpenCV) libraries, is capable of online image processing and thus real-time feedback. We have developed a novel, fully automated, segmentation algorithm for identifying individual cells based on the correlation of pixel intensity surrounding calcium events. Using amplitude based image registration, our system can track the activity of hundreds of identified segments (i.e., neurons) over weeks, maintaining a stable field-of-view and focal plane across recording sessions. By imaging hippocampal CA1 neurons expressing GCaMP6f in freely behaving mice, we have investigated the overlap of neural populations encoding novel contexts and followed the stability of place fields over time. Our system is easily assembled, affordable, and built around

an open-source platform to facilitate collaboration and encourage sharing of future developments.

Title: Optical imaging of baseline and stimulus-induced changes in facial perfusion

Authors: ***M. CORTEZ**[1], N. REA[2], L. HUNTER[2], J. PETERSON[2], J. THERIOT[2], K. BRENNAN[1];
[1]Univ. of Utah Neurol., Salt Lake City, UT; [2]Univ. of Utah, Salt Lake City, UT

Abstract: Objective: Trigeminal and autonomically mediated perfusion changes in the face (e.g. flushing, pallor) can be discerned with the naked eye and can reflect emotional, sensory and other environmental stimuli modulated by the autonomic nervous system. We combine optical imaging techniques developed for animal models of migraine with psychophysical testing and physiological monitoring to characterize craniofacial autonomic outflow. Methods: Subjects were positioned supine and imaged under green filtered light using a high sensitivity CCD camera. Skin reflectance was recorded before, during and after ammonia vapor inhalation. Heart and respiratory rate was monitored throughout the procedure. Additional testing in selected cases included correlation with pharmacological blockade, sensory and emotional stimuli and temperature challenges. Anatomically consistent regions of interest were analyzed in ImageJ for percent-change in skin reflectance. Results: Data was collected in non-headache controls and migraine subjects (a disorder known to have facial autonomic features and altered sensory thresholds). At baseline, low frequency hemodynamic fluctuations in skin reflectance were observed; these fluctuations were distinguishable from reflectance changes due to heartbeat. Oscillation amplitude and frequency increased significantly following ammonia inhalation, compared to baseline. Ammonia-induced craniofacial hemodynamic changes were associated

with a brief, non-sustained (<30 sec) increase in heart rate in most, but not all, individuals. Induced alterations in baseline oscillations were also noted due to non-painful sensory and emotional stimuli, though these differences were not significantly different between migraine and non-migraine subjects. Conclusions: Our optically-based measures of craniofacial trigeminovascular autonomic function appear to provide information independent of systemic cardiovascular function and fill a gap in current autonomic testing. Furthermore, our pilot data suggest that migraineurs and controls may be distinguishable based on baseline and stimulus-evoked facial hemodynamic oscillations. These findings expand on the current data supporting autonomic dysfunction in migraine.

Title: Double-sided voltage sensitive dye imaging of the nervous system of the leech

Authors: *Y. TOMINA[1], D. A. WAGENAAR[2];
[2]Dept. of Biol. Sci., [1]Univ. of Cincinnati, Cincinnati, OH

Abstract: Studies of neuronal mechanisms of sensory processing and motor control are greatly facilitated by technologies that permit recording of the activity of a large population of neurons at once. The medicinal leech *Hirudo verbana* is a classic experimental animal for comprehensive analysis of the function of neural circuits. Voltage-sensitive dye (VSD) imaging combined with electrophysiology is an increasingly powerful technology to assist in such studies. One recent dye in particular, the VoltageFluor VF2.1(OMe).H, is sensitive enough to record subthreshold events even in small cells. In the leech ganglion, all cell bodies are located on the surface of a flattened sphere, making all of them potentially accessible to imaging. However, thus far, imaging experiments have been limited to recording from one side of a ganglion. If we were able

to simultaneously image the other side, we could record the activity of all the neurons in a ganglion, allowing comprehensive analysis of the neuronal activity in the entire system. We have developed a double-sided microscope to do just this, and compared to last year's prototype, we greatly improved the ratio of signal to noise by removing vibrational noise from the CCD cameras. From simultaneously imaged neural activity on both (dorsal and ventral) surfaces of isolated leech ganglia, we successfully reconstructed stereotyped electrical activity associated with local bending behavior in response to P-cell stimulation. The technique should extend readily to other situations where researchers require simultaneous recording of activities from two distinct layers of neurons.

Title: Two photon imaging with genetically -encoded calcium indicators in new world primates

Authors: *J. SHARMA[1], R. LANDMAN[2], F. YOSHIDA[2], H. SUGIHARA[3], M. SUR[4]; [1]Picower Inst. For Learning & Memory, MIT & MGH, Cambridge, MA; [2]Brain and Cognitive Sciences, MIT, McGovern Inst. of Brain Res., Cambridge, MA; [3]Brain and Cognitive Sciences, MIT, Picower Inst. for Learning and Memory, Cambridge, MA; [4]Brain and Cognitive Sciences, MIT, Picower Inst. for Learning and Memory and Simons Ctr. for Social Brain, Cambridge, MA

Abstract: Two photon imaging using calcium sensors has provided important insights into neural circuit mechanisms with unprecedented detail, particularly in mice. With the advent of highly sensitive and targettable genetically encoded-calcium indicators (such as variants of GCaMP) riding on viral backbones of various vectors and aided by cell -specific promoters, the same population of neurons can be repeatedly imaged over several weeks or months to investigate neural circuit function (and dysfunction), and study neural mechanisms and plasticity

underlying perception, cognition, learning and memory. However, achieving a similar level of sophistication in imaging higher mammals, particularly primates with more complex and dense cerebral architecture, poses new challenges. From the published literature, it is already clear that a new set of tools needs to be developed for this purpose. These include hardware for animal stabilization, movement correction of the imaging data, the development of chronic optical windows for accessing population of neurons expressing florescent proteins over several weeks, and the optimization of viral vectors and promoters while keeping brain tissue physiologically viable and in good health. Here we present our experience in developing these tools for 2 photon calcium imaging with GCaMP6 variants for chronic imaging in anesthetized new world monkeys, from several striate and extrastriate areas of the visual cortex. We modified a 2 photon imaging system (Sutter Instruments) to couple with a custom-designed movable objective that affords maximal rotational degrees of freedom along X and Y axes. We also developed a flexible imaging platform that provides precise alignment with the imaging plane of the objective, and can be tailored to suit primates of various sizes. For head stabilization we designed a dual, low-profile head post system that provides excellent rigidity while allowing flexibility to orient the head in any position to target multiple areas on the cortical surface. To minimize body movement due to respiration, we designed a simple trampoline suspension. We have also developed and tested several versions of chronic imaging windows, including sealed, removable and replaceable optical windows that are easy to maintain, while minimizing risk of infection and with flexibility to re-inject viral vectors or remove interfering pial-tissue growth. Large field ex-vivo confocal imaging was used to confirm GCaMP expression in several layers of the cortex with hSynapsin and CaMKII promoters. Two photon imaging in new world primates provides exciting possibilities as the next generation of transgenic primates come online.

Title: Nucleic acid probes for neurochemicals optical tracking

Authors: ***J. L. CHAVEZ**[1], T. O'NEIL[2], R. CLARK[3], S. HARBAUGH[1], M. KADAKIA[3], J. A. HAGEN[1], N. KELLEY-LOUGHNANE[1];

[1]711 HPW/RHXBC, US Air Force Res. Lab., WPAFB, OH; [2]Biochem., Case Western Reserve Univ., Cleveland, OH; [3]Biochem. & Mol. Biol., Wright State Univ., Dayton, OH

Abstract: Recently, the White House Brain Research Initiative has highlighted the need for new tools to provide direct measurements of neurotransmitters like GABA, dopamine, serotonin and neuropeptides with improved temporal and spatial resolution. The information gathered with these tools will allow a deeper understanding of the flow of information across different brain circuits that affect arouse, emotion, motivation, and other processes. Our group is working on developing nucleic acid-based optical probes integrating multiple functional recognition elements to track secretion of different neurochemicals with spatial and temporal resolution during different cognitive processes in the brain. These tools will be used to monitor the release of neurochemicals that currently cannot be tracked directly or whose release is typically inferred by calcium ion activity, allowing a better understanding of neural communication. Our group has designed probes with nanoscale dimensions carrying multiple functionalities to allow precise probe placing on the surface of neurons, and biorecognition elements (BREs) for selective binding of neurotransmitters and neuropeptides. Importantly, these probes show high fluorescence in the presence of the target with minimal background signal in its absence, by utilizing RNA-based green fluorescence protein mimics. As a proof-of-concept, we designed a probe whose fluorescence is turned on by binding dopamine. The probe was optimized by testing different dopamine-binding aptamer clones, each with different sequences, lengths and affinities. Moreover, we supported our probe design by computational methods to optimize the linker section between the fluorescence probe and the analyte binding aptamer. In this presentation we will present the characterization of the probes' response linear range, limit of detection and binding kinetics *in vitro* and will present preliminary results in cell culture.

Title: A multi-scale brain imaging strategy for small animals *in vivo*

Authors: *H. HUI[1,2], D. DONG[2], X. MA[2], X. YANG[2], J. TIAN[2];
[1]Key Lab. of Mol. Imaging, CAS, Inst. of Automation, Beijing, China; [2]Key Lab. of Mol. Imaging, Inst. of Automation, Chinese Acad. of Sci., Beijing, China

Abstract: The development of *in vivo* molecular imaging techniques has allowed the study of brain disease in intact brains of living animals. These imaging modalities can be used for performing the dynamic process both in macroscale and in mesoscale, namely, with resolution from millimeter to sub-micrometer. In this work, we propose a multi-scale strategy for *in vivo* imaging of mouse brain. We have developed a multimodality system for whole body imaging of small animals, in which Computed Tomography (CT), Fluorescence Molecular Tomography (FMT), Positron Emission Tomography (PET) and Magnetic Resonance Imaging (MRI) have been integrated. This hybrid molecular imaging system can be used to acquire anatomical, functional and metabolic information of brain disease in macroscale. To understand the mechanism of brain disease in its neuronal microenvironment, high-resolution imaging technology in mesoscale is required, such as two-photon laser scan microscopy (TP-LSM) because it can significantly reduce the background signal and allow imaging of thick living samples up to about 1mm depth with subcellular resolution. In this approach, a high-speed TP-LSM was used for acquiring imaging data in mesoscale. The setup of multimodality imaging system is shown in Figure 1A. Firstly, *in vivo* imaging is performed by multi-modality system. The segmentation, registration and visualization of the acquired images are conducted by our

developed software 3DMed and MITK to locate the three-dimensional position of brain disease. Then, a small craniotomy is made for the same mouse using a high-speed drill with a small-tip steel burr at the corresponding position. A craniotomy preparation process was carefully conducted for *in vivo* two-photon imaging. An appropriate region of the neural population was chosen. The region of interest (ROI) in the center of the FOV was placed to image neurovascular connections and monitor neural activities. The proposed approach has potential to be applied for monitoring diagnoses and therapy processes of brain disease both in macroscale and mesoscale.

Title: Image processing technique for an implantable image sensor with self-resetting function

Authors: ***K. SASAGAWA**, T. YAMAGUCHI, M. HARUTA, Y. SUNAGA, H. TAKEHARA, M. MOTOYAMA, Y. OHTA, H. TAKEHARA, T. NODA, T. TOKUDA, J. OHTA;
Nara Inst. of Sci. and Technol., Ikoma, Nara, Japan

Abstract: An implantable image sensor deigned and fabricated with sophisticated complementary-metal-oxide-semiconductor (CMOS) technology is expected to be useful for neural activity imaging. The size and weight of the sensor are much smaller and lighter those of an adult mouse. By using a needle shape sensor, it is possible to observe deep brain area with some invasiveness. In order to observe weak intensity change signals, we have proposed to introduce a pixel array with self-reset function and realized approximately 60 dB of signal-to-noise ratio with intense illumination. In the sensor, the function to count the number of self-resetting is not equipped to reduce the pixel size and increase the spatial resolution. In this study, we developed image processing technique to generate intensity change images from images

obtained with the self-resetting image sensor. The pixel of the self-resetting sensor is reset by itself when the received optical energy becomes higher than its threshold. The number of self-resetting increases as the light intensity increases. Thus, there is the possibility that the number of self-resetting is different even if the sensor output is the same. It means that the number of self-resetting should be counted for general purposes. However, in many cases of living tissue observations, it is important to measure intensity changes. Thus, the it is not necessary to count the number of self-resetting. In this study, we performed the observation of blood flow through vessels on a rat brain. First, an image of intensity distribution was obtained with illumination as weak as no self-reset occurs. Next, the illumination was increased. Boundaries of self-reset number are observed as fringes. Here, the pixel intensities on the blood vessels change frame by frame due to blood flow. We enhanced the intensity changes by subtracting a reference image, which is an average image during the observation period as a reference image. The image was normalized by that with the low intensity illumination. On the boundary of the self-reset numbers, we defined a threshold and the output value was corrected if the output change is higher than the threshold. As a result of the image processing, we obtained images clearer than our previous sensors. By using this technique, the implantable self-resetting sensor can be applied for not only blood flow imaging but hemoglobin oxidation state or voltage sensitive dye imaging etc.
