postsynaptic terminals surrounding type I hair cells and compact bouton terminals on type II hair cells. In whole-cell recordings from the rat saccule, extrastriolar calyces were more regular than striolar calyces (Songer & Eatock 2013), consistent with the *in vivo* chinchilla data. Here we report findings from calyces of the mouse utricle in the lateral extrastriola (LES), which extends from the line of reversal of hair bundle polarity to the lateral edge of the sensory epithelium. Utricles were excised from CD-1 mice at 10-30 postnatal days (15 ± 1.7 (SE) days, n=12) and maintained at 25-28°C in L-15 medium. The pipette solution was KCl-based and included sulforhodamine 101 to fill the terminal arbors. The calyces belonged to afferents that each made simple calyces around 2-4 type I hair cells plus 3-10 boutons on type II hair cells. Resting potential was −44 ± 5 mV (n=7); resting input resistance was 125 ± 27 MΩ, and capacitance estimated from electronic compensation was 9 ± 2 pF. Sinusoidal stimulation (2-100 Hz) of hair cell bundles evoked postsynaptic responses that were a mix of epsps (n=3), apparently non-quantal responses (n=3), and both (n=1). Evoked spiking showed broad tuning and less precise phase-locking compared to striolar rat calyces. Spontaneous firing rate was 20 ± 5 spikes/s (n=7); correcting for temperature raises the rate into the *in vivo* range for mouse vestibular afferents. Spike timing in these extrastriolar calyces was, however, more irregular than expected from *in vivo* chinchilla utricular data or *ex vivo* rat saccular data: CV = 1.1 ± 0.1, Fano factor = 0.24 ± 0.1 (n=12). Possible factors are species, organ, development stage, and sub-zone within the extrastriola (lateral vs. mixed lateral and medial extrastriola). The underlying mechanism could be different expression of low-voltage activated K channels, which make firing more irregular.

Title: Voltage-dependent inhibition of N-type calcium current by activation of ORL-1 receptor in vestibular afferent neurons of rat

Authors: *E. SESEÑA MENDEZ[1], A. ORTEGA[2], R. VEGA[2], E. SOTO[2];
[1]Fac. De Medicina, Univ. Autonoma De Puebla, Puebla, Mexico; [2]Inst. de Fisiología, Univ. Autónoma de Puebla, Puebla, Puebla, Mexico

Abstract: The vestibular system is modulated by opioid peptides both at the central and peripheral level. The nociceptin/orphaninFQ peptide (N/OFQ) peptide and its receptor opioid receptor like - 1 (ORL-1) has been found to be expressed in the vestibular nuclei complex, and N/OFQ has been shown to modulate the electrical activity of the medial vestibular nucleus neuron (Sulaiman et al., 1999). However, the expression and effect of N/OFQ has not been studied in the vestibular endorgans. In this work we evaluated the effect of ORL-1 activation in the multiunit discharge of the vestibular afferent neurons in the isolated vestibule and also in the voltage gate calcium current (ICa) recorded in the isolated vestibular afferent neurons (VAN) of the rat. Also immunohistochemical analysis of the ORL-1 expression in vestibular endorgans and vestibular nuclei complex was studied. Extracellular multiunit recording of the ampullary nerve electrical discharge was performed in the isolated vestibule of the rat. Micro-application in the vicinity of the ampulla origin of N/OFQ did not significantly modify the basal discharge of the afferent neurons. Recordings of ionic currents were performed in cultured VAN using the perforated patch clamp technique. The perfusion of N/OFQ decreased the high voltage activated ICa (HVA) without significantly modifying the low voltage activated ICa, (LVA). Inhibition of the HVAICa component was dependent on the concentration used. The specific ORL-1 antagonist UFP101 or the pre-incubation of VANs with pertussis toxin completely occluded the N/OFQ inhibitory action of the Ca2+ current. Else more, the use of ω-ctx-MVIIA (specific N-type Ca2+ channel blocker) also occluded the effect of ORL-1 activation. The effect of the N/OFQ on the HVAICa was also reverted by a pre-pulse to 80 mV. Evidence from confocal microscopy analysis of immunorreactivity to the ORL-1 receptor indicate that it is not expressed in the vestibular endorgan. Studies of ORL-1 expression within the vestibular nuclei complex is under way. These results showed that ORL-1 activation inhibits the N-type ICa in the VANs in a voltage-dependent manner. Since activation of the N/OFQ did not modify the discharge rate of vestibular afferents, we thought that ORL-1 mediates a pre-synaptic modulation of the neurotransmitter release form the vestibular afferent terminals, inhibiting N-type calcium current at the synapse with the vestibular nuclei neurons, constituting a target to negatively modulate the afferent gain of the vestibular nuclei neurons.

Title: Dynamic diversity of horizontal canal afferent neurons in Xenopus laevis tadpoles

Authors: K. GENSBERGER[1], C. GRAVOT[2], *L. F. HOFFMAN[3], M. PAULIN[4], H. STRAKA[1];
[1]Dept. of Biol. II, [2]Grad. Sch. of Systemic Neurosciences, Ludwig-Maximilians-University, Munich, Germany; [3]UCLA Sch. Med., Los Angeles, CA; [4]Dept. of Zoology, Univ. of Otago, Dunedin, New Zealand

Abstract: Spike time variation in information transmission plays a fundamental role for neural coding of sensory stimuli. The large dynamic bandwidth of naturally occurring head motion poses a particular challenge for the vestibular system to faithfully encode these stimuli as spike trains transmitted by afferent neurons to central vestibular circuits. Tadpoles of *Xenopus laevis* provide an outstanding opportunity to investigate how natural head kinematics are encoded in vestibular afferent discharge modulation. In this study we present our findings of the fundamental anatomic and physiologic characteristics of these neurons from *in-vitro* preparations of specimens at mid-larval stage. At this developmental stage vestibular afferents exhibited physiologic characteristics comparable to adult amphibian specimens, and extracellular recordings from single horizontal semicircular canal afferents at rest and during sinusoidal rotation revealed a heterogeneous population that exhibited both phasic and tonic dynamics. Phasic afferents exhibited low resting rates (~0.8 sp/s) and irregular spontaneous discharge (CV >1). During sinusoidal rotation at frequencies > 0.5 Hz, these fibers exhibited discharge volleys that were phase-advanced by ~45° (re: head velocity), independent of the stimulus magnitude. Afferents that exhibited more tonic dynamics had higher resting rates (≥8 sp/s) and more regular interspike intervals (CV≤0.4). The firing pattern of these afferents during sinusoidal rotation was modulated approximately in phase with peak head velocity. The cristae were also probed for cellular features that may be associated with afferent physiologic heterogeneity, and were found to contain a distinct group of afferent dendrites that were immuno-positive for Kv1.1, a low-voltage activated potassium channel that facilitates highly transient discharge patterns. These fibers exhibited particularly large axonal (~4 μm) and corresponding somatic (~18 μm) diameters and projected to the crista epithelium isthmus. The presence of a heterogeneous population of vestibular afferents with complementary morpho-physiological features corresponds to a comparably diverse population of central vestibular neurons and complies with the necessity to encode the large range of head motion dynamics. Using band-limited rotational stimuli derived from measurements of head kinematics during natural swimming in these animals will yield deeper insight into how the components of natural stimuli are encoded and transmitted to central vestibular circuits.

Title: Parallel channels with different timescales encode self-motion information in the vestibular system

Authors: ***M. JAMALI**, J. CARRIOT, M. J. CHACRON, K. E. CULLEN;
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Most sensory neurons transmit information about the sensory world through firing action potentials; however, deciphering their neural code (e.g., rate versus temporal code) has intrigued many neuroscientists for decades. To this end, we took advantage of the vestibular otolith afferents which are well-defined anatomically and physiologically and encode easily characterized sensory stimuli (i.e., linear self-motion) to higher-order brain areas. Interestingly, a hallmark of these neurons is the heterogeneity in the variability of their spontaneous discharge (from regularly to more irregularly spiking afferents), which makes them particularly suitable for exploring whether spike-timing plays a role in self-motion processing. Here, we investigated how sensory information is processed in the otolith afferents by recording from utricular fibers in alert macaques while stimulating each unit along its preferred direction during translations with broad band (0-15 Hz) Gaussian noise linear accelerations. We found an increase in the response gain for both regular and irregular afferents as a function of the stimulus frequency; the gain enhancement was more prominent for irregular units. Interestingly, despite a large difference in gain, responses of both afferent types were similarly coherent with the stimuli except for very low frequencies (≤1Hz) at which regular units displayed slightly higher coherences. These findings suggest that while highly sensitive irregular afferents are more advantageous for transient and dynamic stimuli, the regular units can provide accurate information when the stimulus is less dynamic (e.g. static tilt). Finally, to investigate whether spike timing plays a role in the encoding of linear motion we recorded neuronal responses to repetitions of the same stimuli (i.e., frozen noise). In response to frozen noise stimuli, irregular units exhibited coherence in their responses at frequencies beyond those contained in the stimuli indicating higher temporal resolution in their activity. Further quantification revealed that irregular afferents outperformed regular units in discriminating stimuli using faster timescales signifying that information is contained in the fine temporal structure of their spike trains. In contrast,

regular units operate over relatively longer timescales and use a rate coding scheme to encode the stimuli. Our findings suggest that regular and irregular afferents function as two parallel channels with different but complementary coding strategies to encode linear self-motion.

Title: Spontaneous discharge in mammalian vestibular afferents modelled as Gamma-censored Poisson processes: associations with response dynamics

Authors: L. HOFFMAN[1], K. PULLAR[2], *F. E. SCHWEIZER[3], M. PAULIN[2];
[1]Dept. of Head & Neck Surgery, Geffen Sch. of Med., Los Angeles, CA; [2]Dept. of Zoology, Univ. of Otago, Dunedin, New Zealand; [3]Dept Neurobiol, UCLA, Box 951763, Los Angeles, CA

Abstract: Vestibular primary afferent neurons exhibit broad heterogeneity in spontaneous discharge interspike interval (ISI) distributions, which have been previously modeled by Gamma distributions with shape (k) and scale (θ) parameters. The Gamma model implies a fast Poisson process underlying spontaneous activity, whereby spikes are triggered by integrating Poisson events. However, the temporal characteristics of ISI distributions are inconsistent with simple Gamma models, requiring a temporal offset parameter (d). This parameter is fundamentally different from k and θ in that it represents a fixed offset, not a parameter of a formal stochastic process. Our goal was to generalize the Gamma model to account for temporal offsets in ISI distributions within an underlying stochastic model. The Gamma-censored Poisson process (GCP) is the waiting time for k events in a Poisson process plus 1 event in another, independent Poisson process. In our model, the Gamma process functions to 'gate' events in the second process until a Gamma event occurs, enabling the next Poisson event to occur and the Gamma process is reset. We derived analytical forms of offset Gamma (OG) and GCP processes and fitted these to spontaneous discharge ISIs from several hundred chinchilla horizontal and superior cristae afferents that represented broad ISI heterogeneity. This enabled us to compute parameters of OG (k,θ,d) and GCP (k, θ, τ) models directly from ISI data. Kullback-Liebler divergences (representing differences between probability distributions) were computed between fitted models and ISI distributions. GCP models fit at least as well as OG models for all data and provided better fits for a large fraction of afferents. The associations between parameters of each subcomponent and the broad ISI heterogeneities were explored through regression analyses of

model parameters and spontaneous ISI CV. We found that the Gamma subcomponent k was closely associated with ISI CV for afferents with CV≤0.1 (r^2=0.99); this correlation deteriorated among those with CV>0.1 (r^2=0.67). The parameter τ of the GCP model's Poisson subcomponent was more closely associated with ISI CV for afferents with CV>0.1 (r^2=0.88) than among those with CV≤0.1 (r^2=0.44). We also explored the association between model and evoked discharge parameters to elucidate how underlying factors of spontaneous discharge may be correlated with dynamic response characteristics. The GCP model implies that vestibular afferent spontaneous discharge reflects a Poisson process gated by a separate Gamma process (sum of Poisson processes) that may be associated with synaptic events and dendritic integration, respectively.

Title: Age-related effects of vestibular stimulation on gait

Authors: ***V. TUNG**, T. BURTON, S. QUAIL, A. J. CAMP;
Univ. of Sydney, Sydney, Australia

Abstract: Background: Maintenance of posture and balance are multi-factorial with contributions from proprioceptors, vision and the vestibular system. During natural ageing, loss of balance and subsequent falls become more prevalent. Here we investigate the effect of a simple, non-invasive vestibular stimulus on gait pattern and motor coordination of mice across the murine lifespan. Methods: All experiments were approved by the University of Sydney Animal Ethics Committee. C57/Bl6 mice of ages 1 (n = 3), 10 (n = 7), 13 (n = 6) and 27 (n = 8) months were trained to perform a task of walking 30 cm directly and with no assistance to a darkened goal box. Petroleum jelly was then applied to the hind-feet of the mice, which were then returned to the starting point to perform the task. The petroleum jelly residue remaining as mice walk towards the goal box was used to analyse walking patterns. Mice were then given 1 minute of rest and petroleum jelly was reapplied before they were placed in a custom-built rotator that delivered an angular acceleration from 0 to 3Hz over 20s. Mice were retested immediately after the stimulus. After testing, graphite powder was used to darken the petroleum jelly footprints for analysis. An ellipse was fitted to the walking path of mice, before and after the vestibular stimulus, with the minor axis of the ellipse used to quantify the degree to which the

walking path of each mouse deviated from the direct path between the starting point and the goal box. Results: The angular acceleration (vestibular stimulus) did not show an overall relationship when minor axis length was compared across all ages ($p > 0.05$). Rather, the effect developed after 10 months of age and continued through to 27 months of age. For example, while the gait pattern of 1-month-old mice was not affected by angular acceleration (pre-stimulus: 6.90 ± 1.66 mm vs. post-stimulus: 6.64 ± 1.85 mm) the deviation from the direct path was significantly increased in all other age groups following the stimulus (10-month-old, 24.98 ± 5.93 mm vs. 27.74 ± 6.23 mm, $p < 0.05$; 13-month-old, 23.789 ± 6.85 mm vs. 28.61 ± 8.71 mm, $p < 0.05$; and 27-month-old, 21.70 ± 5.00 mm vs. 30.28 ± 14.13 mm, $p < 0.05$). No differences were seen between the older age groups. Conclusion: A vestibular stimulus of low frequency and duration has minimal effect on the gait pattern of young 1-month-old mice. However, at ages 10 months and above, mice noticeably deviated from the most direct path to complete the task, suggesting impaired motor coordination and recovery from the vestibular stimulus.

Title: Efferent vestibular neurons show homogeneous discharge output and heterogeneous synaptic input profile in mice *in vitro*

Authors: *M. A. MATHEWS[1], R. WIJESINGHE[1], A. MURRAY[2], V. TUNG[1], A. J. CAMP[1]; [1]USYD, Sydney University, Australia; [2]Columbia Univ., New York City, NY

Abstract: Purpose: Our sense of balance is fundamental to our ability to interact with our environment, yet we still know little about the central control of the peripheral balance system. Here we confirm the location, and characterize the output and input properties of efferent vestibular nucleus (EVN) neurons *in vitro*. **Methods:** All procedures were approved by the Animal Ethics committee of the University of Sydney. *Immunohistochemistry:* Transverse serial sections (40μm) were sliced through the 4-week-old mouse brainstem and labelled with antibodies against CGRP (n=7), and ChAT (n=4). Retrograde labelling using fluorogold injected into the posterior semicircular canal of ChAT-Cre tdTomato mice was also used to confirm the location of EVN neurons. *Electrophysiology:* Transverse slices (200μm) were used to characterize intrinsic action potential (AP) and discharge properties of visualized EVN neurons (n=54) in whole-cell current-clamp mode. Synaptic input profiles of visualized EVN neurons were assessed in whole-cell voltage-clamp mode (n=23). Miniature excitatory and inhibitory postsynaptic currents were identified using pharmacological blockade. **Results:** CGRP and

ChAT immuno-positive neurons were identified dorsolateral to the genu of the facial nerve. Spontaneous firing EVN neurons (n=16) show a significantly deeper afterhyperpolarisation when compared with non-spontaneous (n=38) neurons ($p<0.001$). EVN neurons display slower action potential kinetics including rise time ($p<0.001$) and half-width ($p<0.01$) when compared with neighbouring medial vestibular nucleus neurons. In response to both hyperpolarizing and depolarizing steps all EVN neurons respond with a short bust of high frequency APs at the cessation of the inhibitory stimulus or the onset of an excitatory stimulus. This burst is superimposed on a (6.7 ± 7.8 mV) afterdepolarization amplitude that is completely abolished by the selective T-type calcium channel blocker 3,5-dichloro-N-[1-(2,2-dimethyl-tetrahydro-pyran-4-ylmethyl)-4-fluoro-piperidin-4-ylmethyl]-benzamide (TTA-P2). All EVN neurons show combinations of excitatory and inhibitory synaptic input profiles. EVN neurons are either exclusively inhibitory (n=10) or excitatory (n=5), or predominantly excitatory with: GABA(A)-ergic inputs (n=2), glycinergic inputs (n=1), or combination of inhibitory inputs (n=5). **Conclusion:** E-group vestibular neurons are homogeneous in their discharge output and heterogeneous in their synaptic input profiles suggesting that central control of peripheral vestibular structures may be related more to the source of the input these neurons receive**.**

Title: Changes in c-Fos expression in the striatum following electrical stimulation of the peripheral vestibular system

Authors: *L. STILES[1,2], Y. ZHENG[1,2], R. M. NAPPER[3,2], P. F. SMITH[1,2];
[1]Dept. of Pharmacol. and Toxicology, [2]Brain Hlth. Res. Ctr., [3]Dept. of Anat. and Structural Biol., Univ. of Otago, Dunedin, New Zealand

Abstract: Connections between the peripheral vestibular system and the basal ganglia have been studied sporadically in the past; however, the results of these studies are conflicting. As both regions are well known to be involved in the processing of movement and dysfunction of both systems produces movement disorders, in recent years there has been increasing interest in how these regions might be connected and how vestibular signals affect striatal function. Immediate early gene proteins like c-Fos can be used as a marker of neuronal activation in neurons, as their

genes are activated following cellular stimulation. The aim of this study was to investigate whether electrical stimulation of the peripheral vestibular system caused an up-regulation of the c-Fos protein in the striatum. Male Wistar rats (weighing between 300 g and 400 g) were randomly allocated into either stimulation or sham groups. The animals were anesthetised using urethane (1.5 g/kg, i.p.) and the round window of the inner ear was exposed using a retro-auricular surgical approach. A stainless-steel bipolar electrode was placed into the round window as the stimulating electrode. Stimulated rats received unilateral electrical stimulation at 100 Hz at the lowest possible current to produce vestibular nystagmus specific to the animal (between 300 and 400 μA) for 10 minutes. Sham animals underwent the entire surgical procedure but received no electrical stimulation. Ninety minutes post-stimulation the animals underwent cardiac-perfusion with saline followed by 4% paraformaldehyde. The brains were dissected out, post-fixed, frozen and stored at -20° C until sectioning. Serial 40 μm sagittal sections throughout the striatum were cryosectioned using a random, systematic sampling design. c-Fos immunolabelling was performed and the immunostaining was quantified using the optical dissector fractionator method of stereology to count positive cells. Preliminary results show an increase in the number of c-Fos positive cells in the striatum of rats receiving vestibular stimulation compared with sham-treated rats. This increase following electrical vestibular stimulation suggests that the peripheral vestibular organs send signals to the striatum, which then activate the cells to cause activation of the c-fos gene. The striatum is the main input site to the basal ganglia and the connections between the vestibular system and striatum may have clinical implications in the treatment of basal ganglia disorders and other movement disorders.

Title: Role of G-protein-coupled serotonin receptor on synaptic plasticity of excitatory transmission in the vestibular nucleus of rats

Authors: ***Y.-S. CHAN**[1], L. HAN[1], Y. H. LI[1], C. W. MA[1], D. K. Y. SHUM[2];
[1]Dept. of Physiol., Fac Med, The Univ. of Hong Kong, Hong Kong, China; [2]Dept. of Biochem., Fac Med, The Univ. of Hong Kong, Hong Kong, China

Abstract: Serotonergic projections from the raphe nucleus are known to innervate the medial vestibular nucleus (MV) but the contribution of serotonin in the vestibular system remains

fragmentary. Acute administration of serotonin (5-HT) to the MV of P14 rats impaired the performance in rota-rod task, balance beam test and negative geotaxis. Whole-cell patch-clamp recording in MV neurons of brainstem slice preparations showed increase in the amplitude and frequency of spontaneous excitatory postsynaptic current (EPSC) with 5-HT treatment. Among G-protein-coupled 5-HT receptors that modulate synaptic plasticity in excitatory circuitries, we found 5-HT_2 receptor (Gq-coupled) and 5-HT_7 receptor (Gs-coupled) expressed in neurons of the vestibular nucleus. We then pursued the roles of these receptors in MV neurons. Treatment of MV neurons with agonist of the 5-HT_7 receptor induced reduction in the amplitude of evoked-EPSC but not with agonist of the 5-HT_2 receptor. With the use of combinations of single and dual agonist/ antagonist that target the Gs- and Gq-coupled 5-HT receptors, we further found that the suppression of NMDAR-dependent long-term depression in MV neurons was mediated by the 5-HT_7 receptor but not by the 5-HT_2 receptor. Aside from the PKA-dependent signaling cascade, downstream cross-talk with the PKC-dependent pathway was involved. Taken together, our results reveal that Gs- but not Gq-coupled serotonin receptors mediate the expression of long-term plasticity in excitatory synapses within the vestibular nucleus, and suggest their involvement in the expression of vestibular behaviors.

Title: Neural mediation in vestibular nucleus: habituation and sensitization of horizontal semicircular canal-related neurons by galvanic vestibular stimulation

Authors: *G. KIM[1], S. LEE[1], K.-S. KIM[2], E. JEON[2];
[1]Inha Univ., Inchon-City, Korea, Republic of; [2]Otolaryngology-Head & Neck Surgery, Inha Univ. Hosp., Incheon, Korea, Republic of

Abstract: Habituation is observed in neuronal responses while sensitization also occurs by the stimulation as applied for habituation. Vestibular system is known as a sensory system with dynamic processes of habituation and sensitization. To see how these processes occur in vestibular system, we recorded the neuronal responses of habituation and sensitization in

vestibular nucleus (VN). We obtained 62 neuronal activities responding to a series of repeated stimuli, composing of multiple sets of a 3-sec stimulation and a 60-sec resting period. A horizontally rotatory stimulation was used to identify whether the recording signal was originated from the afferent neuron of the lateral semicircular canal. The slopes of habituation and sensitization were calculated off-line, using averaged neuronal firing rates during GVS. The results showed that the responding slopes of habituated and sensitized units followed a normal distribution with their mean and standard deviation of -0.2 and 0.9, respectively, indicating slightly more habituation. However, a statistical test implied that the neuronal habituation and sensitization occurred in a similar amount of neurons (p=0.13, binomial test). Based on our data, we hypothesize the neural mediation by habituation and sensitization in VN can be explained by homeostatic process, which balances the strength (slope) between the habituated and sensitized units. The observed neuronal mediation suggested the modified neural information (habituation) was compensated by its opposite process (sensitization) through regulating their new threshold level after a learning process.

Title: Discharge properties of vestibular neurons during horizontal eye movements in the goldfish

Authors: *A. M. PASTOR[1], P. M. CALVO[1], R. R. DE LA CRUZ[1], H. STRAKA[2], R. BAKER[3];
[1]Dept. de Fisiología, Univ. de Sevilla, Sevilla, Spain; [2]Dept. Biol. II, Ludwig-Maximilians-Universität München, Munich, Germany; [3]Neurosci. and Physiol., New York Univ. Med. Ctr., New York, NY

Abstract: Second order vestibular neurons transform motion-related sensory inputs into respective commands for gaze stabilization and posture control. We have morpho-physiologically characterized these neurons with single-unit recordings and determined their functional role during VOR and oculomotor velocity storage integration in goldfish. Vestibular neurons in the descending octaval nucleus were recorded during visuo-vestibular interactions in alert fish. Sinusoidal optokinetic stimulation demonstrated eye velocity sensitivity whereas visual suppression of the VOR determined head velocity sensitivity. Based on the firing patterns, two main types were found: EIIHI, the most abundant (n=19), and EIHII (n=10). Small proportions of pure HI (n=3) or HII (n=1) were also recorded. Velocity storage signal was tested by long (≥40s) optokinetic steps which showed the build-up firing during the charging of the velocity storage mechanism and the discharge that ensued the optokinetic afternystagmus. Similarly, long head velocity steps resulted in an immediate increase and persistence of the firing rate as a correlate of the velocity storage mechanism with a long time constant (>10s). Visuo-vestibular combinations of long steps resulted in an instant discharge of the velocity storage due to the interaction of the visual and vestibular signals. Intracellular biocytin injection of identified horizontal semicircular canal vestibular neurons demonstrated two main patterns of connectivity within the VOR circuitry. Some vestibular neurons with a disynaptic excitatory input from the ipsilateral horizontal semicircular canal and a contribution to horizontal eye movements had ipsilateral projections to abducens nucleus, area II and intrinsically to vestibular neurons. Other vestibular neurons projected contralaterally to abducens nucleus, area II and descending octaval nucleus. Tract tracing studies with biocytin verified this connectivity. Our study demonstrates the signal processing and connectivity between three hindbrain nuclei responsible for the control of horizontal eye movements. We propose that EIIHI are the excitatory and inhibitory neurons of the VOR reflex arc and EIHII neurons represent a particular class of vestibular neurons that are targeted by three control areas. These areas are the cerebellum, the contralateral vestibular nucleus (as part of the commissural inhibitory system) and the EIIHI neurons as part of an ipsilateral interneuronal inhibition. The pivotal role of the descending octaval nucleus neurons on the control of the VOR reflex arc and storage integrator demonstrates the basic blueprint of eye movement circuits.

Title: Selective encoding of unexpected head tilt by the vestibular nuclei but not by the vestibular afferents

Authors: *I. MACKROUS, J. CARRIOT, K. E. CULLEN;
Physiol., McGill, Montreal, QC, Canada

Abstract: During daily activities, our sensory system is simultaneously activated by self-generated and external events. The distinction between the sensory inputs that are the result of our own action or changes in the external world is essential to ensure perceptual stability and efficient motor control. Recently, it has been shown that the sensory signals carried by the vestibular-nerve afferent encode similarly head motions, regardless of whether they are passively experienced or actively generated. This was shown for passive sinusoidal rotations/translations in the horizontal plane, implying that the vestibular periphery provides faithful information about rotational and linear head movements. Conversely, neurons in the first central stage of processing (i.e., vestibular nuclei) robustly encode passively applied head rotation/translation in the horizontal plane but their responses are attenuated during comparable self-generated head motion. However, natural head movements are not restricted to one plane and create more complex vestibular stimuli because of the presence of the gravity. Therefore, we investigated whether gravity is included in the coding of head motions in order to distinguish between self- versus externally- generated head motion at the periphery and at the central levels. Vestibular afferents and vestibular nuclei neurons responses were recorded in alert macaques during passive and active head-on body tilts. As previously shown in the horizontal plane, the afferents similarly encoded passive and active tilts. Conversely, responses related to actively-generated tilts were significantly attenuated (relative to passively applied tilts) in vestibular nuclei neurons. Moreover, this attenuation was comparable to that observed for active versus passive head translations (67 vs 74%, $p>0.05$). Our findings indicate that the neural coding of self-motion requires an elegant computation of an internal model of active head motion that accounts for gravity at the vestibular nuclei level but such computation does not influence peripheral coding of self-motion.

Title: Reticular formation neurons with vestibular inputs respond to hindlimb movement: comparisons between decerebrate and conscious cats

Authors: *D. M. MILLER, D. J. MILLER, G. H. BOURDAGES, L. A. COTTER, B. J. YATES, A. A. MCCALL;
Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Multisensory integration of vestibular and proprioceptive afferent information within the central nervous system (CNS) is critical to postural regulation. We recently demonstrated in decerebrate cats that hindlimb somatosensory inputs converge with vestibular inputs on neurons in multiple CNS locations that participate in balance control. However, responses of CNS neurons to stimuli can be exaggerated or modified in decerebrate animals. The goals of the present study were to characterize in conscious animals the convergence of limb somatosensory and vestibular inputs onto pontomedullary reticular formation (PMRF) neurons, and to determine if the responses of these neurons to limb movement differed from those in decerebrate animals. PMRF neurons were targeted for study because of their well-established role in control of posture and locomotion. Single unit recordings were obtained from the PMRF in decerebrate and conscious cats while systematically moving the ipsilateral hindlimb through ramp-and-hold movements in the rostral-caudal plane and also while rotating the animals in vertical planes to stimulate the vestibular endorgans. Overall, we isolated 55 PMRF neurons whose activity was modulated by hindlimb movements: 34 in the decerebrate preparation and 21 in conscious cats. We confirmed that hindlimb somatosensory inputs converge with vestibular inputs onto PMRF neurons of the conscious cat. Furthermore, responses to hindlimb movement were similar in conscious and decerebrate animals. Most PMRF neurons in both preparations signaled the movement of the hindlimb in either the flexion or extension directions, but not limb position (74% and 76% of neurons in decerebrate and conscious animals, respectively). Since decerebration did not alter the pattern of responses of PMRF neurons to limb movement, supratentorial areas do not appear to play a critical role in shaping these responses. PMRF neurons that receive convergent limb and vestibular inputs may mediate reticulospinal reflex responses that maintain balance in response to externally applied (exafferent) postural perturbations.

Title: Anatomical and physiological characteristics of vestibulospinal neurons in zebrafish

Authors: *M. W. BAGNALL[1], K. L. HEISEY[2], R. ROBERTS[2];
[2]Anat. & Neurobio., [1]Washington Univ., Saint Louis, MO

Abstract: Sensory information about head movement and orientation with respect to gravity is encoded by vestibulospinal neurons. In mammals, these neurons (also known as Deiters' neurons in the lateral vestibular nucleus, or LVN) send axons exclusively to the ipsilateral spinal cord, with long projections that can reach lumbo-sacral levels. About two-thirds of vestibulospinal neurons increase firing for head tilts to the ipsiversive side, while the rest encode tilts to the contraversive side. Currently, very little is known about the nature of synaptic inputs to vestibulospinal neurons *in vivo*, nor the functional organization of their outputs in spinal cord. Here we show that in larval zebrafish, vestibulospinal neurons exist in a small, ~10 neuron cluster directly under the ear, and that they project ipsilaterally to the caudal end of the spinal cord, similar to the Deiters' population in mammals. Morphology of individual axons reveals that they extend collaterals in each spinal segment. We have also made whole-cell electrophysiological recording from vestibulospinal neurons *in vivo*; neurons are capable of high sustained firing rates, and receive barrages of spontaneous excitatory synaptic events. In voltage clamp, spontaneous excitatory post-synaptic currents exhibit stereotypical amplitudes and temporal profile in a given neuron, suggesting the convergence of multiple fibers each with a characteristic, history-independent amplitude. This frequency independent transmission is likely to arise from vestibular afferents. At these ages, only the anterior otolith (utricle) is a plausible source of information to these neurons, simplifying the analysis of their coding strategies. We conclude that in morphology and physiology, vestibulospinal neurons in zebrafish appear highly homologous to those in mammals, and we plan to explore their genetic specification, spinal cord targets, and functional contribution to righting behaviors.

Title: Plasticity within vestibulo-spinal reflex pathways: implications for use of vestibular prostheses

Authors: *D. E. MITCHELL[1], C. C. DELLA SANTINA[2], K. E. CULLEN[1];
[1]Dept. of Physiol., McGill Univ., Montreal, QC, Canada; [2]Dept. of Otolaryngology - Head & Neck Surgery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: From performing a complex dance routine to calibrating simple reflex behaviors, motor learning is required for the accurate execution of movements. Linking synaptic plasticity with motor learning requires understanding how synaptic efficacy influences behavioral responses. The vestibular system plays a vital role in the generation of vestibulo-spinal reflexes, which work to maintain our posture in response to unexpected self-motion. These reflexes are mediated by a subclass of neurons in the vestibular nuclei, termed vestibular-only (VO) neurons which receive input from the vestibular nerve and in turn send projections to the spinal cord. *In vitro* studies have revealed that repetitive stimulation of the vestibular nerve induces long-term depression at the first central vestibular synapse (McElvain et al., 2010). Whether this type of plasticity occurs in awake behaving animals and, if so, how it contributes to vestibulo-spinal reflexes remains unknown. In order to address these questions, rhesus monkeys were implanted with stimulating electrodes in the horizontal semicircular canals, allowing the temporally precise stimulation of the vestibular nerve during recordings of VO neuron activity. We found that behaviorally relevant patterns of vestibular nerve activation substantially decreased responses of VO neurons receiving direct input from the vestibular nerve (i.e., type I VO neurons), while the responses of afferents remained constant. Thus, plasticity was induced at the synapse between vestibular afferents and these neurons in awake behaving animals. Activation of the vestibular nerve also caused a decrease in evoked head movements, although the magnitude of this decrease was significantly less than that of the neurons. We also recorded from neurons that contribute to the commissural vestibular pathways (type II VO neurons). Surprisingly, regardless of the observed substantial decrease in their input described above (i.e., type I VO neurons), commissural neuron responses did not change following activation of the vestibular nerve. These results suggest that rapid plasticity occurs within the vestibular commissural pathways to compensate for a decreased weight of the first central vestibular synapse and optimize behavioral performance. We speculate that, during natural head motion in everyday life, the first central vestibular synapse does not undergo plasticity to the same extent as during the stimulation we applied here. Nevertheless, plasticity at this synapse in coordination with complementary changes at other sites within the vestibulo-spinal circuitry likely guides the fine tuning of this motor behavior.

Title: Pulsed infrared stimulation of the vestibulo-sympathetic reflex (VSR) pathway

Authors: *G. R. HOLSTEIN[1], S. M. RAJGURU[4], G. P. MARTINELLI[2], V. L. FRIEDRICH, Jr.[3], R. D. RABBITT[5];

Abstract: Studies in humans and experimental animals have demonstrated that the vestibular system influences the sympathetic nervous system control of blood pressure (BP). Linear acceleration, which stimulates the otolith organs, causes transient changes in BP that are attenuated in patients with bilateral vestibular dysfunction. Activation of the otoliths by off-vertical-axis rotation produces increases and decreases in muscle sympathetic nerve activity (SNA) that are in-phase with the head-up and head-down tilt components of the stimulus, respectively. As in humans, linear acceleration and head-up tilt increase SNA and raise BP in experimental animals, while nose-down stimulation decreases both. Numerous studies in experimental animals report that SNA increases during electrical stimulation of the vestibular nerve. We previously demonstrated in rats that there is a direct projection from the caudal vestibular nuclei (VNc) to the rostral ventrolateral medulla (RVLM) that provides a route for vestibular system modulation of neurons controlling SNA. We also demonstrated that this pathway can be activated using tilt or sinusoidal galvanic vestibular stimulation (sGVS), and that activated VSR neurons in both VNc and RVLM accumulate c-Fos. In the present study, pulsed infrared stimulation (pIRs; 1863nm, 100-250pps, 250μs) was directed through the round window toward the utricular macula in rats using customized optical fibers. Changes in BP and heart rate during pIRs were measured to characterize VSR activity. Eye movements evoked by vestibular stimulation were also measured using a video-based eye tracking system (ISCAN Inc, Woburn, MA) and a custom MATLAB program used for analysis. Rats were perfused with mixed aldehydes 90 min after the pIRs and the brainstems were sectioned serially. Sets of sections were used for multiple label immunofluorescence studies of VNc neurons. Activated neurons were identified using c-Fos protein immunodetection, and maps of activated VSR neurons were compared with those obtained using sGVS. This study demonstrated that pIRs can be used to

activate utricular hair cells and central neurons of the VSR with high spatial and temporal specificity.

Title: Sound-evoked responses of abducens neurons in rats

Authors: *H. ZHU[1], J. HUANG[1], X. TANG[1], C. STEWART[2], Y. YU[1], J. LIPPINCOTT[1], W. ZHOU[1];

Abstract: Sound-evoked vestibular myogenic potentials in the sternocleidomastoid muscles (cVEMPs) and in extraocular muscles (oVEMPs) have been widely used in clinics to assess vestibular function. Both cVEMP and oVEMP are currently interpreted as tests of the otolith function. However, there is accumulating evidence challenging this prevailing view. Our recent single unit studies of rat vestibular afferents have demonstrated that acoustic stimulation (clicks and short tone bursts) not only activates the otolithic afferents, but also the semicircular canal afferents (Zhu et al, 2011). Consistent with the single unit recording results, our intra-axonal labeling studies have provided anatomical evidence that sound sensitive afferents innervate horizontal and anterior canal cristae as well as saccular and utricular maculae (Zhu et al., 2014). These new results suggest that semicircular canal contributions to the VEMP should be taken into consideration. Since the oVEMP is mediated by the vestibulo-ocular reflex (VOR) pathway which consists of the peripheral vestibular afferents, the vestibular nuclei, and the abducens nucleus, the current set of experiments examine sound activation of the secondary vestibular nucleus neurons and abducens nucleus neurons of Sprague-Dawley rats. In a previous study, we have reported that non-canal- vestibular nucleus neurons exhibit different frequency tuning response from the Type I and Type II vestibular nucleus neurons (Zhu et al., 2013). In the present study, we have further examined abducens neuron responses to clicks and short latency tones that were delivered into either ear under pentobarbital anesthesia. Preliminary analysis shows that contralateral clicks evoke short-latency (~2.6ms) excitatory responses in abducens neurons, indicating sound-activation of the lateral semicircular canal. Ongoing studies will

elucidate the neural mechanism underlying the oVEMP and provide critical information for the development of more discriminating clinical oVEMP tests.

Title: Exploratory activity, motor coordination, and spatial learning in mice subjected to hindlimb unloading

Authors: *C. STRAZIELLE[1,2], G. HARLE[1], J.-P. FRIPPIAT[1], R. LALONDE[3];
[1]Lab. SIMPA - EA7300, Univ. of Lorraine, Vandoeuvre les nancy, France; [2]Service of Microscopy, Univ. of Lorraine, Vandoeuvre-les-Nancy, France; [3]EA 4699, Univ. of Normandy, Mont-Saint-Aignan, France

Abstract: In view of its effects on vascular parameters, microgravity induced by space flight has been shown to induce oxidative stress and cause neurochemical and metabolic alterations in several brain regions, particularly those linked to the cerebellum such as the vestibular nuclei, the brainstem reticular nuclei, and the precerebellar structures. To mimic microgravity, young adult mice were exposed to hindlimb unloading by tail suspension or not (control group) over a 21-day period and evaluated, after a 15-day period of recovery, for exploratory activity (open-field, elevated plus-maze, and emergence tests), motor coordination on the stationary beam, the coat-hanger version of the suspended bar test, and the rotorod, as well as spatial learning in the Morris water maze to detect possible long-term behavioural alterations. At the end of the behavioural study, animals were killed and brain as well as forelimb and hindlimb muscles removed for measuring regional cytochrome oxydase revealed by histochemistry as a good index of cellular metabolic activity. Both groups of mice increased their body weight in an equivalent manner. No effect was observed in the exploratory activity tests as well as in the Morris water maze, whereas the hindlimb unloaded group of mice were impaired in the stationary beam and the rotorod. Cytochrome oxidase activity decreased in several precerebellar structures as well as regions involved in the planning and control of movement such as the posterior parietal area and the substantia nigra. The present results confirmed a durable effect of microgravity on vestibulo-cerebellar and motor pathways, and muscle function.

Abstract: Spinal neural circuits convey sensory and motor information, perform computation, and are implicated in the development of pathologies such as chronic pain. These circuits are formed by a heterogeneous mixture of neuron types - understanding how each of these types contributes to overall circuit function is a major goal of spinal cord neuroscience. Although optogenetic techniques would greatly facilitate this effort, until now such studies have been stymied by a lack of experimental tools for light delivery to the spinal cord. Here, we overcome the various anatomical and physical constraints that have previously prevented the development of these tools, and show that light can be robustly delivered to the spinal cord of awake, intact mice, over long periods of time without restricting animal locomotion. The methods innovations in this work eliminate a major roadblock in sensory systems neuroscience, and may enable a wide range of studies to elucidate circuits underlying pain, touch, itch and movement.

Title: Identification of excitatory neuron populations that form the dorsal horn mechanical pain circuit

Authors: *C. PEIRS[1,2], S.-P. WILLIAMS[1,2], X. ZHAO[1,2], J. GEDEON[1], R. SEAL[1,2];
[1]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Pittsburgh Sch. of Med., Pittsburgh Ctr. for Pain Res., Pittsburgh, PA

Abstract: Mechanical hypersensitivity, of which the neuronal circuits are poorly understood, is a widespread and intractable symptom of neuropathic pain for which there is a lack of effective therapy. During tactile allodynia, activation of the sensory fibers, which normally detect touch elicit pain. We recently showed that the vesicular glutamate transporter 3 (VGLUT3), a protein that packages glutamate into secretory vesicles for regulated neurotransmission, is required for expression of mechanical hypersensitivity after inflammation or nerve injury. Mice lacking VGLUT3 also have reduced response to acute, intense mechanical stimuli, but have a normal response in all other somatosensory behaviors including innocuous touch. VGLUT3 thus appears to have a very specific and important role in the circuitry underlying mechanical pain. Our recent data support a model in which VGLUT3 expression in the dorsal horn is required for establishing the neural circuit that transmits mechanical pain in the setting of nerve or tissue damage. We also found that loss of VGLUT3 prevent excitatory postsynaptic currents (EPSCs) in lamina I nociceptive specific neurons generated by polysynaptic A-fiber under pharmacological disinhibition. Here, we use Designer Receptors Exclusively Activated by Designer Drugs (DREADD), a modified GPCR that can be activated by its exogenous ligand Clozapine-N-oxide (CNO) to control the activity specifically in restricted populations of cre-expressing dorsal horn cells. Combining pain behavior tests and immunostaining in wild-type and VGLUT3 knock-out mice, we report the critical role of VGLUT3Cre cells in central mechanical pain circuits. From there, we identified intrinsic properties, sensory inputs and neuronal outputs of VGLUT3Cre neurons using transynaptic tracings and electrophysiological recordings. We took advantage of the highly specific role of VGLUT3 to further identify cells that belong to the neuronal pathway underlying mechanical hypersensitivity. Finally, we manipulated these identified cell populations to determine their relationship to the critical VGLUT3Cre neurons.

Title: Painful cervical facet joint injury alters spinal dorsal horn excitatory and inhibitory synapse numbers and astrocytic GLT-1 that is sustained

Authors: *M. E. ITA[1], N. CROSBY[2], B. BULKA[2], B. WINKELSTEIN[2];
[1]Bioengineering, [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The spinal facet joints are a common source of pain. Traumatic facet joint injury in the cervical spine can induce a host of spinal responses characteristic of central sensitization that are also associated with persistent pain. Although spinal hyperexcitability, glial activation and excitatory synaptogenesis have been reported at day 7 after painful facet trauma, it is unknown whether such spinal modifications remain at later times. This study investigated the relationships between pain, spinal synapse numbers, and spinal astrocytic expression of the glutamate transporter, GLT-1, 14 days after facet trauma. Male Holtzman rats underwent either a facet joint stretch or sham surgery (n=5/group); mechanical hyperalgesia was measured for 14 days. At day 14, immunohistochemistry measured co-localization of the pre-synaptic structural protein, bassoon, with each of the excitatory post-synaptic marker, homer1, or the inhibitory post-synaptic marker, gephyrin, separately to quantify excitatory and inhibitory synapses in the dorsal horn. GLT-1 was also co-localized with and normalized to GFAP to quantify astrocytic GLT-1. Hyperalgesia was induced after injury ($p<0.001$). Painful injury induced a significant increase ($p<0.047$) in the number of excitatory synapses in the dorsal horn and a significant decrease ($p<0.003$) in the number of inhibitory synapses. Both total GLT-1 expression and astrocytic GLT-1 ($p<0.047$) increased in the dorsal horn after painful injury. Further, when normalizing astrocytic GLT-1 to total GFAP expression, there is still an increase ($p=0.039$), suggesting that the increase in co-localized GLT-1 and GFAP is not simply due to increased GFAP immunoreactivity after painful injury. The shift in synapse distribution after injury supports the notion that structural plasticity in the spinal cord is sustained after painful facet trauma and likely contributes to the maintenance of joint pain. The increased astrocytic activation is consistent with other reports, whereas the increase in spinal GLT-1 is opposite prior work with this model showing decreases at day 7 in spinal GLT-1 using western blot. However, intrathecal inhibition of GLT-1 has been reported to attenuate neuropathic and inflammatory pain, suggesting that increased GLT-1 in the current findings may contribute to pain. Additional work is needed to define the mechanistic role of GLT-1 in maintaining joint-mediated pain, as well as the relationships between astrocytic responses and synaptogenesis. Nonetheless, these findings implicate long-term modifications of spinal plasticity in pain maintenance after even a transient joint trauma that produces chronic pain.

Abstract: Sensory and nociceptive stimuli are processed by complex neural circuits in the periphery, spinal cord, and brain. Here, we discuss recent efforts we are undertaking to improve our understanding of how the first two steps of this processing occur. We first discuss our recent application of a novel system to deliver light to the spinal cord for optogenetic neuromodulation (for detailed discussion of system methods, see companion abstract: A.J. Christensen, ⋯, S.L. Delp, et al.). We use this system to control many populations of dorsal horn neurons in freely moving animals. We specifically express opsins in defined classes of spinal dorsal horn neurons, and characterize the effects of optogenetic activation of these circuits in freely moving mice on mechanical and thermal measures of pain, and on operant behavior. We also extend previous results in which we demonstrated optogenetic control of primary afferent nociceptors through transdermal illumination in mice injected with AAV6, examining the effects of optogenetic stimulation of the central terminals of primary afferent nociceptors expressing ChR2.

Title: Unitary EPSCs at single primary afferent-lamina I neuron synapses show predominant role of GluN2B- and GluN2D-containing NMDA receptors

Authors: *G. M. PITCHER, A. S. MORRISSY, L. GARZIA, M. D. TAYLOR, M. W. SALTER;
Hosp Sick Children, Toronto, ON, Canada

Abstract: Subunit composition of postsynaptic NMDARs plays a crucial role in excitatory synaptic transmission and plasticity in the CNS. In the spinal cord, NMDARs are expressed in lamina I of the superficial dorsal horn where nociceptive primary afferent information is integrated and relayed to the brain. Because NMDAR subtypes have distinct functional properties and are hypothesized to have differing physiological/pathological roles, a major question has been the specific GluN2 subunit composition contributing to NMDAR function at a given synapse. Here, to elucidate NMDAR subtype at single synapses, we carried out voltage-clamp recordings of lamina I neurons (n=81) in adult rat spinal cord slices and evoked unitary excitatory post-synaptic currents (uEPSCs; Vh: +60 mV) by stimulating a single primary afferent monosynaptic connection to the neuron recorded. uEPSCs exhibited consistent latency, amplitude, and clear stimulation threshold. Potential contributions of different GluN2 subtypes to unitary responses were investigated by analyzing decay time constants and charge transfer of the NMDAR component of uEPSCs using unsupervised hierarchical clustering to determine any relationship between NMDAR kinetics in the 81 recordings. Cluster analysis identified 3 groups and independence of the groups by multivariate anova analysis revealed that charge transfer and decay were indeed different across the 3 groups ($p < 0.0005$) suggesting that NMDAR uEPSCs at individual primary afferent-lamina I synapses derive from NMDARs with distinct kinetic properties. In one group of synapses (32%) the mean decay time constant of the NMDAR uEPSC component was fast (50 ms) and the charge transfer small (0.4 pC). A second subpopulation (18%) had a component with a long decay time constant (1218 ms) and large charge transfer of 6.1 pC. The majority of synapses (50%) had a NMDAR component with an intermediate decay time constant of 296 ms and charge transfer of 1.9 pC. Furthermore, the GluN2B antagonist Ro25-6981 reduced selectively intermediate decay uEPSCs while the GluN2D antagonist DQP-1105 reduced selectively uEPSCs with long time decay. Lamina I glutamatergic synapses are therefore not uniformly identical in terms of NMDAR kinetic properties but occur with fast, intermediate, or slow deactivation kinetics consistent with that of GluN2A-, GluN2B-, or

GluN2D-containing NMDARs, respectively. GluN2B/2D abundance suggests NMDAR subunit composition favoring participation of slow deactivation kinetics and temporal summation, and therefore identifies GluN2B/2Ds as potential molecular targets for treatment of pain associated with prolonged excitation at lamina I synapses.

Title: Optical and computational tools for analyzing somatosensory circuits

Authors: *S. VYAS, A. J. CHRISTENSEN, S. M. IYER, C. RAMAKRISHNAN, K. DEISSEROTH, S. L. DELP;
Stanford Univ., Stanford, CA

Abstract: Optical imaging techniques to observe neural activity in anesthetized mice present a compelling opportunity for the analysis of dorsal horn circuits in response to sensory stimuli. Here, we discuss viral methods to express genetically encoded calcium indicators (GECIs), such as GCaMP6f in the dorsal horn of the spinal cord through intraspinal injection and transsynaptic retrograde spread following intrasciatic injection, and report on the expression levels and degree of signal-to-noise achieved. We then discuss methods to enable direct imaging of neural activity in anesthetized preparations. These methods involve the placement of a coverslip superficial to the spinal cord, and the placement of a clamping system to enable reduction of motion artifacts during imaging. We present preliminary imaging results from animals that have received such an imaging implant. We also discuss methods to process and analyzing the resulting data, focusing on two questions: 1) identification of specific neural sub-graphs that are formed in response to particular patterns of sensory input, 2) analysis of how these sub-graphs contribute to the transition from sensory input to read-out of this information at the spinal cord and brain. These tools may provide for a system to assess how sensory stimuli are represented in the spinal cord, and how this information is transferred to the brain.

Title: A machine learning methodology for the selection and classification of spontaneous spinal cord dorsum potentials allows disclosure of structured (non-random) changes in population neuronal activity induced by nociceptive stimulation

Authors: ***P. RUDOMIN**[1,2], M. MARTIN[3], J. BEJAR[3], E. CONTRERAS-HERNÁNDEZ[1], D. CHAVEZ[1], G. ESPOSITO[3], U. CORTES[3], S. GLUSMAN[1];

Abstract: Fractal analysis of spontaneous cord dorsum potentials (CDPs) generated in the lumbosacral spinal segments of the anesthetized cat has revealed that these potentials are produced by ongoing structured (non-random) neuronal activity. Previous studies aimed to disclose the changes produced by nociceptive stimulation on the functional organization of the neuronal networks generating these potentials used predetermined templates to select specific classes of spontaneous CDPs. Since this procedure was time consuming and required continuous supervision, it was mostly limited to the analysis of two types of CDPs (negative CDPs and negative-positive CDPs), thus excluding potentials that could reflect activation of other neuronal networks of presumed functional relevance. Here we present a novel procedure based on machine learning that allows the semi-automatic, efficient and unbiased selection of a variety of spontaneous CDPs with different shapes and amplitudes that is used to build a dictionary by grouping the CDPs in coherent classes. The reliability and performance of the method was evaluated by examining the changes in the probabilities of generation of several types of spontaneous CDPs induced by the injection of small amounts of capsaicin in the plantar hind paw of the anesthetized cat. The results obtained with our selection method allowed detection of spontaneous CDPs that are assumed to represent the activation of functionally coupled sets of dorsal horn neurons that acquire different and structured configurations in response to

nociceptive stimuli. A relevant characteristic of our method is its capability to identify a basic dictionary of CDP classes that show statistical stability through different experimental manipulations. These dictionaries are also able to confirm (and to extend) the expert knowledge, characterizing changes in the CDPs activity and identifying patterns in raw data recorded under normal and pathological situations that would remain undetected with the use of predetermined templates.

Title: Chasing morphological changes of neuronal processes in the spinal dorsal horn in an inflammatory pain model by using two-photon microscopy

Authors: ***S. MATSUMURA**[1], W. TANIGUCHI[2], K. NISHIDA[1], T. NAKATSUKA[3], S. ITO[1]; [1]Med. Chem., Kansai Med. Univ., Hirakata, Japan; [2]Dept. of Orthopaedic Surgery, Wakayama Med. Univ., Wakayama, Japan; [3]Pain Res. Center, Kansai Univ. of Hlth. Sci., Kumatori, Japan

Abstract: Long-term *in vivo* imaging by two-photon microscopy has recently enabled analysis of structural synaptic plasticity in adult neural circuits, such as the structural dynamics of neocortical neurons in the normal and in the injured adult brain. While the pain system in the spinal cord is phylogenetically primitive and easily exhibits behavioral changes such as hyperalgesia in response to inflammation, there is no report on structural changes of dendrites in the dorsal horn, as done in the hippocampus and neocortex, because of spinal cord movements caused by respiration and heart beats and because of the difficult surgical access to the dorsal horn as compared with that to the brain. With our past experience of *in vivo* patch-clamp recordings, we succeeded in establishing experimental procedures to prepare the spinal cord sufficiently for chasing morphological changes of neuronal processes *in vivo* by using two-photon microscopy. Here we demonstrated inflammation-induced structural changes in dendrites in the spinal dorsal horn of two transgenic mice, one expressing enhanced green fluorescent

protein in dorsal spinal neurons and the other expressing yellow fluorescent protein specific to the nervous system over the course of several hours. Structural changes such as the formation of spine-like structures and swelling of dendrites were observed in the spinal dorsal horn within 30 min after the multiple-site injections of complete Freund's adjuvant, a chemical irritant, to a leg; and these changes continued for 5 h. Both AMPA and NMDA receptor antagonists, and gabapentin, a presynaptic Ca2+ channel blocker, completely suppressed the inflammation-induced structural changes in the dendrites in the spinal dorsal horn. The present study first demonstrates by *in vivo* two-photon microscopy imaging that structural synaptic plasticity occurred in the spinal dorsal horn immediately after the injection of complete Freund's adjuvant and may be involved in inflammatory pain. Furthermore, acute inflammation-associated structural changes in the spinal dorsal horn were shown to be mediated by glutamate receptor activation.

Title: The paired-domain transcription factor Pax2, as a possible nuclear marker for adult GABAergic spinal dorsal horn neurons

Authors: *P. SZUCS[1,2], L. L. LUZ[4,5], F. DORA[1,2], M. SIVADO[1,2], E. KOKAI[1,2], Z. MESZAR[3]; [1]MTA-DE-NAP B-Pain Control Res. Group, Debrecen, Hungary; [2]Dept. Physiol., [3]Dept. Biol., Univ. of Porto, Fac. of Med., Porto, Portugal

Abstract: Confirmation of the inhibitory nature of biocytin labelled interneurons in the spinal dorsal horn is technically challenging. The most accepted method, demonstration of vesicular inhibitory amino acid transporters (e.g. VGAT) in axon terminals of the neuron, has several pitfalls. The method requires sufficient labelling of the axon in recorded neurons and,

furthermore, the demonstration of the fact that the VGAT positive axon terminals are indeed connected to the neuron to be identified. An ideal and more convenient way to identify inhibitory neurons, even in case of partially labelled neurons, would be to use somatic or nuclear markers. Several lines of evidence support the model where differentiation of GABAergic interneurons in the dorsal cord depends on the paired-domain transcription factor Pax2, with several other factors (including Lhx1 and Lhx5) helping to activate and maintain Pax2 expression in these cells. Pax2 as a marker has already been used to identify future GABAergic neurons in development studies and recently it was also utilized to identify neuronal groups labelled with intrauterine electroporation in the postnatal period. In this study we systematically tested the expression of Pax2 in adult rodent spinal dorsal horn neurons to quantify the overlap with the inhibitory population defined by the presence of GAD2 or VGAT in the soma and terminals, respectively. We found that Pax2 labels the somata of inhibitory neurons in the adult rodent spinal dorsal horn with good reliability making it a putative marker for individually labelled inhibitory neurons.

Title: Control of nociceptive responses by spinal cholinergic tone after peripheral neuropathy

Authors: *M. CORDERO-ERAUSQUIN[1], M. MEDRANO[1], D. DHANASOBHON[1], I. YALCIN[1], R. SCHLICHTER[2];
[1]CNRS, Strasbourg, France; [2]CNRS - Univ. de Strasbourg, Strasbourg, France

Abstract: Endogenous acetylcholine (ACh) is an important modulator of nociceptive sensory processing in the spinal cord. While a basal tone of spinal ACh seems to modulate the threshold for nociceptive responses, this tone appears to be disrupted in neuropathic animals. However, the underlying network and mechanisms are unknown. The aim of this study was to elucidate the spinal cholinergic tone in naïve and neuropathic animals, through behavioral experiments and *in vivo* electrophysiology. Our behavior experiments confirm the existence of a spinal cholinergic tone modulating mechanical nociceptive responses in naïve mice, involving nicotinic but also muscarinic receptors. While this tone was thought to be completely lost in neuropathic animals,

our results demonstrate that it is still present, although with an altered efficacy. We then performed *in vivo* extracellular recordings in the mouse dorsal spinal cord to unravel what neurons were affected by the cholinergic tone and how. We could distinguish two populations of neurons responding to nociceptive stimulation, one of which was modulated by the topical application of cholinergic antagonists in naïve animals. In neuropathic animals, responses to peripheral stimulation as well as to cholinergic antagonists were modified in both populations. Our study therefore provides important insights into the spinal cholinergic system in nociception. In addition, it provides novel data about the exact nature of the plasticity occurring after neuropathy. Answering these questions should enable the identification of novel therapeutic targets for the treatment of chronic pain.

Title: Intradermal serotonin enhances warming-evoked responses of superficial dorsal horn neurons in the mouse

Authors: *T. AKIYAMA[1], M. NAGAMINE[2], M. I. CARSTENS[2], E. CARSTENS[2];
[1]Dermatol. & Anat. and Cell Biol., Temple Univ., Philadelphia, PA; [2]NPB, UC Davis, Davis, CA

Abstract: Itch is often triggered by warming the skin in patients with itchy dermatitis, but the underlying mechanism is largely unknown. We presently used electrophysiological methods to investigate if intradermal injection of pruritogens (histamine or serotonin) enhances warming-evoked responses of mouse superficial dorsal horn neurons. Under pentobarbital anesthesia, a laminectomy exposed the lumbar spinal cord for single-unit recording in C57BL/6 mice. Once a mechanosensitive unit was isolated, we tested the unit responsiveness to light brushing, followed by pinching, and subsequently thermal stimuli (37°C) to the hindpaw. Then, either histamine (50 µg/µl; 1 µl injection volume) or serotonin (50 µg/µl; 1 µl injection volume) was injected. Unit responses to application of the same thermal stimuli were determined 5-min, 10-min, 15-min, and 30 min postinjection. At the conclusion of the recording, an electrolytic lesion was made. Recordings were made from a total of 85 units located primarily in the superficial dorsal horn. Of 85 characterized units, 35 (41%) responded to brush and pinch of the hindpaw receptive field

(wide dynamic range=WDR), and 50 (59%) to pinch only (high threshold=HT). 20/85 (24%) responded to warm stimuli. 16/30 (53%) responded to histamine. 14/51 (27%) responded to serotonin. In serotonin-responsive units, mean warming-evoked responses were significantly greater following intradermal injection of serotonin compared to pre-injection. Responses evoked by same warming stimulus were not affected following intradermal injection of serotonin in serotonin-insensitive units, or following intradermal injection of histamine that either did or did not increase neuronal firing. Serotonin-responsive superficial dorsal horn neurons may be involved in warming-evoked itch.

Title: Activity-dependent calcium dynamics in spinal cord lamina I neurons

Authors: *E. K. HARDING[1,2], M. W. SALTER[1,2];
[1]Hosp. For Sick Children, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: Lamina I neurons of the spinal cord are critical for the integration and relaying of nociceptive information from the periphery to the brain. However, little is known about the function of voltage-gated calcium channels (VGCCs) in these neurons. Calcium is an integral second messenger that initiates activation of gene transcription that leads to potentiation of neuronal output. Here, we sought to understand how the activity of lamina I neurons changes calcium concentration in cellular compartments. We made current-clamp recordings from the soma of lamina I neurons, which were loaded via the patch pipette with the calcium indicator

Oregon Green Bapta-1 (OGB1) and the reference fluorophore Alexa Fluor-594 (AF-594). Using this method we were able to perform simultaneous two-photon calcium imaging and current-clamp recordings. We first defined the threshold for visualization of calcium responses in the somata of lamina I neurons. 5ms current injections were able to induce single action potentials, which resulted in robust rises in OGB-1 fluorescence (quantified as ΔG/R). We found that these rises in calcium to single action potentials were visible in the somatic cytosol (peak ΔG/R = 0.09 +/- 0.02, n = 6 neurons), dendrites (peak ΔG/R = 0.2 +/- 0.02, n = 20 neurons), and dendritic spines (peak ΔG/R = 0.07 +/- 0.01, n = 7 spines from 3 neurons). We found that the nucleus of these neurons also showed a calcium rise in response to a single action potential (peak ΔG/R = 0.03 +/- 0.01, n = 6 neurons). However, we found that that both the rise and decay times of the nuclear response were significantly slower (rise time; somatic cytosol = 45ms +/- 11ms, n = 6 neurons; nucleus = 238ms +/- 52ms, n = 6 neurons; dendrite = 35ms +/- 3ms, n = 20 neurons; dendritic spine = 46ms +/- 9ms, n = 7 spines from 3 neurons) (decay time; somatic cytosol = 4.3s +/- 1.2s, n = 6 neurons; nucleus = 21s +/- 15s, n = 6 neurons; dendrite = 2.2 +/- 0.4s, n = 20 neurons; dendritic spine = 1.4s +/- 0.2s, n = 7 spines from 3 neurons). We found that all calcium responses were prevented by the addition of tetrodotoxin to block action potential generation. Bath application of 100μM cadmium significantly reduced the calcium rise in all measured compartments (somatic cytosol = 106% +/- 4%, n = 3 neurons; nucleus = 84% +/- 4%, n = 3 neurons; dendrite = 86% +/- 3%, n = 3 neurons), indicating that the calcium rise due to action potential firing is dependent on VGCCs. These findings suggest that when a lamina I neuron fires single APs, this opens VGCCs and elicits calcium entry into the dendritic arbour and nucleus. This activity-dependent rise in nuclear calcium could be capable of encoding changes that alter gene transcription to upregulate excitability.

Title: Regulation of lipids in the spinal cord reflects activation of microglia after sciatic nerve transection

Authors: X. DONGMIN[1], *T. OMURA[2], N. MASAKI[3], H. ARIMA[1], M. HANADA[1], T. BANNO[1], M. SETOU[3], Y. MATSUYAMA[1];
[1]Orthopaedic Surgery, Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan; [2]Hamamatsu Univ. Sch. of Med., Hamamatsu, Shizuoka, Japan; [3]Cell Biol. and Anat., Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Background Sciatic nerve transection (SNT) induces massive transcriptional changes in the motor neuron, DRG as well as in the spinal cord. Lipids, such as PUFA-containing phosphatidylcholines (PUFA-PCs) release arachidonic acid (AA) or docosahexaenoic acid (DHA) which plays an important role in the central nervous system (CNS). However, little is known about the PUFA-PCs in the spinal cord after SNT and how the release of PUFA-PCs are associated with glial cells which are the essential cells in CNS. Methods To elucidate is the regulation of lipid within the spinal cord after peripheral nerve injury, we studies lipid regulation of the spinal cord in C57BL/6JJmsSlc mice after SNT. We used matrix-assisted laser desorption/ionization imaging mass spectrometry (MALDI-IMS) to analyze the distribution of arachidonic acid-containing phosphatidylcholines (AA-PCs) and docosahexaenoic acid-containing phosphatidylcholines (DHA-PCs). Immunohistological analysis was performed to quantify the glial cells in the spinal cord after SNT. Results Seven days after, SNT [PC (16:0/20:4)+K]+ was increased in the ipsilateral ventral and dorsal horns of the spinal cord. The remaining PUFA-PCs species showed no significant difference 7 days after SNT. The temporal analysis of the [PC (16:0/20:4)+K]+ revealed significantly higher regulation in the spinal cord from day 3 to day 28 after SNT. Furthermore, immunohistochemistry analysis demonstrated that both the spatial and temporal expression patterns of Iba1 positive microglial cells, but not GFAP positive astrocytes resembled the expression of [PC (16:0/20:4)+K]+. Conclusions Our study suggest that the increased expression of [PC (16:0/20:4)+K]+ is related with the activated microglial cells, and the expression of [PC (16:0/20:4)+K]+ could be considered as a characteristic feature in response to nerve injury.

Title: Diode laser nociceptive primary afferent-selective activation of spinal dorsal horn neurons

Authors: ***J. ZHANG**[1], D. J. CAVANAUGH[2], A. I. BASBAUM[3], M. I. NEMENOV[4,5]; [1]Univ. of Utah, Salt Lake City, UT; [2]Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [3]Anat.,

Univ. of California San Francisco, San Francisco, CA; [4]Lasmed LLC, Mountain View, CA; [5]Anesthesia, Stanford Univ., Stanford, CA

Abstract: Neuropathic pain can be triggered by activity of diverse primary afferent pathways, including mechano-insensitive and mechano-heat nociceptors. To what extent these afferents differentially contribute to mechanical allodynia and spontaneous pain is not clear. Selective activation of these afferents for experimental analysis, however, is difficult, as these afferents terminate at different skin depths. We recently documented that a diode laser fiber-type selective stimulation (DLss) allowed homogeneous activation of epidermal and dermal C or Aδ nociceptive fibers in rodents and in patients with painful neuropathy. Here, in a mouse model we used DLss combined with *in vivo* extracellular recordings to study the differential input from C or Aδ fiber to spinal heat-responsive neurons in superficial and deep dorsal horn (including presumptive laminae I and V projection neurons). We focused on heat-responsive afferents that innervate the hindpaw. The response properties of these spinal cord neurons to DLss were compared to their responses to conventional Peltier contact thermode stimulation, in mice pretreated with intrathecal vehicle, or capsaicin to ablate TRPV1+ afferents. Protocols for the C or Aδ laser stimuli were based on stimulus-induced withdrawal in normal, awake animals. We found that all spinal cord neurons that responded to the contact thermode stimulus also responded to DLss. This included all nociceptive-specific and wide dynamic range neurons in both laminae I and V. The response delays of these neurons to DLss, we conclude reflect the different conduction velocities of C and Aδ afferents and firing rates correlated both with the receptive field temperature and the relative laser energy applied. The input to the spinal cord neurons was highly convergent: all cells received input from C fiber stimulation, and ~75% of the cells in lamina I and all in lamina V received input from Aδ fibers. Although our initial search strategy was biased to mechanosensitive neurons, in lamina I we recorded one cell that only responded to C and Aδ laser stimuli, but not to noxious contact heat or mechanical stimuli. Unexpectedly, in capsaicin-treated mice, we recorded two heat-insensitive cells (one in lamina I and one in lamina V) that responded to DLss-generated Aδ fiber activation. These findings establish the utility of DLss activation of afferents to study convergent C and Aδ input to the spinal cord. The DLss is also useful in the analysis of nociceptive inputs that cannot be engaged with more conventional heat stimuli.

Title: An exploratory analysis of the variation in firing properties among rat spinal dorsal horn neurons responding to knee joint movement in the monosodium iodoacetate sensitized rat

Authors: *J. A. MIRANDA[1], E. PITT[2], K. GORE[2], M. WHITLOCK[2], H. REES[1];
[1]Pfizer Neurosci. and Pain, Cambridge, United Kingdom; [2]Res. Statistics, Pfizer Clin. Res., Cambridge, United Kingdom

Abstract: Classification of the physiological responses of neurons can aid in revealing the underlying mechanisms of neural processing, particularly when combined with pharmacological investigations. In spinal cord sensory processing neurons, this is often done using subjective criteria based on assumptions about peripheral inputs to these integrating cells. Such classification approaches risk introducing bias, resulting in an incomplete picture of the neural network of interest. We previously established a preclinical physiological assay to test pharmacological modulation of spinal neuron responses to knee joint movement in Sprague Dawley rats. Animals were injected with 1mg of monosodium iodoacetate into the left knee joint and peripheral sensitization was allowed to develop over 14-17 days. In an effort to support the 3Rs (Replacement, Reduction and Refinement) aspect of animal experimentation and make the most of all animal data collected, we have cataloged all data collected from this assay. After repeated runs of the assay, including positive and negative controls, we have accumulated action potential firing profiles for over 200 cells. Here we present our analyses aimed at understanding the variation in firing properties among those cells using multivariate statistical methods on factors such as ongoing activity, phasic firing responses, tonic firing responses, afterdischarge, stimulus-response profiles and the interrelationship among these factors. The preliminary conclusion is that clear-cut subjective classification of response types may not be justified given the high level of heterogeneity among cells in this dataset. Further analysis with a larger sample size is continuing with a goal to provide a clearer picture of knee joint pain and movement processing in the rat spinal cord.

Title: Region-specific organization of mammalian dorsal spinal cord pain circuits

Authors: *W. P. OLSON, J. NIU, A. VYSOCHAN, W. LUO;
Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: It is well established that the organization of motor and autonomic nervous system spinal cord circuits varies based on body region. However, the region-specific variability of the functional organization of somatosensory circuits in the dorsal spinal cord is much less clear. I used an inducible Cre mouse line (MrgprDCreERT2) and an alkaline phosphatase reporter mouse line (RosaiAP) to sparsely label non-peptidergic-type nociceptors. AP staining of whole mount skin and spinal cord tissue reveals the morphology of individual peripheral and central terminal arbors of non-peptidergic nociceptors. Interestingly, while the peripheral arbors of this population show a surprising similarity between body regions, we found clear morphological differences in the central terminal morphology of axially- vs. distally- innervating neurons. Non-peptidergic nociceptors innervating the trunk have exclusively long and thin central terminals in the thoracic spinal cord. In contrast, those that innervate the paws, head, and tail display rounded central terminals in the medial cervical enlargement, medial lumbar enlargement, medulla, and sacral spinal cord. This regional variability in nociceptor morphology has not previously been described and suggests key differences in the organization of pain circuits innervating axial and distal body regions. I am currently investigating potential differences in nociceptor overlap between paw and trunk regions to provide a likely mechanism governing the spatial acuity of different regions (since distal body regions have a heighted spatial acuity for both the light touch and pain systems). In addition, I am testing potential mechanisms that could establish this regional diversity during development.

Title: Characterization of Gbx1 neurons in the mouse spinal dorsal horn

Authors: *K. HAENRAETS[1,2], H. WILDNER[1], S. THERIN[1], H. U. ZEILHOFER[1,2];
[1]Univ. of Zurich, Inst. of Pharmacol. and Toxicology, Zurich, Switzerland; [2]Inst. of Pharmaceut. Sci., Swiss Federal Inst. of Technol. (ETH) Zurich, Zurich, Switzerland

Abstract: Inhibitory interneurons of the spinal dorsal horn play key roles in the processing of sensory information arriving in the CNS from the trunk and extremities. These neurons constitute a highly heterogeneous population. Only recently, techniques became available that allow

linking subtypes of dorsal horn interneurons to specific functions in sensory processing. Here, we focused on a subpopulation of inhibitory dorsal horn interneurons expressing the homeobox gene Gbx1. We found that about half of the neurons expressing the inhibitory marker Pax2 also express Gbx1. Gbx1-positive neurons were concentrated in lamina I - III. Using Gad67^{eGFP} and GlyT2::eGFP reporter lines, we found that 47 ± 5% of Gbx1 neurons in laminae I/II expressed Gad67^{eGFP}, and 74 ± 7% of Gbx1 neurons in lamina III expressed also GlyT2::eGFP. In order to investigate the function of Gbx1 neurons and their integration in pain and itch pathways, we generated a transgenic mouse line expressing the Cre recombinase under the control of the endogenous Gbx1 locus. We ablated Gbx1 neurons unilaterally by intraspinal injection of a Cre-dependent diphtheria toxin fragment A-expressing adeno-associated virus (AAV). Starting at day 5 after AAV injection, Gbx1 neuron-ablated mice exhibited licking and biting directed to the ipsilateral hind limb resulting in hair loss and skin lesions, and flinches of the affected hind limb. Around day 11, the mice became more responsive to mechanical von Frey filament stimulation. At the same time, latencies of withdrawal responses to noxious heat stimulation increased. Injection of a cre-dependent eGFP-expressing AAV into the dorsal horn revealed that not only dorsal horn neurons but also a heterogeneous population of dorsal root ganglion (DRG) neurons expresses Gbx1. About 10% of the DRG neurons innervating the AAV-injected segments expressed eGFP, including cells, which were NF200-immunoreactive, IB4-binding or CGRP-immunoreactive. These neurons may underlie the reduced heat sensitivity observed in our experiments. In order to characterize the integration of dorsal horn Gbx1 neurons in descending pathways, we performed retrograde monosynaptic rabies virus-based tracing experiments to identify neurons presynaptic to Gbx1 neurons. Labeled neurons were found in the raphe nuclei and the reticular formation, in the vestibular nuclei and the cuneate nuclei, the red nuclei and the somatosensory/motor cortex. Our experiments suggest that dorsal horn Gbx1 neurons control the spinal processing of noxious signals. Their activity appears in turn to be controlled by several brain areas including some with hitherto unidentified roles in pain processing or modulation.

Title: Investigating the viability and excitability of adult dorsal horn neurons using a double-sectioning assay

Authors: *A. DEDEK[1], K. FARMER[2], T. BOSNIC[2], M. E. HILDEBRAND[2];
[2]Neurosci., [1]Carleton Univ., Ottawa, ON, Canada

Abstract: The dorsal horn of the spinal cord is an essential processing network within the nociceptive pathway. Hyperexcitability within the dorsal horn contributes to pain hypersensitivity in many chronic pain syndromes. Studying the molecular underpinnings of this hyperexcitability requires the use of adult rats, as behavioural hypersensitivity is most robust and translatable to human conditions in adult animal models of chronic pain. However, studying the electrophysiological properties of adult dorsal horn neurons *in situ* is limited by the sensitivity of these neurons to insults induced by spinal dissection and sectioning. Moreover, the conditions most critical for preserving neuronal viability during these procedures have not yet been identified. Thus, we developed an assay to assess neuronal health in the spinal cord dorsal horn following sectioning for electrophysiology. We sectioned spinal cords at a standard thickness (300µm) and found that it was not possible to quantify neuronal viability using only light microscopy. Thus, we fixed the spinal sections and stained them with a neuronal marker (NeuN) and a cell death marker (Fluoro-Jade B). However, we found that the thickness of the slices prevented marker penetration as well as resolution of individual neurons. We therefore embedded fixed 300µm sections in gelatin and re-sectioned to 40µm to allow for effective staining. Using this assay, we are currently exploring which cytoprotective conditions maximize neuronal viability in the adult dorsal horn. Beyond optimization of spinal slicing procedures, this double-sectioning assay allows us to explore the molecular mechanisms that underlie electrical properties within individual dorsal horn neurons by combining immunofluorescent staining and neuronal recordings.

Title: Parabrachial nucleus mediates itch-induced scratching behavior

Authors: *Y. SUN, D. MU, K.-F. LIU, J. DENG, Y. SHI, Q. MAO;
Inst. of Neurosci., Shanghai, China

Abstract: Itching, or pruritus, is defined as an unpleasant cutaneous sensation that serves as a physiological self-protective mechanism to prevent the body from being hurt by harmful external

agents. However, millions of people are suffering from chronic itch, most of which are resistant to current treatment. Based on the responsiveness to antihistamine, itch can be classified into histamine-dependent and histamine-independent itch. Recent studies have demonstrated the molecular mechanism of histamine-dependent and -independent itch, however, the circuitry mechanisms of itch signal processing in brain still remain unknown. By using c-Fos as a neuronal activity marker, we found that parabrachial nucleus in the brainstem is activated by intradermal injection of histamine and chloroquine, which induce histamine-dependent and -independent itch respectively. We thus determined the functional role of parabrachial nucleus in the itch signal processing. Using pharacogenetics to suppress the neuronal activity of parabrachial nucleus, we found that scratching behavior in response to histamine and chloroquine is significantly suppressed. Most of the projection neurons in parabrachial nucleus are glutamatergic neurons, which employs vGluT2 to load glutamate into synaptic vesicles. By stereotaxic injection of AAV-Cre virus into parabrachial nucleus of vglut2f/f mice, we selectively knocked out vGluT2 from glutamatergic neurons of parabrachial nucleus. And we found that the release of glutamate is largely abolished as detected by *in vitro* patch clamp recording. Consistently, we found that blocking the release of glutamate release of parabrachial nucleus decreased the scratching number in both histamine-dependent and histamine-independent itch models. Moreover, the scratching behavior in allergic and chronic itch models is also suppressed. More interestingly, the pattern of scratching is also affected as detected by high resolution scratching behavior recording. In contrast, pain is not affected in animals with vGluT2 deleted from parabrachial nucleus. Our study thus demonstrates that parabrachial nucleus plays an essential role in mediating the itch-induced scratching behavior.

Title: Integration of bilateral nociceptive signals in the human central nervous system: evidence for novel and distinct modulatory mechanisms in the spinal cord and brain

Authors: *N. RUSTAMOV, J. TESSIER, M. PICHÉ;
Dept. of chiropractic, Univ. du Quebec a Trois-Rivieres, Trois Rivieres, QC, Canada

Abstract: The aim of this study was to examine spinal and cerebral integration of bilateral signals arising from the limbs. Two experiments were conducted, in which nociceptive flexion reflex (NFR) and scalp somatosensory evoked potentials (SEP) were evoked by electrical stimulation. In both experiments, the right sural nerve was stimulated at an individually adjusted intensity (120 % of NFR threshold). For experiment 1 (n=25), the contralateral stimulus was applied to the left sural nerve and intensity was adjusted individually to 60, 120 or 140 % of NFR threshold. For experiment 2 (n=18), the contralateral stimulus was applied to the dorsum of the left hand and intensity was adjusted to 60, 120 or 140 % of the pain threshold. In experiment 1, participants were instructed to attend either the right or left stimulus. In experiment 2, participants were instructed to attend the right stimulus only. Right sural SEP were obtained using a subtraction analysis (difference wave): SEP evoked by bilateral stimulation at 60, 120, or140 % of NFR threshold on the left and 120 % of NFR threshold on the right - SEP evoked by left unilateral stimulation at 60, 120, or 140 % of NFR threshold, respectively. These difference waves were compared with right unilateral sural SEP. In experiment 1, NFR amplitude was significantly increased by contralateral stimulation only when the shock was nociceptive (120 and 140 % of NFR threshold, p's < 0.001). However, these effects were not modulated by attention (p = 0.3). In contrast, the amplitude of difference waves was significantly decreased compared with SEP evoked by right unilateral stimulation for all 3 conditions, including 60, 120 and 140 % (p's < 0.001), while attention had no effect (p = 0.8). In experiment 2, the NFR was facilitated by stimulation of the left hand only when the shock was nociceptive (120 and 140 % of pain threshold, p's < 0.001). Similarly to experiment 1, the amplitude of difference waves was significantly decreased compared with the SEP evoked by right unilateral stimulation for all 3 conditions (p's < 0.001). These results indicate that contralateral stimulation facilitates the NFR when the stimulus is concurrent and nociceptive, independently of the attentional focus. Facilitation occurred with contralateral stimulation of either lower or upper limb, suggesting the involvement of descending pathways originating in the brain. In contrast, brain activity specifically evoked by stimulation on the right was decreased by the contralateral stimulus. These results provide evidence for novel and distinct mechanisms for the integration of nociceptive signals in the brain and spinal cord, which may allow unique and adapted protective responses.

Title: Characterization of spinal VGF expression and localization following spinal cord injury

Authors: *J. L. COOK, M. S. RIEDL, J. MAXON, A. M. PARR, L. VULCHANOVA; Univ. of Minnesota, Minneapolis, MN

Abstract: VGF is a granin-related neuropeptide precursor whose expression is rapidly and robustly increased in dorsal root ganglion and dorsal horn neurons following peripheral nerve injury. We have demonstrated that intrathecal administration of several VGF peptides derived from the C-terminal region of the precursor results in thermal hyperalgesia and furthermore, that VGF-derived peptides contribute to both the development and maintenance of hypersensitivity after peripheral nerve injury and inflammation. We hypothesized that VGF levels would also increase after spinal cord injury (SCI), another nervous system insult that results in hypersensitivity and inflammation and ultimately in chronic pain. VGF expression was examined by immunohistochemistry at 28 days post-thoracic SCI, a time-point at which mechanical allodynia and thermal hyperalgesia are present. Rostral to the injury,VGF immunoreactivity -(ir) was decreased in the superficial dorsal horn of SCI animals compared to sham controls. At the injury site, VGF-ir was increased throughout the entirety of the gray matter, with highest levels in the dorsal horn and surrounding the central canal. Caudal to the injury, VGF-ir was increased in the dorsal horn of the spinal cord. These changes were seen through six spinal cord segments caudal to the injury site. The VGF derived peptide TLQP-21 has been shown to activate the Complement 3a (C3aR1) receptor. Signaling via C3aR1 is known to activate the mitogen-activated protein kinase family, including ERK, and activated ERK (phosphorylated ERK, or pERK) is increased in microglia after SCI and is associated with hypersensitivity. Following thoracic SCI, the number of Iba1+ cells appeared to be increased at the site of injury, with some cells exhibiting hypertrophic morphology. Iba1+ cells with hypertrophic morphology were also present caudal to the injury in SCI compared to sham animals. pERK-ir was increased at injury level in the dorsal horn and in the gray matter surrounding the central canal, and caudal to the injury in the lumbar cord, SCI animals had increased pERK staining in the spinal dorsal horn. These results suggest that SCI is associated with persistent changes in VGF expression, microglial activation, and ERK phosphorylation at time-points where pain-related behavior has been recorded.

Title: Dual frequency temporal patterns improve efficacy and efficiency of spinal cord stimulation

Authors: *T. ZHANG[1], J. J. JANIK[5], W. M. GRILL[1,2,3,4];
[1]Biomed. Engin., [2]Electrical Engin., [3]Neurobio., [4]Surgery, Duke Univ., Durham, NC; [5]Stryker Corp., Kalamazoo, MI

Abstract: Spinal cord stimulation (SCS) is an established therapy for treating refractory chronic pain, but fewer than 60 % of patients experience 50 % or greater pain relief, and this success rate has improved little over time. Conventional single frequency SCS (sfSCS) generates both excitation and inhibition in the dorsal horn network, and sfSCS must be applied at a sufficiently high frequency (typically 50 Hz) for SCS-mediated inhibition to overcome SCS-mediated excitation. We hypothesized that SCS could be improved using dual frequency SCS (dfSCS) to disperse SCS-mediated excitation while preserving SCS-mediated inhibition. We simulated the effects of dfSCS on the firing rate of the output neuron in a validated computational model of the Gate Control circuit by delivering two different frequencies of SCS concurrently to distinct groups of dorsal column fibers. We identified dfSCS pairs that were more effective at inhibiting model neuron activity than sfSCS applied at the average of the constituent frequencies and that had average frequencies lower than clinically used 50 Hz (i.e., more efficient). Furthermore, appropriately selected dfSCS frequency pairs continued to inhibit the model spinal sensory neuron even after the GABAergic synapses onto the model neuron were weakened by 50 % to simulate the transition to neuropathic pain. We then measured in urethane anesthesized healthy rats the change in firing rate of spinal sensory neurons produced by dfSCS during concomitant sciatic stimulation. An appropriately selected dfSCS pair generated significantly greater inhibition (i.e., more effective) of spinal sensory neurons *in vivo* than sfSCS applied at each of the two constituent frequencies or at the average of the two constituent frequencies and did so at an average frequency less than 50 Hz (i.e., more efficient). In a subset of experiments, the $GABA_A$ receptor antagonist bicuculline was applied intrathecally prior to SCS to mimic the progression of neuropathic pain. Despite loss of GABAergic inhibition, select dfSCS frequency pairs still produced greater inhibition of spinal sensory neurons *in vivo* than sfSCS applied at the average of the constituent frequencies or at 50 Hz. These computational and experimental results support dual frequency SCS as a novel strategy to improve the efficacy and efficiency of SCS as a therapy for treating chronic pain.

Title: Spinal integration of bilateral asynchronous nociceptive signals

Authors: *S. BEN MANAA[1], N. RUSTAMOV[2], S. BOIS[2], J. TESSIER[2], M. PICHE[2];
[1]Dept. de chiropratique, Lab. De Neurophysiologie De La Douleur, Trois Rivieres, QC, Canada;
[2]Dept. de Chiropratique, Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: We recently observed that the lower limb nociceptive flexion reflex (NFR) is facilitated by a concurrent contralateral stimulation. This was observed for stimulation of the contralateral lower or upper limbs, suggesting that facilitation involves descending pathways originating in the brain that modulate spinal circuits. In the present study, we examined whether spinal integration of peripheral and cerebrospinal inputs is modulated when bilateral stimuli are asynchronous. The right and left sural nerves were stimulated in 20 healthy participants at an individually adjusted intensity (120 % of NFR threshold) in five conditions: 1) unilateral right stimulation; bilateral stimulation with 2) no delay 3) a 50-ms delay 4) a 100-ms delay 5) a 500-ms delay. Based on previous results, we anticipated that bilateral stimulation would facilitate the NFR. However, based on the latency of the crossed-extension reflex and reciprocal innervation (agonist/antagonist reciprocal inhibition), we hypothesized that this facilitation would be attenuated or abolished in 50-ms and 100-ms delay conditions. As expected, NFR amplitude was significantly different across the 5 conditions ($F(4,76) = 3.0$, $p = 0.43$; ($\eta p2 = 0.14$). Dunnet's test for multiple comparisons further indicated that NFR was facilitated for the no-delay or 500-ms delay conditions compared with the right unilateral condition ($p = 0.03$ and $p = 0.007$, respectively) while NFR amplitude was not significantly modulated for the 50-ms and 100-ms conditions ($p = 0.2$ and $p = 0.084$, respectively). The present results confirm our hypothesis and indicate that the spinal cord integrates competing inputs from the periphery and from descending modulatory pathways during bilateral stimulation. This study also suggests the existence of spinal circuitry allowing the interaction and regulation of peripheral nociceptive input from both lower limbs. This mechanism may allow adapted protective responses depending on the context.

Title: Properties of cutaneous and muscle afferent synapses onto lamina I projection neurons in the developing rat spinal cord

Authors: ***J. LI**[1], M. BACCEI[2];
[2]Anesthesiolgoy, [1]Univ. Cincinnati, Cincinnati, OH

Abstract: Previous work suggests that muscle afferents are more effective at inducing hyperexcitability within spinal cord circuits (i.e. 'central sensitization') compared to cutaneous afferents, and musculoskeletal pain in children is more common than pain of cutaneous origin. However, the reasons for this are still unclear because nothing is known about whether superficial dorsal horn neurons process sensory input from muscle vs. skin differently at the synaptic level. Here we investigated the functional properties of monosynaptic inputs from sensory afferents traveling in the gastrocnemius (GS; predominantly innervating muscle) or sural (largely cutaneous) nerves onto identified lamina I projection neurons (PNs) using *in vitro* patch clamp recordings in an intact neonatal spinal cord preparation. Paired-pulse stimulation experiments demonstrated a significantly lower paired-pulse ratio in response to stimulation of the GS nerve compared to the sural nerve, suggesting a higher probability of glutamate release at muscle afferent synapses onto ascending spinal PNs. Nonetheless, muscle and cutaneous afferent synapses displayed a similar degree of short-term depression following repetitive stimulation and recovered with a similar time course. Long-term synaptic plasticity at these synapses was investigated using a spike timing-dependent plasticity (STDP) protocol involving the pairing of highly correlated presynaptic and postsynaptic firing. A significantly greater percentage of lamina I PNs showed long-term potentiation (LTP) in response to GS nerve stimulation compared to sural nerve activation, which was accompanied by a greater magnitude of LTP at muscle afferent synapses. While the mechanisms underlying the enhanced plasticity of muscle afferent synapses remains to be fully elucidated, it is unlikely to reflect differences in the subunit composition of postsynaptic NMDARs within lamina I PNs, as both the decay kinetics of isolated NMDAR currents and the sensitivity to a NR2B-selective antagonist were similar following GS and sural nerve stimulation. Overall, the present results reveal novel heterogeneity in the properties of primary afferent synapses onto the key output neurons of the developing

spinal nociceptive circuit, which may contribute to the greater ability of muscle afferents to evoke central sensitization.

Title: Spinal manipulation decreases experimental back pain: specific effects on temporal summation of pain

Authors: *C. RANDOLL[1], N. RUSTAMOV[1], J. TESSIER[1], V. GAGNON-NORMANDIN[1], J. O'SHAUGHNESSY[1], M. DESCARREAUX[2], M. PICHÉ[1];
[1]Chiropractic, [2]Sci. de l'activité Physique, Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: Several studies have examined the effects of spinal manipulation (SM) on experimental and clinical pain. In spite of some negative results, SM produced hypoalgesic effects for the majority of these studies. However, some studies did not control for potential nonspecific effects. Moreover, there is still limited evidence on how these hypoalgesic effects are produced. The aim of the present study was to examine the hypoalgesic effects of thoracic SM on pain and temporal summation of pain, while controlling for potential nonspecific effects. The study comprised 2 experiments including 16 and 15 healthy participants, respectively. The experimental design included 6 sessions allowing to compare changes in perception or temporal summation for painful vs non-painful electrical stimulation 1) in a control condition 2) after a control light mechanical stimulus 3) after SM. Stimulation was applied locally at the T4 thoracic spine segment, where SM and the control mechanical stimulus were applied. In experiment 1, electrical stimulation was applied as a single 1-ms pulse and perception was rated for each stimulus. In experiment 2, stimulation consisted in a train of five 1-ms pulses delivered at 2 Hz, in order to induce temporal summation. In this case, participants were instructed to rate the strongest sensation for each stimulus train. SM involved articular cavitation while the control mechanical stimulus was a calibrated force of approximately 25 N applied for 2 seconds. In

experiment 1, perception was not significantly altered by SM or the control mechanical stimulus for either the painful (interaction: $F(4,60) = 1.9$; $p = 0.12$) or non-painful (interaction: $F(4,60) = 0.9$; $p = 0.46$) stimulation. In experiment 2, temporal summation was observed for both the painful (main effect: $F(1,14) = 42.0$; $p < 0.001$) and non-painful (main effect: $F(1,14) = 23.7$; $p < 0.001$) stimulation. However, temporal summation was marginally decreased across sessions and blocks (time) for the painful (interaction: $F(4,56) = 2.1$; $p = 0.08$) but not non painful (interaction: $F(4,52) = 0.1$; $p = 0.9$) stimulation. Bonferroni-corrected planned contrasts revealed that temporal summation of pain was significantly decreased after SM compared with baseline ($p = 0.009$) but this effect was not maintained 10 minutes after SM ($p = 0.16$). Planned contrasts also revealed that the control mechanical stimulus did not significantly modulate temporal summation of pain ($p > 0.05$). These results indicate that SM produces transient hypoalgesic effects on temporal summation of pain, while a control mechanical stimulus is ineffective. This suggests that SM-induced hypoalgesia relies in part on a spinal mechanism.

Title: Identification of spinal circuitry for mechanical pain by intersectional genetics

Authors: *B. DUAN[1], L. CHEN[1], M. GOULDING[2], Q. MA[1];
[1]Dana-Farber Cancer Institute, Harvard, Boston, MA; [2]Salk Inst., La Jolla, CA

Abstract: Pain information processing in the spinal cord has been postulated to rely on nociceptive transmission (T) neurons receiving inputs from nociceptors and Aβ mechanoreceptors, with Aβ inputs gated through feed-forward activation of spinal inhibitory neurons (INs). Here, we used intersectional genetic manipulations to identify these critical components of pain transduction. Marking and ablating different populations of spinal excitatory

and inhibitory neurons, coupled with behavioral and electrophysiological analysis, showed that excitatory neurons expressing somatostatin (SOM) include T-type cells, whose ablation causes loss of mechanical pain. Inhibitory neurons marked by the expression of dynorphin (Dyn) represent INs, which are necessary to gate Aβ fibers from activating SOM+ neurons to evoke pain. In addition, our findings using other Cre lines that mark distinct subsets of SOM lineage neurons showed that these neurons represent a heterogenous population of excitatory neurons that transmit distinct forms of mechanical pain.

Title: Effects of early life stress vary across paradigm: a comparative analysis of sex-specific alterations in viscerosomatic pain

Authors: *D. PRUSATOR[1], B. GREENWOOD-VAN MEERVELD[2];
[2]Oklahoma Ctr. for Neuroscience, Dept. of Veterans Affairs, [1]Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Early life stress (ELS) serves as a risk factor for the development of functional pain disorders such as irritable bowel syndrome (IBS) in adults. The long-term effects of ELS are multifaceted and complex to study in patients, therefore the mechanisms leading to long-term consequences of ELS remain poorly understood. Although rodent models have been developed to mirror different forms of ELS experience, the use of predominantly male animals has led to limited information related to sex-related differences in the persistent effects of ELS on pain behaviors in adulthood. In the present investigation, we test the hypothesis that the context or nature of ELS experience may interact with sex-differences to influence the development of chronic pain. In this study, three rodent models mimicking different facets of adversity were used to investigate the long-term effects of ELS on pain perception in rats. As neonates, male and female rat pups were exposed to either maternal separation (MS), limited nesting (LN), or a classical conditioning paradigm, odor-attachment learning (OAL). Following maturation to adulthood, visceral sensitivity and somatic sensitivity were assessed at ~postnatal day 90 via visceromotor response to colorectal distension or von Frey probe, respectively. Our study demonstrates that visceral and somatic sensitivity are increased in male rats exposed to neonatal MS or LN, whereas female rats were unaffected compared to controls that were left undisturbed.

In the OAL model, only females exhibited visceral hypersensitivity in response to unpredictable odor-shock conditioning, but not somatic hypersensitivity. Males were seemingly unaffected following OAL exposure. Our overall analysis suggests that the development of heightened pain behaviors in adulthood is not only influenced by individual ELS experiences, but also by sex-differences. Specifically, this study indicates that male and female animals may exhibit vulnerability or resilience for the development of heightened pain perception based on the specific type of ELS experienced.

Title: Chronic stress-induced lower back pain in a rat trigeminal neuropathic pain model: central mechanisms that contribute to comorbid pain conditions

Authors: J.-L. YANG, S.-P. ZOU, W. GUO, K. REN, *R. DUBNER, R. TRAUB, F. WEI; Dept Neural and Pain Sci., Univ. Maryland Dent. Sch., Baltimore, MD

Abstract: Chronic pain and stress impact on each other and are potentially modifiable risk factors for poor health outcomes. Clinical data have identified an association between perceived stress and various pain syndromes including orofacial and abdominal pain. However, the mechanisms underlying how psychological stress exacerbates pain experiences are poorly understood. In the present study, we investigated the effects of chronic stress on behavioral hypersensitivity in the rat trigeminal neuropathic pain model induced by chronic construction injury to the infraorbital nerve (CCI-ION). Ten days after CCI or sham surgery, male and female Sprague-Dawley rats were subject to 3 day forced swim stress (10 min on the first day, 20 min on the 2nd and 3rd day) and subsequently tested daily for mechanical sensitivity. While CCI-ION induced mechanical hyperalgesia and allodynia to cutaneous stimulation in the dermatome innervated by the injured nerve (V2) and secondary hyperalgesia in the adjacent mandibular division (V3), they were not exacerbated by forced swim stress. To determine if secondary hyperalgesia or spreading pain develops out of the orofacial area, we tested mechanical sensitivity in the fore paw, hind paw and lower back (region of referred pain from the lower GI tract). There were no significant changes in mechanical nociception at both fore and hind paws in the CCI+stress group. However, there was persistent mechanical hypersensitivity in the lower back starting one day after the last forced swim. This distal hypersensitivity persisted at least 11 days in female rats but only 7 days in male rats, suggesting that subchronic stress induces spreading lower back pain in the presence of an existing orofacial neuropathic pain. This is comparable to our model of masseter muscle inflammation followed by stress inducing chronic abdominal pain. The current model further demonstrates a potential sex difference. In order to explore involvement of central mechanisms, the selective 5-HT3R inhibitor Y25130 (120 fmol/10ul, i.t.) was administered at 7d after forced swim. Hyperalgesia in the lower back was significantly reduced 1 and 3 h after drug treatment and totally recovered at 5 h. This finding indicates that spinal 5-HT3 receptors are involved in stress-induced low back hyperalgesia after nerve injury, suggesting that 5-HT-dependent descending facilitation mediates comorbid chronic stress-induced gastrointestinal hypersensitivity in an orofacial neuropathic pain model.

Title: Opposing roles of estradiol and testosterone on stress-induced visceral hypersensitivity in rats

Authors: Y. JI[1,2], X. HU[1], *R. J. TRAUB[1,2];
[1]Neural and Pain Sci., Univ. of Maryland Sch. of Dent., Baltimore, MD; [2]UM Ctr. to Advance Chronic Pain Res., Baltimore, MD

Abstract: Stress can be both pro- and anti-nociceptive. Acute stress generally attenuates pain (i.e. stress-induced analgesia). In contrast, chronic stress exacerbates acute pain and triggers pain in chronic conditions such as irritable bowel syndrome, temporomandibular disorder, fibromyalgia and others. Female predominance, especially during reproductive years, strongly suggests a role of gonadal hormones in these chronic pain disorders. However, the mechanisms underlying gonadal hormone modulation of stress induced pain hypersensitivity are not well understood. In the present study, we tested the role of estradiol (E2) and testosterone (T) on stress-induced visceral hypersensitivity (SIVH) in male and female Sprague-Dawley rats using a forced swim (FS) paradigm as a subchronic stressor. Visceral sensitivity was assessed by recording the visceromotor response (VMR) to colorectal distention. Following baseline recording, rats were subjected to 3 daily sessions of FS (10 min, 20 min, 20 min; 26°C H2O). The VMR was recorded 2,6,10 and 18 days after the last swim session. In female rats FS induced visceral hypersensitivity that lasted 2-3 weeks. In contrast, in males, visceral hypersensitivity was apparent only at 2 days post stress. SIVH was not observed in ovariectomized rats, suggesting a facilitating effect of female gonadal hormones. Intrathecal administration of the estrogen receptor (ER) antagonist ICI-182,780 30 min prior to each FS attenuated the visceral hypersensitivity in intact female rats, further supporting a facilitatory role of E2. The pronociceptive effect of E2 in SIVH was also observed in males; E2 injection every 4 days (which mimics the cyclic changes of estrogen level in intact female rats) dramatically increased visceral hypersensitivity at all timepoints through 18 days. E2 without stress had no effect on the VMR in males. In contrast to E2, Testosterone was found to be protective/antinociceptive. Gonadectomy increased the duration and magnitude of SIVH compared to intact males. Implanting testosterone capsules in females attenuated SIVH, overcoming the facilitation by E2.

Serum levels of E2 in injected males and T in capsulated females were within the physiological range of intact females/males, respectively. Western blot analysis in male tissue revealed the level of the NMDA receptor subunit GluN1 in dorsal spinal cord was increased after E2 injection. In addition, FS decreased spinal mGluR2 expression in E2 injected males. These data suggest that estradiol facilitates and testosterone attenuates stress-induced visceral hypersensitivity by modulating spinal glutamate receptor expression independent of sex.

Title: Stress epigenetically regulates spinal NMDA and mGluR3 expression modulating visceral sensitivity in female rats

Authors: D.-Y. CAO[1,2], *G. BAI[1,3], Y. JI[1,3], R. J. TRAUB[1,3];
[1]Dept. Neural & Pain Sciences, Program Neurosci, Univ. of Maryland Dent. Sch., Baltimore, MD; [2]Stomatological Hosp. Res. Ctr., Xi'an Jiaotong Univ. Hlth. Sci. Ctr., Xi'an, China; [3]Ctr. to Advance Chronic Pain Res., Univ. of Maryland, Baltimore, MD

Abstract: Irritable bowel syndrome (IBS) is a chronic pain condition that is more prevalent in women. It is associated with visceral hypersensitivity that is often exacerbated by stress. However, the underlying mechanisms are not completely understood. We previously reported that spinally administered histone deacetylase (HDAC) inhibitors blocked estrogen-induced visceral hypersensitivity by increasing metabotropic glutamate receptor 2 (mGluR2) activity. In the present study we investigated mechanisms underlying stress-induced visceral hypersensitivity focusing on epigenetic modulation of ionotropic and metabotropic glutamate receptors in the spinal cord. Intact female Sprague-Dawley rats were stressed by 3 daily sessions of forced swim (FS). The magnitude of the visceromotor response (VMR) to noxious colorectal distention increased significantly 1 day after the last FS compared with the pre-stress baseline. This was reversed by intrathecal injection (30 nmol, i.t.) of the NMDA receptor antagonist APV (approximately 50% reduction in the VMR, similar to non-stressed rats). Stress also increased NMDA receptor GluN1 protein and mRNA expression in the dorsal spinal cord compared to naïve rats. Intrathecal injection of the HDAC inhibitor suberoylanilide hydroxamic acid (SAHA; 40 μg/day, 30 min before each FS) blocked the stress-induced increase in the VMR and GluN1 mRNA. APV still attenuated the VMR by ~50%. SAHA also increased mGluR3 mRNA

compared with vehicle pre-treated, stressed rats. The mGluR2/3 antagonist LY341495 (20 nmol, i.t.) following SAHA pretreatment reversed the SAHA-evoked block of the stress-induced visceral hypersensitivity, but did not alter FS-induced visceral hypersensitivity in the absence of SAHA. These results suggest that repeated psychophysical stress epigenetically regulates glutamate receptor expression in the spinal cord altering visceral sensitivity by increasing excitatory receptors; there is an increase in GluN1 subunit expression although the full composition of upregulated NMDA receptors is unknown. Spinal HDAC inhibition modulates stress-induced visceral hypersensitivity via multiple mechanisms: preventing the GluN1 upregulation and increasing mGluR3 expression. These data suggest that increasing histone acetylation may be a potential approach to relieving visceral pain induced or exaggerated by stress, a contributing factor to pain in IBS patients.

Title: Voluntary exercise can prevent or reverse comorbid urogenital and mood disorders resulting from early life stress in male mice

Authors: *I. FUENTES, A. N. PIERCE, R. WANG, J. A. CHRISTIANSON;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Chronic prostatitis patients are commonly co-diagnosed with or suffer symptoms of interstitial cystitis/painful bladder syndrome. This overlap in symptomology complicates proper diagnosis and hinders the development of effective treatment strategies. Common within this cohort of patients is a history of early life stress or adversity, which has been shown to disrupt proper functioning of the hypothalamic-pituitary-adrenal (HPA) axis. Voluntary exercise has

been shown to reverse many of the symptoms attributed to HPA axis dysfunction, both in clinical and preclinical studies. Here we are investigating the therapeutic potential of voluntary wheel running in either preventing or reversing urogenital and anhedonic behaviors and associated molecular changes in a male mouse model of neonatal maternal separation (NMS). Mice were born in-house and underwent NMS from postnatal day 1 to 21. Mice given an early exercise intervention (-Eex) were pair-housed in cages equipped with running wheels at 4 weeks of age, mice given a late exercise intervention (-Lex) were tested for baseline behaviors at 8 weeks of age and were then singly housed in cages equipped with running wheels. Sedentary controls for each group (-Esed and -Lsed, respectively) remained in their home cages. NMS-Esed and NMS-Lsed mice displayed perigenital mechanical allodynia, increased micturition rates, and anhedonic behavior; all of which were not observed in either NMS-Eex or NMS-Lex mice. Dysregulation of the HPA axis was observed by increased histological evidence of mast cell degranulation in the bladder and prostate of NMS-Esed and NMS-Lsed mice and central gene changes within the hypothalamus, amygdala, and hippocampus. Exercise decreased mast cell degranulation in both groups of NMS mice, as well as increased the levels of brain-derived neurotrophic factor (BDNF) mRNA in the hippocampus of both naïve and NMS mice. Interestingly, a correlation between anhedonic behavior and urogenital sensitivity was observed only in sedentary NMS mice, suggesting that these comorbidities are mechanistically linked. Also, NMS mice ran shorter distances than naïve mice, suggesting that reward pathways may be disrupted following NMS. Taken together, these data suggest that NMS in male mice may provide a novel pre-clinical model for studying commonly co-diagnosed urogenital and mood disorders and that voluntary exercise may provide an excellent therapeutic option for increasing limbic regulation of the HPA axis.

Title: Investigating comorbidities in an early life stress model of chronic urogenital pain in mice

Authors: O. K. ELLER[1], A. N. PIERCE[1], I. M. FUENTES[1], P. T. O'NEIL[1], R. WANG[1], G. O. DUSSOR[2], *J. A. CHRISTIANSON[1];

Abstract: Urogenital pain patients often suffer from comorbid symptomology involving pain in adjacent and distant locations in the body. Many of these symptoms are induced or exacerbated by acute stress, which has been associated with dysfunction within the hypothalamic-pituitary-adrenal (HPA) axis. We have developed a mouse model of neonatal maternal separation (NMS) that exhibits evidence of increased urogenital sensitivity and dysfunction, likely due to disrupted limbic regulation of the HPA axis. Here we are investigating whether these mice also exhibit behavioral or molecular evidence indicative of fibromyalgia and migraine. Mice were born in-house and underwent NMS from postnatal day 1 through 21. At 8 weeks of age, mice were evaluated for forepaw mechanical sensitivity using graded von Frey monofilaments. NMS mice displayed significantly reduced mechanical withdrawal thresholds compared to naïve mice, indicating forepaw mechanical allodynia. Mice were then placed in cages equipped with running wheels (exercised, -Ex), or remained in their home cages (sedentary, -Sed), to evaluate the efficacy of voluntary exercise to reverse mechanical allodynia. At 12 weeks of age they were retested for forepaw mechanical sensitivity and NMS-Ex mice had significantly higher mechanical withdrawal thresholds than NMS-Sed mice and their own baseline measurements. Interestingly, naïve-Sed mice displayed significant mechanical allodynia compared to naïve-Ex mice. Mice were sacrificed and the dura mater was dissected and processed for either whole mount histological staining with acidified toluidine blue to visualize mast cell contents or for protein isolation and Western blotting with antisera to protease activated receptor 2 (PAR2). Bilateral hippocampi were also dissected and processed for mRNA isolation and real-time PCR to detect mRNA levels of glucocorticoid receptor (GR) and exons I, IV, and IX of brain-derived neurotrophic factor (BDNF). NMS-Sed mice displayed a significant increase in histological evidence of mast cell degranulation and a trend towards increased PAR2 protein levels. Exercise reversed these observations in NMS mice and increased BDNF exons IV and IX and GR mRNA levels in the hippocampus of both NMS and naïve mice. These data suggest that NMS in mice results in wide-spread increases in sensitivity, and could be used as a model for commonly observed comorbidities, including interstitial cystitis, vulvodynia or chronic prostatitis, fibromyalgia, migraine, and depression, for the development of potential therapeutics, including the use of voluntary exercise to strengthen limbic regulation of the HPA axis.

Title: Somatic complaint in dysmenorrhea and other visceral pains

Authors: R. ZUCKERMAN[1], J. KANE[2], R. L. SILTON[3], *K. M. HELLMAN[2,1], F. F. TU[2,1]; [1]Univ. of Chicago, Chicago, IL; [2]OB/GYN, NorthShore Univ. HealthSystem, Evanston, IL; [3]Psychology, Loyola, Chicago, IL

Abstract: Increased self-report of somatic complaint, somatization, is a risk factor for many chronic pain conditions including dysmenorrhea, painful bladder syndrome, and irritable bowel syndrome. Individuals with high levels of somatic complaint have demonstrated sensory amplification, widespread bodily sensitivity and indicators of central sensitization, suggestive that the central nervous system plays an important role in visceral pain. Dysmenorrhea, in contrast, has been largely explained as the result of enhanced endometrial tissue breakdown and accompanied exaggerated release of prostaglandins, which support a role for peripheral factors. In the present study, we aimed to characterize peripheral vs. central contributions. We examined the relationship between somatic, psychological and peripheral factors, and dysmenorrhea compared to non-menstrual visceral pain using an online questionnaire (n=1012). We performed a dominance analysis to dissociate somatic complaint, bodily pain complaint, the effect of hormonal contraception, age, menstrual pain, psychological factors and non-menstrual pelvic pain in a regression model. Whereas 11% of the variance in the intensity of menstrual pain was accounted for by peripheral factors such as heavier periods and hormonal contraception, 19% of the variance was associated with somatic complaint, bodily pain, and the intensity of non-menstrual pelvic pain. In contrast, 7% of the variance in the magnitude of other visceral pelvic pain was associated with menstrual factors, while 37% of the variance was associated with somatic complaints and bodily pain. Notably, anxiety and depression were not significant factors because of their collinearity with somatic complaint. Anxiety and depression were correlated with somatic complaint (R2= 55%) and bodily pain (R2=36%). Thus, the effects of anxiety and depression in dysmenorrhea and other visceral pains, often reported in other studies, could be mediated by increased somatic sensitivity. Given that somatic complaint and bodily pain explain significantly more variance than menstrual history factors in dysmenorrhea, this suggests central nervous system dysfunction needs further investigation in this presumed peripherally maintained pain state.

Title: Neural correlates of sensory amplification in dysmenorrhea and other visceral pain conditions

Authors: K. E. DILLANE[1], S. HARTE[2], K. L. POLNASZEK[3], F. F. TU[1,4], *R. L. SILTON[3], K. M. HELLMAN[1,4];

Abstract: Increased painful and non-painful somatic complaint is reported in dysmenorrhea and other visceral pain conditions. We hypothesized that women with dysmenorrhea and other visceral pain conditions have increased sensory amplification that could mediate painful and non-painful somatic complaint. To test this hypothesis, we developed a rapid visual task that could be measured with EEG. Women with dysmenorrhea (n = 12) and healthy controls (n = 6) participated in a passive viewing task that involved watching an annular checkerboard alternating at 12.5 Hz between a positive and negative contrast at 5 different levels of brightness. After each 20-second trial at each level of brightness, participants were asked to rate the unpleasantness of the visual stimulus. During this task, electroencephalography (EEG) was recorded using a 32 channel EEG cap. Evoked activity was measured by performing spectral analysis and measuring the amplitude of the first harmonic (25 Hz). Women with dysmenorrhea reported significantly higher levels of somatic complaint and unpleasantness during the visual task than healthy controls. Increasing brightness during the task was associated with increased evoked EEG activity in parietal and occipital cortical regions ($p<0.001$). Women with dysmenorrhea had less of an increase in parietal activity in response to increasing brightness than healthy controls ($p<0.001$). To specifically examine the role of sensory amplification, we also analyzed a cohort of women who reported higher visual unpleasantness ratings (>10 on a 0-20 scale) compared to the other women in the study. In this cohort, changes in brightness only increased responsiveness in occipital cortical regions. In contrast, the other participants had increased evoked activity in frontal, central and parietal regions. Thus, a wide-spread attention-control network may contribute to suppressing visual unpleasantness. Our results imply that in some women with dysmenorrhea or other visceral pains disorders, network activity that suppresses sensory amplification is awry. Utilization of this rapid EEG task can be used to further examine the mechanisms of sensory amplification in future studies.

Title: The effects of depression, dysmenorrhea, and sensory amplification on resting state brain activity

Authors: ***K. BRANDSTATT**[1], K. E. DILLANE[2], K. M. HELLMAN[2,3], F. F. TU[2,3], R. L. SILTON[1];
[1]Loyola Univ. Chicago, Chicago, IL; [2]OB/GYN, NorthShore Univ. HealthSystem, Evanston, IL; [3]Ob/gyn, Univ. of Chicago, Chicago, IL

Abstract: Depression, dysmenorrhea and sensory amplification/somatization are often comorbid and are known to effect brain activity. Our prior research has suggested that the combination of dysmenorrhea and increased somatic complaint are associated with the presence of other visceral pain conditions. In this preliminary analysis (n=17), we examined spectral analysis of resting state electroencephalography (EEG) activity in women with varying levels of menstrual pain. Four periods of resting state activity with eyes closed (60 seconds each) and four periods with eyes open (60 seconds each) were recorded with a 32-channel EEG system. Relative power was used to identify frequency bands altered in relationship to depression, dysmenorrhea, and sensory amplification. Depression was associated with decreased relative frontal alpha and delta activity, but increased frontal gamma activity (p's <0.05). Depression was also associated with more left alpha activity in parietal cortical regions ($p=0.015$), but not right. Dysmenorrhea was associated with decreased relative frontal theta but increased frontal and temporal gamma activity. No significant findings emerged in relation to sensory amplification. Since increased gamma activity is known to be associated with increased local blood-oxygenation, metabolic activity and excitatory activation, frontal cortical regions appear to be more engaged during resting state in depression and dysmenorrhea. Since depression and dysmenorrhea are associated with visceral pain in women and are related to frontal cortical activation, these findings support the idea that changes in central nervous system could contribute to risk for visceral pain. In contrast, our lack of ability to find resting state changes related to sensory amplification suggests that sensory

amplification is mediated by an alteration in a dynamic process rather than the network activity engaged in the resting state.

Title: Alterations in expression of aspartate aminotransferase and glutaminase in drg neurons: comparison between rat models of arthritis and inflammatory bowel disease

Authors: ***K. E. MILLER**[1], Z. ZHANG[1], B. R. BOLT[1], S. DAS[1], R. JOHN[1], M. B. ANDERSON[1], C. KIM[1], K. TYLER[2], B. GREENWOOD-VAN MEERVELD[2];
[1]Dept Anat. & Cell Biol, Oklahoma State Univ. Ctr. Hlth. Sci., Tulsa, OK; [2]Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Glutamate synthesis in neurons occurs by two enzymes, aspartate aminotransferase (AST) and glutaminase (GLS). Our previous studies examined alterations in expression of AST and GLS in rat dorsal root ganglion (DRG) neurons during several somatic and visceral injury/inflammation models including unilateral adjuvant-induced arthritis (AIA) and TNBS-induced colitis resembling that seen in inflammatory bowel disease (IBD). We have noted that there are similar alterations in AST and GLS expression in the DRG with these two models. The purpose of the current study, therefore, was to compare the temporal alterations of AST and GLS in the AIA and IBD models. The L4 DRG was examined for the AIA model, whereas the S1 DRG was studied for the IBD model. Temporally, there is a biphasic expression pattern observed in both models. Increased production of AST and GLS (25-40%) in the DRG occurs within 24-hr of AIA or colonic inflammation and is sustained for 1-2 days. By day 4, AST and GLS levels return to baseline, but elevate again (20%) in small diameter DRG neurons by 8 days of AIA or colitis. By day 16, AST and GLS levels are near baseline in the AIA model, but remain elevated (5-10%) in small diameter neurons for more than 30 days in the IBD model. This study illustrates a common pattern of expression for AST and GLS in DRG neurons during injury and/or inflammation. A shared blueprint of neurogenic inflammation, multiple inflammatory mediators, and neurotrophic factors may be responsible for the similarities in expression patterns. Elevated AST and GLS levels in DRG neuronal perikarya leads to increased glutamate production in peripheral and central terminals. The hypersensitivity observed in both models,

therefore, may have similar mechanisms involving altered glutamate synthesis and release. Interventional therapies for diminishing altered glutamate synthesis may hold promise for pain relief in both somatic and visceral injury and inflammation.

Title: The role of glutamatergic colonic innervation in trinitro-benzene-sulphonic acid (TNBS)-induced colitis in rats

Authors: S. DAS[1], Z. ZHANG[1], M. B. ANDERSON[1], *K. S. CURTIS[2], B. GREENWOOD-VAN MEERVELD[3], K. E. MILLER[1];
[1]Dept. Anat. and Cell Biol., [2]Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK; [3]Hlth. Sci. Ctr., Univ. of Oklahoma, Oklahoma City, OK

Abstract: Inflammatory bowel disease (IBD) is a prevalent visceral disorder characterized by abdominal cramping and pain. Pharmacologic therapy for IBD is limited and, based on our previous studies; this led us to investigate the role of the glutamatergic innervation of the colon during TNBS-induced colitis in rats, a model of IBD. Experimentally, rats received an intracolonic infusion of TNBS and colons and lumbosacral dorsal root ganglia (DRG) were collected and examined at different time points. Inflammation in the colon was robust at day 2 after TNBS infusion and we observed that glutaminase (GLS)-immunoreactive (IR) nerve fibers come into close contact with immune cells, CD161-IR (NK) cells, indicating a neuroimmune interaction during colitis. We sought, therefore, to block both the neuronal and immune components by pretreatment and co-treatment of rats with a glutaminase (GLS) inhibitor, 6-diazo-5-oxo-L-norleucine (DON) or the glucocorticoid (GC), hydrocortisone. Both DON and GC reduced colonic inflammation to control levels. For example, the mRNA for the anti-inflammatory cytokine, IL-10, was reduced at day 2 of colitis, but DON or GC pre-treatment brought IL-10 mRNA back to control levels. We also investigated the effect of DON and GC on phenotypic alterations, e.g., elevated GLS expression, in sacral DRG neurons during TNBS-induced colitis. TNBS treatment increased GLS-IR in sacral DRG neurons at day 2 and this

increase in GLS-IR was attenuated by DON or GC treatment. Our results indicate that TNBS-induced colitis has strong neurogenic and neuroimmune components and that interruption of these components provides substantial reduction in colonic inflammation.

Title: Asymmetrical involvement of the left and right central amygdala in bladder pain

Authors: *K. E. SADLER, A. M. TROUTEN, B. J. KOLBER;
Dept. of Biol. Sci., Duquesne Univ., Pittsburgh, PA

Abstract: Hemispheric lateralization is a widely recognized theme in neuroscience. First made popular by identification of brain regions like Broca's and Wernicke's areas, asymmetrical involvement of the two hemispheres is now attributed to many different neural processes outside of language cognition. Lateralization is observed in many species from the most basic invertebrates to humans. Recently this phenomenon has been reported in the central amygdala (CeA) during pain processing in rodents. As a member of the limbic system, the left and right CeA are well positioned to integrate both affective and sensory information that is generated during chronic pain conditions like interstitial cystitis/bladder pain syndrome (IC/BPS). Our lab has previously demonstrated the importance of the right CeA in bladder pain processing using genetic, pharmacological, and optogenetic techniques, however the involvement of the left CeA in these processes is unknown. In this report, we use optogenetics to activate both the left and right CeA in the context of bladder distension to determine each nucleus's contribution to this specific type of visceral pain. Increases in bladder pain-like responses are observed only during activation of the right CeA; activation of the left CeA has no effect on pain-like responses. Immunohistochemical analysis demonstrates equal cellular activation levels and basal neuron densities between the two nuclei, suggesting that another mechanism must be responsible for the observed physiological asymmetries.

Abstract: Background: Bilateral electrical pudendal nerve stimulation (bPNS) anecdotally reduces pain in humans with pain due to interstitial cystitis (IC) and we have reported that it reduces bladder hypersensitivity in rat models. Concurrent medication use can alter responses to neuromodulation and so prior to the development of a clinical trial, the interaction between use of the GABA-B receptor agonist, baclofen, and acute bPNS was examined. Methods: Bladder hypersensitivity was produced by neonatal bladder inflammation in rats pups coupled with a second inflammatory insult as an adult. A dose-response function for baclofen (1-5 mg/kg i.p.) was established. Then baclofen was administered acutely (1 mg/kg i.p.) or chronically (5 mg/kg i.p. daily for 2 weeks prior to the final experiment). Acute bPNS consisted of bilateral biphasic electrical stimulation (10 Hz, 100 μsec biphasic pulses for 10 min) of the mixed motor/sensory component of the pudendal nerves using embedded hook electrodes. Visceromotor responses (VMRs; abdominal muscle contractile responses to urinary bladder distension, UBD) were used a nociceptive endpoints. Results: Baclofen produced a dose-dependent inhibition of VMRs to UBD. bPNS resulted in statistically significant inhibition of VMRs to UBD in hypersensitive rats that had received acute or chronic i.p. baclofen injections. Conclusions: This study suggests that inhibitory effects of bPNS can be evoked in subjects who are receiving baclofen therapy, thus giving guidance to potential clinical trials for treating episodic pain in IC.

Title: Macrophage-derived high mobility group box 1 participates in the development and maintenance of pancreatic pain through the activation of RAGE and CXCR4 in mice with cerulein-induced acute pancreatitis

Authors: *Y. IRIE[1,2], M. TSUBOTA[1], F. SEKIGUCHI[1], H. ISHIKURA[2], M. NISHIBORI[3], A. KAWABATA[1];
[1]Kinki Univ. Sch. Pharm., Higashi-Osaka, Japan; [2]Div. Emerg. Critical Care Med. Fukuoka Univ. Hosp., Fukuoka, Japan; [3]Okayama Univ. Grad. Sch. Med., Okayama, Japan

Abstract: High mobility group box 1 (HMGB1), a nuclear protein, is passively or actively released from various cells including macrophages, and facilitates inflammatory responses by targeting multiple molecules including toll-like receptor 4 (TLR4) and receptor for advanced glycation endproducts (RAGE). HMGB1 also forms a complex with two molecules of CXCL12, a chemokine, and enhances the activation of CXC chemokine receptor 4 (CXCR4) by CXCL12 through the receptor dimerization. We have reported that HMGB1 participates in processing of somatic and bladder pain via the activation of TLR4 and/or RAGE. Here we investigated the role of HMGB1 in the development and/or maintenance of pancreatic pain accompanying cerulein-induced acute pancreatitis in mice. Repeated i.p. administration of cerulein induced acute pancreatitis characterized by increased serum amylase activity and pancreatic weight, and also referred hyperalgesia in the upper abdomen, an indicator of pancreatic pain. The referred hyperalgesia, but not the pancreatitis symptoms, was prevented by pretreatment with the anti-HMGB1 neutralizing antibody or recombinant human soluble thrombomodulin (rhsTM), known to delete HMGB1. They, even when administered after the establishment of acute pancreatitis, reversed the referred hyperalgesia accompanying the pancreatitis. Similarly, low molecular weight heparin (LMWH), known to inhibit RAGE, or AMD3100, a CXCR4 antagonist, exerted both preventive and therapeutic effects on the referred hyperalgesia accompanying the pancreatitis, while LPS-RS, a TLR4 antagonist, showed only the preventive effect. The protein levels of CXCL12, but not HMGB1, in the pancreatic tissue increased following repeated treatment with cerulein. Minocycline, an inhibitor of the activation of macrophage/microglia, or ethyl pyruvate, known to inhibit the release of HMGB1 from macrophages, suppressed cerulein-evoked referred hyperalgesia, but not the pancreatitis symptoms. Together, our data suggest that macrophage-derived HMGB1 contributes to the development and maintenance of pancreatic pain accompanying cerulein-induced pancreatitis through the activation of RAGE and CXCL12/CXCR4 pathways, and that the HMGB1/TLR4 signals participate only in the developmental process of pancreatic pain.

Title: Zinc deficiency aggravates bladder pain accompanying cyclophosphamide-induced cystitis through the enhanced activity of $Ca_v3.2$ T-type Ca^{2+} channels in mice

Authors: ***T. OZAKI**[1], J. MATSUOKA[1], M. TSUBOTA[1], S. TOMITA[1], F. SEKIGUCHI[1], T. MINAMI[2], A. KAWABATA[1];
[1]Kinki Univ. Sch. Pharm., Higashi-Osaka, Japan; [2]Kinki Univ. Sch. Sci. Engineer, Higashi-Osaka, Japan

Abstract: The function of $Ca_v3.2$ T-type Ca^{2+} channels is suppressed by zinc and enhanced by zinc chelators and also hydrogen sulfide (H_2S). We have reported that intracolonic (i.col.) administration of N,N,N',N'-tetrakis(2-pyridylmethyl)-ethylendiamine (TPEN), a zinc chelator, or H_2S causes $Ca_v3.2$-dependent colonic pain in mice. In the present study, we asked if the decreased zinc levels affect the bladder pain accompanying cyclophosphamide (CPA)-induced cystitis in mice, considering our recent evidence for the involvement of the increased H_2S generation by the upregulated cystathionine-γ-lyase (CSE) and the enhanced $Ca_v3.2$ activity in the same bladder pain model. In the mice fed on zinc deficient diet [Zn(-) mice] for 14 days, the zinc levels greatly decreased in the plasma, but not bladder tissue, compared with the mice fed on the control diet [Zn(+) mice]. Intraperitoneal administration of CPA at 400 mg/kg, but not 200 mg/kg, induced bladder pain-like nociceptive behavior, referred hyperalgesia and increase in bladder weight, an indicator of bladder edema, in Zn(+) mice. In Zn(-) mice, however, CPA even at 200 mg/kg, as CPA at 400 mg/kg did, caused bladder pain/referred hyperalgesia and bladder edema. Similarly, in mice that received i.p. administration of TPEN at 5 mg/kg, the subeffective dose, 200 mg/kg, of CPA induced the bladder pain/referred hyperalgesia and bladder edema. NNC 55-0396, a T-type Ca^{2+} channel blocker, or zinc chloride, administered i.p. after the development of CPA-induced cystitis, reversed the bladder pain/referred hyperalgesia, but not bladder edema, induced by the subeffective dose of CPA in the Zn(-) mice and in the mice pretreated with TPEN. Finally, TPEN in combination with CPA at 200 mg/kg did not mimic the upregulation of CSE in the bladder caused by CPA at 400 mg/kg. These results suggest that zinc deficiency aggravates CPA-induced bladder pain by enhancing the activity of Cav3.2 T-type Ca^{2+} channels, and bladder edema in $Ca_v3.2$-independent manner.

Title: Bladder pain accompanying cyclophosphamide-induced mouse cystitis involves HMGB1 release upstream of the cystathionine-gamma-lyase/H2S/Cav3.2 pathway in the bladder tissue

Authors: ***A. KAWABATA**[1], M. TSUBOTA[1], K. YAMAGUCHI[1], S. HIRAMOTO[1], F. SEKIGUCHI[1], J. TANAKA[1,2], H. ISHIKURA[2], M. NISHIBORI[3];
[1]Kinki Univ. Sch. of Pharm., Higashi-Osaka, Japan; [2]Fukuoka Univ., Fukuoka, Japan; [3]Dept. of Pharmacol., Okayama Univ. Grad. Sch. of Med., Okayama, Japan

Abstract: High mobility group box 1 (HMGB1), a nuclear protein, is passively released from necrotic cells and actively secreted by certain cells such as activated macrophages, promoting inflammatory and pain signals. The active secretion of HMGB1 is facilitated by histone acetyltransferase (HAT) and suppressed by histone deacetylase (HDAC). Our previous evidence has demonstrated that HMGB1 contributes to the bladder pain in mice with cyclophosphamide (CP)-induced cystitis through the activation of receptor for advanced glycation endproducts (RAGE). On the other hand, we have also reported that endogenous hydrogen sulfide (H2S), generated by the upregulated cystathionine-gamma-lyase (CSE), participates in the bladder pain accompanying CP-induced cystitis via the enhancement of Cav3.2 T-type calcium channel activity. Here we investigated a cross talk between the HMGB1 signals and CSE/H2S pathways in the CP-induced bladder pain. CP caused bladder pain-like nociceptive behavior and referred hyperalgesia accompanying the increased bladder weight, an indicator of bladder edema. The bladder pain/referred hyperalgesia, but not bladder edema, was prevented by deletion of HMGB1 with the neutralizing antibody or with recombinant human soluble thrombomodulin (rhsTM) that sequesters HMGB1 and promotes its degradation. Ethyl pyruvate, known to inhibit the release of HMGB1 from macrophages, also inhibited the CP-induced bladder pain/referred hyperalgesia. DL-propargylglycine (PPG), a CSE inhibitor, administered i.p. before CP treatment, abolished the bladder pain/referred hyperalgesia and partially inhibited the increased bladder weight. CP treatment induced downregulation of HDAC1 in addition to the upregulation of CSE in the bladder tissue. The CP-induced upregulation of the bladder CSE was inhibited by the anti-HMGB1 neutralizing antibody or rhsTM, whereas the CSE inhibition by PPG did not affect the CP-induced HDAC1 downregulation. Thus, in the mice with CP-induced cystitis, HMGB1 is considered to be secreted by macrophages and other cells in the bladder tissue possibly following

its accelerated acetylation attributable to downregulation of HDAC1, and cause the upregulation of CSE and subsequent increased formation of H2S, leading to the Cav3.2-dependent bladder pain.

Title: Central connectivity of the bladder afferent terminals in the rat spinal cord

Authors: ***Y. BAE**, S. PARK, A. P. DEVI, J. BAE, W. MAH, Y. KIM, Y. CHO;
Sch. of Dentistry, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Visceral afferents from urinary bladder project to L6 spinal cord and is involved in voiding and nociception. At present, little is known about how the visceral information from urinary bladder is processed in the 1st relay nucleus of the spinal cord. To address this issue, we investigated central connectivity of the bladder afferent terminals and involved neurotransmitters in the superficial dorsal horn (DH) and lateral horn (LH) of the rat L6 spinal cord by retrograde tracing with Cholera toxin B subunit-horseradish peroxidase (CTB-HRP), quantitative ultrastructural analysis and electron microscopic immunogold staining with GABA, glycine and glutamate antisera. CTB-HRP labeled bladder afferent boutons contained clear round vesicles. Most of the labeled boutons also contained large dense core vesicles. Labeled boutons were presynaptic to dendrites and frequently received axoaxonic synapse from pleomorphic vesicles containing endings (p-endings). Most of the labeled boutons showed simple synaptic connectivity with one or two postsynaptic dendrites in the DH. Whereas considerable fraction showed complex synaptic arrangement with 3 or more postsynaptic dendrites in the LH. P-endings frequently showed GABA-immunoreactivity (IR) and/or glycine-IR, suggesting that bladder afferents receive GABAergic and/or glycinergic presynaptic modulation. Fraction of the labeled boutons presynaptic to dendritic spines was significantly higher in the LH than in the DH, suggesting higher synaptic plasticity in the LH than in the DH. These findings suggest unique and different processing of bladder-related visceral information between in DH and LH of the L6 spinal cord.

Title: Glutamate metabolism and pleural inflammation in heat-killed tuberculosis induced pleurisy

Authors: *Z. ZHANG[1], S. DAS[1], S. GANDHAPUDI[2], M. ANDERSON[1], K. TEAGUE[2], K. E. MILLER[1];
[1]Anat. & Cell Biol., Oklahoma State Univ-CHS, Tulsa, OK; [2]Integrative Immunol. Ctr., Univ. of Oklahoma Sch. of Community Med., Tulsa, OK

Abstract: Pleurisy, the inflammation of the visceral and parietal pleura, can make breathing or coughing painful after pulmonary infection. The infection is treated depending on the cause, while pleuritic pain often is not adequately addressed. Parietal and visceral pleura have sensory innervation from thoracic DRG neurons and pleuritic pain is conveyed to the spinal cord by these DRG neurons using glutamate as their neurotransmitter. Glutamate is synthesized by glutaminase (GLS) in DRG neurons. In previous studies, we have shown that increased GLS levels in DRG neurons responding to peripheral inflammation contribute to the pain hypersensitivity in the inflamed skin and colon. The goal of this study is to determine in *tuberculosis*-induced pleurisy: 1) the response of DRG neurons, i.e., GLS levels, to pleural inflammation and 2) the potential anti-inflammatory effects of inhibiting GLS in the pleura. Heat-killed *Mycobacterium tuberculosis* (hk-TB) were injected into the rat pleural cavity, whereas control groups received saline injections. At 1, 2, 4 and 8 days, the pleural cavity was washed and the pleural contents collected. Leukocytes were harvested for FACS analysis and inflammatory cytokines in pleural effusion were analyzed. T1 to T4 DRGs were collected bilaterally and pooled to evaluate GLS expression level using quantitative immunohistochemistry and western blot. A GLS inhibitor, 6-diazo-5-oxo-L-norleucine (DON), was administrated as a pretreatment to evaluate the effect of GLS inhibition on hk-TB-induced pleurisy. Intrapleural injection of hk-TB caused a substantial pleural effusion and leukocyte recruitment in the pleural cavity. The leukocyte population shifted from neutrophils to macrophages as the inflammation progressed. Pretreatment with DON, GLS inhibitor, significantly suppressed the leukocyte infiltration induced by hk-TB. In the DRG, an increase in GLS immunoreactivity was observed at 1-2 days of pleural inflammation. These results demonstrate that chronic pleural inflammation causes elevated GLS expression in the DRG neurons, indicating an increase in glutamate synthesis in the peripheral and central terminals of sensory afferents innervating the pleura. The overproduction of glutamate at peripheral terminals leads to aggravation of inflammation, manifesting as a neuro-immune

interaction at the inflamed tissue. With this information, our goal is to close the knowledge gap between pleural inflammation and pleuritic pain and to identify potential novel anti-inflammatory and analgesic targets for treating pleurisy.

Title: A pan-trk inhibitor with low brain penetration inhibits NGF-induced pharmacological responces, and exerts analgesic effect comparable to Morphine in rat osteoarthritis pain model

Authors: T. YASUHIRO, K. ODA, T. NAGAURA, *K. MITSUI, S. KATSUMATA, Y. HIROTA;
ONO Pharmaceut. Co., Ltd., Osaka, Japan

Abstract: Background and aimsPeripheral tropomyosin receptor kinase (Trk) A, specific receptor for NGF, is a promising target for inhibition of the signaling processes that contribute to the manifestation of chronic pain. The importance of these processes has been highlighted by the anti-NGF antibodies which have demonstrated significant analgesic effects when compared to non-opiate medications in patients with chronic pain. We discovered an orally available small molecule pan-Trk (TrkA, TrkB and TrkC) inhibitor with low brain penetration and evaluated its effects in rat peripheral NGF-induced increase of dermal blood flow, hyperalgesia and the MIA osteoarthritis pain model. Methods The pan-Trk inhibitor (0.1 to 3 mg/kg) was administered orally, 12 hours later NGF (1 μg/site) was injected intradermally into the plantar of hind limb. 3 hours after NGF injection, changes in dermal blood flow by thermal stimulation were measured using laser speckle blood flow imager. For assessment of hyperalgesia, NGF (5 μg/site) was injected intramuscularly into calf. Three hours after NGF injection, pressure hyperalgesia to the plantar of hind limb was evaluated by a Randall-Selitto analgesiometer. The osteoarthritis model was established by MIA (3 mg/site) injection intraarticularly into the knee . The pan-Trk inhibitor (0.1 to 10 mg/kg) was administered orally twice a day from 14 to 21 days after MIA injection. The pain-related behavior was evaluated weight bearing on hind limb using a Linton Incapacitance Tester. Results The pan-Trk inhibitor dose-dependently inhibited NGF-induced increase of dermal blood flow and hyperalgesia, and the dose of 3 mg/kg was maximum effect in both models. Moreover, this compound dose dependently inhibited the pain-related behavior in

the MIA osteoarthritis model, and the analgesic effect at ≥1 mg/kg b.i.d. was comparable to that of morphine at 3 mg/kg. Conclusion The pan-Trk inhibitor showed potent analgesic effects in osteoarthritic pain model comparable to strong opiate. The effective plasma concentration of this compound in osteoarthritic pain model was similar to that at 3 mg/kg; the dose required to significantly inhibit peripheral NGF-induced increase of dermal blood flow and hyperalgesia in rats.

Title: Cav3.2-expressing low-threshold C fibres in human hairy skin contribute to cooling allodynia - a non-TRPV1- and non-TRPM8-dependent phenomenon

Authors: ***D. A. MAHNS**, M. S. SAMOUR, S. S. NAGI;
Univ. of Western Sydney, Penrith, Australia

Abstract: Background: It is generally agreed that cold allodynia is a consequence of impaired (Aδ-fibre-mediated) central inhibition of C-nociceptive inputs. However, it is also known that C polymodal nociceptors are not activated at innocuous low temperatures. We recently showed that another form of allodynia, namely tactile allodynia, in which the peripheral driver is typically ascribed to large myelinated afferents, can be mediated by low-threshold C mechanoreceptors, termed C-tactile fibres (CTs). In the current study, we investigated whether this, or a related, C-fibre class contributes to cooling allodynia. Methods: In 30 healthy and 3 chronic-pain subjects, a series of normally innocuous, localized, thermal stimuli were applied to the skin overlying a painful tibialis anterior muscle (induced by infusion of 5% hypertonic saline). The effects of thermal stimulation on muscle pain were observed prior to and following conduction block of myelinated fibres by compression of sciatic nerve. Furthermore, intradermal capsaicin, menthol and TTA-A2 were used for desensitization of TRPV1, TRPM8 and T-type calcium (Cav3.2) channels respectively. Results: Prior to muscle pain, all thermal stimuli were reported as non-

painful regardless of whether myelinated fibres were conducting or not. During muscle pain, dynamic skin cooling (32°C→20°C) evoked significant and reproducible increases in the overall pain intensity (allodynia). This increase was short-lived and locked to the dynamic phase of cooling with pain levels returning to baseline during sustained cooling. Dynamic warming (32°C→39°C) had no effect on pain levels. Cooling allodynia persisted following nerve compression and TRPV1 and TRPM8 desensitization, but was abolished by localized Cav3.2 blockade. In clinical subjects, C-fibre-mediated allodynia was observed without the need for experimental pain-producing manipulations. Conclusion: Cooling allodynia represents a non-TRPV1- and non-TRPM8-dependent phenomenon, which is mediated by low-threshold Cav3.2-expressing C fibres. Further investigations are underway to examine the effect of Cav3.2 suppression on tactile allodynia in experimental and clinical pain conditions.

Title: Spinal microglial activation in a murine surgical model of osteoarthritis is driven by joint damage

Authors: *P. B. TRAN[1], R. E. MILLER[1], S. ISHIHARA[1], R. J. MILLER[2], A.-M. MALFAIT[1]; [1]Intrnl. Med. Rheumatology, Rush Univ. Med. Ctr., Chicago, IL; [2]Northwestern Univ., Chicago, IL

Abstract: Osteoarthritis (OA), the most common form of arthritis, is a leading cause of chronic pain. Mechanisms of chronic pain associated with OA are poorly understood. We characterized a murine surgical model of OA, in which joint damage progresses slowly over 16 weeks after destabilization of the medial meniscus (DMM). In association with joint damage, mice develop progressive mechanical allodynia, which is maintained for 16 weeks. Behavioral changes indicative of chronic pain, along with accelerated joint damage, first appear 8 weeks after DMM surgery. The aim of this study was to characterize molecular and cellular changes that may be associated with the persistence of pain. We assessed fractalkine (CX3CL1) release by DRG neurons as well as microglial activation in the dorsal horn (DH) over 16 weeks following DMM. We also investigated whether joint protection could attenuate these changes by using *Adamts5* null mice, which are protected from developing OA and mechanical allodynia. Methods: DMM

or sham surgery was performed in the right knee of 10-week old male wild type or *Adamts5* null C57BL/6 mice. At 4, 8 and 16 weeks post surgery, L3-L5 DRG cells from DMM, sham or age-matched naïve control mice were harvested and cultured for 4 days; supernatants were collected for CX3CL1 ELISA. For immunohistochemistry, mice were perfused transcardially with paraformaldehyde, and the spinal column decalcified prior to cryosectioning. To assess microglial activation in the DH, L4 spinal sections were immunostained with Iba1 antibody and the number of activated microglia was quantified based on the morphology of Iba1 immunoreactive microglia, using established methods. Results: In wild-type mice, 4 weeks after DMM, DRG cultures released similar amounts of CX3CL1 as naïve controls. However, at 8 and 16 weeks post-DMM, DRG cells released more CX3CL1 than controls. There were also increased numbers of activated microglia in the DH at 8 and 16 weeks post-DMM compared to sham and age-matched naïve controls. In contrast, 8 weeks after DMM in *Adamts5* null mice, cultured DRG cells did not release increased levels of CX3CL1, and microgliosis in the DH was not detected. Conclusion: In the DMM surgical model of OA, microglial activation occurs in the DH during the chronic pain phase. The temporal correlation of CX3CL1 release with microglial activation suggests that CX3CL1 may contribute to microglial activation. The reduction in microglial activation in *Adamts5* null mice compared to wild-type mice suggests that protecting the joint and preventing peripheral sensitization can attenuate central sensitization.

Title: Antinociceptive effects of ONO-2952, a TSPO antagonist, on acidic saline-induced mechanical hyperalgesia in rats

Authors: *S. KATSUMATA[1,2], K. MITSUI[3], Y. EZAKI[4];
[1]ONO Pharmmaceutical Co., Ltd., Osaka, Japan; [2]Discovery Res. Loboratories I, ONO Pharmaceutical. CO., LTD., Osaka, Japan; [3]Discovery Res. Alliance, ONO Pharmaceut. CO., LTD., Osaka, Japan; [4]Exploratory Res. Labs. IV, ONO Pharmaceut. CO., LTD., Tsukuba, Japan

Abstract: Acidic saline-induced hyperalgesia is recognized to be a model of fibromyalgia. We evaluated effects of ONO-2952, a TSPO antagonist, on mechanical hyperalgesia in this model and TSPO occupancy in several brain regions to clarify relationship between the effective dose and occupancy rate. Male Crl: CD (SD) rats (5 weeks old) were used. Hundred μL of saline at pH 4.0 was injected twice, 5 days apart, into left gastrocnemius muscle of rats. Saline was

injected for control group. Vehicle (0.5% methylcellulose, b.i.d.), ONO-2952 (0.1, 1 and 10 mg/kg, b.i.d.), duloxetine (30 mg/kg, q.d.) or pregabalin (20 mg/kg, b.i.d.) were orally administered for 6 days from 7 days after second injection (Day1) to Day6. On Day 7, each solution was administered once in the morning. Vehicle was administered to control group. Withdrawal thresholds of right and left paw were determined in Randall-Selitto test at just before and 2 hours after first administration on Day1 and Day7. After evaluation, hippocampus, midbrain and pons and medulla were dissected. Homogenates were prepared to determine specific binding of ^{3}H-PBR28 for the calculation of TSPO occupancy in each region. On Day1, paw withdrawal thresholds (PWTs) of both paws in control group were significantly lower than those of normal group. PWTs in ONO-2952 or duloxetine group were not different from those in control group. PWTs after administration in pregabalin group were significantly higher than those of control group. On Day7, PWTs of both paws in control group were significantly lower than those of normal group. PWTs in ONO-2952 and duloxetine group both before and after administration were significantly higher than those of control group. Left PWT before administration and left and right PWTs after administration were significantly higher than those of control group. ONO-2952 occupied TSPO in 3 regions with about 30% at 0.1 mg/kg, 80% at 1 mg/kg and 95% at 10 mg/kg. There was no significant difference in specific binding of ^{3}H-PBR28 in each region. Thus, ONO-2952 inhibited acidic saline-induced mechanical hyperalgesia with repeated oral administration at the doses of 0.1, 1 and 10 mg/kg in rats. The effects were exerted with more than 30% occupancy of TSPO in the brain and reached maximum at 80% occupancy. These results suggest that ONO-2952 would be an efficacious treatment for fibromyalgia.

Abstract: Fibromyalgia (FM) is a musculoskeletal syndrome characterized by chronic widespread pain, tenderness to palpation and various concomitant symptoms, including affective disorders such as depression. In addition, several surveys have reported that approximately 80 to 90 % of FM patients are women and has been reported that hormonal abnormalities due to an early age-of-onset menopause might play an important role in the altered processing of somatosensory information. Drugs with confirmed efficacy for the treatment of FM produce adverse effects that promote treatment discontinuation. Scientific studies have corroborated analgesic and anti-inflammatory effects of flavonoids. Rutin (quercetin-3-O-rutinoside) is a glycoside of the well known aglycon quercetin. In this study we analyzed the antihyperalgesic and antiallodynic effect of rutin by using the reserpine-induced myalgia model of FM. Eight groups (n=8/group) of female Wistar Rats (200-250 g) were ovariectomized 14 days before reserpine (1 mg/kg, s.c. during 3 consecutive days) injection. An extra healthy control group was added. Rutin was administrated at increasing doses (30-1000 mg/kg, i.p.). Pramipexole (1 mg/kg s.c.) was used as the reference drug. All drugs were evaluated on day 5 after the last reserpine injection. The muscle pressure, tactile response and cold allodynia thresholds were measured before drugs' administration and 30, 60,120, 150, 180, 210 and 240 min after treatments. Analysis by two-way repeated-measures ANOVA revealed that subcutaneous injection of reserpine produce significant diminution in the muscle pressure and tactile response thresholds in 48 % and 70 %, respectively. Whereas, in the cold allodynia test, injection of reserpine increased 8 times the time response in acetone spray test. Rutin, in a dose-dependent manner, reverted the effects of reserpine on muscle pressure (ED30=288 mg/kg), tactile response (ED30=894 mg/kg) and cold allodynia (ED30=929 mg/kg), reaching its maximum effect after one hour. The antihyperalgesic and antiallodynic effects of rutin at 562 mg/kg were similar to that observed with pramipexole. In conclusion, these results give evidence that systemic rutin administration produces analgesic effects in an experimental model of FM supporting the potential of rutin for the FM therapy.

Title: Long term muscle involvement after neonatal pain

Authors: A. B. SIMÕES[1], J. A. ALVES[1], F. J. DIAS[1], E. C. CARMO[2], N. L. B. MACHADO[2], L. S. SANADA[2], *V. S. FAZAN[3];

Abstract: Nociceptive stimuli applied soon after birth play an important role in the development of pain in adult life. Previous studies in our laboratory have shown that pain in the neonatal period can cause a number of changes both in the central nervous system and the musculoskeletal [1], but experimental substrates for these changes still need investigation. We designed an experimental study to explore whether pain in the neonatal period can cause long term changes in the locomotor system. The pain groups (male and female Wistar rats, N = 10 per group) were stimulated with a needle on the right paw, twice a day, since birth, for 15 consecutive days. The control groups (male and female Wistar rats, N = 10 per group) were stimulated with a cotton swab. Final experiments were performed 180 days after birth. In order to evaluate the motor function of the hind paws, grip strength tests were conducted. All tests were performed by one single observer that was blind to animals' experimental groups (pain or control). Maximum and average (mean of three consecutive measures) grip strength was studied. Lateral (LG) and medial gastrocnemius (MG) muscles, obtained by surgical biopsy, were frozen and stained with the techniques for nictotinamide adenine dinucleotide (NADH) and mitochondrial succinate dehydrogenase (SDH). For muscle morphometry, the number of fibers was counted and their area and diameter were measured. Specific statistic tests were applied and differences were considered significant when $p<0.05$. The grip strength was higher in males compared to females in both, control and pain groups, but smaller on pain groups, in both genders, compared to controls. Preliminary histological results showed, for NADH staining, larger area of the dark fibers on the right LG compared to the right MG, without difference between right LG and left LG. Also, no differences between right MG and left MG were observed. For SDH staining, no significant differences were observed for any type of fibers analyzed (dark, intermediate and light). Our results are suggestive that pain in the neonatal period caused a reduced grip ability that was maintained long term after the painful stimulus was ceased, with a slightly better performance on older females. Increasing the number of animals for the histological studies will help the identification of the type of muscle fibers that are being related to the grip ability alterations observed in this model of pain. Title: Reliability of pressure pain threshold and tolerance determined by an automated pressure system in knee osteoarthritis patients

Authors: *J. R. SCOTT[1], K. PHILLIPS[2], D. J. CLAUW[1], S. E. HARTE[1];
[1]Dept. of Anesthesiol., [2]Dept. of Rheumatology, Univ. of Michigan, Ann Arbor, MI

Abstract: Introduction: Quantitative sensory testing (QST) is commonly used in pain research however its long-term reliability in chronic pain patients over the course of months and years is not well established. This lack of reliability standards limits the application of QST in longitudinal studies of chronic pain. Here we present six-month QST reliability in patients with knee osteoarthritis (KOA). Methods: QST was performed in KOA patients (n = 23) using a computer-automated pressure delivery system. Discrete pressure stimuli were delivered to the dominant thumbnail following a standardized ascending method of limits protocol. Pressure pain threshold (PPT) and tolerance (PTT) was obtained at three observation points: baseline (T1), 12 weeks (T2) and 24 weeks (T3). Subjects underwent an 8-week intervention with an FDA approved oral or topical KOA medication, with a 4-week washout prior to each QST session. Intraclass Correlation Coefficients (ICC) were calculated using a mixed effects model and type consistency. Correlation between observations were evaluated using Pearson's product-moment correlation coefficient (r). One-way analysis of variance (ANOVA) for repeated measures assessed for differences between observations. Results: Mean PPT was 2.63 ± SE 0.23 kg/cm2, 2.33 ± 0.27 and 2.20 ± 0.21 at T1, T2 and T3, respectively. ANOVA revealed no significant differences in mean PPT between observations ($DF = 2$, $F = 2.97$, $p = 0.062$). The intraclass correlation coefficient (ICC) for all three observations was 0.79. Inter-observation correlation coefficients for T1/T2, T2/T3 and T1/T3 were $r = 0.58$, 0.61 and 0.52 (all $p < 0.01$), respectively. Mean PTT values were 5.85 ± SE 0.35 kg/cm2, 5.70 ± 0.30 and 5.59 ± 0.29 at T1, T2 and T3, respectively. ANOVA revealed no significant differences in mean PTT between observations ($DF = 2$, $F = 0.494$, $p = 0.614$). The ICC for all observations was 0.85. Inter-observation correlation coefficients for T1/T2, T2/T3 and T1/T3 were $r = 0.65$, 0.77 and 0.58 (all $p < 0.01$), respectively. Anxiety scores were not significantly correlated to PPT or PTT at any observation period (all $p > 0.12$). Conclusion: This study showed that QST using an automated stimulus delivery method demonstrated high test-retest reliability across three observation points, conducted over a period of six months in KOA patients. Inter-observation correlations were moderate to strong, while intraclass correlation was substantial in both PPT and PTT. These results suggest that automated QST provides potential value in longitudinal assessment of pain sensitivity in chronic pain patients.

Title: Effects of interferential current on pain relief in people with chronic nonspecific low back pain: a randomized placebo-controlled trial

Authors: *R. LIEBANO[1], J. B. CORRÊA[2], N. T. B. OLIVEIRA[2], L. O. P. COSTA[1], K. A. SLUKA[3];
[1]Physical Therapy, [2]UNICID, Sao Paulo, Brazil; [3]Univ. of Iowa, Iowa City, IA

Abstract: Background and aims: Low back pain is an important public health problem. Interferential current (IFC) is commonly used for pain relief, but the effects of carrier frequency of the current and its action on pain relief remain unclear. The aim of this study was to evaluate pain over time and after 12 sessions treatment. Methods: A three-arm randomised controlled trial with patient and assessor blinded to the group allocation: IFC 1 kHz (n= 50), IFC 4 kHz (n= 50) and placebo (n= 50). The interferential current was applied three days per week over four weeks. Results: After treatment, there was no statistically significant difference on pain among the groups 1 kHz x placebo -0.9 (mean difference) 95% CI -2.0 to 0.2, 4 kHz x placebo -0.8 (mean difference) 95% CI -0.3 to 1.9, 1 kHz x 4 kHz 0.01 (mean difference) 95% CI -1.1 to 01.0. The estimated number of sessions needed for a 50% decrease in the pain relief score was 3.82 (95% CI: 2.84 to 4.79) in the 1 kHz IFC group, 5.01 (CI: 3.77 to 6.25) in the 4 kHz IFC group, and 6.09 (CI: 4.82 to 7.37) in the placebo IFC group. There was statistically significant differences only in 1 kHz IFC group compared to IFC placebo group ($p = 0.03$). Conclusions: There was no difference between active IFC and placebo IFC in resting pain intensity after treatment. However, when compared to placebo IFC, subjects receiving 1 kHz IFC took less time to achieve a 50% reduction in pain intensity.

Title: A model of chronic pain from human prostate cancer cells implanted into the mouse tibia

Authors: *M. ENOMOTO, H. KABURAGI, T. HIRAI, Y. WAKABAYASHI, K. YAGISHITA, T. YOKOTA, A. OKAWA;
Tokyo Med. & Dent. Univ., Tokyo, Japan

Abstract: Metastatic bone tumors are often found in patients with prostate or breast cancer. Recently developed treatments such as bisphosphonates increase patient survival, but it will also be necessary to control cancer pain to improve quality of life. Experimental rat models of bone metastasis have been developed by injection of cancer cells into long bones (Blouin et al., Clin. Exp. Metastasis 2005). The current study developed a metastatic bone tumor model by implantation of human prostate cancer cells into the mouse tibia. After implantation, tumor progression was followed using microcomputed tomography (microCT). Mice were observed weekly for 4 weeks after implantation for symptoms of chronic pain, changes in sensitivity to cutaneous stimulation. PC3 human prostate carcinoma cells expressing GFP (PC3-GFP cells) were cultured. After one passage, the cells were concentrated and 5 µl of cell suspension ($1X10^5$ or $2X10^5$ cells/µl) was implanted into the tibia of BALB/cSlc-nu/nu mice. Cutaneous hypersensitivity to both tactile and heat stimulation was observed beginning 3 weeks after implantation. microCT demonstrated the presence of osteolytic lesions around the implant site. A large lesion was observed in the tibia with $2X10^5$ cells/µl. After final observations, frozen sections of tibias and L4 dorsal root ganglia (DRG) were obtained and H&E staining and immunohistochemistry were performed. Immunohistochemical evaluation revealed neurofilament positive fibers around the GFP-positive area. Small DRG neurons from the ipsilateral hind leg expressed increased TRPV1 compared to the contralateral control leg. The findings indicate a chronic pain-like state is induced following implantation of human prostate carcinoma cells. Thus, the current mouse model could be useful to elaborate the molecular mechanism of cancer pain due to metastatic bone tumors.

Title: Chronic low back pain is mediated by increased NGF in intervertebral discs: Therapeutic effect of active lifestyle and pharmacological interventions in mice

Authors: *M. MILLECAMPS[1], M. SUZUKI[2], Y. SUN[1], A. DANCO[1], A. P. MATHIEU[3], A.-J. CHABOT-DORE[1], B. XUE[1], J. KIM[1], L. S. STONE[1];
[1]McGill Pain Ctr., Montreal, QC, Canada; [2]Chiba Univ., Chiba, Japan; [3]Douglas Hosp., Montreal, QC, Canada

Abstract: Chronic low back pain (LBP) affects up to a third of the global population and is the leading cause of disability world-wide. Intervertebral disc (IVD) degeneration is a major factor contributing to chronic LBP. However, the causal relationships between disc degeneration (DD), axial LBP and radiating leg pain are still under debate. Nerve Growth Factor (NGF) is elevated in painful degenerating human IVDs, where it is thought to promote nociceptive nerve ingrowth and peripheral nerve sensitization. We recently demonstrated pathological increases in sensory IVD innervation in our clinically-relevant SPARC-null mouse model of progressive age-dependent DD-related LBP. The Aims of the current investigation were to a) determine if NGF is upregulated in degenerating SPARC-null mouse IVDs; b) assess how an active lifestyle that decreases LBP symptoms, affects NGF levels; and c) investigate the therapeutic benefit of anti-NGF therapy on behavioral indices of LBP in this model. Methods. Animals were 3-20 month old, male SPARC-null and age-match C57Bl6 Wild Type (WT) mice. Behavior included measures of radiating leg pain (cold allodynia in the acetone test) and axial LBP (grip test and tail suspension assays). DD was assessed using X-ray and T2-MRI imaging. NGF expression was examined in protein extracts from lumbar IVDs using commercially available ELISA kits. The effect of increased physical activity on LBP behavior and disc health was investigated by providing unlimited access to running wheels in home cages and the effect of anti-NGF therapy on LBP behavior was investigated by systemic treatment with an anti-NGF antibody. Results. NGF expression was significantly elevated in IVDs from old SPARC-null mice. At baseline, SPARC-null mice presented behavioral signs of both radiating and axial discomfort. Daily access to running wheels significantly decreased radiating cold allodynia, disc degeneration severity, and NGF content. NGF therapy resulted in a complete reversal of cold allodynia. Conclusions. SPARC-null mice show signs of axial LBP and radiating leg pain associated with intervertebral disc degeneration. NGF is over-expressed in aging degenerating IVDs from

SPARC-null mice. Both increased physical activity and anti-NGF therapy were efficacious against behavioral indices of LBP. These data suggest that NGF over-expression in degenerating IVDs contributes to DD-related LBP, potentially as a result of increased innervation and/or sensitize spinal nerve roots. Furthermore, this study suggests that targeting NGF either through lifestyle changes or pharmacological intervention may be an effective treatment for DD-associated chronic LBP.

Title: Molecular-genetic tools to study spinal cord anterolateral tract neurons and their projections to the brain

Authors: *S. CHOI, D. D. GINTY;
Dept. of Neurobio., Harvard Med. Sch., Boston, MA

Abstract: The perception of pain is critical for animal welfare. We protect ourselves from potentially harmful environments by sensing and avoiding noxious stimuli. Noxious stimuli, including hot/cold temperatures, intense mechanical pressure and chemical irritants, activate the peripheral endings of nociceptive sensory neurons. These, in turn, form synapses upon second-order neurons, including interneurons and projection neurons of the spinal cord. Most pain and temperature information is transmitted from the spinal cord to higher order brain regions through anterolateral tract (ALT) projection neurons whose axons decussate and ascend in the ventrolateral white matter of the spinal cord. A great deal is known about how noxious stimuli are detected by primary sensory neurons in the periphery. However, how pain and temperature information is processed in the spinal cord is less well understood in part because of a lack of tools to interrogate second-order neurons of pain pathways, including ALT neurons. We have developed several mouse molecular genetic tools to visualize and functionally manipulate ALT neurons. First, we generated a knock-in mouse line in which tamoxifen-inducible Cre recombinase (CreERT2) is inserted into the *Robo3* locus, because Robo3 is transiently expressed in commissural neurons of the developing spinal cord, including ALT neurons. Second, we generated a knock-in mouse line in which CreERT2 is inserted into the *NK1R* locus, because a

subset of NK1R-positive neurons is labeled by retrograde tracers injected into target brain regions. Third, we screened transgenic GFP mouse lines from the GENSAT project, and identified lines that exhibit GFP expression in the superficial lamina (Lamina I) of the spinal cord dorsal horn, where a large fraction of ALT neurons reside. These knock-in and BAC-GFP transgenic mouse lines are currently being used to assess morphological and physiological properties of ALT neurons, and to elucidate the roles of these neurons in conveying discriminative and affective somatosensation from the periphery to the brain. This study will advance our understanding of the neural circuits underlying pain perception; particularly how nociceptive information is processed in the spinal cord and propagated to the brain.

Title: Joint perception task activates motor-related areas in healthy subjects: a functional magnetic resonance imaging study

Authors: *H. HIROYUKI[1], Y. HIRANO[2], C. SUTOH[4], D. MATSUZAWA[3], R. NAGAI[5], E. SHIMIZU[2];
[1]Chiba Univ., Fujiwara, Funabshi-shi, Japan; [2]Res. Ctr. for Child Mental Develop., [3]Chiba Univ., Chiba-city, Chiba, Japan; [4]Chiba Univirsity, Chiba-city, Chiba, Japan; [5]Ichikawa-city Rehabil. Hosp., Ichikawa-city, Chiba, Japan

Abstract: Motor imagery has been shown to activate the brain similarly with active actual movement, and its application is considered to be effective in the rehabilitation for stroke patients to improving their motor function. However, some stroke patients feel quite difficult in imaging the movement of their hands and legs, thus easy tasks are demanded. A previous report revealed that the motor-related brain areas were activated when subjects imagined a joint perception. Although perception task may be application to treatment, the neural mechanism is not clear. Our study investigated the brain activation by comparison of perception task with active and passive movement task using functional magnetic resonance imaging (fMRI, 1.5T, Toshiba). Seven healthy volunteers were recruited. The task consisted of four parts, (i) active movement task (AMT), (ii) passive movement task (PMT), (iii) joint position sense task (passive movement and perceptive question, JPST), and (iv) control (CON). Subjects' right hand was used in the AMT, PMT and JPST. In the AMT, subjects moved their wrist with extension and flexion. In the PMT, an examiner moved subject's wrist comparable with the AMT in frequency and the range of motion. In the JPST, the examiner moved their wrist randomly ranging five

steps of height, and the subjects were asked to answer the position of their wrist in their mind (position number from 0 to 4). No movement was demanded in the CON. Subjects were scanned once a week for performing four tasks. The MRI data were analyzed using MATLAB and SPM8. JPST was shown activation in premotor area and supplementary area. The JPST was similar activation with AMT. No activation was observed in the CON in any motor-related areas. Considering the observed activation in the JPST, it is suggested that the prediction of the joint movement can activate the related motor brain areas comparable with the motor imagery. In conclusion, JPST can be effective in the rehabilitation of stroke patients who cannot move the affected limb.

Title: Neural activation induced by the perception of sticky tactile stimuli

Authors: *J. YEON[1], J. KIM[2], J. RYU[3], J.-Y. PARK[3], S.-P. KIM[1];
[1]Human and Systems Engin., Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of; [2]Brain and Cognitive Engin., Korea Univ., Seoul, Korea, Republic of; [3]Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Tactile perception is generally divided into three dimensions from the view of psychophysics: rough/smooth, hard/soft, and sticky/slippery. Among them, sticky perception is the most controversial one; not only specific features that arouse sticky feelings are not well understood, but also, to our best knowledge, the sticky/slippery dimension has not yet been investigated in focus. Since the sticky perception has rarely been explored up to date renders itself as one of the fundamental dimensions in tactile perception, we set our study goal to finding the spatial neural activation patterns during processing of sticky senses. 12 participants (5 females; Mean age = 24.58) participated in the study. 8 different sticky silicone stimuli made with different concentration levels of silicone hardener (5, 6, 7, 8, 9, 10, 20 and 30% consistency) were prepared. Lower levels of hardness provided stickier silicone stimuli. A sham stimulus was prepared using an acrylic panel, providing no sticky sense. Before scanning, a behavioral test was done with all sticky silicone stimuli. Participants touched each stimulus with the right index finger and determined whether it was sticky or not. During scanning, 6 sticky

stimuli (5, 6, 7, 8, 10, 30% consistency) and sham stimulus were provided. Participants put their right index finger on a given stimulus when heard a "Ready" sound and detached the finger with a beep sound. The behavioral test results revealed that the stimuli with 5, 6, and 7% consistency were perceived to be 'sticky', whereas other 5 stimuli were 'non-sticky'. In the fMRI data analysis, basal ganglia including corpus callosum, bilateral caudate tail and caudate body as well as right dorsolateral prefrontal (DLPFC) areas were activated ($p<0.005$, unc.) for 'Sticky (5, 6, 7%) - Sham' contrast. In comparison, for 'Non-sticky (8, 10, 30%) - Sham' contrast, only basal ganglia area including right caudate tail and left caudate body was activated ($p<0.005$, unc.). The activation of the right DLPFC may imply that the sticky stimuli were treated as aversive ones as a sticky stimulus could be believed to signal that the skin tissue was stretched and thus induce a feeling of potential damage, a lacerated wound. The right DLPFC is also known to be activated in rewarding situations and might reflect rewards associated a pain relief during sticky sense processing, which could occur when participants detached their finger from a sticky stimulus and felt as escaping from the aversive stimulus. Our results may suggest a specific characteristic of neural processing underlying the perception of sticky tactile stimuli.

Title: Writing lies and feelings of alleviation caused by hand soap: Neural underpinnings of the Macbeth effect

Authors: C. DENKE[1], M. SCHAEFER[2], H.-J. HEINZE[2], *M. SCHAEFER[1];
[1]Dep. of Anesthesiol & Intensive Care Medicine, Charité Univ. Berlin, CVK, Berlin, Germany;
[2]Dept. of Neurology, Otto-von-Guericke Univ. Magdeburg, Magdeburg, Germany

Abstract: The Macbeth effect describes a link between physical cleansing and moral transgressions. Behavioral experiments showed that guilt induced by transgressions can be reduced by cleaning the body. This Macbeth effect has been explained by an embodiment of moral cognitions. Here we aimed to explore the neural underpinnings of the Macbeth effect by means of an fMRI experiment. Thirty-five participants were prompted with short scenarios. Subsequently they were asked to put themselves into the shoes of the protagonist and behave in either a moral incorrect way (writing a lie on a clipboard) or acting in a moral correct way (writing a true message on a clipboard). Then the participants had to evaluate the desirableness of hand soap products and noncleansing goods. Behavioral result demonstrated that participants evaluated hand soap products (but not noncleansing goods) more desirable when writing a lie

before (in contrast to writing the truth), thus replicating the Macbeth effect ($t(34) = 2.03$, $p < 0.05$). FMRI results showed that this Macbeth effect was correlated with activation in somatosensory brain areas (in particular the primary somatosensory cortex) during the evaluation phase. We argue that these results strongly suggest that somatosensory brain regions play an important role for embodied moral cognitions.

Title: Spatiotemporal neuronal and hemodynamic integration in sensorimotor cortex of mice upon external stimuli

Authors: *E. BAEG[1], J. SIM[1], S. BAE[2], H. RYU[3], M. SUH[1,2,3];
[1]CNIR, Inst. For Basic Sci. (IBS), Suwon, Korea, Republic of; [2]Biol. Science, Sungkyunkwan Univ., Suwon, Korea, Republic of; [3]Biomed. Engineering, Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: We investigated the spatiotemporal neuronal dynamics of sensorimotor cortex to study macroscopic cortical facilitation and suppression that is modulated by external stimuli. The coupling between neuronal activities and hemodynamic change was addressed to understand the degree to which vascular response is coupled to neuronal activation. Voltage sensitive dye (VSD) was applied over large regions of the mouse cortex to directly image the neuronal membrane potentials in sensorimotor cortex. Additionally, single units and local field potentials were recorded in order to observe the transition from depolarizing membrane potential to resulting activities of neuron. Cortical blood volume change was accessed using intrinsic optical signal (IOS). One or two adjacent whiskers of slightly anesthetized or awake mouse were stimulated simultaneously or serially at various inter-stimulus intervals. A single brief whisker deflection induced highly distributed depolarizing cortical sensory responses in VSD signal, which started in the barrel cortex and subsequently spread out (<8ms) to the whisker motor cortex. Facilitated depolarizing responses were observed to the stimulation of two adjacent whiskers when deflected simultaneously. Short delay (<5ms), given between deflections of the two whiskers, however, made slower and weaker depolarizing response, representing suppressive process. Single units in barrel cortex also showed facilitated responses when the two whiskers deflected simultaneously. However, obvious increase of blood volume was not

observed in motor cortex, although apparent dynamic volume changes in barrel cortex according to applied deflections. Cortical network or function is likely to be the result of the relative strength of cortical conductance and of the temporal relationship in space and time, with the support of non-linearly acting hemodynamic responses.

Title: Muscle proprioceptors and their central connections in the adult rodent

Authors: H. M. GABRIEL, J. A. VINCENT, *P. NARDELLI, A. S. DEARDORFF, R. E. W. FYFFE, T. C. COPE;
Wright State Univ., Dayton, OH

Abstract: Despite the increased use of rodents to study the development and function of spinal sensorimotor circuits, data on the central trajectory and connectivity of physiologically identified muscle proprioceptors is limited in the adult rodent. A complete account of the peripheral encoding along with the central connectivity of rodent muscle proprioceptors is critical to understanding the manner in which proprioceptive feedback influences rodent spinal circuits. In the present study, intraxonal records were obtained of tricep surae proprioceptive afferents *in vivo* from adult female wistar rats. Following the collection of intra-axonal data, 12 of these afferents (4 Ia, 4 group II, and 4 Ib) were labeled with Neurobiotin for detailed anatomical analysis of their central trajectory and terminal distribution. Afferent responses during isometric twitch contractions were used to distinguish muscle spindles (1a/group II) from tendon organs (Ib). Befitting with their role as dynamic sensors, Ia afferents achieved much higher peak firing rates, and displayed larger dynamic index (DI) values in response to varying stretch amplitudes and velocities. Group II afferents achieved much lower peak firing rates, lower DI values, and unlike Ia afferents frequently fired on the release from stretch. These firing properties are consistent with those obtained in the cat (Matthews 1972), and more recently in the rat (De-Donker et al., 2003, Bullinger et al., 2011). Interestingly a large proportion of our Ib afferents also generated robust firing in response to muscle stretch in the physiological range, but displayed lower peak firing rates. Overall, each afferent type showed a characteristic central morphology and trajectory that was consistent with observations in the cat. Terminal arborizations for 1a and group II afferents were limited to lamina V//VI, lamina VII, and Lamina

IX. While 1b afferent collaterals were limited to lamina VI and LVII. The highest level of variability between afferent types was the characteristic density and distribution of synaptic contacts within each target lamina. These distinguished areas of termination of muscle afferent fibers in the rat revealed some variance with the terminal organization of synaptic contacts found in the cat. These data, for the first time in the adult rodent, demonstrate the central trajectory, terminal distributions, and peripheral encoding of muscle proprioceptors, and provide valuable insight into their organization and functional contribution to spinal sensorimotor circuits. Additionally, these results suggest that the findings, so far only available in the cat, are generalizable to other mammalian species. .

Title: Neural encoding of saltatory tactile velocity in human glabrous hand using fMRI

Authors: *H. OH[1,2], R. CUSTEAD[2,3], S. M. BARLOW[1,2,3];
[1]Biol. Systems Engin., Univ. of Nebraska, Lincoln, NE; [2]Ctr. for Biology, Brain and Behavior, [3]Special Educ. & Communication Disorders, Univ. of Nebraska - Lincoln, Lincoln, NE

Abstract: BACKGROUND: Among the functions of the somatosensory system, processing information about the location and velocity of tactile stimuli on the body surface is presumed essential for the development and maintenance of fine motor control of the hand. However, limited data exist on the cortical representation of moving tactile stimuli on the glabrous skin of the digits in humans. OBJECTIVE: The aim of this study was to map the relation between saltatory pneumotactile stimulation at 3 velocities on the glabrous hand and cerebral BOLD activations in neurotypical adults. METHODS: Participants - 15 neurotypical, right-handed adults, age 19-30 years. A Galileo somatosensory tactile array was programmed to deliver punctate (50 ms duration, 9 ms rise/fall) pneumotactile sequences through acetyl TAC-Cells (6 mm ID) placed on the glabrous skin of the right hand, including p1, p2 segments of D3 (middle finger); p1, p2, p4 segments of D2 (index finger), and p4, p1 of D1 (thumb). Programmed time delays between individual TAC-Cells resulted in a saltatory velocity sequence traversing the tips of D2, D3 through the basal phalyngeal segments to the distal phalaynx of the thumb. A randomized-balanced block design (40 s) included the following 5 conditions: Saltatory velocities @ 25, 45, and 105 cm/sec, simultaneous TAC-Cells ON, and all cells OFF. An MPRAGE sequence (1 mm isotropic, TE=30ms, TR=2400ms) was followed by 3 functional

scans using a 3T Siemens Skyra (32-ch head coil). Functional images: T2*-weighted EPI sequence, 36 slices (1.7x1.7x.2.0mm, TE=24ms, TR=2500ms, FOV=220mm). Using SPM12, 990 acquired brain volumes/subject were realigned, and smoothed with an isotropic Gaussian kernel (FWHM=6 mm). RESULTS: Significant BOLD responses were localized to the contralateral hemisphere, including digit (D1, D2, D3) representations within BA 3b of S1 and a second BOLD ROI in the left supramarginal gyrus. The spatial extent of the evoked BOLD response is highly dependent on saltatory tactile velocity with the largest response apparent at 25cm/s. Resultant peak-level BOLD response statistics for S1: 25 cm/s [MNI (mm)= -34, -27, 72; T=8.09, p<.001], 45 cm/s [MNI (mm)= -36, -27, 72; T=6.89, p<.001], and 105 cm/s [MNI (mm)= -36, -27, 72; T=6.79, p<.001]. Peak-level BOLD response statistics for supramarginal gyrus: 25 cm/s [MNI (mm)= -56, -22, 20; T=6.66, p<.001], and 45 cm/s [MNI (mm)= -63, -22, 20; T=5.42, p<.001]. CONCLUSIONS: fMRI BOLD results suggest the presence of a scalable cortical network (localized to contralateral BA 3b and supramarginal gyrus), which encodes saltatory pneumotactile velocity on the glabrous hand in humans. Title: Vagal sensory neuron subtypes that differentially control breathing

Authors: *D. E. STROCHLIC[1], R. B. CHANG[2], E. K. WILLIAMS[2], B. D. UMANS[2], S. D. LIBERLES[2];
[1]Cell Biol., Havard Med. Sch., Boston, MA; [2]Cell Biol., Harvard Med. Sch., Boston, MA

Abstract: Breathing is essential for survival, and under precise neural control. The vagus nerve is a major conduit between lung and brain required for normal respiration. Here, we identify two populations of mouse vagus nerve afferents (P2ry1, Npy2r), each a few hundred neurons, that exert powerful and opposing effects on breathing. Genetically guided anatomical mapping revealed that these neurons densely innervate the lung and send long-range projections to different brainstem targets. Npy2r neurons are largely slow-conducting C fibers, while P2ry1

neurons are largely fast-conducting A fibers that contact pulmonary endocrine cells (neuroepithelial bodies). Optogenetic stimulation of P2ry1 neurons acutely silences respiration, trapping animals in exhalation, while stimulating Npy2r neurons causes rapid, shallow breathing. Activating P2ry1 neurons did not impact heart rate or gastric pressure, other autonomic functions under vagal control. Thus, the vagus nerve contains intermingled sensory neurons constituting genetically definable labeled lines with different anatomical connections and physiological roles.

Abstract: Introduction C-tactile afferents are unmyelinated mechanoreceptors in the human hairy skin that are involved in the processing of pleasant and erotic touch. They are optimally activated for a slow, light stroking of the skin. The C-tactile afferents are an analog to the C-fiber low-threshold mechanoreceptors (C-LTMRs) found in animals. Association between hair movement and C-LMTRs was suggested in early studies in rodents, cats and monkeys. Recent histological studies in rodents using genetic techniques to stain C-LTMRs have found that the nerve endings are located around hair follicles. The location of the C tactile nerve endings in human skin is unknown. We aimed at exploring the relationship between the number of hair follicles and perceived eroticism and pleasantness of a gentle brush stimulus in healthy human adults. Method Thirty-six healthy, adult participants took part in the study (23 female; age 26.22 ± 5.7 years). The participants received tactile stimulation with velocities optimized for C tactile activation (1, 3, 10 cm/s) and suboptimal for C tactile afferent activation (0.3 and 30 cm/s) on the

dorsal side of the forearm in a highly standardized fashion. For each stimulus, participants rated the perceived eroticism, pleasantness and intensity. Hair follicle count was performed on a 1cm2 area of the body part, using the cyanoacrylate skin stripping method. Additionally, all participants completed the Social Touch Questionnaire (STQ), as well as a questionnaire regarding partnership and sexual activity. Results There was a significant positive correlation between the number of hair follicles and the eroticism ratings for the C tactile optimal velocity of 3 cm/s (r_s=0.375, p=0.029). The sample was split into participants with higher and lower sexual activity. Participants with higher sexual activity had a significantly more hair follicles per cm2 than those with lower activity ($t(32)$=-2.308, p=0.028). Additionally, the high sexual activity group had higher scores on the STQ, indicating that this group is more positive to social touch. Conclusion These preliminary findings indicate a connection between C-tactile afferents and hairs in the human perception of erotic touch.

Abstract: Proprioceptive feedback is very important for movement planning and execution; however its role in both healthy subjects and patients with neurological diseases that affect sensorimotor functions is poorly understood. The aim of this work was to investigate the neural basis of proprioceptive input during ankle joint position sense matching tasks using functional MRI. In this ongoing study four healthy subjects were recruited to perform two matching tasks which required a combination of passive and active movements. Task 1 consisted in unilateral matching task, where subjects had to reply a determined position of the ankle joint with the

ipsilateral foot. Task 2 consisted in bilateral matching task where subjects had to reply a determined position of the ankle joint using the controlateral foot. The fMRI experiment was acquired with a block design paradigm (30 sec rest + 30 sec task) while an operator shifted the foot to different inclination values using a custom built MRI compatible device and the subjects matched as described above. In addition, the experiment included three active tasks involving plantar-dorsi flexion movements cued by a metronome set at 0.7 Hz: ipsilateral active task with left foot, right foot and bilateral active task with both feet moved in anti-phase. Feet were firmly strapped into the MRI compatible device that allowed one degree of freedom movement in the sagittal plane. The device was developed in order to minimize head movement during ankle plantar-flexion. The typical motor and sensorimotor network was recruited during the active tasks while areas of the parietal cortex were recruited during both matching tasks. Moreover, unilateral matching task showed activations not only in the controlateral emisphere but also in the ipsilateral one. These results suggest that, with proprioceptive target, also passive movements can elicit activations that are similar to the one produced by active movements. Finally, we found highly disseminated activations patterns for both matching tasks, indicating that subjects required an higher cognitive effort with respect to running simple motor tasks.

Title: Defining the populations of pruritogen-sensitive neurons in the mouse dorsal root ganglion

Authors: *S. S. ESPINO, R. TEICHERT, B. OLIVERA;
Biol., Dept. of Biology, Univ. of Utah, Salt Lake City, UT

Abstract: Itch is defined as a sensation in the skin that causes the reflex to scratch. The sensation of itch is detected by nerve endings in the skin whose cell bodies are located in the dorsal root ganglion (DRG) or in the trigeminal ganglion (TG). There are two types of itch namely: histamine dependent and histamine independent. Chloroquine, an anti-malarial drug, defines histamine independent itch. Pharmacologically, itch is a heterogeneous somatosensory modality. Can the same heterogeneity be said for populations of DRG neurons (pruriceptors) that mediate the sensation of itch? To address this question we identified and characterized pruriceptors in the

adult mouse DRG using calcium imaging of the dissociated neurons. Three major populations that are senstitive to the pruritogens histamine and chloroquine were identified in the dissociated DRG neurons of the adult mouse. These populations include cells that respond to histamine only, cells that respond to chloroquine only and another population that respond to both histamine and chloroquine. Combinations of ion channels expressed by these histamine and chloroquine-sensitive cells were also identified. To achieve this goal we used conotoxins that are specific antagonists of various ion channel subtypes. For example using conotoxins κM-RIIIJ and κJ-PlXIVA which selectively inhibit specific voltage-gated potassium channel subtype, we identified subpopulations within the population of histamine and chloroquine-sensitive cells. Using a combination of pharmacological agents and ion channel specific conotoxins, we were able to refine the definition of the populations of cells that are sensitive to histamine and chloroquine in the adult mouse DRG. This fine-tuned definition of the histamine and chloroquine-sensitive populations and the identification of the unique constellation of ion channels and receptors present in these cell populations will be useful in the refinement of our understanding of itch. Furthermore, the ion channels and receptors identified are potential therapeutic targets for the treatment of itch.

Title: Functional comparison of Cav3.2-expressing and TRPV1-expressing sensory neuron subpopulations

Authors: *D. M. DUBREUIL[1], D. S. KIM[1,2], S. DENOME[1], D. LIPSCOMBE[1];
[1]Brown Univ., Providence, RI; [2]Dept. of Anat., Soonchunhyang Univ., 330-090, Korea, Republic of

Abstract: Diverse subpopulations of somatosensory neurons collaborate to detect and encode thermal, mechanical, and chemical stimuli. Genetic, functional, and anatomical classification schemes have been proposed to distinguish distinct subpopulations, but there have been few analyses of single subpopulations regarding all three criteria. In this work, we seek to understand

the functional contribution of $Ca_V3.2$-expressing and TRPV1-expressing sensory neurons to somatosensation and their synaptic input to the dorsal horn of the spinal cord. $Ca_V3.2$ low-voltage activated T-type calcium channels regulate neuronal excitability by lowering the action potential firing threshold and are thought to increase the sensitivity of low-threshold mechanosensory neurons. In contrast, TRPV1 cation channels are activated by noxious heat and are expressed in high-threshold, thermosensory nociceptors. Previous analyses of isolated dorsal root ganglia neurons have shown that TRPV1 and $Ca_V3.2$ channels are expressed in distinct subsets of sensory neurons, consistent with the hypothesis that they differentially contribute to somatosensation *in vivo*. Using a novel *Cacna1h*-Cre or existing *Trpv1*-Cre driver strain, we have expressed ChR2-EYFP or TdTomato reporter proteins in $Ca_V3.2$- or TRPV1-expressing neurons throughout development. Blue light stimulation of the hindpaws of awake *Cacna1h*/ChR2-EYFP and *Trpv1*/ChR2-EYFP adult mice is sufficient to drive a nocifensive paw withdrawal response, suggesting that $Ca_V3.2$- and TRPV1-expressing sensory neurons both carry nociceptive information; however, prolonged activation of either subpopulation, in the absence of inflammatory mediators, was insufficient to generate hypersensitivity to mechanical or thermal stimuli. Furthermore, by functional analyses, we show that TRPV1 and CaV3.2 are rarely co-expressed in sensory neurons. Fixed sections of isolated dorsal root ganglia from *Trpv1*/TdTomato mice revealed highly overlapping expression of TRPV1 and the proalgesic neuropeptide CGRP. In fixed spinal cord sections, TRPV1-expressing afferents specifically terminate in superficial layers of the dorsal horn (lamina I-II), whereas $Ca_V3.2$-expressing afferents terminate throughout the superficial dorsal horn (lamina I-IV). In order to understand the synaptic function of these subpopulations, we are using whole-cell electrophysiology in acute spinal cord sections. This combined approach of behavioral, functional, and imaging analyses will allow us to form a comprehensive definition regarding the anatomy and physiology of specific genetic subpopulations of sensory neurons in somatosensation and nociception.

Title: Peripheral sensory perception of diabetics using Semmes Westein 5.07 monofilament

Authors: *N. M. JOSEPH[1], V. A. EGWUONWU[2];
[1]Col. of Medicine, Nnamdi Azikiwe Univ., Awka, Nigeria; [2]Med. Rehabil., Nnamdi Azikiwe Univ., Nnewi, Nigeria

Abstract: Gradual loss of sensation in the foot is a major consequence of diabetes mellitus. It is a precursor to foot ulcers, which may necessitate amputation eventually. Early detection of peripheral sensory loss in the foot would help to prevent further complications. In developed countries the ability to perceive 5.07 monofilament is accepted as normal, but in Nigeria the assessment of peripheral sensory perception with 5.07 monofilament method is not common, and its relevance not appreciated. The aim of this study was to compare peripheral sensory perception in patients with diabetes mellitus and those without, using Semmes Westein 5.07 monofilament. The experimental group included 100 patients diagnosed with diabetes mellitus, while the control group comprised 100 subjects without diabetes mellitus, recruited using purposive non-probability sampling technique, with informed consent and ethical approval. Skin sensation was tested on eleven pressure points on the sole and the dorsum of the right foot using 5.07 Semmes Weinstein monofilament in all the subjects. Data were analysed using independent student t-test, and one way ANOVA. Results showed that 71% of subjects with diabetes had intact sensation while 29% had impaired sensation. In control subjects, 96% had intact sensation while 4% had impaired sensation. Subjects with diabetes had significantly lower peripheral sensory perception than the control subjects ($p>0.05$). Age and gender had no influence on subjects' peripheral sensory perception ($p>0.05$). It was concluded that peripheral sensory perception was significantly lower in subjects with diabetes than in apparently healthy control subjects. The use of Semmes Westein 5.07 monofilament is hereby recommended for preliminary diagnosis of peripheral neuropathy in subjects with diabetes mellitus.

Title: Stochastic resonance in the brain elicited by optogenetic noise-photostimulation

Authors: *E. MANJARREZ[1], P. LINARES[1], N. HUIDOBRO[1], A. MENDEZ-FERNANDEZ[1], B. DE LA TORRE VALDOVINOS[1], I. MENDEZ-BALBUENA[2], A. FLORES[1], R. GUTIERREZ[3];

[1]Inst. de Fisiologia, [2]Fac. de Psicologia, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico; [3]Dept. Fisiol. Biofis. y Neurociencias, CINVESTAV IPN, Mexico DF, Mexico

Abstract: Stochastic resonance is a phenomenon in nonlinear systems characterized by a response increase of the system induced by a particular level of input noise. This phenomenon occurs in many physical and biological systems. The aim of the present study was to implement a new optogenetic approach based on noise-photostimulation to examine causal features of the generation of stochastic resonance in the *in vivo* mouse brain. In order to apply noise-photostimulation directly to specific neurons within the barrel cortex (layers 2/3, 4 and 5) we used 6 anesthetized Thy1-ChR2-YFP mice (line 18) expressing Channelrhodopsin-2 under the Thy1 promoter. Furthermore, we used other 5 wild-type littermate mice as a control. The periodic input signal consisted of subthreshold mechanical stretching of the mice vibrissae; whereas the noise-photostimulation consisted of optogenetic noisy-light delivered via optic fiber to the brain. We implemented a novel noise-photonics system to apply noise-photostimulation. It included a Wavetek noise generator and a Thorlabs' optogenetics device with a 470 nm blue light-emitting diode source. The area of the brain stimulated with the blue noise-photostimulation was the barrel somatosensory cortex. Stable extracellular unitary recordings of identified neurons from layers 4-5 of the same illuminated barrel cortex were obtained by means of a minimatrix system from Thomas Recording (5 to 7 MΩ). Recorded neurons were selected for their response to vibrissae stretching performed by a Chubbuck mechanical stimulator-transducer. We found that in all transgenic mice the total number of neuronal spikes measured from the peristimulus histogram exhibited an inverted U-like form as a function of the noise-photostimulation level. The maximal increase of the number of spikes for 16 neurons for optimal noise was about 300 % relative to the zero noise condition. We used the nonparametric Friedman test to examine the statistical significance of the total number of spikes, between the three conditions (optimal noise ON, zero noise ZN and high noise HN) in all the mice. The results showed significant differences between the three conditions (Wilcoxon test; $p<0.001$). A subsequent post hoc analysis uncovered significant differences between ZN and ON ($p<0.001$) and between ON and HN ($p<0.001$). Importantly, in wild-type mice, the same levels of noise-photostimulation did not produce any stochastic resonance effects in 17 neurons recorded. To the best of our knowledge, these results are the first demonstration of the phenomenon of stochastic resonance produced by optogenetic noise-photostimulation on the brain.

Title: Mesoscopic calcium imaging reveals the presence of modules of synchronized activity delimited by strong boundaries and dependent on behavior context

Authors: *M. P. VANNI[1], G. SILASI[2], D. XIAO[2], A. CHAN[2], J. LEDUE[2], T. MURPHY[2]; [1]Dept. of Psychiatry, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Brain function arises from assembly of neurons computing similar features which could operate at very long distance within cortex. Correlation methods previously showed that several clusters of synchronized activity can co-exists within cortex. However, the limits of these clusters and their number were underexplored, especially under the context of behavior modulation and the relationship with the topography of connections between areas. Wide field calcium imaging was performed on mice to explore what rules this parcellation at different mesoscopic scales. Transgenic mice expressing the calcium indicator GCaMP (Emx1-cre;CaMK2a-tTA;TITL-GCaMP6: Ai93 and Ai94) were implanted with a chronic window covering most of the cortex including sensori-motor, cingulate, retrosplenial and visual cortex. Wide-field fluorescence was collected on anesthetized animals or awake head-fixed quiet or performing a task (pulling a lever to get a water reward). The correlations signals between each pair of pixel were calculated to generate seed pixel correlation maps as well as distance parcellation. Seed pixel correlation maps revealed between 2 and 3 main clusters of correlated activity delimitated by stable boundaries (gradient). This spatial organization was confirmed by other parcellation methods such as distance tree, K-means or community structure. Interestingly, the number and structure of these clusters was strongly dependent of the behavior activity for at least, three different conditions: 1) anesthetized or awake quiet, 2) learning a task (pulling a lever) and 3) performing a learned task. Inside each cluster, between 1 and 3 remote islands of correlated activity derived from seed pixel correlation maps revealed the long range topography of connection between areas: between primary visual cortex and extrastriate areas or between primary motor and somatosensory cortex. These results were confirmed with single unit electrophysiology, as well as anatomical tracing (Allen Brain Institute Database) These results showed that within mouse cortex, several functional modules run in parallel and their spatial limits are directly related to behavior. Interestingly, the topography and cortical area boundaries appeared to be a weak constraint for functional clustering. Taken together, this contextual parcellation of mesoscopic calcium signals represents one of the first attempts to link brain function with behavior and could open new avenues in the interpretation of brain imaging data.

Title: Electroencephalographic correlates of tactile vs. visual guidance during a tracing task

Authors: P. J. LEE, R. N. HUYNH, *S. N. KUKKE;
Biomed. Engin., The Catholic Univ. of America, Washington, DC

Abstract: Physical therapy for upper extremity motor disorders usually focuses on the practice of visually-guided motor tasks. However, touch also provides a strong input to hand function, and is often weakened in individuals with brain injuries, including cerebral palsy and stroke. The recovery of hand function may therefore benefit from both visuo- and tactile-motor task practice. To explore neural mechanisms by which sensory input can guide movement, we investigated EEG correlates of tactile vs. visual feedback. 7 right-handed, healthy adults (20-22 yrs) were included in this IRB-approved study. Volunteers traced 6 irregular shapes (path length = 45.7±3.6 cm on a 156 cm2 plate) 10 times with the right 2nd digit in 2 feedback conditions. In the tactile-motor (TM) task, movement was guided only by tactile feedback of semi-circular bumps along the path (height = 0.13 cm, spacing = 0.76 cm). In the visuo-motor (VM) task, movement was guided only by vision of dots along the path (dia = 0.13 cm, spacing = 0.76 cm) seen through a circular window (dia = 3 cm) at the fingertip. EEG data were recorded from 28 scalp leads. Cortical activation, and connectivity between regions were quantified by task-related power (TRPow) loss, and coherence (Coh) between pairs of leads, respectively. ANOVA was used to test effects of feedback modality, cortical region, and frequency band (alpha = 8-12 Hz, beta = 13-20 Hz) on TRPow. TRPow loss was greater during the VM vs. TM task. In both tasks, the central, temporal, and parietal regions had more TRPow loss than the frontal and occipital regions, likely due to sensory processing and movement. There was more TRPow loss in the alpha vs. beta band in the VM task, but no difference between frequencies in the TM task. In both frequency bands and both hemispheres, there was more within-hemisphere Coh among frontal leads, and also among posterior leads in TM vs. VM trials. In contrast, there was more within-hemisphere Coh between parietal and temporal regions in VM vs. TM trials. Between-hemisphere Coh was greater in frontal leads in TM vs. VM trials and greater in posterior leads in VM vs. TM trials. There was no difference in trace time between TM and VM trials (t-test, $p = 0.17$). This study provides evidence of cortical activation and connectivity patterns that are specific to the sensory modality used during movement. Our results suggest that inclusion of both touch and vision in motor practice can stimulate a broad range of neural networks. Future studies are needed to test the extent to which repeated exposure to sensorimotor tasks with either feedback modality alone or both combined can lead to adaptive changes in EEG parameters that correlate with behavioral changes.

Title: Upward propagation of spiking activity across cortical layers

Authors: *G. PLOMP[1], C. QUAIRIAUX[2], C. MICHEL[2];
[1]Dept. of Psychology, Univ. of Fribourg, Fribourg, Switzerland; [2]Univ. of Geneva, Geneva, Switzerland

Abstract: We previously observed a pattern of functional interactions directed upward along the layers of cortical columns in primary sensory cortex (S1) of rats, both in S1 contralateral to whisker stimulation and in the ipsilateral S1. The interactions between the two S1s, however, selectively targeted granular and infragranular layers, suggesting that the upward information flows allow for integration of local and large-scale neocortical processes (Plomp et al. 2014). If each layer functionally drives the one above it, then spiking activity should follow a similar pattern: spikes should propagate mostly upward within columns, not downward. Likewise, after spikes in one S1, spikes in the other S1 should follow first in deeper layers, and then propagate up to higher layers. To test this we determined spiking activity at each cortical layer, both in stimulus evoked activity and at rest. We then calculated the delay with which subsequent spikes occurred in other layers of the same S1, and in layers of S1 in the other hemisphere. We found that spike-to-spike delays systematically increased with upward distance: when a spike occurred e.g. in L5, it took longer for a subsequent spike to occur in L3 than in L4, and again longer for L2 and L1. This increased delay held for spikes in each layer and was observed both in stimulus-evoked and in spontaneous activity. Importantly, spike delays were constant in the downward direction and the observed delays could not be attributed to differences in spike rate per layer. When we time-locked LFPs to the spikes in each layer we found a similar pattern: for spikes in any layer, peaks of the spike-triggered LFP in the layers below preceded the spike, while the peaks in the layers above followed the spike. In addition, spikes in one hemisphere were time-locked to LFPs in the other hemisphere, showing an ongoing coupling between the S1 activities in both hemispheres. The systematic spike delays and spike-triggered LFP results are in line with an information flow from deeper layers to local processing in superficial layers.

Abstract: This study demonstrates invasive functional mapping of finger-related areas in the human brain in the gamma band and the feasibility of distinguishing the fingers from each other by observing spatial activity changes. Data were collected during a vibrotactile finger stimulation paradigm (see Figure 1) and showed significant cortical activation in the high-gamma range over the contralateral somatosensory cortices (SCX) of two patients who participated. The results are consistent with previous studies that used fMRI in test subjects without implanted electrodes. Activation was detected in the SCX from anterior and inferior for the thumb to more posterior and superior for the little finger (see Figure 2). A previous study states that there is a distance of 2 mm between the ring and the little finger, which is reproduced here and explains the relatively small difference in activation observed between those two fingers. In patient 1 an electrode grid with higher spatial resolution has been used that led to a much better ability to discover the spatial distribution of activation depending on the finger that is stimulated in contrast to a standard ECoG grid. The distances between cortical finger representations, and the fact that fMRI studies currently map the SCX with resolutions below 1x1x1 mm, encourage minimizing the size of the electrodes used in future ECoG studies. As fMRI provides rather high time-constants, only this new approach could increase both the temporal and spatial resolution of study data.

Abstract: Introduction Dysfunction in the system for the mental representation of one's own body is believed to be the basis for the body image disturbance, one of the key features of anorexia nervosa (AN). This mental representation is a result of the multisensory integration of visual, tactile, vestibular and proprioceptive inputs. Tactile stimuli can not only disclose dysfunction in this system, but also help to cure it. In this study we aim to investigate brain mechanisms for the gentle touch processing in patients with AN. Gentle stroking over the skin has a quality of not only being descriptive (i.e. gives information about stroking velocity and pressure), but also having an affective component (subjects can experience it as either pleasant or unpleasant). Methods Study includes 25 patients with AN and 25 healthy subjects. All subjects completed a scanning session in magnet camera, in which structural, functional, resting state and diffusion weighted images were collected. During the collection of functional images subjects were gently stroked over their underarm and asked to rate the pleasantness of the stroking. In addition, all subjects have filled a battery of questionnaires, which included Social Touch Questionnaire (STQ) (an instrument that assesses comfort and preferences regarding touch that occurs in social situations). Results AN patients rated skin stroking as less pleasant than healthy subjects. They also scored higher in STQ, which means that their experience of the touch that occurs in social situations is less frequent and less enjoyable. The analysis of functional data shows the significant difference between healthy and AN subjects in the extrastriate body area (EBA). While healthy subjects activate this area during the skin stroking, AN patients show hypoactivation. We also conducted an extensive connectivity analysis between EBA and the rest of the brain, which shows that EBA has central importance in the body image network of the brain. Conclusions Our results are in agreement with the findings in previous studies which investigated visual body perception in patients with AN. Since the system for the perception of our own body is activated by touch, our results open for the application of gentle touch as additional form of therapy in AN.

Title: Retrosplenial interconnectivity with motor and medial frontal cortical areas in the mouse

Authors: *N. YAMAWAKI, G. M. G. SHEPHERD;
Physiol., Northwestern Univ., Chicago, IL

Abstract: The retrosplenial cortex (RSC) appears anatomically linked with medial areas of the frontal cortex via axonal projections in both directions. To characterize this RSC-frontal circuit electroanatomically, we used optogenetic labeling to photostimulate presynaptic axons in brain slices together with whole-cell recordings from pyramidal neurons identified by laminar location and/or retrograde labeling. In the RSC→frontal direction, RSC axons excited pyramidal neurons across multiple layers and projection classes in medial frontal cortex, including RSC-projecting corticocortical neurons and corticospinal neurons. The origin of these RSC axons was traced to both the dysgranular (mainly layer 2/3 and 5A) and granular (mainly layer 5A) regions of the RSC. In the reverse direction, frontal→RSC axons originating from medial motor/frontal areas primarily innervated the dysgranular RSC, especially layer 2/3 pyramidal neurons, including corticocortical neurons with axonal projections back to frontal cortex. Our findings thus indicate (1) that the RSC and medial frontal cortices are extensively yet intricately interconnected through inter-areal projections that excite each other's reciprocally projecting corticocortical neurons; (2) that dysgranular and granular RSC areas are distinct in their laminar patterns of interconnections with frontal cortex; and (3) that multiple projection classes including corticospinal neurons are engaged by these circuits, providing divergent output to downstream networks. These results provide new insight into the cellular organization of synaptic circuits linking the RSC to frontal areas including medial motor cortex and thus from dorsal hippocampal networks involved in memory and navigation to neocortical/spinal networks involved in sensorimotor integration and motor control.

Title: Spatial-temporal functional reorganization of somatosensory area 3b and area 1 of squirrel monkeys after spinal cord injury

Authors: *L. CHEN[1], R. WU[1], L. SU[2], P.-F. YANG[1];
[1]Radiology and Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN; [2]Duke Univ., Durham, NC

Abstract: Spatial-temporal Functional Reorganization of Somatosensory Area 3b and Area 1 of Squirrel Monkeys After Spinal Cord Injury Ruiqi Wu, Langting Su, Pai-Feng Yang, Li Min Chen **Keywords:** optical imaging; hand; touch; primates; dorsal column **Abstract:** Somatosensory cortices of adult primates reorganize after sensory loss such as that caused by disruptions of dorsal column afferents. Correlated cortical reorganization and behavioral recovery led to the hypothesis that cortical reactivation and reorganization mediate functional and behavioral recovery after spinal cord injury (SCI). However, since parallel reorganizations have been observed in multiple somatic areas, it is not clear how different cortical areas work together to restore or compensate for the loss of function. As a first step to address this question, with the high spatial and temporal resolution afforded by the optical imaging of intrinsic signals (OIS), we quantified the spatial-temporal features of the cortical responses in areas 3b and 1 several weeks after a unilateral dorsal column lesion. Three adult squirrel monkeys were included in this study and were imaged under light anesthesia before and after SCI. Specifically, we measured the areas, magnitudes and temporal profiles of OIS responses to 8Hz vibrotactile stimulation (in 3.5 seconds duration) of individual digits. We found that the magnitudes of OIS signals obtained several weeks after the lesion were significantly decreased in both areas 3b and 1. OIS signals also peaked significantly earlier than those obtained prelesion. The size of activation in area 3b was larger, indicating more diffused responses to stimuli. A similar activation size increase was observed in area 1, but statistically the increase was not significant. Together, these results demonstrated that contralateral area 3b and area 1 underwent similar spatial and temporal reorganization after lesion, which were characterized as weaker, shorter and more diffused responses. These altered response properties may be responsible for the partial recovery of the loss of sensory functions.

Title: Thermal Pattern Identification on the Hand

Authors: *L. A. JONES, A. SINGHAL;
Dept Mechanical Engin., MIT, Cambridge, MA

Abstract: Changes in skin temperature are encoded in the responses of cold and warm thermoreceptors at a rate that depends on the baseline temperature of the skin and the rate at

which the temperature is changing. In contrast to the wealth of sensations that are evoked by tactile stimulation of the skin, in response to thermal stimulation there is perceptible warming or cooling and this can be quantified in terms of the intensity and duration of the thermal stimulus. The spatial properties of the thermal stimulus such as its area, shape and location are poorly resolved due to the pervasive effects of spatial summation. With the exception of studies on the effect of the rate of temperature change on thermal thresholds, the temporal aspects of thermal stimulation have not been extensively studied. Previous research has demonstrated that the time to process thermal stimuli within the innocuous range is relatively slow in comparison to other sensory modalities. The objective of the present experiments was to determine whether thermal patterns created by varying the direction, magnitude and rate of temperature change could be reliably identified when presented on either the thenar eminence or the index finger. Three thermal profiles (square wave, step and ramp) were used, each of which had two values to give a total of six patterns. A thermal display based on a Peltier device was used to present the stimuli and the temperature of the display and hand were measured continuously using thermal sensors. Each thermal pattern was presented 8 times to 10 participants who had to identify the stimulus using a visual template of the change in skin temperature. The temperature of the skin tracked that of the thermal display but did not reach the minimum and maximum intensities of the display within the presentation time. Preliminary experiments on the response of the skin to various types of thermal inputs indicated that waveforms such as square waves, sinusoids and triangular waves resulted in very similar changes in skin temperature and so were unlikely to be perceptually distinguishable. The three profiles selected did produce distinct changes in temperature as reflected in the participants' performance. The individual mean scores associated with the six thermal stimuli ranged from 80% to 98% on the thenar eminence and from 81% to 88% on the index finger with overall means of 91% and 84% respectively. The information transfer values for the thenar eminence averaged 2.26 bits and for the finger 1.86 bits. These findings demonstrate that with sufficiently long presentation times, the information processing capabilities of the thermal sensory system may rival those achieved with vibrotactile inputs.

Title: Functional, acoustic and articulatory outcomes of speech training: a multi-modal investigation of native and non-native imitation

Authors: *D. CAREY[1], M. MIQUEL[3], B. EVANS[4], P. ADANK[5], C. MCGETTIGAN[2]; [1]Royal Holloway, Univ. of London, Surrey, United Kingdom; [2]Royal Holloway, Univ. of London, London, United Kingdom; [3]Dept. of Physics, Queen Mary, Univ. of London, London, United Kingdom; [4]Speech, Hearing and Phonetic Sci., [5]Univ. Col. London, London, United Kingdom

Abstract: Flexibility of vocal behaviour is a critical skill in human communication. This flexibility can be placed under strain when acquiring the phonemes of a second language, particularly for adult L2 learners, where native perceptual and articulatory processes may dominate. Yet, to date, relatively little research has explored the articulatory and acoustic outcomes of speech learning in association with functional activation in speech production networks. Here, we used a speech training paradigm combined with fMRI and real-time imaging of the vocal tract (rtMRI) to explore vocal imitation skill. Participants were trained to imitate a (native) front vowel and (non-native) front rounded vowel prior to scanning. Their performance on imitation of these vowels and a similar untrained pair was then measured during approximately 1 hour of task performance, while we measured fMRI of bloodflow responses, rtMRI of vocal tract dynamics and in-scanner acoustic recordings of speech output. Behavioural results showed that acoustic imitations of non-native vowels were less accurate than for the corresponding native vowels, with considerable individual differences in imitation success. fMRI results showed significantly greater activation in somato-motor cortex, IFG and superior temporal cortex when participants produced non-native vowels versus native vowels. Using representational similarity statistics (Kriegeskorte et al., 2008), we were able apply a novel analysis approach, by directly comparing rtMRI of vocal tract articulators to fMRI activity during phoneme production. By generating representational similarity matrices to describe the articulation of different vowel categories, we were able to probe the functional fronto-temporal speech production network to identify regions representing the categorical dimensionality of trained and untrained vowels. These results help to inform our account of speech imitation as a skill, with respect to acoustic, articulatory and neural indices.

Title: A possible challenge to sensorimotor adaptation

Authors: *B. J. MARTIN[1], T. A. THRASHER[2], C. S. LAYNE[2], B. LEE[2];
[1]Industrial & Operations Engin., Univ. of Michigan, Ann Arbor, MI; [2]health and Human performance, Univ. of Houston, Houston, TX

Abstract: Learning compensation strategies through practice has been demonstrated for a large variety of tasks, including adaptive responses to unpredictable external force perturbations as well as trips and slips. It has been hypothesized that improvement of responses to perturbation is primarily associated with the adaptation of motor commands through the update of an internal model. The evolution of the internal model allows a progression from primarily feedback to primarily feedforward correction of significant perturbation-induced error, as feedback control is too slow to engender effective compensatory movements. The aim of this study was to determine whether a short lead time vibrotactile cue could improve trip recovery and challenge adaptation. A split belt treadmill was controlled to produce a trip by the abrupt stop of one of the belts at the foot loading phase and resume its motion after the first heel strike of the non-trip foot. An algorithm identified all gait events. Trip occurrence was randomized within a series of strides. Two experiments involving two different groups of young adults were designed to compare trip recovery performance resulting from the learning by repetition method and from vibrotactile cuing, respectively. Experiment I evaluated trip recovery learning only from repeated exposure to perturbation. Experiment II investigated the effects of vibrotactile cuing on recovery as a function of the stimulus application location (upper arm, trunk, lower leg) and lead time (250, 500 ms before the trip). To characterize trip recovery kinetic and kinematic responses, seven outcome measures were defined: response step time, maximum response step force, recovery time, maximum trunk flexion angle, maximum trunk flexion velocity, trunk flexion angular dispersion, and maximum whole body center of mass velocity. In Experiment I, trip recovery improved progressively from the 4th to the 8th trial to reach an ‘adapted response’. In Experiment II, from the first cued trial all cued trip recoveries were equivalent to the ‘adapted response’. These results suggest difference in the mechanisms underlying recovery in the cued versus the adapted response to external perturbations. More importantly, their contrast suggests that “immediacy” opposes “adaptive evolution” and the likelihood of a pre-existing generic internal model derived from life experiences. The associated feedforward response may be modulated by peripheral mechanisms.

Title: Anatomical basis of spiking correlation in upper layers of somatosensory cortex

Authors: *U. CZUBAYKO[1], G. BASSETTO[3], R. T. NARAYANAN[4], M. OBERLAENDER[4], J. H. MACKE[2,3], J. N. D. KERR[1];
[1]Dept. of Behaviour and Brain Organization, [2]Res. Ctr. Caesar: A Max Planck Inst., Bonn, Germany; [3]Neural Computation and Behaviour, Max Planck Inst. for Biol. Cybernetics and Bernstein Ctr. for Computat. Neurosci., Tuebingen, Germany; [4]Computat. Neuroanatomy Group, Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany

Abstract: In neuronal populations of the sensory cortex, stimulus responses are shaped by the cortical architecture on anatomical scales from tens of microns to millimeters. In particular, in L2/3 rodent vibrissal cortex we previously observed that whisker deflection evokes pairwise correlations that decrease both with distance between neurons and distance to the center of the whisker-associated column (Kerr, de Kock, Greenberg, Bruno, Sakmann, and Helmchen. (2007). J. Neurosci. 27: 13316-28). One possible explanation for this finding is that these correlations arise from anatomically structured common inputs. L4 spiny stellate (SS) cells send vertical axon fibers to L2/3 that are confined within the borders of the whisker-associated column and neuronal pairs closer together could exhibit greater dendritic overlap. Therefore, for pairs closer to the column center more of this overlap will intersect with SS projections. We tested this hypothesis using 2-photon targeted patching of L2/3 pyramidal pairs in anaesthetized rats to record sub- and suprathreshold stimulus responses followed by anatomic reconstruction of the neurons and barrel field. We found a positive and statistically significant association between correlated AP firing and dendritic overlay inside the whisker-associated column. This effect was strongest for suprathreshold activity evoked shortly after whisker deflection (~20 ms), and decayed rapidly thereafter. It was also robust with respect to the voxel size, determined by the L4 axon reconstructions, used to quantify dendritic overlap. No relationship was detectable for offset responses or spontaneous activity. These results support the notion that the spatially structured correlations observed for short-latency stimulus-evoked spiking arise from anatomically structured feed-forward projections.

Title: Variations in corticospinal excitability associated with different modes of hedonic touch

Authors: I. AL-BUHAISI[1], A. REMAUD[3], *F. TREMBLAY[2];
[1]Sch. Rehab Sc, [2]Sch. of Rehabil. Sci., Univ. of Ottawa, Ottawa, ON, Canada; [3]Clin. Neurosci., Bruyere Res. Inst., Ottawa, ON, Canada

Abstract: In real life situations, touch sensations can arise from multiple sources. For example, one may accidentally bump into an object (external) or come in contact with another person (interpersonal). One may also get sensations from intra-personal (self) touch. In recent years, touch sensations have been further categorized on the basis of whether they served a primary discriminative function as opposed to a more hedonic (social) function (see McGlone, et al Neuron 82, 2014). This categorization reflects in large part different neural mechanisms subserving each touch function from periphery to cortex (McGlone 2014). In the present report, we sought to determine whether hedonic touch would lead to a differential modulation in brain excitability when sensations arise from intra vs. inter-personal contact or from contact with an object. Corticospinal excitability was assessed by monitoring changes in MEPs elicited in the first dorsal interosseous (FDI) of the resting left hand in response to right TMS while blindfolded participants (n=11, 24.3± 1.7 years) were subjected to different modes of hedonic touch applied to the dorsum of the hand. The modes consisted in: 1) INTRA, self-induced touch with the right index finger, 2) INTER, touch via the experimenter's finger contact and 3) EXT, external touch via a paint brush. In all modes, the stimulation consisted in a single stroke displacement of ~ 1 cm/s from the base of 3rd knuckle to the wrist line (15 MEPs/mode, randomized sequence). Analysis of MEP modulation revealed that MEPs under the INTRA mode were significantly larger than those in either the INTER or EXT mode (Tukey, post-test, $p<0.05$). Consistent with this, MEP latency was also significantly reduced during INTRA when compared to INTER touch. Interestingly, INTRA (self) touch was rated as the least pleasant by participants (10/11), whereas the brush was rated as the most pleasant (8/10). The increased excitability seen with INTRA-touch likely reflects the more extensive recruitment of sensorimotor areas associated with active movement and bilateral interactions between left and right motor cortices (Ackerley et al, Front Behav Neursc 2012). The fact that it was also rated as the least pleasant mode can be linked with the sensory cancellation phenomena (Chapman and Tremblay, 2015) Scholarpedia, 10(3):7953). The observation that passive modes (INTER and EXT) elicited lesser facilitation might be linked with recent observations showing that passive touch was associated with less intense and more restricted activation in contralateral somatosensory areas than active touch (Ackerley et al 2012).

Title: Intracellular responses induced by transcranial magnetic stimulation

Authors: J. BANERJEE[1,3], M. SORRELL[1,3], P. CELNIK[2], *G. PELLED[1,3];
[1]Radiology, [2]Physical Med. and Rehabil., Johns Hopkins Sch. of Med., Baltimore, MD;
[3]Kennedy Krieger Inst., Baltimore, MD

Abstract: Transcranial Magnetic Stimulation (TMS) is a non-invasive brain stimulation technology that has been shown to induce changes in neural excitability that outlast the period of stimulation by induction of weak electric currents using a rapidly changing magnetic field. TMS has shown preliminary success as a therapeutic tool in the clinic in adult neurological diseases such as stroke, epilepsy, major depression and migraines. Nevertheless, the cellular mechanisms targeted by TMS remain unknown. Therefore, we have sought to investigate the cellular mechanisms affected by TMS by using intracellular electrophysiology and calcium imaging methods. Whole-cell patch-clamp recordings of spiking activity and intracellular steady-state currents were performed in excitatory pyramidal neurons located in the primary somatosensory cortex in live rat brain slices. Excitatory neurons were identified by GFP expression driven by CaMKII promoter. Current-clamp recordings showed that 20 Hz TMS (frequency often used in clinical setting) induced spiking activity in the neurons even at sub-threshold depolarization. Additionally, voltage clamp experiments show that TMS increased the steady-state currents at these sub-threshold voltages. The results together suggest that TMS activates specific voltage gated ion channels leading to changes in neuronal excitability. For imaging experiments, cortical neurons obtained from E15-E16 mouse embryos were co-cultured with cortical glia obtained from P0-P2 mouse pups. The cell cultures were loaded with the calcium indicator fura-2/AM and the percent change in fura-2 ratio at 340/380 nm excitation was calculated from the images. In agreement with the electrophysiology results, the imaging experiments showed that 20 Hz TMS induced increases in intracellular calcium concentrations, indicative of neuronal activity. The above results cumulatively show that TMS affects the excitability of excitatory neurons and also shows increased calcium responses. Understanding the exact mechanism by which TMS alters cellular excitability may help to refine and improve treatment strategies. Title: Multi-joint proprioception deficits at the shoulder, elbow and wrist post stroke

Authors: *L.-Q. ZHANG[1], D. XU[1], Y. REN[1], H. PARK[2], S. KANG[3], Y. LEE[3], Y.-S. LIN[3]; [1]Rehabil. Inst. of Chicago, Chicago, IL; [2]KAIST, Daejeon, Korea, Republic of; [3]RIC, Chicago, IL

Abstract: It is well known that sensorimotor functions of multiple joints (shoulder, elbow, wrist and hand) of the upper limb are impaired post stroke. In particular, stroke survivors often have sensory deficit, which significantly affects motor control, motor learning, and recovery of functional activities after stroke. Sensory impairment was reported as one of the main predictors for motor recovery of stroke survivors. Past research has been focused on characterizations of single-joint or end-point proprioception and there has been a lack of characterization of multi-joint proprioception. Considering that human functional activities almost always involve multiple joints simultaneously in the upper limb, examination and treatment of multiple joint is needed. Multi-joint and multi-DOF proprioception was investigated in six patients post stroke and six healthy controls using a multi-joint rehabilitation robot called IntelliArm. When selected, the shoulder was moved in horizontal abduction or adduction, and the elbow and wrist was moved in flexion or extension. With the shoulder, elbow or wrist joint randomly selected, the joint was moved at a slow speed of 0.5 degree/sec by the IntelliArm robot, with the subject not looking at the joints. Subjects were asked to push a hand-held switch as soon as he/she felt a joint movement and to tell the operator which joint was moved and in which direction. Proprioception acuity of the horizontal abduction (Sh-HAb) and adduction (Sh-HAd), elbow flexion (El-Fl) and extension (El-Ex), and wrist flexion (Wr-Fl) and extension (Wr-Ex) of stroke survivors showed considerable impairments. Patients post stroke had higher proprioception thresholds at the shoulder, elbow and wrist than their counterparts of healthy controls. Multi-joint sensory characterizations are helpful in understanding sensorimotor deficits post stroke and in planning subsequent impairment-specific neurorehabilitation.

Title: fMRI reveals altered processing of affective touch in heterozygous carriers of a nerve growth factor beta (NGFB) mutation influencing C tactile afferent pathway

Authors: *I. MORRISON, I. PERINI;
Linköping Univ., Linkoeping, Sweden

Abstract: In this fMRI study we investigated the effects of a rare nerve growth factor beta (NGFB) mutation on affective touch perception, both for directly-experienced and touch and observation in others. This mutation (R221W) causes a reduction in unmyelinated C fibers, which include C nociceptors and C-tactile (CT) afferents. CT afferents contribute to the processing of hedonic touch, with preferential responses to caressing speeds which are rated as most pleasant (Löken et al, Nat Neurosci, 2009). Homo- and heterozygous carriers with low C-afferent density evaluate affective touch differently than controls, and show cortical-level differences in the processing of such stimuli (Morrison et al, Brain, 2011). The present study further explored behavioral and hemodynamic affective touch variables in a group of healthy heterozygous R221W carriers with milder reductions in C afferent density. We compared 12 heterozygote carriers with age-, gender-, and education-matched controls. CT-optimal vs non-optimal skin stroking speeds (3 cm/s vs 30 cm/s) were contrasted for both experienced and observed touch (see Morrison et al, J Neurosci, 2011). In both groups, posterior/mid insula and parietal opercular cortex responded to CT-optimal touch (3cm/s) vs CT-non-optimal (30 cm/s) touch. However, only the controls showed a selective increase in orbitofrontal cortex activation, suggesting processing of CT-optimal stroking speeds in reward-related terms. Crucially, the results were similar for the observation condition, indicating that seeing others' affective touch interactions also engages these areas. In addition, carriers' mean pleasantness ratings were lower than controls'. To determine the neural correlates of rating patterns, we extracted the value for the negative quadratic coefficient for each subject, reflecting the fit to a typical CT-related, inverted U-shaped curve across speeds (see Löken et al, 2009; Perini et al, Front Hum Neurosci,

2015).We used these values as covariates of interest during CT targeted touch (3 cm/s). Whereas the carriers' ratings covaried with parietal somatosensory and sensorimotor areas (primary somatosensory cortex, angular gyrus), the controls engaged areas associated with affect, reward, and social relevance (orbitofrontal cortex, ventral anterior insula, and superior temporal sulcus). These findings suggest that despite overall similarities in affective touch processing, evaluation of affective touch in R221W carriers is limited to somatosensory networks, while controls shift from somatosensory to more specific reward- and evaluation-related processing during caress stimulation.

Title: C-tactile afferent stimulating touch carries a positive affective value

Authors: *S. C. WALKER[1], R. PAWLING[1], P. D. TROTTER[1], P. R. CANNON[2], F. P. MCGLONE[1];

Abstract: The rewarding sensation of touch in affiliative interactions is hypothesised to be underpinned by a specialised system of nerve fibres called C-tactile afferents (CTs), which respond optimally to slowly moving, gentle touch, typical of a caress. However to date, there is little empirical evidence to support the theory that CTs encode socially relevant and rewarding tactile information. Here, we employed psychophysiological and behavioural measures to examine whether CT activation carries an innate reward value. Firstly we used electromyography (EMG) to measure the facial responses of two key emotion-related muscle sites (zygomaticus major & corrugator supercilii), while participants evaluated the pleasantness of experimenter administered stroking touch, delivered using a soft brush, at CT optimal velocity (3cm/sec) and at a faster, CT non-optimal speed (30cm/sec). Subsequently, in an evaluative conditioning paradigm, participants rated the approachability of emotionally neutral faces. During conditioning, a subset of each participant's most neutrally rated faces was paired with tactile stimulation of their forearm, delivered by a stroking robot. For half the faces stroking was CT-optimal (3cm/sec), for the other half, stroking was faster (30cm/sec). Heart rate and skin conductance were recorded throughout. In the EMG study, a significant location x speed

interaction was found, with increased activation at the zygomaticus major seen to 3cm/sec stroking on the forearm, a response indicative of positive affect. In the conditioning study, a significant touch-type x time interaction was found. Whilst rated equally approachable at first, post-conditioning, faces paired with CT-optimal touch showed a significant increase in approachability, those paired with the faster control touch did not. Physiologically, we observed significantly greater heart rate deceleration and lower skin conductance responses to CT-optimal touch versus control. These results offer the first empirical evidence that tactile stimulation, which optimally activates CTs, carries an affective value that can be imbued to socially relevant stimuli. Furthermore, our findings support the theory that CT activation can reduce arousal levels, perhaps underpinning their role in social support and nurture.

Title: Combining theta burst motor cortex stimulation with spinal cathodal DC stimulation to promote motor functional recovery after corticospinal tract injury

Authors: *W. SONG, D. RYAN, A. AMER, J. MARTIN;
City Col. of the City Univ. of New York, New York, NY

Abstract: Corticospinal tract (CST) damage produces weakness or paralysis. An important strategy for promoting the function of spared CST connections is to harness activity-dependent plasticity. Previously we found motor functional improvement after 6 hours of M1 stimulation each day for 10 days in pyramid-injured rats. To further facilitate activity dependent plasticity, in this study we combine forelimb M1 activation, with co-activation of its spinal target, to strengthen CST functional connections and to promote motor recovery in pyramid-injured rats. We hypothesized that combined stimulation would augment CST connections and this would increase axon terminal extension within the spinal cord and, in turn, promote motor functions after injury. To activate M1, we developed an electrical analog of intermittent theta burst stimulation (iTBS), using epidural stimulation to activate cortical motor output, and concurrently cervical spinal circuits were co-activated by cathodal trans-spinal direct current stimulation (c-

tsDCS), which independently facilitated motor output. We found that after unilateral pyramid transection, rats showed a significant contralateral forelimb impairment while performing skilled ladder walking. After testing, rats were assigned to either a stimulation group or a control group without stimulation. The stimulation group was treated with combined stimulation (iTBS/c-tsDCS) 25 min a day for 10 days. There was a significant reduction in motor threshold during the treatment period. Importantly, motor function was significantly improved, beginning 1 week after cessation of stimulation, with reduced errors in the ladder task. In contrast, the non-stimulated control group maintained significantly higher error scores. One month post injury, the CST was traced in the stimulated and control groups. There was a significantly higher density of axon outgrowth on the impaired side of the spinal cord (ipsilateral to M1 stimulation) in the stimulated group than the control group. Our results suggest that combining "top down" M1 stimulation with "bottom up" spinal stimulation activates the entire corticospinal system to induce durable CST structural changes within the spinal cord. And this, in turn, promotes motor function after pyramidal injury. The combined stimulation may be sufficiently robust to provide treatment after a severe spinal cord injury.

Title: Electrophysiological assessment of the cervical spinal cord networks of intact rats based on profiles of spinal evoked potential amplitudes and delays in multiple forelimb muscles

Authors: *L. MOORE[1], H. ZHONG[2], R. R. ROY[3], V. EDGERTON[3], D. C. LU[4];

Abstract: Abstract: Epidural spinal cord stimulation (electrical enabling motor control, eEmc) is an emerging therapy for the treatment of paralysis resulting from spinal cord injury. When applied to the lumbosacral spinal cord, eEmc enhances voluntary limb control in paraplegic patients (Harkema et. al., 2011). To begin to determine whether this therapy could also be used to enhance arm function, we studied the electrophysiological properties of the cervical spinal cord networks converging to multiple forelimb motor pools in intact adult male Long Evans rats (n = 13). Selected arm/forearm muscles were implanted bilaterally with intramuscular EMG electrodes. Epidural electrodes were implanted medially at spinal cord levels C4, C6, and C8. Bipolar stimulation was applied at 1 Hz across pairs of epidural electrodes in six different combinations and evoked potentials were recorded *in vivo* from the muscles implanted with

EMG electrodes. Data from the homologous muscles bilaterally were grouped for analysis and the evoked responses were evaluated based on their amplitudes and delays. Stimulation from C6+C4- and C8+C4- were least effective in evoking responses in the forelimbs. The C6 to C8 region showed the unique property of effectively evoking forelimb responses regardless of the direction of stimulation. Our data indicate that eEmc at the C6 to C8 segments produces the largest responses in multiple upper limb muscles. The data presented here combined with data obtained after a paralyzing injury may provide a guideline for the more effective sites to stimulate in order to neuromodulate the excitability of specific motor pools and muscles and, thus, to facilitate the success rate in completing motor tasks post-injury.

Title: Changes in step height following locomotor training are not related to change in reflex excitability or voluntary muscle strength

Authors: *E. C. FIELD-FOTE[1,2], K. J. MANELLA[3], L. MELBOURN[4];
[1]Shepherd Ctr. / Crawford Res. Inst., Atlanta, GA; [2]The Miami Project to Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL; [3]Physical Therapy, Univ. of St Augustine for Hlth. Sci., Austin, TX; [4]Physical Therapy, Rosalind Franklin Univ. of Med. and Sci., Chicago, IL

Abstract: Background and Purpose: In individuals with motor-incomplete spinal cord injury (iSCI), inadequate step height during walking contributes to decreased walking efficiency and increased risk of falls. In the absence of changes in strength, an increase in step height is a possible indication of increased corticospinal control after locomotor training. To date, no study has examined the effect of different body weight supported locomotor training (BWSLT) approaches on step height during overground walking in persons with iSCI. The purpose of this study was to determine if locomotor training influences step height during walking, how different approaches influence changes in step height, and whether these changes are related to dorsiflexor or hip flexor strength, or to spinal reflex excitability. **Participants:** Twenty-eight subjects with chronic (> 1 year) SCI who participated in a larger study to compare locomotor training approaches. **Methods:** Subjects were randomized to 1 of 4 BWSLT groups: treadmill-based training with manual assistance (TM), treadmill-based training with electrical stimulation

(TS), overground training with electrical stimulation (OG), and treadmill-based training with a locomotor robot (LR). Data were captured before and after 12 weeks of training. Step height during overground walking was analyzed based on 3D motion capture. Biomechanical and electrophysiologic measures of lower extremity reflex excitability included pendulum test, H-reflex excitability and post-activation depression, reciprocal inhibition, and flexor reflex excitability. **Results**: Across all locomotor training groups there was a significant increase in step height during self-selected overground walking speed ($p=0.031$); between-group differences in step height were not significant. Changes in reflex excitability did not correspond to changes in step height, however, in the OG group there was greater modulation of H-reflex low frequency depression, reciprocal inhibition, and flexor reflex excitability. There was no significant relationship between change in dorsiflexor or hip flexor motor scores and change in step height. **Conclusions and Clinical Relevance:** Motor control related to ability to clear the foot during walking is improved with locomotor training, and appears to be unrelated to changes in voluntary control of the ankle dorsiflexors or hip flexors. These changes also appear not to be reliant on changes in lower limb reflex excitability. These results support the concepts of task-specific training for improved quality of movement.

Title: Changes in activity of spinal postural networks at different time points after spinalization

Authors: *T. DELIAGINA, P. V. ZELENIN, V. F. LYALKA, L.-J. HSU, G. N. ORLOVSKY; Karolinska Inst., Stockholm, Sweden

Abstract: Spinalization, i.e., a complete transection of the spinal cord results in loss of postural functions, which do not recover over time. Instead, spastic, incorrectly-phased motor responses to postural sensory signals gradually develop, and later, bursting activity in muscles appears, suggesting plastic changes in the spinal postural networks. The aim of the present study was to reveal these plastic changes, i.e., to characterize the activity of spinal postural networks at different time points after spinalization. For this purpose, rabbits in 3, 7, 14, and 30 days after

spinalization (at T12) were taken in acute experiments. After decerebration, the head and vertebral column were rigidly fixed, whereas the hindlimbs were positioned on a platform. Lateral tilts of the platform caused sensory inputs from limbs. In preparations with intact spinal cord, these inputs evoked postural limb reflexes, i.e., activation of extensors in the loaded and flexing limb and decrease in extensor activity in the opposite (unloaded and extending) limb. Activity of different motoneuron pools was assessed by recording EMGs of hindlimb muscles. Putative spinal interneurons were recorded extracellularly in L5. The data were compared with those obtained in our earlier studies on rabbits with intact spinal cord (Control) and in rabbits after acute spinalization. As in Control, at each time point after spinalization, neurons whose activity correlated with platform tilts were found, suggesting that they receive tilt-related sensory input from the limbs. It was found that during the first month after spinalization, the proportion of neurons activated with ipsi-limb flexion and its extension, as well as the source of their modulation did not change (as compared to the acute state). In contrast, their activity and depth of modulation (which exhibited a significant decrease just after acute spinalization as compared to control) reached the control value in 3 days after spinalization. At this moment, motor responses to platform tilts were practically absent. This result suggests that there are two processes of plastic changes in the postural networks, which are triggered by spinalization - a slow process of recovery of the motoneuronal excitability (taking months), and a rapid process of restoration of the normal activity level in spinal interneurons (taking days). In addition, considerable changes in the receptive fields of neurons were observed. During one month after spinalization, there was a dramatic increase in the relative number of neurons activated from skin receptors (60% vs 7% and 4% in control and after acute spinalization, respectively).

Title: Using silicon probe electrode recording arrays to examine changes in spinal cord neuronal activity produced by spinal cord direct current stimulation

Authors: *J. H. MARTIN[1], W. SONG[2];
[1]Physiol, Pharmacol & Neurosci, [2]Physiology, Pharmacol. and Neurosci., The City Col. of the City Univ. of NY, New York, NY

Abstract: Transspinal direct current stimulation (tsDCS) has been shown to modulate cortical motor output, potentially to promote motor function after injury, including immediate expansion of the motor cortex (M1) motor map (Song et al, 2015). The spinal cord contains myriad neuron types and processes in different locations, with different sensory and motor functions. It is not known if spinal cord neuronal activity in the various regions is differentially modulated by applied DC currents. Here we used a two-dimensional silicon probe electrode array in the cervical spinal cord to record local field potentials (LFPs) simultaneously from 32 sites to M1 or peripheral stimulation. We determined changes produced by applied cathodal and anodal DC currents. LFPs were recorded in anesthetized rats to phasic M1 (motor evoked spinal potentials, MESP) or cutaneous stimulation (sensory evoked spinal potential, SESP). DC was passed between a stainless steel screw implanted in the C7 vertebra and a skin patch electrode. We constructed latency and amplitude maps of the first negative peak that arises from the initial (presumably monosynaptic) depolarization of the neurons around the recording area. MESPs showed polarity dependent changes during tsDCS. Difference maps of latency and amplitude showed distinct patterns depending on whether the recordings were located dorsomedially, corresponding approximately to the medial dorsal horn, or ventrolaterally, in the lateral intermediate zone and motor pools. Dorsomedial neurons were activated first and c-tsDCS shortened latencies and increased amplitudes, whereas anodal tsDCS (a-tsDCS) had the opposite, and smaller, effect. C-tsDCS strongly increased the power of the evoked oscillatory activities, after wavelet decomposition, from low (alpha/beta) to high (gamma) frequency bands in the ventromedial spinal cord, whereas a-tsDCS showed the opposite effect. SESP latency was shortest dorsomedially and amplitude, largest ventrolaterally. tsDCS changed latency minimally. C-tsDCS increased responses ventrolaterally whereas a-tsDCS decreased responses. C-tsDCS decreased evoked oscillatory activity power dorsomedially and increased ventrolaterally, whereas a-tsDCS showed a weaker opposite effect. Our results show that tsDCS immediately and differentially modulates spinal network excitability depending on location and DC polarity, including the ventral motor regions of the gray matter. Our study provides further evidence for using tsDCS as a “bottom up” rehabilitation method after motor systems injury.

Title: Effect of interlimb coupling on spinal reflexes during cycling

Authors: *R. ZHOU[1,2], J. ASSH[2], L. ALVARADO[3], S. CHONG[3], V. MUSHAHWAR[2,1]; [1]Ctr. for Neurosci., [2]Div. of Physical Med. & Rehabil., [3]Univ. of Alberta, Edmonton, AB, Canada

Abstract: The spinal networks in the cervical and lumbar cord are actively coupled during locomotion, and the involvement of the arms shapes leg activity. The nature of coupling and modulatory interactions between the arm and leg centres in the spinal cord during locomotion still remains largely unknown, especially after spinal cord injury (SCI). The goal of this study was to investigate the spinal arm-leg intersegmental connectivity during cycling through the modulation of spinal reflexes. Fifteen people with intact nervous system and 4 with chronic (>1 year) incomplete SCI (iSCI) participated in the study. The injuries were between C3 and C7. All iSCI subjects received 60 hours of coupled arm-and-leg active cycling training over 3 months. Intact participants underwent 2 experimental sessions. In the 1st, the role of leg cycling on modulating the H-reflex amplitude in the flexor carpi radialis (FCR) muscle was studied. Stimuli for evoking 50% maximal H-reflex were delivered in a randomized order, with the leg positioned in each of 4 quadrants within the cycling revolution to assess phasic modulation. The legs either actively cycled or were passively placed in one of the quadrants to investigate the influence of dynamic leg movement on the upper limb spinal reflex. The stimuli were delivered to the FCR when the muscle was relaxed or contracted at 10% maximal isometric voluntary contraction (MIVC). In the 2nd session, a similar procedure examined the effect of arm cycling on the Soleus (SOL) H-reflex amplitude. The peak-to-peak amplitude of H-reflex in FCR or SOL was compared across all conditions (stationary vs. cycling; phase-dependency; muscle at rest or 10%MVIC) using a 3-way ANOVA. The iSCI participants only completed the 2nd session with the SOL muscle at rest; the testing was conducted pre- and post-training. Results from the intact participants showed significant reduction in the amplitude of both FCR and SOL H-reflexes during dynamic cycling of the opposite limbs ($p \leq 0.026$) but no significant effect at various phases. In participants with iSCI, there was no significant reduction in the SOL H-reflex during dynamic arm cycling either pre- or post-training; however, the 3-month coupled arm-and-leg training tended to decrease H-reflex amplitude ($p=0.078$), indicating a reduction in spasticity. The results demonstrate that rhythmic movements significantly decrease spinal reflexes of the arms and legs through intraspinal connectivity in the intact nervous system. Although this intersegmental modulation was disrupted in people with chronic iSCI, the leg spinal reflexes may still be substantially reduced after a longitudinal training intervention.

Title: A tilting task for brain-machine interface control of balance after spinal cord injury

Authors: *M. MEYERS, N. BRIDGES, J. GARCIA, K. A. MOXON;
Sch. of Biomed. Engineering, Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA

Abstract: Postural control is a critical function of the lower body that is impaired after spinal cord injury (SCI). Brain-machine interfaces could be used to by-pass the injury, taking control signals from supraspinal structures and using them to control functional electrical stimulation below the level of the lesion. However, little is known about supraspinal control of posture and the impact of spinal cord injury on those neural control signals. Since the rat is a good model of human spinal cord injury, there is a need to develop a task that can be used to study postural control before and after SCI in the rat. Previous studies used a task in which a rat maintains balance on a platform that rotates or tilts in the frontal plane. After severe SCI animals will require body-weight support (BSW) in order to continue working in this task. To characterize the impact of BWS, the center of pressure (CoP) when healthy animals were tilted with and without BWS were compared. Female Long-Evans rats were trained to stand stationary on a tilting platform, and their behavior was monitored by three single-point load cells which measured the normal forces between the paws and the platform. The platform moved in a trapezoidal trajectory, with stationary periods at neutral and tilted positions. The CoP of the ground reaction force distribution was computed from the load cell signals in both the anterior-posterior dimension and the left-right dimension. The experiment was repeated with and without the animals connected to the BWS device, and three parameters of the CoP trajectory were compared between the two conditions: the mean CoP during the stationary period at zero degrees, the net displacement of the CoP during an early period of motion, and the mean CoP during the stationary period at the tilted position. Two different weight-support devices were used: one consisting of a Velcro strip connecting the animal to a horizontal bar, able to pivot up and down and supported by a spring (Overhead BWS), and the other consisting of a sling supporting the animal from below (Sling BWS). When the Overhead BWS was used, significant differences were found between the weight supported and control conditions in all three CoP parameters, suggesting that the animals relied on the BWS to maintain balance. When the Sling BWS was used, the difference in CoP parameters between conditions was attenuated. These results suggest that animals rely less on the Sling than the Overhead BWS. Therefore, studies investigating postural control systems after SCI should use a Sling BWS. This task and the Sling BWS were also used in a study of trunk muscle EMG and for a closed-loop BMI for posture.

Title: Interlimb coordination: Effect of training strategy and locomotor task post-SCI

Authors: ***K. A. CHEFFER**[1,2,3,4], W. A. O'STEEN[1,3,4], K. L. WHYLAND[1,3,4], S. K. WINTER[1,3,4], N. PELISCH[1,3], D. R. HOWLAND[1,2,3,4,5];
[1]Kentucky Spinal Cord Injury Res. Ctr., Louisville, KY; [2]Anatom. Sci. and Neurobio., [3]Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [4]Robley Rex VA Med. Ctr., Louisville, KY; [5]Kosair Charities Ctr. for Pediatric Neurorecovery, Louisville, KY

Abstract: Proper coordination of fore-hindlimb movements is important for efficient and stable quadrupedal locomotion. This coordination is mediated by long propriospinal tracts connecting cervical and lumbosacral levels of the spinal cord in addition to input from supraspinal regions. Also important is right-left hindlimb coordination which can be mediated by segmental commissural neurons and modified by descending pathways. A lateral thoracic hemisection partially disrupts descending pathways to the lumbosacral cord, but does not directly modify segmental connections. The purpose of this study is to characterize recovery and determine how training impacts spatiotemporal coordination features during different voluntary gait challenges. Adult, spayed, female cats with low-thoracic, lateral hemisection injuries are divided into three groups: 1) Untrained; 2) Basic trained with a focus on reciprocal stepping in overground and/or treadmill environments; and 3) Skill trained which combines use of basic and adaptive tasks. Adaptive tasks included a 2” wide narrow beam and custom horizontal ladder. All animals are followed for 16-20 weeks post-injury. Semi-quantitative and quantitative analyses are used and include footfall and support pattern diagrams, phase diagrams, and E1-F interval analysis. Preliminary results suggest that recovery is impacted by training with respect to onset of general performance recovery. Trained groups show accelerated recovery in their ability to cross the ladder and narrow beam compared to untrained animals. Trained groups also incorporated the ipsilesional hindlimb earlier and to a greater degree. Pre-injury, regardless of task, fore-hind and right-left limb coordination is characterized by a 1:1 ratio and consistent spatiotemporal features and patterns at moderate gait speeds. At acute post-injury time points, the ratio and coordination are disrupted across tasks. Spatiotemporal features show the earliest and greatest recovery during basic overground walking. The more challenging tasks show greater disruptions and persistence of alterations. Strategies used post-injury show not only distinct differences compared to pre-

injury, but also across tasks. These new features of spatiotemporal coordination which emerge after injury include changes in the limb stepping ratios between the fore- and hind-limbs as well as the right and left hindlimbs. Analyses are being run to assess for correlations between spatiotemporal features, training approaches, and numbers of supraspinal and long propriospinal neurons with descending axons crossing the lesion site.

Title: Cortical control of balance using an interactive brain-machine interface

Authors: *N. BRIDGES[1], R. MADINENI[2], A. SHARAN[2], J. GARCIA[1], M. MEYERS[1], K. A. MOXON[1];
[1]Sch. of Biomed. Engin. Sci. and Hlth. Systems, Drexel Univ., Philadelphia, PA; [2]Thomas Jefferson Univ., Philadelphia, PA

Abstract: After severe spinal cord injury (SCI) at the mid-thoracic level, postural control is impaired, contributing to paraplegia. Studies examining cortical reorganization after SCI suggest that these networks learn novel control strategies that contribute to functional recovery. Little is known, however about the plasticity in the adult cortex involved with learning new control strategies for maintaining posture. Brain-machine-interfaces (BMIs) serve as a unique tool for studying such processes because they provide the animal a means to relate neurophysiological modulations with observed outcomes through an investigator-determined nervous system framework (i.e. a decoder). To this end, we developed a novel closed-loop BMI balance task driven by neuronal activity in response to postural perturbations. 16-channel microwire arrays (Microprobe, Gaithersburg, MD) were bilaterally implanted chronically within the hindlimb sensorimotor cortex of Long Evans rats. Rats were subjected to rotational tilts in the lateral plane. Tilts of varying initial jerk (acceleration change) were applied at random intervals. Neuronal activity was continuously recorded and the magnitude of the initial jerk was decoded. If the magnitude of the initial jerk was correctly decoded, the animal was rewarded by having the platform return to the neutral position. If the initial jerk was incorrectly classified, the platform was moved to a 25 degree tilt and held for 2.5 seconds before returning to the neutral condition.

Rats were able to successfully use the BMI to control the platform and neuronal tuning properties changed over time. These findings suggest that our task is uniquely suited to study feedback-based learning processes in postural systems.

Title: Changes in corticomotor excitability and hand use in persons with tetraplegia following stimulation-augmented task-specific versus resistance training

Authors: ***J. GOMES-OSMAN**[1], J. TIBBETT[2], K. BRISSON[2], K. ROACH[2], E. C. FIELD-FOTE[3];
[1]The Miami Project to Cure Paralysis, [2]Univ. of Miami, Miami, FL; [3]Crawford Res. Inst., Shepherd Ctr., Atlanta, GA

Abstract: Purpose/Hypothesis: Small improvements in hand function can make a meaningful difference in the lives of persons with tetraplegia. Somatosensory stimulation may increase voluntary drive through spared corticospinal pathways after spinal cord injury (SCI). We hypothesized that peripheral nerve somatosensory stimulation plus functional task practice training (PNSS+FTP) would be associated with greater improvements compared to PNSS alone, or conventional resistance training (CRT; universal gym). We also hypothesized that the changes in hand function would be reflected in changes in cortical excitability. Participants: Forty-nine individuals with chronic (> 1 year) tetraplegia due to SCI with neurological of level C7 or above. Materials/Methods: In this single-blind, randomized clinical trial, subjects were randomized to 1 of 3 groups PNSS+FTP, PNSS alone, or CRT; they participated 5 days/week for 4 weeks). Motor evoked potentials (MEPs) acquired with transcranial magnetic stimulation (TMS) were used to assess cortical excitability. Pinch and grip forces were measured via dynamometer. Eleven items from the Chedoke Arm and Hand Activity Inventory (scored based on 7 levels of assistance) were used to assess change in hand function associated with the interventions. Results: Baseline values of MEPmax and area under the recruitment curve were significantly lower for the PNSS+FTP group compared to CRT or PNSS. Post training change in these measures was also lowest the PNSS+FTP group. Conversely PNSS+FTP was associated with the greatest change in pinch (weaker hand=1.5±2.8 lbs, stronger hand=1.9±3.7 lbs) and grip force

(stronger hand=2.5±7.4 lbs). On average, PNSS+FTP improved 28.6% of Chedoke items that primarily involved pinch, compared to 20% and 15% for the PNSS and CRT groups. In contrast, CRT improved 31.4% of Chedoke items that primarily involved grip, compared to 24.5% and 22.9% for PNSS+FTP and PNSS. Conclusions and Clinical Relevance: Despite significantly lower baseline levels of cortical excitability in the PNSS+FTP group, this training was associated with the largest increases in pinch, grip strength, and functional pinch performance. CRT was associated with the largest increases in functional grip performance. PNSS is a clinically accessible approach to augmenting the effects of FTP, and this combined intervention appears to be valuable for improving hand function.

Title: Cholinergic inputs on motor neurons are modulated by manipulating the corticospinal projection

Authors: *Y. JIANG, J. H. MARTIN;
Physiology, Pharmacol. and Neurosci., The City Col. of the City Univ. of NY, New York, NY

Abstract: Corticospinal (CS) axons are one major pathway that conveys motor commands from motor cortex to spinal cord. CS inputs are integrated with sensory inputs and modulated by interneurons before reaching motor neurons. Premotor cholinergic interneurons receive CS inputs and directly innervate motor neurons, and thus may be particularly important in this process. In this study, by manipulating the corticospinal projection, we found a close association between changes in CS axons and that of cholinergic terminals on motor neurons. We hypothesize that cholinergic inputs to motor neurons are modulated by corticospinal projection and, in turn, influence motor output. We compared changes in cholinergic terminals on motor neurons, putative “C-boutons,” in 4 groups of animals in which CS axons were manipulated in different ways. 1) Pyramidal tract lesion (PTx), which complete disrupts contralateral CS projections from one hemisphere; 2) Unilateral M1 inactivation with Muscimol (10mM) infusion (Inact), which suppresses the excitability of CS axons; 3) Cervical dorsal rootlet rhizotomy (DRX) which completely deprives sensory inputs and induces competitive sprouting of CS

axons; and 4) Proprioceptive afferent stimulation (ES) which induces sprouting of PA and CS axon retraction. We anterogradely trace CST with BDA from motor cortex, and visualized cholinergic interneurons by immunohistochemical staining with ChAT antibody. In the medial intermediate zone, cholinergic interneurons receive direct CS projection, whereas proprioceptive projection is very rare, indicating that corticospinal axons are one of the primary inputs to premotor cholinergic interneurons. We showed significant loss of contralateral CS axons and/or projections in PTx, Inact and ES groups of animals, and increased CS projections in DRx animals compared with that of control. C bouton density was analyzed and found to decrease in response to PTx, M1 inactivation, or electrical stimulation of PA. In contrast, it significantly increased after DRx. The change in cholinergic terminals paralles that of the corticopsinal projection in each group, thus suggesting that the projection from corticospinal axons positively regulate cholinergic inputs onto motor neurons. Due to the lack of direct CS projections onto motor neurons in rodents, the modulation of cholinergic inputs to motor neurons induced by CS axonal change could be the key mechanisms that affects motor function, especial after PT lesion. Cholinergic interneurons thus are a potential target for restoring impaired motor function after injury.

Title: Mapping intermuscular force dependent reflex pathways selectively using intramuscular stimulation in the decerebrate cat

Authors: *M. A. LYLE, A. CLOUTIER, T. R. NICHOLS;
Sch. of Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: Force feedback from Golgi tendon organs (GTOs) are well known to have widespread intermuscular connections that are mediated by interneurons that share inputs from muscle spindles, among others. Because current methods to study the strength and distribution of GTO circuits use nerve stimulation or muscle stretch, both of which also activate muscle spindle afferents, the selective role of GTOs remains uncertain. Here, we tested the hypothesis that intramuscular stimulation could be used to examine GTO circuits selectively. The hypothesis was evaluated by measuring the effects of intramuscular stimulation evoked contraction with that

of muscle stretch as donor inputs on the motor output of recipient muscles. Recipient muscle motor output was the force magnitude in response to 2 mm ramp-hold-release stretches. Each trial included 20 to 40 stretch repetitions with alternate stretches paired with a donor muscle input. Stimulation evoked contraction and muscle stretch as donor inputs were evaluated in separate trials. Muscle pairs evaluated included those already known in the cat to exchange muscle spindle afferents only (medial & lateral gastrocnemius), GTO afferents only (flexor hallicus longus & gastrocnemius), and muscle pairs that share both afferents (gastrocnemius & soleus). It was found that muscle stretch, but not intramuscular stimulation, provided excitatory inputs to the recipient muscles when the muscle pair shared only muscle spindle afferents. Both muscle stretch and intramuscular stimulation inhibited recipient muscles similarly when the muscle pair shared GTO afferents only. In muscle pairs evaluated that shared both muscle spindle and GTO afferents, intramuscular stimulation evoked inhibitory effects only. These preliminary data collectively support the hypothesis that direct muscle stimulation evoked contraction can be used to selectively map intermuscular interactions attributed to GTO circuits. Beyond the ability to selectively activate GTOs, stimulation evoked muscle contraction, the well-known physiological stimuli for GTOs, is versatile and noninvasive in contrast to current methods. We propose this approach could be used to substantially advance our understanding of the functional role of intermuscular force feedback.

Title: Kinematics analysis using 3D sagittal and novel multiple plane models for the study of gait recovery in quadrupeds with neurological disorders

Authors: ***N. PELISCH**[1,2], K. A. CHEFFER[1,2,3,5], N. BROWN[1,4,5], K. L. WHYLAND[1,2,5], S. K. WINTER[1,2,5], W. A. O'STEEN[1,2,5], G. BERTOCCI[1,4], D. R. HOWLAND[1,2,3,5,6];

Abstract: Three dimensional (3D) kinematic gait analysis is an important noninvasive technique to assess and quantify normal gait features as well as changes following neural injury in quadrupeds. Challenges and effects due to choices made during data capture, manipulation, and

analyses are compared using data from SPF, purpose-bred, intact cats and those with thoracic spinal injuries. Cats are conditioned to cross a range of runways from a flat, wide surface to those requiring paw placement precision and significantly challenge balance. A 10-camera Vicon Motion Analysis system, and custom code, is used for all analyses. Typical techniques track pelvic and hindlimb markers in the sagittal plane. Typical marker positions include: iliac crest, greater trochanter, stifle (knee), lateral malleolus, and base of the fifth metatarsal. Due to skin movement during gait, a tracked stifle marker does not accurately identify the joint position. We compare three approaches to generate a projected stifle using different inputs: 1. Lengths of proximal and distal hindlimb segments; 2. Distal hindlimb segment length + a vector marker on the distal fibula 2-3 cms proximal to the hock (ankle joint); and 3. Lengths of proximal and distal hindlimb segments + vector marker. For many reasons, markers may not be tracked at various points. Effects regarding the minimum number of cameras required for initiating and tracking a marker as well as gap filling options are presented. Although sagittal plane capture is the most common approach in animal laboratories, it does not directly quantify key out-of-plane motions typical of recovered and/or adapted gaits. To more effectively capture clinically relevant kinematic changes, we are developing and evaluating a pelvis and bilateral hindlimb model using joint coordinate systems. Kinematic outcomes using this multiple plane approach include flexion-extension (also represented in the sagittal plane model), as well as internal-external rotation, and abduction-adduction of the hind limb joints. In addition to evaluating stifle projection techniques, virtual marker generation accuracy (as compared to actual marker placement) is tested as a method to replace lost and/or obstructed markers. Furthermore, the importance of a static marker capture, limb position during capture and impact on accuracy of marker generation during different step cycle subphases are evaluated. Valuable insights regarding movement and recovery can be achieved using many approaches, but comparisons across kinematic models and data capture, tracking, and analysis methodologies indicate when data may be compromised and results should be interpreted cautiously.

Title: Lack of adaptation during prolonged split-belt locomotion in the intact and chronic spinal-transected adult cat

Authors: V. KUCZYNSKI[1], Y. THIBAUDIER[1], M.-F. HURTEAU[1], C. DAMBREVILLE[1], A. TELONIO[1], *A. FRIGON[2];
[1]Pharmacology-Physiology, [2]Physiol. and Biophysics, Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: In human adults, the pattern of coordination between the legs adjusts during prolonged assymetrical locomotion on a split-belt treadmill where the speed of the left and right sides is independently controlled. Specifically, some interlimb parameters, such as double support periods and step lengths return towards symmetry during prolonged split-belt locomotion and show after-effects upon returning to tied-belt (equal left-right speeds) locomotion (Reisman et al. 2005, J Neurophysiol 94:2403-15). The adaptation (return towards symmetry and after-effects) to split-belt locomotion is considered to be one of the first stages of motor learning. However, the neural structures involved in locomotor adaptation are largely unknown. Due to the central role of the spinal cord in producing the basic pattern of locomotion, we hypothesized that locomotor adaptation could be achieved, at least in part, by intrinsic spinal mechanisms. To test this hypothesis, 4 intact and 4 spinal-transected (spinalized) adult cats performed 2 min of tied-belt locomotion (Tied1), followed by 10 min of split-belt locomotion and a return to tied-belt locomotion for 2 min (Tied2). The fast-slow speed ratios used ranged from 1.5 to 2.0. During experiments, video recordings were made from the left and right sides. Stance durations, double support periods and step lengths were measured bilaterally. Stance durations for the left and right hindlimbs were approximately equal on the left and right sides (i.e. symmetric) during Tied1. During split-belt locomotion, stance duration on the slow side was longer than on the fast side and this did not change over the course of 10 min for both intact and spinalized cats. Left-right symmetry returned immediately during Tied2. Double support periods and step lengths showed a similar adjustment pattern, with left-right symmetry during Tied1, slow-fast asymmetry that did not change during 10 min of split-belt locomotion and a return to left-right symmetry immediately during Tied2 in both intact and spinalized cats. Therefore, intact and spinalized cats do not appear to display locomotor adaptation during prolonged asymmetrical stepping, at least with the fast-slow speed ratios used. The lack of return towards left-right symmetry might be due to the more stable nature of quadrupedal locomotion in the cat and/or to differences in the neural structures involved in adjusting stepping in asymmetrical conditions when compared to human adults that walk in an upright bipedal position.

Title: Examination of the mechanisms that contribute to the induction and maintenance of a peripheral memory

Authors: *M. M. STRAIN[1], J. D. TURTLE[1], K. C. HOY[2], J. W. GRAU[1];
[1]Dept. of Psychology, Texas A&M, College Station, TX; [2]Dept. of Neurosci., MetroHealth Med. Ctr., Cleveland, OH

Abstract: Prior work has shown that spinal neurons can support some simple forms of learning. In particular, instrumental learning can be shown in spinally transected rats by administering a leg shock (to the tibialis anterior [TA] muscle) whenever the hindleg is extended. Rats trained in this manner exhibit a progressive increase in flexion duration. This training produces both a central modification (that fosters future learning) and a peripheral change (that maintains the shocked leg in a flexed position for over 30 min). The latter effect has been related to alterations at the neuromuscular junction (NMJ) (i.e., training with contingent shock increases both acetylcholine (ACh) and NMDA receptor (NMDAR) labeling). Further, once the behavioral modification (the memory) is induced, it is maintained minus input from the spinal cord. Additionally, we have shown that microinjection of a NMDAR (MK-801) or ACh (curare) antagonist into the TA eliminates the behavioral modification. The current study further explores the mechanisms that contribute to the induction and maintenance of this peripheral memory. It begins by examining whether training induces a peripheral modification by measuring the strength of the muscular response using electromyography (EMG). Results found that spinally transected rats given 30 min of training with response-contingent (controllable) shock exhibited a stronger EMG relative to subjects that received non-contingent (uncontrollable) shock. Further, microinjecting MK-801 into the TA eliminated this effect. We hypothesize that efferent input from the spinal cord, in conjunction with TA stimulation, could induce the peripheral memory. To explore this possibility, spinally transected rats had their sciatic nerve cut and had stimulation applied to the peroneal nerve, either paired or explicitly unpaired with TA stimulation. Preliminary results show that pairing nerve stimulation with TA muscle activation causes a lasting (30 min) increase in flexion vigor. On-going experiments are examining how this effect is related to stimulus number, duration, and temporal order.

Title: Intra-spinal network for motor learning revealed by dI3 interneuron silencing in complete spinalized mice

Authors: ***N. STIFANI**[1], A. SAMPALLI[1], I. WRIGHT[1], T. V. BUI[3], T. AKAY[1], R. M. BROWNSTONE[2];
[1]Med. Neurosciences, [2]Med. Neurosciences and Neurosurg., Dalhousie Univ., Halifax, NS, Canada; [3]Dept. of Biol., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Progressive recovery of locomotor function following complete spinal transection has been described in cats and mice. In humans, treadmill training provides rhythmic sensory inputs to spared spinal networks leading to significant improvement in gait. These observations suggest an evolutionarily conserved spinal network that undergoes rearrangement to restore fundamental locomotor function. Yet, to date mechanisms responsible for this functional recovery are unknown. dI3 interneurons (INs) are a population of glutamatergic dorsal spinal INs genetically characterized by the expression of LIM homeodomain protein Isl1. dI3 INs have been implicated in spinal processing of sensory afferents and have been shown to be essential for grasping function. In order to reveal spinal networks responsible for locomotor recovery, we studied mice in which the output of dI3 INs has been genetically silenced (dI3OFF mice). dI3OFF mice exhibit only minor locomotor deficits compared to their control littermates. After complete spinal transection at lower thoracic level, all mice exhibited initial hindlimb paralysis. Treadmill locomotor training induced a progressive functional recovery in control animals but had limited effects in dI3OFF mice. Our results demonstrate that dI3 INs are not crucial for locomotion under normal conditions, yet they are critical for locomotor recovery after complete spinal transection. Our results reveal the nature of intra-spinal circuits involved in locomotor recovery. These circuits have the potential to restore locomotion after spinal cord injury.

Title: Examining the molecular mechanisms underlying activity-dependent corticospinal axon growth

Authors: ***N. ZAREEN**[1], S. DODSON[2], K. ARMADA[2], R. MISIR[2], J. H. MARTIN[2]; [1]Physiology, Pharmacol. and Neurosci., The City Col. of the City Univ. of New Yor, New York, NY; [2]Physiology, Pharmacol. and Neurosci., The City Col. of the City Univ. of NY, New York, NY

Abstract: The corticospinal tract (CST), which originates from the primary motor cortex (M1) and projects to spinal motor circuits, is the main pathway for evoking skilled voluntary movements. Spinal cord injury can interrupt this pathway, resulting in significant weakness or paralysis. We have shown in healthy adult rats, that CST neurons respond to increased neuronal activity produced by chronic M1 electrical stimulation by sprouting axons into the spinal gray matter, forming novel synapses with existing motor circuits and enhancing evoked muscle response. In animals with unilateral pyramidotomy, we showed that stimulation of the intact M1 results in complete restoration of skilled motor function. Thus, chronic stimulation is an effective repair strategy following CST injury. Our aim was to understand the molecular mechanisms underlying this activity-dependent sprouting. We focused on the role of the mTOR pathway. We used epidural electrodes to stimulate M1 for 6 hrs/day (330 Hz, 45 ms trains/2 sec) in adult Sprague-Dawley rats, using our published protocol (Brus-Ramer et al, 2007; Carmel et al, 2010) and anterogradely traced CST projections to monitor CST sprouting stereologically. M1 stimulation upregulated the expression of the neuron activity marker, cFos, in cortical neurons. Western blots and immunohistochemical data show that following both 1 day and 10 days of M1 stimulation, the levels of an mTOR activity marker, phospho-S6 (pS6) protein, are upregulated in neurons, especially in layer V, of the stimulated M1 but not in that of the sham animals. Elevated pS6 levels associated with significantly more segmental axons crossing the midline, more sprouting into the spinal gray matter, and a greater number of putative CST synapses. This suggests the mTOR pathway could be involved in CST axon sprouting following M1 stimulation. To test if mTOR is necessary for activity-dependent CST sprouting we blocked mTOR with rapamycin. pS6 levels in cortical neurons failed to increase in stimulated, rapamycin-treated animals. Notably, we found fewer segmental axons crossing the midline, less gray matter sprouting, and fewer synapses compared to the vehicle treated group, showing mTOR activation is crucial to CST remodeling following M1 stimulation. Activity-dependent CST remodeling is a proven strategy for recovering from CST injury and here we provide insight into its underlying molecular mechanism. The mTOR pathway integrates various extracellular signals to regulate protein synthesis and has been shown to associate with CST axon regeneration. We now show that the mTOR pathway is also responsible for activity-dependent CST axon sprouting in healthy adults.

Title: Timing errors during lower limb cycling under various conditions

Authors: *A. VALY[1], J. LACZKO[2,1];
[1]Pazmany Peter Catholic Univ., Budapest, Hungary; [2]Information Technol. and Biorobotics, Univ. of Pécs, Pécs, Hungary

Abstract: Timing errors in movements of 15 able bodied individuals (age 24 ±4) were studied during lower limb cycling against various resistances at specific speeds. Maintaining cycling speed during training or rehabilitation exercises is often desirable but always a difficult task for participants performing lower limb cycling. A number of physical and neurological factors contribute to what speed a subject performs each complete revolution. The goal of this research is to present a method which significantly imporves speed control during cycling when feedback on speed is available. Voluntary able bodied paticipants cycled on an ergometer (SciFit ISO7000R, Germany) at two cadences and three resistance conditions (at 45 rpm: 2,55 Nm, 9,55 Nm, 22,30 Nm, at 60 rpm: 2,55 Nm, 15,92 Nm, 34,24 Nm), resulting in six exercise sessions each with the duration of 20 seconds. The participants received visual feedback on their speed via the ergometer touchscreen. We measured lower limb movement kinematics using a Zebris CMS-HS system (Isny, Germany), with 7 ultrasonic kinematic markers to calculate crank and joint angles. For the whole duration of the exercises we also calculated the time instants at which the crank would have returned to the top dead center (TDC, designated 0 degrees) if the cycling speed was constant. From our measurements we extracted the actual times at which the crank was at the TDC and calculated the time difference between ideal and measured time instances at which the crank would return to the TDC. This error increased through consecutive complete revolutions during each session for each individual. Increased timing errors were associated to successive cycles. There was no significant difference between the timing errors observed in different resistance conditions (t test, p=0.05). Comparing the participants, we found that at low resistance the difference between timing error of the fastest and slowest participant was 1240 ms at 45 rpm and 810 ms at 60 rpm. At medium resistance this dropped to 580 ms at 45 rpm and 690 ms at 60 rpm. Going to high resistance timing errors further dropped but at a lower rate, to 460 ms at 45 rpm and 640 ms at 60 rpm. High resistance may result at an earlier fatigue. From the aspect of physical training and medical rehabilitation our results suggest, that employing a medium crank resistance when cycling on an ergometer enables subjects to better keep the desired cycling cadence producing smaller timing errors.

Title: The role of rat trunk muscles in postural control

Authors: *J. GARCIA, N. BRIDGES, M. MEYERS, K. A. MOXON;
Sch. of Biomed. Engineering, Sci. & Hlth. Systems, Drexel Univ., Philadelphia, PA

Abstract: Understanding the role of trunk muscles during postural control is important for restoring function after injury. Severe spinal cord injury results in loss of supraspinal control of lower body musculature leading to loss of postural control. Previous studies suggested that enhanced supraspinal control of trunk muscles could compensate for this loss. To understand how these muscles are activated during postural control a task in which a rat maintains balance on a platform that rotates or tilts in the frontal plane was used. Female Long-Evans rats were tilted in the frontal plane with varying initial jerk. The target angle of the tilt was set to either 15 or 25 degrees. Animals were trained to stand on the tilting platform and then chronically implanted with electromyography (EMG) electrodes into the rostral and caudal (relative to T8) longissimus unilaterally and spinotrapezius bilaterally. For each trial, after reaching the target angle the platform remained in this position for one second before returning to the neutral position. There was a 2 second inter trial interval where the platform remained in the neutral position. The position of the platform was monitored using an accelerometer and timestamps indicating the beginning and end of platform movement were recorded. After a 3-5 day recovery period, rats were again placed on the platform. EMG was acquired at 5 kHz, filtered (10-500 Hz, 4th order Butterworth) and rectified. Bursts were determined using a threshold equal to baseline activity plus 3 standard deviations. Probability of a burst and average number of bursts per unit time were examined in four windows: NEUTRAL position, START of tilt, HOLD at max tilt and RETURN to neutral position. Overall, the probability of a muscle burst was dependent on the degree of tilt. Differences in activation of spinotrapezius muscles compared to longissimus muscles was dependent on the direction of tilt (left versus right) and the magnitude of tilt. Understanding the role of these muscles in normal animals will lend insight into the changes that occur after spinal cord injury and help to develop strategies to restore posture.

Title: Spinal pathways for the coordination of swallow and cough

Authors: *T. PITTS[1], S. KING[2], D. R. HOWLAND[2];
[1]Kentucky Spinal Cord Res. Ctr., [2]Univ. of Louisville, Louisville, KY

Abstract: The respiratory spinal network is activated by both cough and swallow. However current computational models do not account for local changes in excitability with the spinal cord. We compared in silico simulations to *in vivo* data from anesthetized cats. Coughs were elicited by mechanical stimulation of the intra-thoracic trachea. Electromyograms (EMG) of the parasternal (PS) and transversus abdominis (TA) muscles identified cough . Swallow was elicited by injection of water into the pharynx and EMGs of the thyroarytenoid (ThAr), PS, and geniohyoid (GH) identified swallow. Simulations predicted PS EMG amplitude of "post-swallow" cough would be greater than "pre-swallow" cough and this effect was observed *in vivo*. However, important temporal features that govern cough and swallow coordination when both behaviors are co-expressed were not observed in silico, such as, during repetitive coughing, the expiratory phase (E2) of cough is prolonged when swallow is present. We conclude the current model is predictive; the in silico simulations reproduce several important features of *in vivo* airway protection; however some temporal relationships between cough and swallow are not currently accounted for by the model. Title: A three-dimensional map of the hindlimb motor representation in the lumbar spinal cord in sprague dawley rats

Authors: *J. A. BORRELL[1,6], S. B. FROST[2,3], J. PETERSON[4], R. J. NUDO[5,3];
[2]Molec. & Integrat. Physiol., [3]Landon Ctr. on Aging, [4]Neurosurg., [5]Rehab. Med., [1]Univ. of Kansas Med. Ctr., Kansas City, KS; [6]Bioengineering, Univ. of Kansas, Lawrence, KS

Abstract: The purpose of this study was to derive a three-dimensional topographical map of functional motor outputs from the lumbar spinal cord to hindlimb skeletal muscles as defined by intraspinal microstimulation (ISMS). Experiments were carried out in healthy, adult, male, Sprague Dawley rats using commercial neurophysiological recording equipment. Under ketamine/xylazine anesthesia, fine wire electromyographic (EMG) electrodes were implanted into 4 muscles in both hindlimbs: the lateral gastrocnemius (LA), tibialis anterior (TA), vastus lateralis (VL), and biceps femoris (BF) (total 8 muscles). After a laminectomy of the T13-L1 vertebrae and removal of the dura matter, a four-shanked microelectrode array (NeuroNexus Technologies) was used for ISMS. Shanks were 200 µm apart, and each shank had four 40 µm diameter stimulation sites that were 200 µm apart. Each stimulation site had an impedance in the range of ~30-40 kΩ at 1 kHz. The electrode array was inserted into the spinal cord at the lumbar level (under vertebrae T13-L1) along a three-dimensional (200 µm by 200 µm by 200 µm) stimulation grid. Stimulation sites ranged from ~140-2200 µm below the dorsal surface of the spinal cord, from ~400-800 µm lateral to the midline on both sides of the spinal cord, and from ~0.6-10 mm from the caudal end of the T12 vertebra. Three pulse biphasic trains with 200 µs duration square-wave per pulse at 300 Hz per train and each train separated by 1 sec were used to determine evoked movements and EMG activity. Movement threshold was determined by the lowest stimulation current that evoked a visible and consistent joint displacement. Stimulus-Triggered Averaging (StTA) was used on rectified EMG data to determine response latency. The ISMS responses typically consisted of leg, hip, knee, ankle, and toe movements. There was predominant hip movement in rostral T13. In caudal T13, there was a shift towards medial leg rotation. Moving caudally to L1, there was a mixture of ankle movement, digit movement, and medial leg rotation with no clear arrangement in either hindlimb. Further caudally in L1, there was predominant knee movement in both hindlimbs. StTAs of EMG activity showed a latency of ~4 ms. The derived motor map gives insight into the layout of the motor neuron pools within the hindlimb area of the normal spinal cord.

Title: Increase in fALFF-measured spontaneous neuronal activities in sensorimotor cortices after muscle fatigue

Authors: *Z. JIANG[1,3], G. H. YUE[2,3,4];
[1]Human Performance and Engin. Res., [2]Human Performance & Engin. Ctr., Kessler Fndn., West Orange, NJ; [3]Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ; [4]Physical Med. & Rehabil., Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: Background: Prolonged muscle exertion results in muscle fatigue that may cause reduced performance and productivity, and increased chances of injury. Although peripheral mechanisms underlying voluntary muscle fatigue are relatively well known, central contributions to the fatigue are much less understood. The current study investigated brain signal oscillations during resting state before and immediately after a muscle fatigue task (MFT). Resting state functional MRI (rsfMRI) data of the sensorimotor cortices were analyzed by computing fractional amplitude of low-frequency fluctuation (fALFF). Recent rsfMRI studies have demonstrated that fALFF of BOLD signals are associated with spontaneous neuronal activities especially those involved over long distance communication in the brain. We hypothesized that sensorimotor network in the brain after MFT would experience abnormal fALFF compared to before MFT. Aim: Identify muscle fatigue-related dynamic signal adaptations during resting state in sensorimotor cortices by using rsfMRI signal-based fALFF, a novel frequency-domain signal analysis tool. Method: Ten subjects performed a 20-minute intermittent (3.5s ON/6.5s OFF, 120 trials total) handgrip task using the right hand at 50% maximal voluntary contraction (MVC) force level that induced significant fatigue. The rsfMRI slices covering the primary motor (M1) and somatosensory (S1) cortices were collected before and after the task using a 3T Siemens Trio scanner and an echo planar imaging sequence. All rsfMRI data were first motion corrected followed by spikes and linear trends removal using AFNI. Images were co-registered to high resolution structural scans collected in the same session. Region of interests were obtained from parcellation results using Freesurfer. The fALFF analysis was carried out using scripts released by 1000 Functional Connectomes Project (http://fcon_1000.project.nitric.org). Minor modifications were made to set up the batch running for our own data. Result: We observed marked shifting to higher fALFF in all analyzed brain regions: bilateral S1 and bilateral M1. Wilcoxon signed rank test confirmed significant fALFF increases in all regions (all $Ps<0.001$). This finding suggests augmented exchange of information among the M1 and S1 regions over a relative long distance (crossing hemispheres) after muscle fatigue. Conclusion: The increase of fALFF represents likely a physiological recovery process related to restoration of normal resting-state signal oscillations in the sensorimotor cortices after a temporary perturbation from the normal state by stressful muscle fatigue.

Title: Unbiased estimate of the spinal cord neuronal population involved in primate motor control

Authors: *N. WILSON, P. ROSE, S. SCOTT;
Queen's Univ., Kingston, ON, Canada

Abstract: The spinal cord plays an essential role in the sensory and motor functions that give rise to behaviours ranging from simple reflexes to complex goal directed movements. The ratio between motoneurons and interneurons in the spinal cord has been commonly computed to understand the relative computational capabilities of spinal motor networks (Walloe, 2011). Currently, there are few accurate estimates of the number of motoneurons and interneurons within the non-human primate spinal cord and this ratio is not well defined. Neurons within the spinal cord grey matter of non-human primates were quantified to provide a more robust anatomical framework for modelling upper limb motor control. The spinal cords of rhesus monkeys (Macaca mulatta) were examined from segments C2 to T1 using stereological methods to estimate the total number of neurons in specific areas of the grey matter. These areas included both those containing motor neurons (Lamina IX) as well as those containing interneurons associated with motor pathways (Laminae V - VIII). Total number of neurons was calculated to be 216,600 ± 5000 in laminae V and VI, 140,100 ± 4100 in VII and VIII and 52,500 ± 3300 within lamina IX. A ratio of 1:25 in the rhesus monkey was calculated using motoneuron and interneuron estimates. This ratio is higher than that of other mammalian and non-mammalian vertebrates, indicating that a more robust spinal network may underlie the ability of primates to generate complex upper limb movements.

Title: Feasibility of using causality changes to monitor fatigue during forearm repetitive movement in typically developing children

Authors: ***Y.-N. WU**[1], Y. CAO[2], C. STARK[1], K. CHAN[1], S.-C. YEN[3];
[1]Physical Therapy, [2]Computer Sci., Univ. of Massachusetts Lowell, Lowell, MA; [3]Northeastern Univ., Boston, MA

Abstract: Fatigue contributes to declined motor performance in people with and without neurological disorders. When the high repetition of movement is required to engage neural plasticity during neurorehabilitation or skill learning, excess practice can cause fatigue that might be detrimental (causing longer period of rest that interrupts the neurorehabilitaiton routine). A reliable way to monitor fatigue developing and then guide practice is valuable yet less available. Fatigue is task and population dependent. Weakened muscle contraction force might not be a sensitive indicator to reflect fatiguing during sub-maximum contractions, which are often involved in nuerorehabilitation. Meanwhile electromyography (EMG) amplitude and spectrum analysis of maximum voluntary contraction has been extensively used to study muscle fatigue, but it lacks the dynamic information. On the other hand fMRI study demonstrating neural network disconnection due to muscle fatigue implies coupling changes occur when fatigue develops. To seek a potential tool for real-time fatigue monitoring, we aimed to apply EEG with Granger causality algorithm to examine the causal relation between motor function-related cortical areas during repetitive forearm movement. Eight typically developing children (9.7±1.9 y/o, 4 boys and 4 girls) were recruited in the study. 32-channels EEG with 10-10 system for electrode positioning was used to capture brain activities. Surface EMG electrodes were placed on the forearm muscles of both upper extremities of the child. The child was then seated in front of the robot that has sensors to recognize forearm motion. Through this robot, the child played ten (or less) 3-minute video games by repetitively rotate the left forearm. EEG, EMG, kinetic data and a modified perceived exertion scale were recorded for each game the child played. The task stopped before reaching 10th game if a child expressed really hard to perform (exertion scale= 7) at the end of the game just played. Signals of selected five electrodes overlying five distinct motor function-related cortical areas including C3, C4, Cz, Fz and Pz were used to examine any causality at each game using bi-vitiate Granger causality. The preliminary results show a trend of decreased causality strength, particularly between C4 and Pz while comparing the first 3-minute data and the data when a child first expressed starting to feel hard to perform the task. The decreased causality strength might be due to strengthened coupling of many brain areas activation, such as M1, PM, S1 and bilateral PFC reported in fMRI studies. Our results added another piece of evidence of using EEG as a tool to assist rehabilitation practice.

Title: Motor cortical input-output characteristics of the lower extremity in young and old adults

Authors: *H. HASSANLOUEI, C. W. SUNDBERG, J. SENEFELD, A. KUPLIC, S. K. HUNTER;
Physical Therapy, Marquette Univ., Milwaukee, WI

Abstract: Changes in corticospinal excitability may be partially responsible for the age-related decline in neuromuscular function of the lower limb. Whether there are age-related differences in the input-output characteristics in lower limb motor cortical areas is not known. The purpose was to compare the input-output curves of motor evoked potentials (MEPs) elicited in motor cortical areas targeting the quadriceps muscles of young and old adults. MEPs of the vastus lateralis (VL) were recorded from 8 recreationally active young (19-30 yr, 3 women; 55 ± 25 MET.hr/week) and 11 old adults (61-79 yr, 5 women, 52 ± 40 MET.hr/week) with bipolar EMG electrodes by delivering single-pulse transcranial magnetic stimulation (TMS) over the motor cortex contralateral to the knee extensor muscles. The active motor threshold (AMT) was determined as the minimum stimulator intensity eliciting MEPs in the VL in at least 4 of 8 trials while subjects performed intermittent isometric contractions at 10% maximal voluntary contraction (MVC) (~3 s contraction, ~7 s relaxation). Ten stimuli were delivered (1 per 3 s contraction) at each stimulator intensity ranging from 90-165% of the AMT in 5% increments until: 1) a minimal increase in MEP amplitude was observed with increased stimulator intensity, or 2) the maximum stimulator output was reached. Electrical stimulation of the femoral nerve was used to elicit the maximal compound muscle action potential of the VL (Mmax). All VL MEP amplitudes were expressed as a percentage of Mmax and plotted against the stimulator output (%AMT) to generate an input-output curve. Input-output curves were fit with a 3-parameter Boltzman sigmoidal function to obtain the estimated maximal MEP amplitude (MEPmax), the stimulus intensity required to elicit a response equal to half MEPmax (S50), and the peak slope of the sigmoidal curve. The Mmax was less in old adults (7.7 ± 3.5 mV) compared with young adults (13.1 ± 3.5 mV, $P<0.05$). AMT was similar between the young and old adults (49.6 ± 8 vs 49.2 ± 8 % stimulator output). When the MEP amplitudes were expressed as a percentage of Mmax, there were no differences between young and old adults in MEPmax (30.2 ± 20.6 vs 35.3 ± 17.2 %), S50 (118 ± 10 vs 121 ± 14 %) and the peak slope (0.095 ± 05 vs 0.080 ± 02, $P>0.05$). Thus, among active older adults, aging does not appear to interfere with the motor cortical input-output characteristics of the lower limb during low-level volitional activity.

Title: Peripheral motor neuron inhibition using novel inhibitory opsins

Authors: *C. GORINI, C. RAMAKRISHNAN, K. DEISSEROTH, S. DELP;
Bioengineering, Stanford Univ., Stanford, CA

Abstract: Peripheral motor neuron disorders, such as spasticity and cerebral palsy, result in excessive muscle tone and hyperreflexia. Modulation of motor neurons responsible for these dysfunctions is often difficult; however, optogenetic tools provide a method by which this hypertonia may be relieved. Viral methods for sufficient inhibitory opsin expression have proved difficult, as different virus types can produce dramatically different levels of opsin expression and trafficking. Here, we focus on achieving peripheral motor neuron inhibition using an AAV6 viral vector in conjunction with novel inhibitory, light-activated opsins in both wild type and nude mice. Two to five weeks after injection of the viral opsin construct into the medial and lateral gastrocnemius of four week old mice, we observe a reversible decrease in electrically generated Achilles tendon force upon light illumination of the sciatic nerve. This decrease is accompanied by a corresponding reduction in EMG activity in the medial gastrocnemius. Additionally, histology indicates robust retrograde transduction of opsin in the nerve and spinal cord following intramuscular injection of the gastrocnemius. Future directions include testing a variety of inhibitory opsins and viral routes, as well as classifying opsin trafficking malfunctions and any immune response preventing transfection of motor neurons.

Title: Muscle coordination patterns underlying dynamic hand function

Authors: *N. M. COLE[1,2], A. B. AJIBOYE[1,2];
[1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]FES Ctr. of Excellence, Rehab. R&D Service, Louis Stokes Cleveland Dept. of Veterans Affairs Med. Ctr., Cleveland, OH

Abstract: A long standing theory of motor control is the neuromotor system simplifies control of multi-degree-of-freedom (DOF) movements by recruiting coordinated patterns of muscle activation (muscle synergies), which are combined to produce motor output. While there exists debate about whether muscle synergies are a physiological phenomenon, a muscle synergy based framework may simplify control of functional electrical stimulation (FES) arm and hand neuroprostheses. While many studies have extracted synergies associated with naturalistic arm reaching and static hand postures, the current study aimed to investigate muscle activation synergy patterns underlying dynamic hand tasks involving everyday object manipulations. In able-bodied persons, we recorded electromyogram (EMG) signals from twelve intrinsic and extrinsic hand muscles that were representative of muscles typically implanted for current FES hand systems. Fine wire electrodes, along with ultrasound image guidance ensured selective recording of the tightly bundled muscles. Hand kinematics (18 finger and wrist joint angles) were recorded with a CyberGlove. Each subject performed 10 - 15 trials of 13 tasks that replicate activities of daily living and include different postures, gross and fine movements, and various force levels (e.g. opening a jar, turning a doorknob, or writing). Synergies were extracted from the EMG recordings using a cross-validated NNMF decomposition algorithm. Synergy models are determined for each subject and compared across subjects to identify common patterns during the dynamic hand tasks involving object manipulation. We found that the 13 tasks and 12 muscles could be reduced to 6-8 static muscle synergy patterns accounting for 77 - 95% of the variance in the recorded data. Identified muscle synergy patterns could be visualized as whole hand opening (finger, thumb, and wrist extensors), hand closing (finger, thumb, and wrist flexion), and opening of the thumb and index finger (extensor indicus, distal thumb extension, and thumb abduction). Overall, this study establishes a set of generalizable muscle synergy patterns, with several of the identified patterns found to be similar across subjects. This work lays the foundation for evaluating if the identified synergies can be used for closed-loop control of an implanted FES hand system.

Title: Rabies virus retrograde tracing of monosynaptic premotor spinal interneuron networks extended to mature animals

Authors: L. GOMEZ-PEREZ, R. W. GRIFFITH, *F. J. ALVAREZ;
Physiol., Emory Univ., Atlanta, GA

Abstract: Locomotion matures during postnatal development. In human infants this is evidenced by the reversal of reflex signs and a progressive decline in co-contraction, suggesting spinal circuit modifications. However, possible changes in the connectivity of premotor interneurons (INs) are unknown because lack of methods to map their connections throughout development. Recently, a modified rabies virus (RV) vector was used to identify premotor networks in neonatal animals, but this technique reportedly does not work in mature animals. The method relies on infecting motoneurons (MNs) with a RV lacking the glycoprotein (Gly) gene necessary for infection replaced by a fluorescent protein. Transduction of MNs with AAVs carrying the Gly gene allows passage of mCherry or EGFP RV to INs connected to these MNs. RV does not move beyond this first monosynaptic step because INs lack the Gly gene, resulting in labeling the assembly of INs monosynaptically connected to the infected motor pools. Co-injection of both vectors in specific muscles has been used to dual infect motor pools. We confirmed that co-injections in the lateral gastocnemius muscle (LG) result in abundant IN labeling when done at P5, but not at P15. To characterize MN transduction by RV and AAV we systematically injected mCherry-RV and EGFP-AAV1 in the LG of animals of different ages (P5, P10, P15, P30, adult) and studied transduced MNs and INs at different postinjection times. RV infection is rapid but results in MN degeneration, with the period of MN stability becoming progressively shorter with age. RV-infected MNs are stable for two weeks after P5 infections, but only for a week at P15. Also, RV infection rates diminish at P30. Moreover, co-infection of muscle fibers with mCherry-RV and AAV1-Gly optimizes the number of RV-infected MNs, likely because muscle becomes a source of RV particles. In contrast, AAV1 MN transduction peaks two weeks after injection and the temporal mismatch between MN survival and AAV transduction increases with age causing the decrease in efficiency of the method. To overcome this problem we used mouse transgenics and sequential injections to express the Gly-AAV1 in muscles and/or MNs prior to RV infection and successfully extended the age range of the method. The preliminary results suggest that the complement of INs premotor to the LG pool does indeed change from P5 to P15. We are working to optimize RV infection past P30 and characterize the RV passage mechanism because when Gly is highly expressed in MNs labeling of high numbers of glial cells suggest abundant extrasynaptic transfer. In addition, RV virus enters both MNs and sensory afferents and both sources need to be considered.

Title: A novel wireless microelectrode array implanted chronically provides reliable and selective stimulation

Authors: G. S. BENDALE[1], A. KANNEGANTI[1], F. DEKU[1], S. BREDESON[3], *J. L. SEIFERT[2,4], P. TROYK[3], S. COGAN[1], M. I. ROMERO-ORTEGA[1,4];
[1]Bioengineering, UT Dallas, Richardson, TX; [2]Bioengineering, UT Dallas, Little Elm, TX; [3]Biomed. Engin., Illinois Inst. of Technol., Chicago, IL; [4]UT Southwestern, Dallas, TX

Abstract: Peripheral neural interfaces play a vital role in providing motor control and sensory feedback following nerve damage due to injury or disease. These interfaces must be highly stable, chronically reliable, biocompatible and safe for long-term use. It is also important to meet patient needs in terms of comfort and ease of operation. Tethered electrodes have long wires and bulky external head-stage connectors that are potential points of failure and have been shown to be sources for inflammation. Wireless technology has vastly improved the field of biomedical devices and addresses many of the limitations of current interface designs. In this ongoing study, we have examined the stability and reliability of wireless floating microelectrode arrays (WFMAs) implanted in the sciatic nerve of adult female Lewis rats over a period of 6 months, by evaluating behavioral responses to *in vivo* stimulation. At various time points (days 1, 71, 141 and 172 post-implantation), stimulation thresholds were measured for each of the 16 electrodes on two different WFMAs, by correlation with hind limb motor response. The threshold current values (i.e., the minimum current required to elicit the motor response) did not change significantly over time ($p \geq 0.05$), thus supporting the reliability of the interface. We observed three distinct movements elicited by stimulation: dorsiflexion, plantar flexion and abduction. The types of movement elicited corresponded with the location and size of the electrodes, providing for stimulation specificity. The measured charge per phase for each electrode was below the tissue damage limit of 4nC/phase over the entirety of the time points evaluated, indicating the safety of the interface. In order to assess whether stimulation was causing pain, behavior was evaluated in an awake animal with repeated stimulation at the pre-determined threshold level. No signs of pain or discomfort were observed, i.e., biting, licking, vocalization, or chewing, thus indicating that the wireless stimulation does not activate pain fibers at the motor threshold level. The various sizes and heights of electrodes can be used to interface specific fascicles, thus

targeting unique muscle groups, which can be relevant in a wide range of clinical conditions. We thus propose that the specific distribution of electrodes along with the independence offered by the wireless interface will help achieve safe, reliable, targeted interfacing.

Title: A concurrent TMS/tACS approach to investigate the function of intrinsic brain oscillations in the motor system

Authors: *N. WENDEROTH, K. RUDDY, M. BÄCHINGER;
Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland

Abstract: The functional role of intrinsic oscillatory brain activity for motor control remains largely unknown. It has been suggested that alpha oscillations reflect functional inhibition of task irrelevant regions, as a means of directing information flow in the brain (Jensen & Mazaheri, 2010). Further, using electroencephalography (EEG) it has been reported that motor evoked potentials (MEPs) resulting from transcranial magnetic stimulation (TMS) are smaller when power in the alpha band is high and larger when it is low (Sauseng et al., 2009; Zarkowski et al., 2006). Even within the alpha cycle, it is possible that phase dependant modulation of excitability may occur, as has been demonstrated already for the visual system (eg. Busch et al., 2009). No such evidence exists for the motor system. It has been shown previously that intrinsic brain oscillations can be entrained by transcranial alternating current stimulation (tACS). This method is most efficient when the externally imposed frequency matches the individual's endogenous peak alpha frequency. Here we applied tACS with the intention to (1) synchronize alpha oscillations in the brain of the participant with the external, alternating current and to apply TMS in a phase locked manner; and (2) to increase the power of the alpha rhythm over primary motor cortex. TMS was applied before, during and at three timepoints after tACS stimulation (alpha frequency of tACS stimulation matched to individual alpha peak measured with EEG, 2 mA peak-to-peak intensity), to probe the excitability of corticospinal projections to the first dorsal interosseous (FDI) muscle. During stimulation, TMS was timed to coincide with peaks, troughs, rising and falling edges of the imposed tACS alpha cycle. Participants returned for two additional control conditions on separate days; one with tACS+sham TMS, and another with TMS+sham tACS. The order of sessions was counterbalanced across subjects. Preliminary results suggest no systematic decreases in MEP amplitude as a result of tACS stimulation, and

shed light on important methodological considerations for performing TMS recordings during tACS entrainment.

Title: Isolation and purification of actively translated rna from spinal motor neuron axon terminals

Authors: ***J. SHADRACH**[1], B. PIERCHALA[2];
[2]Biologic and Materials Sci., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Coordinated motor function is achieved by proper communication between spinal motor neurons (MNs) and muscle fibers at a specialized synapse called the neuromuscular junction (NMJ). While dysfunctions of the neuromuscular system that lead to diseases such as spinal muscular atrophy (SMA) and amyotrophic lateral sclerosis (ALS) have complex disease etiologies, recent evidence suggests that deficient RNA processing and trafficking might form a common mechanism that underlies disease pathogenesis. To better understand the types of motor axon mRNA transcripts required for the normal maintenance of the NMJ, we have utilized the RiboTag transgenic mouse model developed by Sanz et al. 2009 to specifically isolate ribosomal complexes and their associated mRNA transcripts. Crossing RiboTag mice to a Cre line results in the expression of an HA-tagged RPL22 (RPL22-HA) protein in Cre expressing cells. As a core member of the ribosome particle, this RPL22-HA is incorporated into the ribosome complex such that the entire complex and any associated mRNA transcript can be immunoprecipitated with an HA-antibody. We expressed RPL22-HA specifically in MNs by crossing RiboTag mice with choline acetyltransferase (ChAT)-Cre mice. As expected, spinal MNs in these RiboTag;Chat-Cre mice demonstrate strong HA+ immunofluorescence. Additionally, HA-tagged ribosomes can be efficiently immunoprecipitated from both spinal cord tissue and skeletal muscles, indicating that RPL22-HA is not only being efficiently incorporated into ribosome particles within the MN cell body, but those complexes are also trafficked into distal axons. Finally, in preliminary studies, we have successfully isolated high integrity RNA transcripts (RIN>8) from immunoprecipitated ribosome complexes from both spinal cord and skeletal muscle tissues; however, especially for RNA isolated from the muscle we are currently working on ways to improve efficiency and further reduce the background noise. Ultimately, using RNAseq we will identify a pool of mRNA transcripts that are specially trafficked into motor axons *in vivo*. While this may shed light onto normal processes required for maintenance at the

NMJ, future application of this technique to models of nerve injury or neuromuscular degeneration will provide a unique insight into how the MN terminal responds to its environment.

Title: Motor control differs for increasing and releasing force

Authors: ***S. PARK**, M. KWON, D. SOLIS, N. LODHA, E. CHRISTOU;
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Control of the motor output depends on our ability to precisely increase and release force. However, the influence of aging on force increase and release remains unknown. The purpose of this study, therefore, was to determine whether force control differs while increasing and releasing force for young and older adults. Sixteen young adults (22.5 ± 4 years, 8 females) and sixteen older adults (75.7 ± 6.4 years, 8 females) increased and released force from 0 to 15% MVC during an ankle dorsiflexion isometric task. We recorded the force output and multiple motor unit activity from the tibialis anterior muscle and quantified the following outcomes: 1) variability of force using the SD of force; 2) mean discharge rate and variability of discharge rate of multiple motor units (MU); 3) power spectrum of the multiple MU from 0-4, 4-10, 10-35, and 35-60 Hz. Participants exhibited greater force variability while releasing force, independent of age ($p < 0.001$). Increased force variability during force release was strongly associated with decreased modulation of multiple MU from 35-60 Hz ($R2 = 0.82$). Changed modulation from 35-60 Hz was further correlated to the change in multiple MU discharge rate ($r = 0.66$) and modulation from 0-4 Hz ($r = -0.64$). In conclusion, these findings suggest that force control is impaired when releasing force due to an altered modulation of the motor units.

Title: Transcranial optogenetic mapping revealed longitudinal changes in motor maps of ipsi-lesional and contra-lesional cortex following mild traumatic brain injury

Authors: *T. NGUYEN, X. JIN;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Mild traumatic brain injury (mTBI) commonly results in short- or long-term cognitive, behavioral, and emotional impairments in patient, but the current clinical and laboratory evaluations of mTBI subjects cannot reveal specific structural and functional brain alterations, and the mechanism of mTBI is not poorly understood. To better understand functional changes of the cerebral cortex following mTBI, we applied a minimally-invasive optogenetic stimulation method to map motor cortex in transgenic mice that expressed light-sensitive channelrhodopsin-2. A closed-head mTBI model was created by using a controlled cortical impact device. Longitudinal optogenetic mappings of the forelimb areas of the ipsilateral and contralateral motor cortex were made by scanning a beam of blue laser on the skull at 2h, 6h, 12h, 1 day, 3 days, and 5 days post injury. Optogenetically evoked responses were recorded with electromyography (EMG) from the forelimb and electroencephalography (EEG) in the cortex. Optogenetic mapping revealed immediate suppression of EMG response and smaller motor maps of the ipsi-lesional cortex within 2 hours post-mTBI, which returned to the baseline level in 6 hours after injury. In contrast, there was an increase in motor map size of the contra-lesional motor cortex within the first 12 hours, which recovered at day 5 post-mTBI. Motor behavioral test using Rotarod showed a decreased mean riding time of the mTBI mice within the first 10 days after mTBI, suggesting a lasting effect of motor behavior. Our data suggest that optogenetic mapping of the motor cortex is a useful technique for longitudinal study of cortical functions following mTBI, and that mTBI induces a transient loss of cortical excitability on the ipsilateral motor cortex but a progressive hyperexcitability of the contralateral cortex after injury. These early electrophysiological changes may have important significance to subsequent posttraumatic neurological deficits and brain functional recovery.

Title: Exploration of neuromuscular modeling approaches and gait adaptation across terrain types as a basis for prosthetic limb development

Authors: *T. R. CLITES[1], A. S. ARNOLD[2], H. M. HERR[1];
[1]Biomechatronics Group, Media Lab., MIT, Cambridge, MA; [2]Concord Field Station, Dept. of Organismic and Evolutionary Biol., Harvard Univ., Bedford, MA

Abstract: Current control paradigms for lower limb prostheses are unable to match innate gait adaptability, especially across terrains with varying mechanical properties. This deficiency leads to dramatic losses in comfort, efficiency, and patient acceptance of prosthetic devices. To create improved biomimetic controllers that interpret and react to varying ground surfaces, it is first essential to identify and characterize the mechanisms that underlie terrain adaptation. The purpose of this study was to develop and validate a neuromusculoskeletal model that predicts ankle moments, in a goat model, with sufficient accuracy to elucidate the neuromuscular dynamics that allow the animals to adapt to different terrains. The overarching aim of this work is to demonstrate a robust, neurally- and mechanically-integrated prosthesis in this animal model, and, ultimately, in human patients. Kinematic, kinetic, and electromyographic data were recorded in two goats walking on an instrumented walkway. The stiffness and damping properties of the walkway were varied to represent a range of natural conditions. Two different modeling approaches were used to develop a neuromusculoskeletal model of the ankle and surrounding muscles. In one approach, the bone geometry, joint kinematics, and muscle force-generating properties were measured in a cadaveric specimen and scaled to the goats of interest. In the other approach, an optimization algorithm was used to solve for the muscle-tendon properties that reproduce the joint moments from inverse dynamics while minimizing metabolic cost at the animals' chosen walking speed. The two modeling approaches were tested against published *in vivo* measurements of muscle fascicle lengths (obtained using sonomicrometry) and time-varying forces (obtained using an implanted tendon buckle) in goats of the same breed. The refined models allow inferences to be drawn about the neuromuscular dynamics that enable gait adaptation, and the comparisons with *in vivo* data provide new insights into the accuracy of neuromusculoskeletal models used in prosthetic controllers.

Title: A novel neuromuscular model for a robotic prosthesis based on velocity-dependent muscle activation

Authors: *U. TAHIR, J. L. PETAK, K. C. NISHIKAWA, J. TESTER;
Norther Arizona Univ., Flagstaff, AZ

Abstract: Despite the success of the sliding filament theory, the goal of predicting muscle force output during movements remains elusive, suggesting that the accepted model of muscle contraction is incomplete. We developed a new radical model, the winding filament hypothesis (WFH) that includes a role for the giant protein titin that spans the half sarcomere. The elastic region of titin is composed three parts; the N2A region joins two springs with varying stiffness, the Ig domains (which collectively function as a compliant spring) and the PEVK region (which functions as a stiff spring). According to the WFH, titin is activated upon calcium influx, and the N2A region binds to the thin filament. The crossbridges, which not only translate, but also rotate the thin filament, wind the PEVK region of titin upon actin during muscle contraction, storing elastic energy. The mdm mutation in mice produces a deletion in the N2A region of the titin gene, resulting in different active and passive properties compared to wild-type mice. To predict changes in force during natural movements, we need to understand how the velocity-dependent behavior of muscle changes with activation. We investigated this using isovelocity stretch and shortening experiments in active and passive muscles from wild-type and mdm mice. Soleus muscles from mice were isolated and attached to a servomotor force lever. The muscles were stretched or shortened through a range of initial lengths, velocities and activation levels. Activation ranging from 0% to 100% was achieved by modulating stimulation voltage and frequency. Damping coefficients and the force-velocity relationship (FVR) scaled linearly in activated wild-type muscles. In passive muscles, the damping coefficient was smaller, suggesting that activation reduces viscosity. Passive isovelocity tests suggest that a mechanism in addition to crossbridges is needed to explain the FVR in the absence of activation. In contrast to wild-type muscles, mutant muscles demonstrated differences between the passive and active FVR, suggesting that the mechanism for decreased viscosity in response to activation is absent. Based on studies such as these, we developed control algorithms for a foot-ankle prosthesis; the iWalk BiOM. We implemented our WFH-based controller and tested subjects under a variety of conditions including level walking, stair ascent and uneven terrain. Our results indicate that the WFH-based control algorithm is capable of produces ankle torques during level walking, stair ambulation and uneven terrain that are similar to torques produced by intact individuals using a simple activation pattern and no change in parameters.

Title: Methodological study to identify trunk and hip muscle representation in motor cortex

Authors: *A. M. ALBISHI[1], J. ARMOUR SMITH[2], B. FISHER[2];
[2]Div. of Biokinesiology and Physical Therapy, [1]USC, Los Angeles, CA

Abstract: Background: Trunk and hip muscles contribute significantly to postural control, balance and locomotion. With aging, changes in activities of these muscles are evident. While modifications in motor behavior are linked to altered muscle representational areas in motor cortex, the relationship between motor cortex organization of the trunk and hip muscles and changes in motor behavior in older adults has yet to be established. Transcranial Magnetic Stimulation (TMS) has been used to identify muscle representation in the motor cortex. Mapping the trunk and hip muscles is challenging due to the small representations of these muscles in the medial motor cortex. Purpose: Establish a methodology to quantify the spatial representation of trunk and hip musculature in young and older adults. Method: Six young females participated in the study. Motor evoked potentials (MEPs) were quantified in the external oblique (EO), lumber longissimus (LES) and gluteus medius (GEMD) using a double cone coil and surface electromyography. After motor thresholding, mapping of a 6 by 4cm grid over the pre-central gyrus was conducted using neuronavigation during a submaximal active contraction (20% of maximum voluntary isometric contraction) for all three muscles. Average peak-to-peak amplitude of MEPs was calculated for each map location and utilized to determine the center of gravity (COG) for each muscle. Results: MEPs were elicited consistently in all three muscles. The average COG for GMED was medial to that of LES and EO. COG for all three muscles was localized within primary motor cortex (approximate x, y, z coordinates; GMED 12, -17, 63mm , LES 15, -17, 63mm, EO 14, -17, 63mm in Tailarach space). However, in some individuals the caudal supplementary motor area also contributed significantly to the motor maps. Conclusion: Initial data demonstrate that this methodology is feasible and can identify distinct trunk and hip representations in the motor cortex.

Title: Neural mechanisms of central fatigue during a prolonged motor task in patients with cancer related fatigue

Authors: *D. ALLEXANDRE[1], A. HOXHA[2], G. YUE[2];
[1]Human Performance and Engin. Lab., Kessler Fndn. Res. Ctr., West Orange, NJ; [2]Kessler Fndn., West Orange, NJ

Abstract: Background: We previously found a greater after-to-before fatigue task twitch force (TF) ratio in CRF than in controls (62%), suggesting that the muscle was less fatigued at the time of perceived exhaustion for cancer patients, pointing to greater contribution of central fatigue to ask failure compared to control subjects. Objective: To investigate neural markers of central and peripheral contributions to motor task failure in patients with cancer-related fatigue (CRF) by studying changes in cortical muscle coherence (CMC) and in EEG sources activity associated with the task. Methods: 14 patients with CRF who were off chemo and radiation therapies and 10 healthy controls with similar age and body mass index were enrolled. All participants completed Brief Fatigue Inventory (BFI) and performed a fatigue task consisted of intermittent elbow-flexion contractions at submaximal (40% maximal) intensity till self-perceived exhaustion. Each contraction lasted 4 seconds with a 2-second rest between trials. To assess the mechanism of neuromuscular fatigue, twitch force (TF) (elicited by supramaximal electrical stimulation) of biceps brachii (BB) muscle at rest before and immediately after the fatigue task, electromyography (EMG) of the BB and brachioradialis muscles, and scalp electroencephalogram (EEG) activities were measured throughout the trials. Results: BFI scores were higher ($P<0.001$) in CRF than controls, indicating greater feeling of fatigue in CRF patients than controls. The after-to-before fatigue task TF ratio in CRF (81%) is higher ($P<0.05$) than that of controls (62%), suggesting that the muscle was less fatigued at the time of perceived exhaustion in CRF patients than controls. Conclusions: Task failure is more of central origin in cancer patients. Ongoing analysis of EEG data will help shade lights on the neurophysiological mechanisms of central fatigue.

Title: Effect of aerobic exercise intensity dose on corticomotor excitability, intracortical inhibition and intracortical facilitation

Authors: *S. KEIL[1], D. CORCOS[2], S. MADHAVAN[1], M. RAFFERTY[1];
[1]Univ. of Illinois Chicago, Chicago, IL; [2]Northwestern Univ., Chicago, IL

Abstract: Background: Single bouts of aerobic cycling have been shown to have an immediate effect on corticomotor excitability, intracortical inhibition, and intracortical facilitation measured with transcranial magnetic stimulation (TMS). The purpose of this study was to determine whether the response was sensitive to aerobic intensity dose. Prior experience with high intensity exercise was examined as a possible predictor of variability in dose response. Methods: Twenty-two participants completed 20 minutes walking at a brisk pace on an incline at 65% and 80% of their age-predicted maximum heart rate on two, non-consecutive days. They were tested with single and paired pulse TMS before and after exercise. Results: Across all participants, there was a dose response where MEP amplitude increased following moderate intensity exercise, but did not increase following high intensity exercise ($p=0.05$). There was also a trend toward lengthened CSP duration following moderate intensity exercise and no change or shortened CSP duration following high intensity exercise ($p=0.09$). The subset of 11 participants who were identified as low-moderate intensity exercisers had a significant increase in resting motor threshold following both exercise doses compared to the high intensity exercisers ($p=0.02$). Discussion: Immediate changes in corticomotor excitability and intracortical inhibition tends to occur following moderate intensity, but not high intensity exercise. Some changes in TMS measures may be driven by inter-individual differences in frequency of high intensity exercise experience. Future research should include increased numbers of participants due to the variability observed in TMS measures.

Title: The Pasta gnawing test: A simple and stress-free test for motor behavior

Authors: *R. RABL, M. FARCHER, D. AMSCHL, B. HUTTER-PAIER;
QPS Austria Gmbh, Grambach, Austria

Abstract: Measuring motor behavior in rodent disease models is often performed in long lasting tests with time consuming evaluations (paper pencil) under high stress conditions (e.g. Rota Rod, Challenging Beam Walk). Beyond that, results of these tests are influenced by body constitution (esp. bodyweight) and the emotional status of the animals. In 2011, Kane et al. noticed, that when performing a Pasta handling test for evaluating the lesion rate of 6-OHDA, unilateral lesioned rats, not only the number of adjustments with each paw was altered, but also the gnawing noise was different. To check whether this finding could also be observed in motor impaired transgenic mice, we evaluated the gnawing noise of three mouse models of three different indications containing motor deficits and compared it with the performance in the Rota Rod Test. Mouse models of Parkinson`s disease (TNWT#61), ALS (TAR6/6) and Niemann Pick`s disease (NPC1) were tested in the Pasta gnawing test and Rota Rod test over time and the gnawing speed and the number of gnaws within one gnawing interval, as well as the latency to fall of the Rod (Rota Rod) were evaluated. Our results revealed that the Pasta gnawing test, evaluating a natural and unforced behavior, did display motor impairment in transgenic murine disease models similar to commonly used motor tests like the Rota Rod, in which the animals are forced to move. Furthermore, we found out, that this measurement was independent from by the body weight, other than for the Rota Rod performance. The Pasta gnawing test is a reliable, easy to perform and stress-free test to evaluate motor performance in mice.

Title: Online vs offline learning of challenging balance tasks post-stroke

Authors: R. LOPEZ-ROSADO[1], *D. A. BROWN[2];
[1]Physical Therapy and Human Movement Sci., Northwestern University, Feinberg Sch. of Med., Chicago, IL; [2]Dept Physical Therapy, Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Purpose/Hypothesis: The aim of this study was to investigate online (within session) and offline (between sessions) task performance of stroke survivors in a balance training

program for both their paretic and non-paretic lower extremities, using three different approaches (clinician guarded, high repetitions; robot-guarded, high repetitions; and robot-guarded, low repetitions with increased height difficulty). We hypothesized that participants who received the robot-guarded, training program while challenged by increasingly difficult heights would demonstrate greater online and offline gains in both extremities. Number of Subjects: 36 stroke survivors, randomly assigned to one of 3 groups: 1) clinician guarded, high repetitions (N=12); 2) robot-guarded, high repetitions (N=12); and robot-guarded, low repetitions with increased height difficulty (N=12). Materials/Methods: The KineAssist® Balance and Gait Training Robotic System was used to guard participants. Part of a larger scope balance training study, although all participants practiced 9 x 5 minute repetitive practice tasks per week, with both the paretic and nonparetic leg dominating the task, we analyzed six of the tasks over a six week period (step up on step, step up on foam, forward reach, long step, hurdle, sit to stand). Task height level of difficulty, number of repetitions and exercise load (# of reps x step height) for each task was recorded. Results: Improved online performance occurred during the sessions where participants were progressed to more difficult task levels within each five- minute practice period (robot-guarded, low repetitions with increased height difficulty). With respect to offline learning over the course of six weeks, on average all participants tested at higher task difficulty levels in all groups for both the non paretic and paretic lower limbs (offline learning gains). Exercise load was generally higher for the clinician-guarded regimens, even though the progression in learning was lesser for this group. Conclusions: Robot-guarded training provides a suitable environment for stroke survivors to practice very challenging, and often risky, challenging balance tasks. When the task is made increasingly difficult so that loss of balance occurs, the robot-guarded condition allows for continued online learning. Clinical Relevance: This study provides evidence that learning is improved when individuals post- stroke are challenged to succeed at balance tasks at high difficulty levels beyond their initial ability.

Title: Postural adaptive strategies of young basketball players in different conditions: possible impact of a proprioceptive training protocol

Authors: *R. A. MEZZARANE, T. C. L. BEZERRA, L. C. GOMES, D. C. SILVA, L. HAGSTROM, T. G. RUSSOMANNO;
Univ. of Brasilia (unb), Brasília, Brazil

Abstract: A number of approaches can be used to evaluate the risk or minimize the occurrence of injury due to sports practice. The analysis of time and frequency-domain parameters in challenging postural conditions can be useful to detect changes in motor control strategies after different interventions (such as proprioceptive training). Significant differences in bilateral modulation of the soleus (SO) muscle activity between elderly and young participants have been recently reported during quiet upright stance. Coherence analysis of the rectified electromyogram (EMG) showed that the main effects were confined to two distinct frequency regions, 0-4 Hz and 8-12 Hz. Here, we investigated postural oscillations and the co-modulation of the SO muscle of young basketball players (12-17y) in different conditions. Twelve participants remained in quiet upright stance over a force platform during 70 seconds in 4 conditions, eyes open, eyes closed, standing on a high-density foam pad with either eyes open or closed. All subjects gave written informed consent and the procedures were approved by a local human ethics committee. The EMG was simultaneously recorded from the SO muscle of both legs at a frequency of 2 kHz. Magnitude squared coherence was estimated for each subject using Welch's averaged modified periodogram method in order to identify common oscillations between both EMG signals. The FFTs of 12 segments were averaged. A Hanning window with 10000 points was specified (without overlapping) resulting in a spectral resolution of 0,2 Hz. Both the root mean square (RMS) and the mean velocity (MV) of the center of pressure were calculated. The coherence estimates of each subject were converted into z-scores and the averaged regions of interest were compared trough a two-way (type of support x vision) repeated measures ANOVA. The same statistical procedure was applied to both MV and RMS. The significance level was set at $p < 0.05$. Lack of visual input strongly affected MV over the foam (significant interaction; $p<0.05$). Significant difference in the z-score was found only for the factor "support" in the range of 0-4Hz ($p<0.05$) consistent with an increased bilateral modulation of motor unit discharges from both legs. This might be ascribed to the disrupted proprioceptive input induced by the foam pad that affects the balance control performed by the central nervous system. We expect that some of these parameters change after the same group of participants undergoing a proprioceptive training period of eight weeks. Eventual changes in these posturographic parameters could indicate adaptive alterations resulted from neuronal plasticity induced by the training ptrotocol.

Title: Role of body asymmetry in control of vertical posture

Authors: *B. CHEN, Y.-J. LEE, A. ARUIN;
Univ. of Illinois At Chicago, Chicago, IL

Abstract: Humans frequently assume asymmetrical postures while walking or standing in a crowded space with an object in one hand (a cellphone or a cup of coffee) and experience a body perturbation. Understanding the role of such a body asymmetry in the presence of the body perturbation is important for the optimization of the postural control. 10 young healthy individuals stood on the force platform and held an object in the right (target) hand. They were exposed to external perturbations applied to their shoulders while standing with either normal or narrow base of support (BOS). Bilateral eletromyographic activity (EMG) of dorsal and ventral trunk and lower extremities muscles and center of pressure (COP) displacements were recorded during the phases typical for the anticipatory and compensatory postural adjustments. Integrals of EMG and indexes of co-contraction (C) and reciprocal (R) activation of muscles were calculated and analyzed. Reciprocal activation of muscles on the target side and co-activation of muscles on the contralateral side was observed when standing asymmetrically and being symmetrically perturbed. Decreased magnitudes of co-contraction and reciprocal muscle activation in APA phase were seen while standing with the narrow BOS. Peak COP displacement was increased when participants stood with the narrow BOS. The findings highlight the importance of investigating the role of body asymmetry in control of vertical posture and provide a foundation for future studies focusing on improvement of postural control in individuals with body asymmetry due to unilateral impairment.

Title: Balance strategies of professional ballet dancers with a history of low back pain are more similar to non-dancers than dancers without low back pain: Analysis of balance with non-linear measures

Authors: *P. W. HODGES, J. GILDEA, W. VAN DEN HOORN;
Univ. Queensland, Brisbane, Australia

Abstract: Balance is critical in ballet. Although dancers are presumed to have superior balance ability to non-dancers, available data are conflicting. One possible reason for the variable results of previous studies of ballet dancers is the failure to consider history of low back pain (LBP) in this group. LBP is highly prevalent in dancers and although LBP is associated with compromised balance in non-dancers, its impact on the balance of dancers is unclear. Further, interpretation of balance in dancers is complicated by the assumption that better balance ability is characterized by less movement, and by the analysis of data with linear measures that provide little detail of balance mechanisms. This study aimed to compare balance between professional ballet dancers with and without LBP and non-dancers, when standing with feet parallel and in the dance-specific turned out "first" position. Centre-of-pressure (CoP) trajectory in the anteroposterior and mediolateral directions was analyzed using linear and non-linear measures in 22 dancers (15 with LBP, 7 without LBP) and 15 pain-free, age-matched non-dancers. Diffusion analysis of CoP trajectories demonstrated that dancers without LBP had greater movement away from an equilibrium position and moved further before correction in the short-term component of balance control (critical point distance; non-LBP vs. non-dancers: $P<0.02$) and displayed greater movement towards an equilibrium position in the long-term component of balance control than non-dancers (parallel feet, anteroposterior direction). This observation of greater motion was supported by some linear measures. Dancers with LBP demonstrated a similar strategy to non-dancers characterized by reduced critical point distance (LBP vs. non-LBP: $P<0.02$, LBP vs. non-dancers: $P=1$) and greater long-term diffusion rate (LBP vs. non-LBP: $P<0.01$, LBP vs. non-dancers: $P=1$). These data show that to control balance, dancers without LBP generally used more movement whereas dancers with LBP used less movement. The balance strategy of dancers with LBP was more similar to non-dancers than to their LBP-free counterparts. The results imply that less movement does not define optimal balance in dancers. Furthermore, impaired balance in dancers with a history of LBP may impact performance quality.

Title: Ballet dancers take more advantage of additional sensory information to reduce their postural sway

Authors: *R. B. GARBUS[1], R. C. MARINHO[2], S. M. S. F. FREITAS[2];
[1]Univ. Cidade De São Paulo, Santos, Brazil; [2]Univ. Cidade De São Paulo, São Paulo, Brazil

Abstract: In daily activities, ballet dancers perform several movements that need an adequate balance or postural stability. Additional somatosensory information provided by the light touch of the index fingertip on a fixed surface is able to reduce the postural sway of individuals during quiet standing. However, it is still unknown in the literature whether ballet dancers are able to take more advantage of the light touch to improve their postural stability during upright stance. Nine ballet dancers and nine non-dancers, all women, right-handed stood, as quiet as possible, on an AMTI force plate during 35 seconds. Participants performed three trials for each visual condition (open and closed eyes) and each touch condition (with and without the right index fingertip touching a fixed bar composed by a force sensor ATI Nano 17). For the touch condition, participants were instructed to maintain the elbow in extension while touched a rigid surface using their right index finger and applied force less than 1 N. If the force greater than 1 N was applied, the computer emitted a beep sound to inform the participants to reduce it. The time series of forces and moments of the force plate as well as the force of the touch bar were recorded at 100 Hz and later used to compute the center of pressure (COP) at anterior-posterior and medial-lateral directions. The area, mean sway amplitude and velocity of COP at both directions and the mean and standard deviation of the force applied on the bar during the trials with touch were assessed. The values of COP area, mean sway amplitude and velocity increased when participants stood with closed eyes compared to trials with open eyes. Participants of both groups reduced the COP area, mean sway amplitude and velocity when they touched the bar regardless of the visual conditions. None of this observed effects differed between groups. The applied force was less than 1 N for both groups; however, ballet dancers applied less force compared to the non-dancers. Overall, the results suggest that women who practice ballet are able to take more advantage of the additional somatosensory information provided by the light touch to reduce the postural sway, in spite of the fact that they applied less force on the external surface.

Title: Effects of lower leg muscle and balance training on periodic floor oscillation task with fixing the knee, hip and trunk in the elderly

Authors: *K. FUJIWARA[1], N. KIYOTA[2], M. IREI[3], C. YAGUCHI[4], H. TOYAMA[1]; [1]Kanazawa Gakuin Univ., Kanazawa, Japan; [2]Japan Hlth. Care Col., Eniwa, Japan; [3]Osaka Hlth. Sci. Univ., Osaka, Japan; [4]Hokkaido Bunkyo Univ., Eniwa, Japan

Abstract: Effects of lower leg muscle and balance training on periodic floor oscillation task with fixing the knee, hip and trunk were investigated in the elderly. Thirty-six elderly subjects were divided into three groups: only lower leg muscle training without balancing (MT); lower leg muscle training with balancing (BT); and untrained control groups (CON). Each training group performed 100 trials per day using a balance board over 4 weeks. Before and after the training period, the subjects maintained a standing posture with the knee, hip and trunk immobilized by the brace while the platform oscillated in the anterioposterior direction at 0.5 Hz with 2.5-cm amplitude. For 5 trials of 1-minute oscillation, the center of foot pressure in the anterioposterior direction (CoPap), Electromyogram (EMG) of the tibialis anterior (TA), gastrocnemius (GcM), and soleus (Sol) and event-related brain potential (ERP) from a Cz electrode were measured. In addition, dorsi- and plantar flexor strength at the ankle and muscle thickness of TA, GcM and Sol were measured with sitting at 90° knee and hip flexion. In MT and BT, significant training effects were found as follows: increases in the both flexor strength, and all muscle thickness. Before the training, mean speed of CoPap fluctuation did not change with the trial repetition in all groups. Only in BT, spectrum amplitudes of CoPap at 0.5 Hz significantly decreased through the training. This effect was recognized in the initial trial, and then it became prominent with the trial repetition, especially in balance against backward disturbance. An individual difference in the peak timing of GcM and Sol activation decreased in BT after the training, whose activation peaks were observed around the anterior reversal. On the other hand, TA activation peak was recognized around the posterior reversal. Negative ERP peaks were found around the anterior reversal more than the other phase. Before the training, there was a significant correlation between these ERP and EMG peak times in all groups. After the training, the highest correlation was found in BT. Peak amplitude of the negative ERP was tend to slightly increased through the training in MT and BT. These results suggest that in the elderly, anticipatory postural control restricted mainly to the ankle would not be improved by only muscle training of the lower leg. However, lower leg muscle training with balancing, including the neural control, improved the postural control restricted to the ankle.

Title: Response of the plantarflexor muscles to maintaining balance on an unstable platform

Authors: *C. L. POLLOCK[1], D. BACHMANN[2], J. M. WAKELING[1];
[1]Dept. Biomed. Physiol. and Kinesiology, Simon Fraser Univ., Vancouver, BC, Canada; [2]ETH Zurich, Zurich, Switzerland

Abstract: There is a moderate relationship between the excitation of the plantarflexor muscles of the ankle and the displacement of the centre of pressure (COP) during quiet standing. This relationship has been suggested to demonstrate the contribution of the ankle plantarflexors to anterior-posterior postural sway, and it is quantified using cross-correlation analysis of the muscle excitation (EMG) to the position of the COP. It is less well understood how this relationship changes when the balance task is made increasingly less stable. The purpose of this study was to examine the relationship of ankle plantarflexor EMG with the anterior-posterior centre of pressure (AP-COP) under conditions of increased challenge to standing balance. Methods: Participants stood with both feet on a single force platform with their arms crossed across their chests to decrease upper extremity involvement in balance. Three conditions were tested: standing with eyes open, and standing on an unstable base of support with eyes open and with eyes closed. The novel unstable base of support condition was achieved by mounting the force platform on custom made rockers that decreased the stability in the anterior posterior direction and required continuous postural adjustment to remain stable. Participants were instructed to remain standing tall with bias to ankle strategy to maintain balance on the board, practice was provided prior to data collection. Each condition was collected for one minute. Parameters measured included; COP displacement, surface EMG of the tibialis anterior, soleus (SOL), medial (MG) and lateral (LG) gastrocnemius muscles. Kinematics were measured for the ankle, knee and hip joints. The EMG intensities were cross-correlated with the AP-COP displacement, and the time-shifts and maximum correlation values determined. Results: Each plantarflexor muscle demonstrated a moderate relationship with AP-COP during quiet standing. The SOL muscle tended to show stronger relationship with AP-COP under the increasingly challenging tasks of the unstable base ($p<0.1$). The LG muscle tended to demonstrate a decrease in strength of relationship between modulation of EMG and AP-COP during the unstable base conditions ($p<0.1$). The MG muscle did not demonstrate significant difference between the conditions. Conclusions: These data suggest a difference between the soleus muscle and the gastrocnemius muscles in response to increased challenge to standing balance and provides insight into the role of each of the plantarflexor muscles during conditions that challenge standing balance.

Title: Revealing the person-specific characteristics of the control of upright balance in younger adults

Authors: ***H. A. OMAÑA, JR**[1], B. W. N. BADIUK[1], V. G. DEPAUL[1,2], W. E. MCILROY[1]; [1]Applied Hlth. Sci., Univ. of Waterloo, Waterloo, ON, Canada; [2]Toronto Rehabil. Inst., Toronto, ON, Canada

Abstract: Currently, literature depicts young healthy adults as a homogeneous group with a comparable ability to control upright stability. There is a lack of attention to the meaning of measured between subject variability. Evidence of individual differences accounting for variation in other behaviors such as cognitive capacity, raises the possibility of important person-specific differences in the capacity to control upright stability. The study tested the hypothesis that, among a cohort of healthy young adults, there would be systematic between-person differences in measures of postural sway across a range of task challenges. Individuals would be characterized by consistent within-group performance rankings across tasks of varying difficulty. It is proposed this pattern would reflect an important trait contribution to the control of balance in young healthy adults. Thirteen healthy young adults (age 24.7 years; SD ± 3.6 years; 8 males) were recruited. Two main factors were manipulated: stance width (shoulder width, Romberg, tandem), and vision (eyes open, eyes closed). Five, one-minute trials were completed for each condition. Center of pressure variability, mean velocity, mean frequency and path length were measured from two force plates. Individual performance was ranked across each task condition and then averaged for all individuals in order for comparisons to be made. As hypothesized, increasing postural challenge increased the amplitude of postural sway, path length and velocity. Important to the present study, individuals relative postural performance (sway), compared to other subjects, remained similar across task challenge. There were significant differences across individuals with respect to average ranks. Individuals who had greater sway in the easier tasks tended to have greater sway in the more challenging tasks. In addition, this relative difference was similar across measures of sway (frequency and amplitude) suggesting this was not a difference in control strategies. The unique between-subject differences in relative performance across tasks provides support for the idea that the capacity to control upright stance varies even in healthy young adults. The determinants of this trait contribution to balance control would

provide an important complement to our existing understanding of state factors that influence postural sway. This study provides an initial step towards the understanding of between subject variability that may be useful for highlighting aspects of the central nervous system control of upright balance in a range of postural tasks and that may inform about age-related changes in some older adults.

Title: Key factors leading to falls in stroke survivors: insights from biomechanical analysis of laboratory-induced falls

Authors: *M. NEVISIPOUR[1], M. GRABINER[3], C. HONEYCUTT[2];
[2]Sch. of Biol. and Hlth. Systems Engineering, Ira A. Fulton Schools of Engin., [1]Arizona State Univ., Tempe, AZ; [3]Dept. of Kinesiology and Nutr., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Stroke survivors are at a significant risk of falling which can cause severe injury and death. Our limited understanding of the mechanisms resulting in the increased prevalence of falls in this group necessitates further study on falls. The purpose of this study was to identify the key kinematic and stability factors predict a fall in stroke survivors. Our secondary objective was to evaluate the specific strategies that stroke survivors utilize to avoid a fall. The long term goal of this study is to create training programs that target these key factors and train the most ideal strategies to reduce falls in stroke survivors. Seventeen subjects with unilateral stroke were evaluated during dynamic balance challenges designed to evoke a fall. Three posterior directed perturbations of varying difficulty were delivered to subjects while they stood on a treadmill. For safety, the intensity was delivered small to large while they had a harness on. Body kinematics (e.g. trunk flexion angle and angular velocity, step length, etc.) and stability measures (e.g. anteroposterior distance of center of mass (COM) from base of support (BOS), etc.) were evaluated at step initiation and heel strike. Further, clinical scores of function (e.g. Berg balance) were analyzed. We found that the ability to arrest body movement prior to heel strike, the length of the first compensatory step, and stability measures were the most critical response features to avoid a fall. Interestingly, these features have been previously identified as the most important features in fall avoidance in older adults (Owings et al., 2001). Therefore despite the significant

differences between older adults and stroke survivors (e.g. spasticity, delayed responses), stroke survivors fall for remarkably the same reasons as older adults. Three strategies utilized by stroke survivors were identified. A traditional compensatory step (36.4% of fallers used during all trials), pivot strategy(63.6% of fallers and 67% of non fallers used this strategy at least once) and a hopping strategy (18.2% of fallers and 66.7% of non fallers used it). We are the first to identify these strategies but more research about effectiveness of these strategies is needed. Clinical scores were not different between fallers and non-fallers further supporting the literature that these tests are not sensitive enough to predict fallers. Our most significant finding was that stroke survivors fall for similar reasons as older adults. As we have found previous success in modifying the critical factors that lead to falls in older adults, this result suggests our programs developed to decrease falls in older adults may translate for stroke survivors.

Title: Ankle joint positioning sense following soccer induced fatigue

Authors: D. K. LARSEN, A. LORENTZEN, G. K. JEPPESEN, S. FRICKE, N. MRACHACZ-KERSTING, *U. G. KERSTING;
Aalborg Univ., Aalborg, Denmark

Abstract: Causes of soccer ankle injuries are multifactorial, but muscular and neural fatigue are often identified as risk factors (Woods *et al*. 2004 *Br J Sports Med* 38: 36–41), specifically since most injuries occur during the latter half of the game. Currently no data exists on the amount of fatigue and its effect on joint position sense during the cause of a soccer match. The aim of this study was to quantify the effect of a soccer-specific fatigue protocol ($SAFT^{90}$, Small *et al*. 2010. J Sci Med Sport 13: 120-125), on central and peripheral fatigue and joint position sense in the ankle joint. Eight experienced male soccer players participated in two randomized testing sessions where they were asked to perform the $SAFT^{90}$ or to rest for the same duration of time. Presence of fatigue was defined as a reduction of the maximal voluntary contraction (MVC) force. Voluntary activation (VA), resting twitch (RT) and the H-reflex and V-wave measured during static and dynamic (running) tasks were used to evaluate the extent of central and/or peripheral fatigue. Finally, joint position sense (JPS) of the ankle at 15° and 30° plantar flexion was evaluated. All measurements were performed before (T_0) and after (T_{90}) the $SAFT^{90}$ or

resting protocol. The MVC force decreased by 22% from T_0 (1016±209N) to T_{90} (788±220N; p=0.007) and remained unchanged for the rest condition. The mean VA decreased by 3% and the RT force by 7% following the fatigue protocol while for the control session both parameters increased by 10 and 11% respectively. The static H-reflex decreased by 9% while the dynamic H-reflex increased by 15% following the $SAFT^{90}$. Similarly, the static V-wave decreased by 9%, while the dynamic V-wave increased by 13% following the $SAFT^{90}$. This trend could not be observed for the control session data. The absolute error in JPS increased by 22% for 15° and by 55% for 30° plantar flexion. In the control session, the absolute error decreased by 22% for 15° and increased by 50% for 30° plantar flexion. Preliminary results for this ongoing study reveal that the $SAFT^{90}$, a test deigned to mimic a real soccer game, was successful in inducing fatigue as evaluated by the decrease in the MVC force. While the typical measures of VA, RT force and static H-reflex and V-waves support previous studies on fatigue, this is the first study to demonstrate that H-reflexes and V-waves elicited during dynamic tasks are not decreased but in fact increased. This has important implications for our understanding of fatigue mechanisms during real-life tasks such as soccer games and may provide a platform for investigating further how fatigue during the latter half of the game may be linked to the high occurrence of ankle injuries in this popular sport.

Title: Three phases of postural adjustments during obstacle avoidance in a real and virtual environment

Authors: *H. IDA[1], S. MOHAPATRA[2], A. S. ARUIN[3];
[1]Jobu Univ., Isesaki, Japan; [2]Sch. of Physical Therapy and Rehabil. Sci., Univ. of Montana, Missoula, MT; [3]Dept. of Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL

Abstract: This study was aimed to investigate postural control while lifting a leg to avoid a real or virtual obstacle. To this end, electrical activity of seven legs and trunk muscles was recorded and analyzed during the early postural adjustments (EPAs), anticipatory postural adjustments (APAs), and compensatory postural adjustments (CPAs). Ten healthy adults were asked to stand

upright and avoid colliding with an approaching block presented in a real or virtual environment by lifting their left leg while supporting their body with the right leg. Display conditions were (1) real environment and (2) virtual environment of computer-simulated animation presented in stereoscopic head mount display. The approaching blocks of three heights (10, 20, and 30 cm) were used. The surface electromyography (EMG) signals were recorded bilaterally from the tibialis anterior (TA), medial gastrocnemius (MG), rectus femoris (RF), biceps femoris (BF), rectus abdominis (RA), erector spinae (ES), and external oblique (EO). The EMG signals of the supporting side (right) were then integrated from -550 to -150 ms (EPAs), from -150 to +50 ms (APAs), and from +50 to +250 ms (CPAs) in relation to the moment of the initiation of the leg lifting (T0). The same time windows were used for the analysis of the integrated EMG signals of the lifting side (left). A two-way ANOVA (display × height) for the EPAs showed a significant main effect of display in MG of the supporting side (right), and post-hoc analyses indicated that the virtual condition evoked lower EMG activity than the real condition. For the APAs on the supporting side, the virtual condition also yielded significantly lower EMG activities than the real condition in TA, MG, RA, and ES. Furthermore, during the CPAs, TA, MG, and RF showed significantly lower activities in the virtual condition as compared to the real condition. Decreased EMG activity in the muscles on the lifting side (left) were observed in the virtual condition in RF during the early phase, in RF and ES during the anticipatory phase, and in TA and BF during the compensatory phase. Significant main effects of the block height on the EMG activities were found only in the compensatory phase (EO, RA, ES of the supporting side and RF, BF, and EO of the lifting side). The results indicate that postural control is modulated depending on the display conditions: such a modulation starts during EPAs although it becomes more obvious during APAs and CPAs. However, the effect of the obstacle height was seen mainly in the compensatory phase. The findings suggest that dealing with virtual objects affects the control of posture.

Title: Developmental changes from childhood to adolescence in activation patterns of postural muscles during bilateral arm flexion

Authors: *T. KIYOTA[1], K. FUJIWARA[2], K. KUNITA[1], K. ANAN[1], C. YAGUCHI[3];
[1]Sapporo Intl. Univ., Sapporo, Japan; [2]Fac. of Sports and Hlth., Kanazawa Gakuin Univ.,

Kanazawa, Japan; [3]Dept. of Physical Therapy, Fac. of Human Sci., Hokkaido Bunkyo Univ., Eniwa, Japan

Abstract: We investigated the developmental changes from childhood to adolescence in the activation patterns of postural muscles during bilateral arm flexion. A total of 244 subjects participated in this study (number of subjects (n): 3-4 years: n = 48; 5-6 years: n = 69; 7-8 years: n = 25; 9-10 years: n = 27; 11-12 years: n = 36; 13-14 years: n = 39). Subjects stood on the force platform with closed stance. In response to a visual stimulus (LED signal) presented at 1-3 s after a warning signal, the subjects initiated bilateral arm flexion as quickly as possible and then stopped their arms voluntarily at a horizontal position. After 5 practice trials, 10 test trials were performed with a 30 s-rest between the trials. Electromyogram activity of the following muscles were recorded from surface electrodes: the anterior deltoid (AD), rectus abdominis, erector spinae (ES), rectus femoris, biceps femoris (BF), tibialis anterior (TA), and soleus. The reaction time of the activation onset of AD (D0) in response to the LED signal was measured. Activation rate calculated as the percentage of trials with the burst activation among 10 trials. Time difference between D0 and the activation onset in the postural muscles were calculated as the start time of postural muscles. The activation rate of posterior muscles in the trunk and thigh (ES and BF) was more than 90% in every age group. However, even in 11-12 years, the rate of anterior muscles (RA, RF and TA) was more than about 40% and these rates at 13-14 years were significantly decreased than at 11-12 years. A significant effect of age was observed for the start time of ES and BF, which showed high activation rate. The start time of ES and BF was shortened with age. The start time of ES was significantly earlier than D0 after 5-6 years. The start time of BF was significantly shortened at 7-8 years than at 3-4 and 5-6 years. However, even in 13-14 years, the activation of BF was not preceded to that of AD, with simultaneous activation. These results suggest that for the trunk muscle, the adult-like postural control would be organized by 5-6 years old, but for the thigh muscle, even the early adolescence would be still in the process of development of postural control in spite of the remarkable change in the activation timing at 7-8 years old.

Title: Muscle Synergies in the Neck

Authors: *J. B. FICE[1], P. A. FORBES[2,1], G. P. SIEGMUND[1,3], J.-S. BLOUIN[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Delft Univ. of Technol., Delft, Netherlands; [3]MEA Forensic Engineers & Scientists, Richmond, BC, Canada

Abstract: Muscle synergies are the coordinated activity of different muscle groups that can be combined to produce a wide variety of movements. Some researchers suggest they reduce the complexity faced by the central nervous system (CNS) when controlling multi-muscle systems (Trech & Jarc, 2009; Bizzi & Cheung, 2013). Muscle synergies have not been evaluated in the neck despite it being a complex multi-muscle system that could benefit from them. Here we investigate if neck muscle activity during gaze shifts to visual targets can be decomposed into a small number of muscle synergies. Subjects sat facing a board fitted with 17 light emitting diodes (LEDs) arranged with one LED at the centre, and two concentric circles at visual angles of 17° and 35° with 8 equally spaced LEDs each. Their torso was constrained and the central LED was placed at eye level in their neutral posture. Subjects were told to reorient their gaze as quickly as possible with a peripheral LED when it illuminated and hold until it turned off, and then return to centre. Subjects performed 3 trials for each LED (48 trials in total). Muscle activity was recorded using wire electrodes inserted under ultrasound guidance into the sternohyoid, sternocleidomastoid, splenius capitis, occipital capitis inferior, rectus capitis posterior major, and semispinalis capitis. Head motion in space and eye motion relative to the head were tracked using helmet mounted markers and a motion tracking system plus a glasses frame mounted gaze tracking system. Electromyography (EMG) signals were rectified, low-pass filtered (20Hz), integrated over non-overlapping 10ms windows, and averaged over 3 repetitions. We used an optimization algorithm to generate sets of muscle synergies (d'Avella et al., 2006) that were combined to best match the experimental EMG traces by scaling the amplitude and shifting the time of each synergy. Timing and amplitude across the muscles within each synergy was fixed. Four synergies were needed to fit the experimental EMG data well (R^2>0.80). The effect of some but not all of the synergies on head motion could be implied from the biomechanics of the muscles involved. For example, one synergy likely generates head extension due to the strong involvement of extensor muscles (semispinalis capitis and rectus capitis posterior major). This work shows that the motor signals to the neck muscles during gaze reorientation involving head motion can be well described by a small number of synergies. This work could be used to simplify muscle control in head and neck models. Further work is needed to determine if these neck muscle synergies simply describe EMG patterns, or if they are indeed used by our CNS to control the neck.

Title: Developing a method that is suitable to unveil the relevance of monosynaptic corticospinal projections for motor function

Authors: *C. LEUKEL[1], A. GOLLHOFER[1], W. TAUBE[2];
[1]Univ. of Freiburg, Freiburg, Germany; [2]Univ. of Fribourg, Fribourg, Switzerland

Abstract: Human motor behaviour is remarkably complex and adaptable. The motor repertoire of humans, especially with respect to fine skilled and dexterous movements, outreaches that of other mammals. An important reason for this supremacy has been argued to be the existence of monosynaptic corticospinal projections (called CM projections in the following), directly connecting corticomotoneurons in the cortex with spinal motoneurons (Lemon, 2008). These projections are less developed in old-world primates, absent in the cat, and its developmental status was proposed to be related to the level of dexterity the respective species can achieve. However, such conclusions remain elusive, at least for humans, as there exists no method with which the state of CM projections can be assessed and related to behavioural function. In the present study, we introduce a method that can tonically modulate the excitability of CM projections and thus allows testing how this modulation affects the execution of movements. We used H-reflex conditioning by transcranial magnetic stimulation of the primary motor cortex to selectively assess the excitability of monosynaptic corticospinal projections (Leukel et al., 2012) in 8 healthy subjects. The excitability was quantified and visually displayed as biofeedback to the subjects. In two randomly executed sessions the subjects had to either increase or decrease this excitability analogue to a method previously described for changing spinal reflexes (Thompson et al., 2013). Subjects were rewarded when able to modulate the excitability of CM projections in the requested direction (increase or decrease). As main result, all subjects were able to change the excitability in a single session of 150 trials. The change in excitability was selective, meaning that no other corticospinal projection we tested was affected. We conclude that our method is useful to unveil the relevance of CM projections for human motor function and therefore answer an important open question in motor control. Title: Somatosensory information drives motor cortex activity during feedback, but not feedforward, adaptations of locomotion

Authors: *E. E. STOUT[1], I. N. BELOOZEROVA[1], N. DOUNSKAIA[2];
[1]Barrow Neurol Inst., Phoenix, AZ; [2]Arizona State Univ., Tempe, AZ

Abstract: Previous studies have suggested that somatosensory information plays little role in driving motor cortical neuron activity during locomotion, as temporary loss of somatosensory inflow leads to little change in neuronal discharge patterns during locomotion. To elucidate the role of somatosensory information in the motor cortex during locomotion, we studied the activity of motor cortical neurons with different somatosensory receptive field characteristics in the cat during multiple complex locomotion tasks. These tasks involved perturbations to locomotion that were overcome using feedforward or feedback-driven motor adaptations. We found that when using feedforward motor adaptations, changes to motor cortical neuronal activity were consistent regardless of somatosensory receptive field characteristics. When using feedback motor adaptations, neurons receiving somatosensory information from distal portions of the forelimb (the elbow and wrist) were significantly more likely to exhibit activity changes than other groups. Kinetics analysis of the swing phase of locomotion revealed that the proximal and distal joints played different roles during both feedforward and feedback-driven motor adaptations. Muscle torque at the shoulder generated interaction torque that was the primary cause of motion of the elbow and wrist in each particular condition. Muscle torque at the distal joints was used to make small adjustments in motions of these joints. Although this structure of joint control was used for both types of adaptation, feedforward adaptations in joint control were initiated at the very beginning of the swing phase while feedback-driven adaptations were produces during the last quarter of the motion. The results from both the analysis of motorcortical neuron activity and kinetic analysis support each other and suggest that somatosensory information drives motor cortical activity during locomotion during feedback but not feedforward locomotion adaptations, and that this information is used to guide whole-body movement adaptations.

Title: Variability of motor cortical spiking activity depends on the behavioral context

Authors: *A. RIEHLE[1,2,3], T. BROCHIER[1], S. GRÜN[3,4,5,2];
[1]INT, CNRS - AMU, Marseille, France; [2]Brain Sci. Inst., RIKEN, Wako-Shi, Japan; [3]Res. Ctr. Juelich - INM-6, Juelich, Germany; [4]Res. Ctr. Juelich - IAS-6, Juelich, Germany; [5]Theoretical Systems Neurobio., RWTH Aachen Univ., Aachen, Germany

Abstract: Exploring the nature and origin of neuronal variability is essential for our understanding of information processing in cortical networks. We hypothesize that the variability of spiking activity varies as a function of the behavioral context. We thus analyzed spiking variability in monkey motor cortex during both an instructed delay and movement execution (for the experiment see Riehle et al. 2013) using three different measures. (i) The coefficient of variation (CV) measures the (ir)regularity of spike sequences and is defined as the dispersion of inter-spike-intervals (ISIs). (ii) The Fano factor (FF), computed as the variance of spike counts divided by their mean, provides an estimate of the spike count variability across trials. (iii) The serial rank-order correlation (SRC) between neighboring ISIs is a measure of the deviation from a renewal process (Farkhooi et al. 2009) which is classically predicted as $FF=CV^2$. Because the CV largely overestimates irregularity for changes in firing rate, we use its local measure CV2, introduced by Holt et al. (1996). We analyzed the spiking activity of 3295 motor cortical neurons, recorded during 34 sessions using chronically implanted Utah arrays in two monkeys. We investigated the effect of behavioral context on variability measures by comparing data in selected 500ms-windows during wait (instructed delay) and movement (execution). CV2 and firing rate are significantly lower and FF is significantly higher during wait than during movement. Furthermore, the relation between $CV2^2$ and FF depends considerably on the behavioral context. There is a strong tendency that the renewal prediction ($FF=CV2^2$) is fulfilled during movement, but not during wait, where $FF>>CV2^2$. A higher percentage of neurons has a significant SRC during wait than during movement. Farkhooi et al. (2009) proposed that positive SRCs lead to an increased FF. During wait almost exclusively positive SRCs are encountered, whereas only during movement negative SRCs occur and the amount of negative and positive SRCs is almost balanced. This balance may explain that the null hypothesis for renewal processes is almost satisfied during movement, but not during wait. Our data suggest that during wait, ongoing brain processes dominate, thereby resulting in spike trains that are highly variable across trials, visualized by the increasing FF. During movement, task-related activity increases at

the expense of ongoing processes, and FF decreases. In other words, ongoing processes in cortical networks provide an additional source of variability (Arieli et al. 1996), being not task-related and absent during movement execution.

Title: Neural circuit dynamics in motor cortex linking sensory input to goal-directed motor output

Authors: ***E. ZAGHA**, X. GE, D. A. MCCORMICK;
Dept. of Neurobio., Yale Sch. of Med., New Haven, CT

Abstract: Goal-directed behavior requires making selective and controlled responses to diverse external stimuli. To study neural mechanisms of behavioral control, we implemented a somatosensory detection task in mice. From pharmacological block of motor cortex, we find that this region is essential for strict behavioral control during the task. To understand the neural dynamics underlying this function, we recorded task-related neural activity in motor cortex. Following target onset, we observed one population of neurons that rapidly enhanced activity and a second intermixed population that was simultaneously suppressed. This divergence of neural activity occurred for both correct and incorrect motor responses. Correlation analyses and circuit modeling suggest that enhanced and suppressed neurons are not operating independently, but rather form competing neural ensembles that interact to convert a transient, sensory stimulus to a sustained motor command. During task performance motor cortex neurons were maintained in the activated state, with spiking initiated by large and transient membrane potential depolarizations. Our results reveal the cellular, circuit and subthreshold dynamics of motor cortex neurons and neural ensembles as they link sensory inputs to goal-directed motor outputs.

Title: Motor cortical neurons reflect the active goal-dependent feedback control policy

Authors: *D. J. O'SHEA[1], E. M. TRAUTMANN[2], S. LIN[3], K. V. SHENOY[4];
[2]Neurosciences, [3]Electrical Engin., [4]Electrical Engineering, Neurobiology, Bioengineering,
[1]Stanford Univ., Stanford, CA

Abstract: In both humans and non-human primates, corrective motor responses following mechanical limb perturbations are modulated by contextual factors, such as higher-order task goals and environmental constraints (Scott et al., 2015). Following mechanical perturbations, motor cortical neurons exhibit rapid, context-modulated changes in firing rate, suggesting motor cortex operates as a feedback controller whose control policy is modulated by task context. Here, we tested the hypothesis that primate primary motor (M1) cortical activity might reflect not only the details of the movement presently being produced, but also the particular feedback control policy being engaged, which could then shape the context-dependent response to errors and perturbations. We trained a rhesus macaque to move a haptic feedback device (delta.3, Force Dimension) in the vertical plane, which controlled the position of a visual cursor on a screen, in order to produce brisk, accurate reaches towards visual targets while avoiding virtual obstacles. On 40-75% of trials, we delivered an unpredictably directed, step-force perturbation (3 N) early in the movement. We designed a set of target and obstacle arrangements to vary the control policy employed by the monkey during movement. In the "high-gain" arrangement, the monkey was required to resist lateral perturbations to avoid flanking obstacles, whereas in the "low-gain" arrangement, the monkey needed to respond with less corrective force and re-aim for a more-laterally positioned target. As the initial target was identical in both arrangements, hand kinematics on high- and low-gain non-perturbed trials were nearly identical. However, on perturbed trials, high-gain reaches diverged from low-gain reaches back towards the central target with a latencies of 106-185 ms (Hedges' $g > 0.25$, $p < 0.05$), consistent with goal-dependent modulation of a transcortical feedback loop. We found that most M1 units responded rapidly after perturbation onset (364/405, Kruskal-Wallis test, $p < 0.05$ over 25 ms). However, we also found that in some units, firing rates for high-gain vs. low-gain trials were significantly different before a perturbation was delivered (202/405) and during non-perturbed trials

(314/405). These results suggest that motor cortex (along with other motor feedback regions) might engage different dynamics when different feedback control policies are engaged, enabling the context-specific dynamics to shape neural responses to perturbation and the resulting corrective movements. This suggests that motor cortical dynamics support adaptive feedback control in addition to motor command generation for voluntary movement.

Title: Cortico-cortical coupling during bimanual forces in intact humans

Authors: *J. LONG[1,2], T. TAZOE[1,2], D. SOTEROPOULOS[3], M. A. PEREZ[1,2];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [2]Department: Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [3]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Primary motor cortices (M1s) are involved in the generation of bimanual isometric forces. However, cortical processes involved in M1s interactions during bimanual force generation remain poorly understood. Using coherence analysis between electroencephalographic (EEG) signals from M1s, and the ipsilateral cortical silent period (iSP; a measure of transcallosal inhibition) in an intrinsic finger muscle we examined interactions between M1s during unilateral and bilateral isometric index finger abduction at 10, 40 and 70% of maximal voluntary contraction (MVC) in 16 healthy subjects. We demonstrate that interhemispheric EEG-EEG coherence between M1s in the alpha (8-13 Hz) but not in the beta (13-30 Hz) frequency band decreased during bilateral compared to unilateral contractions at 40% and 70% but not during 10% of MVC. The iSP area increased during bilateral compared to unilateral contractions at 40% and 70% of MVC. Notably, changes in the iSP area and coherence

in the alpha frequency band were negatively correlated at 40% and 70% of MVC, suggesting higher transcallosal inhibition was associated with reduced cortico-cortical coherence. To further examine the relationship between the iSP and coherence we stimulated the ulnar nerve at different frequencies (8 and 30 Hz, at a resting motor threshold intensity for the FDI muscle). We found that peripheral nerve stimulation at 8 and 30 Hz increased coherence in the alpha and beta frequency band, respectively; whereas the iSP area decreased during bilateral 70% of MVC to a larger extent with 8 but not 30 Hz or sham stimulation. These findings suggest that pathways mediating transcallosal inhibition and alpha oscillations between M1s interact during strong bilateral force generation in intact humans.

Title: Crossed corticospinal facilitation between arm and trunk muscles in humans

Authors: *S.-Y. CHIOU[1], P. H. STRUTTON[1], M. A. PEREZ[2,3];
[1]Dept. of Surgery and Cancer, Imperial Col. London, London, United Kingdom; [2]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL; [3]Dept. of Physical Med. and Rehabil., Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: A voluntary contraction of muscles with one arm increases corticospinal excitability in the contralateral resting arm, a phenomenon known as crossed facilitation. Although many motor tasks engage simultaneous activation of the arm and trunk, interactions between corticospinal projections targeting these segments remain poorly understood. Using noninvasive cortical and cervicomedullary stimulation we examined in healthy humans motor evoked

potentials (MEPs) and the activity in intracortical circuits (short-interval intracortical inhibition, SICI) in the resting erector spinae (ES) muscle when the contralateral arm remained at rest or performed 20% of isometric maximal voluntary contraction (MVC) with the first dorsal interosseous (FDI), abductor pollicis brevis (APB), biceps (BB) and triceps brachii (TB). We demonstrate that the size of cortically evoked MEPs in the ES was increased during voluntary contraction of the FDI and BB but not the APB and TB. Notably, SICI measured in the ES was also decreased during voluntary contraction of the FDI and BB but not the APB and TB. In contrast, cervicomedullary MEPs in the ES remained unchanged across conditions. Our findings reveal selective interactions between hand and arm muscles and the trunk - with pronounced crossed facilitation between the index finger and biceps and the trunk related, at least in part, to changes at the cortical level. We argue that these interactions might reflect the different role of these muscles during functionally relevant arm/trunk movements.

Title: Keeping up with a virtual monkey: Representation of self-generated actions vis-a-vis observed actions of a competitor by monkey cortical ensembles during an arm reaching task

Authors: *A. RAMAKRISHNAN[1,2], Z. LI[4], S. SHOKUR[5], M. A. LEBEDEV[1,2], M. A. L. NICOLELIS[1,2,3,5];

Abstract: A ‘shared representational system’ has been postulated to represent both self-generated and observed actions (Prinz 1997). Yet, it is unclear how this system would work when self-generated actions occur concurrently with the action performed by a different individual, for example, a partner or a competitor. To examine such conditions neurophysiologically, we trained rhesus macaques on a reaching task that required them to compete with a virtual monkey. Monkeys operated a hand-held joystick to reach visual targets with an arm image. They simultaneously viewed a virtual monkey, face-to-face. The virtual monkey reached to the same targets (60% of the trials), or to distracting targets (20%), or did not move (20%). The virtual monkey was relevant and attracted attention because the monkeys

received twice as much juice if they acquired the target sooner than their virtual competitor. In a control condition, called 'passive observation', the monkeys were rewarded for observing the virtual monkey move, but did not move themselves. Many neurons in the primary motor cortex (> 63%) were directionally tuned to the monkeys' own movements, and 30% of the neurons were tuned to both self-generated movements and the movements of the virtual monkey. The strongest tuning to the virtual monkey was observed during passive observations. Moreover, the virtual monkey's actions were represented differently depending on whether they were fast (high challenge) slow (low challenge). These results suggest that self-generated actions and the actions of others are represented in distributed fashion by overlapping populations of cortical neurons. The overlap in cortical representations of self versus non-self may facilitate learning in such interactive paradigms.

Title: Spatiotemporal signature of force production in orofacial motor cortex

Authors: *A. A. TOBAA[1], M. D. BEST[2], F. I. ARCE-MCSHANE[1], N. G. HATSOPOULOS[1]; [1]Dept. of Organismal Biol. and Anat., [2]Committee on Computat. Neurosci., Univ. of Chicago, Chicago, IL

Abstract: The amplitude of beta-band oscillations (15-30 Hz) of the local field potential (LFP) in primary motor cortex (MI) attenuates before the onset of tongue movements. This reduction in amplitude coincides with an epoch of enhanced corticospinal excitability, and is thought to reflect the activation of MI neurons. At the same time, it has recently been shown that these neurons undergo changes in their responses during motor skill acquisition (Arce-McShane et al., 2014). Here, we examined how these changes at the single cell level affect the timing and reduction in amplitude of the beta LFP at movement onset. We interpret these properties in the context of motor skill acquisition. We used 96-channel Utah microelectrode arrays to record LFPs from the orofacial MI of two rhesus macaques while they engaged in a tongue force production task (see Arce-McShane et al., 2014 for details). We identified a characteristic spatiotemporal pattern of beta attenuation preceding force onset such that the attenuation timing varied linearly across the motor cortical surface. Although the orientation of this pattern was

generally consistent across days, the relative timing of beta attenuation between electrodes, as well as its overall absolute timing relative to force onset changed as a function of motor skill acquisition. These results suggest that motor skill acquisition refines the recruitment order of neuronal ensembles. References: Arce-McShane, Fritzie I., Nicholas G. Hatsopoulos, Jye-Chang Lee, Callum F. Title: Test-retest reliability of TMS measures of corticospinal excitability across the age spectrum

Authors: *K. COLLINS, N. KENNEDY, A. CLARK, V. POMEROY;
Univ. of East Anglia, Norwich, United Kingdom

Abstract: Background: As people age there are changes within the nervous system such as decreased brain volume (grey and white matter), decreased intra-cortical connections, and microstructure changes within the neural pathways. A key pathway for upper limb function is the corticospinal pathway; which has been frequently studied using transcranial magnetic stimulation (TMS). Research is inconclusive as to how the aging process may influence the corticospinal pathway, and thus its measurement using TMS, and the reliability of TMS measurement. The aim of this project is to investigate the test-retest reliability of TMS measures of corticospinal excitability in neurologically intact adults across the age spectrum. Methods: Fifty-one neurologically intact healthy adults over 18 years of age will be recruited to participate. Participants participated in 2 identical TMS sessions separated by 5-7 days. TMS measures include active and resting motor threshold, recruitment curve, silent period, MEP amplitude, and MEP latency of the bilateral biceps brachii, extensor carpi radialis, and abductor pollicis brevis. Reliability was assessed using the Intraclass Correlation Coefficient (ICC) and the Limits of Agreement (LOA). Results: This project is on-going, data has been collected on 49 participants whose mean age is 43.2± 16.4 years (20-74), 28 women, 21 men. The preliminary findings include the ICC of active and resting motor threshold for bilateral upper extremities. The ICC and 95 % confidence intervals for the biceps brachii is ICC= 0.67-0.77 (0.48-0.87), extensor carpi radialis ICC= 0.60-0.71 (0.38-0.82), and abductor pollicis brevis ICC= 0.53-0.67 (0.30-

0.80). The reliability of additional TMS measures including the silent period, recruitment curve, and the MEP latency will be investigated. Conclusions: These preliminary findings suggest that in this group of participants the biceps brachii and extensor carpi radialis exhibit the highest ICC values for motor threshold. This study will further investigate the possible influence of age, gender and other factors on the reliability of TMS measurement to further evaluate the use of TMS as an assessment tool for people of all ages.

Title: Mapping horizontal connections in primate motor cortex using intracortical microstimulation

Authors: *Y. HAO[1,2], A. RIEHLE[1,3,4], T. BROCHIER[1];
[1]Inst. De Neurosciences De La Timone (INT), CNRS, Marseille, France; [2]Qiushi Acad. for Advanced Studies, Zhejiang Univ., Hangzhou, China; [3]Riken Brain Sci. Inst., Wako-Shi, Japan; [4]Inst. of Neurosci. & Med. (INM-6), FZ Jülich, Germany

Abstract: Exploring the functional organization of motor cortex at the mesoscopic scale provides a unique way to understand how cortical networks control movement. Previous anatomical studies have demonstrated that distant cortical points are interconnected through long range axon collaterals of pyramidal cells (Gatter and Powel, 1978). However, the functional properties of these local connections and the way cortical signals propagate within this cortical network have not been systematically investigated. To address this issue, we used multielectrode Utah arrays chronically implanted in motor cortex of two rhesus monkeys and applied single pulse intracortical microstimulation (sICMS) at one electrode to analyze its effect, on the

neuronal activity recorded at all other electrodes. We quantified the spatio-temporal distribution of single unit (SU) and multiunit (MUA) evoked responses to determine the properties of horizontal propagation. At the recording sites, the typical responses were characterized by a brief excitatory peak followed by inhibition of longer duration. Significant excitatory responses to sICMS could be evoked up to 4 mm away from the stimulation site, but the strength of the response decreased exponentially and its latency increased linearly with the distance. Inhibitory effects had a more limited spatial spread than excitatory ones. We then applied trains of ICMS at each electrode to distinguish between arm, wrist and hand-related sites and questioned how this somatotopic organization influences the spatial propagation of sIMCS effects. We used 2D Gaussian filters to quantify the direction and strength of the propagation from each stimulation site. We observed that following sICMS at hand-related sites, the propagation had no spatial bias towards other hand-related sites. On the other hand, sICMS at arm-related sites induced a propagation characterized by a weak but consistent bias toward other arm-related sites. Overall, these results indicate that the spread of activity does not confine to intra-area domains but show consistent inter-area interactions, i.e., between hand and arm areas. However the fact that these interactions are not entirely symmetrical may characterize a critical functional property of motor cortex for the control of upper limb movements.

Title: Supplementary motor area and voluntary movement initiation: neural population responses and the effects of microstimulation

Authors: *A. H. LARA[1], J. C. CUNNINGHAM[2], M. M. CHURCHLAND[1];
[1]Neurosci., [2]Statistics Dept., Columbia Univ., New York, NY

Abstract: The supplementary motor area (SMA) has long been implicated in voluntary movement initiation. Numerous studies in human and non-human primates have shown that SMA activity precedes movement initiation mainly when movement is self-generated, relative to when movement is initiated in response to an external cue. The SMA has extensive reciprocal connections with primary motor (M1) and dorsal premotor (PMd) cortex, and is thus well positioned to provide an input that could initiate movement. To explore the relative roles of the SMA and M1/PMd, we trained two rhesus monkeys to reach to visual targets under three initiation contexts: cue-initiated, self-initiated and quasi-automatic. In the cue-initiated context, monkeys were shown a target and after a brief delay were cued to reach to the target. In the self-initiated context, a continuously growing target signaled reward size; monkeys reached at times of their choosing based on a tradeoff between the desire for large reward and the growing desire to collect the current reward. In the quasi-automatic context, monkeys made low-latency reaches to intercept moving targets. We used intra-cortical microstimulation (ICMS) to causally probe the role of SMA in initiating movement. In the self-initiated context, ICMS caused early movement initiation by an average of ~300 ms. In contrast, for the cue-initiated context, ICMS tended to delay movement. For the quasi-automatic context, ICMS had essentially no effect. These results support the long-standing hypothesis that the SMA plays a specialized role in self-initiated movements, with the caveat that ICMS also had some clear effects in the cue-initiated context. We then compared the neural population response in SMA with that of M1/PMd using principle component analysis. Context strongly impacted SMA responses but not M1/PMd responses. For example, the SMA activity pattern just before movement onset was quite different for self-initiated vs. cue-initiated movements, consistent with previously reported effects at the single-neuron level. This effect was seen in M1/PMd or in the muscles of the arm. Yet despite robust effects of context, the SMA responded as strongly (on average) for quasi-automatic reaches as for self-initiated reaches. Indeed, the largest response component - 1st principal component - was virtually identical across all three contexts. Taken together, our results support the current hypothesis that the SMA is particularly involved in self-initiated movement. Yet the largest SMA response component was, surprisingly, identical across contexts. This suggests that ‘context-specific’ computations converge onto a ‘context-independent’ decision to move.

Title: Motor cortex but not muscles approximate a dynamical system during a novel cycling task

Authors: *A. A. RUSSO, S. M. PERKINS, B. M. LONDON, M. M. CHURCHLAND; Columbia Univ., NYC, NY

Abstract: Motor cortical response properties remain the subject of much debate. Based primarily on studies of reaching, it has been postulated that motor cortical activity might 1) code high-order commands, 2) code muscle activity, or 3) function as a dynamical system that generates patterns from which muscle activity can be built. While the commonly used reach tasks possess many virtues, reaches are a subset of all possible movements. To further explore and compare the above hypotheses one desires a task where (1) movements can be either brief or sustained, and (2) the three hypotheses predict different time-evolving patterns of activity. To this end, we designed a novel task in which monkeys navigated a virtual environment by grasping pedal with their hand and cycling for prescribed distances. Behaviorally the task is simple - the monkey can only move forward or backward on the virtual track. The task is slightly richer at the kinematic level: the hand traces a two-dimensional trajectory. We expect further increased dimensionality at the level of the muscles reflecting the forces required to accelerate, sustain, and decelerate the device. Additionally, there may exist extra features in the neural responses reflecting population dynamics. We recorded neural responses from motor and premotor cortex of two monkeys (114 and 106 neurons) and EMG recordings from the arm, shoulder, and chest (36 and 22 recordings). Muscle responses were indeed temporally complex relative to the simple kinematics. Yet, neural responses were at least as complex and contained a number of features rarely or never found in the muscle responses, including preparatory activity, doubling or tripling of peaks per cycle, and extra peaks at the beginning or end. To assess whether these extra features reflect the internal dynamics that could create outgoing muscle commands, we fit the neural population response with a linear dynamical system. Fits were surprisingly good ($R^2 = 0.73$ and 0.69) especially when compared to that for the muscle populations ($R^2 = 0.36$ and 0.21). Thus, for the neural population but not the muscle population, the future population state could be predicted from the current state, consistent with strong dynamics. We found that this difference was in large part due to how activity evolved between forward and backward conditions. In neural space, the activity during these conditions evolved orthogonally to one another and thus did not produce opposing flow fields. This was not true in muscle space. These results are compatible with the

hypothesis that motor cortex acts as a dynamical system whose goal is to produce complex muscle commands.

Title: Membrane potential dynamics of single neurons in mouse forelimb motor cortex correlate with movement parameters during voluntary reaching

Authors: ***B. C. VOIGT**[1], L. ESTEBANEZ[1,2], J. F. A. POULET[1];
[1]Max Delbrück Ctr. For Mol. Med., Berlin, Germany; [2]Unité de Neurosciences, Information et Complexité, UNIC-FRE3693, Ctr. Natl. de la Recherche Scientifique, Gif sur Yvette, France

Abstract: Motor cortex (M1) neurons are active during voluntary movement but little is known about the subthreshold activity in awake behaving animals. Here we made whole-cell recordings of layer 2/3 and layer 5 M1 neurons during a targeted reaching task. Head-fixed mice were trained to reach and touch a sensor to obtain a water reward. Injection of the GABA-A agonist Muscimol into M1 abolished reaching. On a slow time scale (seconds), in resting mice, most neurons show slow (3-6 Hz), large amplitude membrane potential fluctuations and low firing rates. During movement, many neurons undergo a change in state and slow oscillations are replaced by smaller amplitude, faster events with low variance. Moreover many neurons show subthreshold correlates with kinetic parameters of arm movement. On a faster time scale (milliseconds), a brief depolarization of the membrane potential was recorded at movement onset, which was internally generated, as it occurs without sensory input from the forelimb. Membrane potential modulations recorded at different phases of the reach were larger in layer 2/3 than layer 5 neurons. Current work focuses on disentangling sensory and motor components of M1 subthreshold activity during reaching.

Title: Spike recordings from the primary motor cortex correlate more strongly with individual muscles or original joint angles than with muscle synergies or joint angle PCs

Authors: *Z. LIU[1], A. G. ROUSE[2], M. H. SCHIEBER[2];
[1]Biomed. Engin., [2]Neurobio. and Anat., Univ. of Rochester, Rochester, NY

Abstract: High-dimensional muscular or kinematic spaces can be reduced mathematically to low-dimensional synergies which capture most of the original variance. Such synergies can reduce the computational burden of controlling neuro-prosthetic devices. The extent to which such synergies are used in natural neural control, and if so, which parts of the CNS generate synergies, remains uncertain. If synergies originate from the primary motor cortex (M1), we hypothesize that the activity of M1 neurons should correlate more strongly with synergies than with the individual muscles or the original joint angles from which the synergies were extracted. We recorded electromyographic (EMG) activity from 14-15 muscles, arm and hand motion as 22 joint angles, and spiking activity from microelectrode arrays implanted in the M1, all while two monkeys (Macaca mulatta) reached and grasped one of four objects each in up to eight different locations. Muscle synergies were extracted from the original EMG recordings with non-negative matrix factorization. Six muscle synergies explained over 86% of the EMG variance in both animals. Kinematic synergies were extracted from the original joint angles with principal component analysis. The first 6 principal components (PCs) explained over 93% of the joint angle variance in both animals. For each single-unit or multiunit spike recording we cross-correlated firing rate with i) each individual muscle's rectified EMG, ii) each of the 6 muscle synergies, iii) each of the 22 original joint angles, and iv) each of the first 6 principal components, all over leads and lags up to ±400 ms. We then compared the maximal absolute value of the cross-correlation (MAXC) achieved with the activity of any muscle to the MAXC achieved with any muscle synergy. We also compared the MAXC achieved with any original joint angle to the MAXC achieved with any joint angle PC. Across the population of significantly correlated spike recordings from each monkey, MAXC values with individual muscles were greater than MAXC values with muscle synergies (monkey L, $p<1e-7$; monkey X, $p<1e-7$, Wilcoxon signed rank tests). Likewise, MAXC values with individual joint angles were significantly greater than MAXC values with kinematic PCs (monkey L, $p<1e-10$; monkey X, $p<1e-2$, Wilcoxon signed rank tests). Our results fail to support the notion that muscle or kinematic synergies originate from the primary motor cortex. Muscle or movement synergies

may be generated from other centers of the motor system, such as the pontomedullary reticular formation and/or the spinal gray matter, while M1 neurons sculpt synergies so as to individuate movements.

Title: Comparison of motor cortical excitability of projections to trunk muscles during anticipatory postural adjustments in standing and lying

Authors: T. REED, M. HURRY, S.-Y. CHIOU, *P. H. STRUTTON;
Imperial Col. London, London, United Kingdom

Abstract: Voluntary movement of the upper limbs is associated with increased activity in the trunk muscles in order to stabilise the body's centre of mass. This activity can occur concurrently with the activity seen in the prime mover muscles; this is too fast to be a result of somatosensory feedback from the induced body movement and is therefore known as an anticipatory postural adjustment (APA). There is evidence to suggest APAs are controlled, in part, by the motor cortex as corticospinal excitability to trunk muscles is increased at the time of upper limb movements. Whether this increase reflects the demands of the trunk muscles in order to maintain the body upright or the nature of the interactions between upper limb and trunk motor control remains unclear. Therefore, the aim of the present study was to examine corticospinal excitability of projections to trunk muscles using transcranial magnetic stimulation (TMS) during voluntary dynamic upper limb flexion in both standing and lying positions, where the postural demands differ. Seventeen healthy subjects performed rapid shoulder flexion in response to a visual cue, a catch trial was included where no cue was presented but TMS was delivered. Electromyographic (EMG) activity was recorded bilaterally from anterior deltoid (AD), erector spinae (ES) at T12 vertebral level and rectus abdominis (RA). TMS was applied to the hotspot for ES over the primary motor cortex at several time points prior to the expected increase in EMG activity of AD; this was calculated using a recognition reaction time task prior to experimentation and in both positions, these were not different between standing and lying. Motor evoked potentials (MEPs) in ES were larger at time points closer to the rise in AD EMG activity; on the contrary, this was not observed in RA. Additionally, the increase in excitability did not differ between the standing and lying positions. Background EMG activity in the trunk muscles did not change

across time points and was not different between standing and lying. The similar profiles of excitability observed in the two positions imply that APAs are coordinated as part of a hard-wired response, since the postural demands between the two positions are different.

Title: Motor cortical excitability of projections to trunk muscles during anticipatory postural adjustments

Authors: *M. HURRY, T. REED, S.-Y. CHIOU, P. H. STRUTTON;
Imperial Col. London, London, United Kingdom

Abstract: The increase in corticospinal excitability prior to voluntary movement has been well characterised in limb muscles directly involved in the task. Voluntary limb movements are also associated with increases in trunk muscle activity, some of which occur within a time window considered too fast to be induced by sensory feedback; these are termed anticipatory postural adjustments (APAs). Animal and human studies suggest there is cortical involvement in APAs, with cortical lesions impairing APAs and stimulation of the motor cortex inducing APAs. However, the excitability of corticospinal projections to the trunk muscles prior to voluntary limb movement has not been investigated and was the purpose of the present study. Seventeen healthy subjects performed rapid shoulder flexion in response to a visual cue whilst standing. Electromyographic (EMG) activity was recorded from anterior deltoid (AD), erector spinae (ES) at T12 vertebral level and its antagonist, rectus abdominis (RA). Transcranial magnetic stimulation was delivered to the hotspot for ES over the primary motor cortex at several time points prior to the expected increase in EMG activity of AD; this was calculated using a recognition reaction time task prior to experimentation. The sizes of motor evoked potentials (MEPs) in ES and RA were examined and compared across time points. MEPs in ES were larger at time points closer to the rise in AD EMG activity. MEPs in RA did not differ over the time course examined. Additionally, background EMG activity in the trunk muscles was minimal and did not change across time points. This study demonstrates the profile of corticospinal excitability of two trunk muscles prior to a voluntary limb movement. Further, it reveals task specificity in cortical control of the trunk and substantiates previous evidence for cortical involvement in APAs. These results highlight the interactions between upper limb and trunk

motor control and underline the importance of using functional task training in subjects with deficits of postural control, e.g. low back pain and stroke, which may be relevant to the development of rehabilitative strategies.

Title: Paired-pulse transcranial magnetic stimulation suppresses ipsilateral motor evoked potentials

Authors: ***A. B. MCCAMBRIDGE**, J. W. STINEAR, W. D. BYBLOW;
Ctr. for Brain Research, Univ. of Auckland, Auckland, New Zealand

Abstract: Skilled movement with the upper-limb requires input from both contralateral and ipsilateral primary motor (M1) cortices. Exactly how the ipsilateral M1 contributes to upper-limb movement is still largely unknown. Paired pulse transcranial magnetic stimulation (TMS) can be used to assess intracortical inhibitory circuits in M1, termed short-interval intracortcial inhibition (SICI). SICI is typically performed by using a subthreshold conditioning stimulus, followed ~ 2 ms later by a suprathreshold test stimulus, to produce motor evoked potentials (MEPs) in muscles of the contralateral upper-limb. To our knowledge, SICI has only been measured from contralateral MEPs. This is the first study to investigate SICI of ipsilateral MEPs (iMEPs). Ipsilateral MEPs are assumed to reflect excitability of an uncrossed oligosynaptic pathway, and can be evoked in proximal upper-limb muscles using high intensity TMS and pre-activation of the muscle. We hypothesized that iMEPs would be suppressed by the conditioning stimulus, therefore demonstrating SICI of iMEPs. TMS was delivered to the dominant M1 to evoke conditioned (C) and non-conditioned (NC) iMEPs in proximal muscles of the non-dominant upper-limb of healthy subjects during weak bilateral contraction. The test stimulus intensity was the lowest stimulus intensity to evoke a reliable iMEP, and a range of conditioning stimulus intensities were tested at short inter-stimulus intervals. The ratio of the C to NC iMEP area at each conditioning stimulus intensity was calculated to assess the amount of inhibition present. Preliminary results show paired-pulse TMS over ipsilateral M1 can suppress iMEPs at short inter-stimulus intervals. Investigating SICI of iMEPs may be a useful tool to better understand the role of ipsilateral M1 and uncrossed motor pathways during upper-limb movement.

Abstract: The summation of synaptic inputs in the dendrites of cortical neurons is shaped by nonlinear interactions over multiple length scales. To study these interactions during behavior, we have constructed a two-photon imaging system that allows rapid (~10 Hz) imaging of up to 300 um of contiguous dendrite while resolving calcium transients in individual dendritic spines. Two galvanometers and a remote focusing mirror (Botcherby et al., 2008) steer 16 kHz lines produced by a resonant mirror arbitrarily in three dimensions. We use this system to image spine and dendritic calcium transients in pyramidal neurons of the anterior motor cortex of mice performing a tactile discrimination task (Guo and Li et al., 2014). Spines on the same dendritic branch have diverse selectivity during sensation, movement perpetration, and movement execution. Our findings imply convergence of sensory and motor information onto individual dendritic segments of frontal pyramidal neurons during decision making.

Title: Reversible inactivation mapping of cortical sites required for voluntary forelimb movements in VGAT-ChR2 transgenic mice

Authors: *R. KATREDDI[1], G. SILASI[1], J. D. BOYD[1], J. M. LEDUE[1], S. H. SCOTT[2], T. H. MURPHY[1];

Abstract: Objectives: The aim of the study is to understand the sensory-motor interactions of the cortical regions that are required to execute a voluntary forelimb movement. Methods: Vesicular γ-aminobutyric acid transporter-channelrhodopsin2(VGAT-ChR2) transgenic mice with chronic cranial windows were water restricted and trained in head fixed stage to pull a robotic lever to get a water reward. In these mice, ChR2 is expressed in all GABAergic interneurons and hence blue laser targeting leads to local inhibition by activation of inhibitory neurons. A blue laser was triggered at contralateral and ipsilateral points of the cortex to cause reversible local inhibition while the mouse pulls the lever repeatedly over a 1 min sampling epoch. The total number of pulls done by the mouse at each cortical point was compared with the control point which was out of the cranial windows to probe their role in directed movements. Results: Different frequencies (10, 50, 100Hz) of the blue laser light at different laser power (1, 3, 6mW) were targeted to the regions of interest. Our preliminary results show a 6mW train of 5ms pulses delivered at 100Hz to the contralateral primary motor cortex(M1) reduced the number of rewarded lever pulls by 90±16.8% relative to a control site, while 50 and 10 Hz were less effective. This extent of inhibition was not seen while photo-activating other contralateral points such as M2, visual, retrosplenial cotex, parietal association area and even ipsilateral M1. Moreover, M1 inhibition was fully reversible as the mouse started pulling the lever within seconds once the laser was off the contralateral M1 site. Conclusions: As expected contralateral M1 is required for the execution of voluntary movement; however, M2 and putative hubs such as the retrosplenial cortex, parietal association area were not required to execute lever pulling.

Title: Functional distinction of interneuron circuits in human motor cortex during motor behaviour

Authors: R. HANNAH, S. JERJIAN, S. CAVANAGH, M. SOMMER, *J. C. ROTHWELL; Inst. Neurol, London, United Kingdom

Abstract: We tested the hypothesis that different excitatory interneuron circuits in primary motor cortex (M1) participate in different types of motor behaviour. We adopted two different approaches. In the first we examined how the excitability of different circuits was affected at distinct stages of a motor task; in the second we assessed whether differentially changing excitability levels in these circuits produced different effects on task performance. A controllable pulse parameter TMS (cTMS; Rogue Resolutions Ltd.; Peterchev et al. 2014, J Neur Eng) device was used to activate distinct interneuron circuits in M1 by changing the coil orientation (posterior-anterior, PA; anterior-posterior, AP) and TMS pulse width (30 - 120 μs). Experiment 1 (n=15): motor evoked potentials (MEPs) were elicited in the first dorsal interosseous muscle using short AP- (AP30) and long PA-directed (PA120) pulses, at various stages during a left/right choice reaction task (CRT) in which a non-informative warning cue appeared 500ms prior to the imperative signal. Participants maintained slight voluntary muscle contraction (5-10% MVC) throughout the CRT. Experiment 2 (n=15): monophasic intermittent theta burst stimulation was applied over M1 (AP45 and PA75) or control site (vertex, V45) in order to precondition the excitability of the two circuits. We measured its effect on simple reaction time, CRT, grip strength and finger tapping rate for the following 30 minutes. MEPs evoked by short AP- (AP30, AP45) pulses had a longer latency than those evoked by long PA-directed (PA120, PA75) pulses, confirming that different excitatory interneurons were recruited by the different combinations of pulse width/orientation. In experiment 1, the excitability of AP-sensitive, but not PA-sensitive, interneurons was suppressed at the time of the imperative stimulus and in the non-selected hand near to the onset of movement in the responding hand. In experiment 2, PA-directed theta burst stimulation facilitated finger tapping rate, whilst there was no significant effect after AP-directed stimulation. Motor performance in the other tasks was unaffected. The present data showed that AP sensitive circuits in M1 are preferentially involved in co-ordinating the inhibition of premature responses and in deselection of the non-responding hand. Additionally, the dissociation of finger tapping rate following AP- and PA-directed theta burst suggests that the interneurons excited by a PA pulse are specifically engaged in the tapping task. Together, these data are suggestive of specific functional roles of AP- and PA-sensitive interneurons in motor preparation and execution.

Title: The role of primary motor cortex in the coordination of digit force and position for dexterous object manipulation

Authors: *P. MCGURRIN[1], P. PARIKH[2], M. SANTELLO[2];
[1]Sch. of Life Sci., [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: To perform object manipulation while reducing the risk for performance errors, i.e., drinking from a cup of coffee without spilling it, the central nervous system must coordinate two variables at the onset of manipulation: digit placement and forces. When subjects grasp an object using self-selected (unconstrained) locations on an object, it has been found that trial-to-trial variability in digit position is compensated by a covariation in digit forces so as to preserve task dynamics (Fu et al. 2010, 2011; Fu and Santello 2014). In the present study we investigated the role of primary motor cortex (M1) in the coordination of digit position and forces for dexterous manipulation in this more natural grasping task paradigm using transcranial magnetic stimulation. We hypothesized that a 'virtual lesion' over M1 would impair the modulation of force-to-position during a manipulation task. Subjects first learned to generate a torque to minimize the roll of an object with asymmetrical mass distribution at object lift-off. Continuous theta burst stimulation (cTBS) was then delivered offline to contralateral M1 or vertex (control site) to understand the effects on digit position-force coordination necessary to generate the learned torque. We found that a 'virtual lesion' over M1, but not vertex, induced a significant impairment in the digit placement on the object, namely a decrease in the vertical distance between thumb and index finger placement for the first post-cTBS trial ($p < 0.001$). Moreover, subjects did not modulate digit forces in reponse to this change in digit placement, i.e. a significant change in digit load forces to compensate for decreased vertical distance between the digits ($p = 0.102$). This transiently imparied subject's ability to modulate digit force to position necessary for generating the learned compensatory torque at object lift onset for the first post-cTBS trial ($p < 0.001$). Subjects in the M1 group re-established the ability to generate the learned torque within ~2 trials, but exhibited significantly greater variability in torque generation ($p = 0.005$) relative to the vertex condition for all trials after the 'virtual lesion' over M1. These results suggest that after learning to perform a manipulation task in an unconstrained context, M1 (1) stores sensorimotor memory about digit placement, and (2) plays a significant role for the modulation of digit forces in response to changes in digit placement. Subject's ability to quickly re-establish pre-virtual lesion grasp behavior suggests that brain regions in the grasp network besides contralateral M1 are important for digit force-to-position coordination.

Title: Corticomotoneuronal cells represent muscle function in the motor cortex

Authors: *D. M. GRIFFIN[1,2,3], D. S. HOFFMAN[1,2,4], P. L. STRICK[1,2,3,4];
[1]Systems Neurosci. Inst., [2]Neurobio., [3]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [4]Res. Service, Veterans Affairs Med. Ctr., Pittsburgh, PA

Abstract: Muscles are multi-functional. They serve as agonists for some directions of movement and as synergists, fixators and antagonists for others. Movement dexterity depends on the central control over the precise timing and amplitude not only of agonist muscle activity, but also of muscles performing other functions. Here we examined the contribution of each "functionally tuned" corticomotoneuronal (CM) cell population to the different functions of individual target muscles. We trained a rhesus monkey for > 9 years to perform a wrist task capable of dissociating intrinsic (muscle-like) and extrinsic (movement-like) parameters of wrist movement (Kakei et al., '99). During task performance we recorded individual neurons in the primary motor cortex concurrently with 12 task related wrist and digit muscles. We used spike-triggered averaging (SpTA) of electromyographic (EMG) activity to identify CM cells and their target muscles. We examined 20 directionally-tuned CM cells and their target muscles during wrist movement in eight directions across three different wrist postures. We found that each CM cell displayed a distinct functional relationship with its target muscles. Some CM cells were selectively active when a specific target muscle was used as an agonist. Other CM cells were selectively active when the same muscle was used as a synergist, fixator or antagonist. Thus, separate populations of CM cells generate one of the muscle functions for a given target muscle.

Title: Neural processes during the preparation and the mental simulation of action

Authors: *C. RUFFINO[1,2], C. PAPAXANTHIS[1,2], I. GREENHOUSE[3,4], L. LABRUNA[3,4], R. B. IVRY[3,4], F. LEBON[1,2];
[1]INSERM U1093 Cognition Action Et Plasticité Sensor, Dijon, France; [2]Campus Universitaire, Univ. of Burgundy, Dijon, France; [3]Univ. of California, Dept. of Psychology, Berkeley, CA; [4]Univ. of California, Helen Wills Neurosci. Inst., Berkeley, CA

Abstract: Motor imagery (MI) is a specific cognitive state, during which the corticomotor system is specifically involved and correlated to the content of the represented action. Interestingly, the neural simulation theory (Jeannerod, 2001) postulates that motor imagery engages similar neurocognitive mechanisms to those operating during movement execution and preparation. In a previous study, we analysed the modulation of corticospinal (CS) excitability, with the transcranial magnetic stimulation technique, during the preparation of imagined movements. We found a dynamic CS inhibition during this preparation, similar to those observed in the preparation of the actual movement (Duque et al., 2009), CS excitability being progressively reduced during the delay period. The purpose of the present study was to probe the neural processes during the transition between preparation and simulation. We used single and paired-pulse TMS to measure CS excitability and short-interval intracortical inhibition (SICI), respectively. Right-handed participants were instructed to prepare and to imagine a left or right finger movement, in response to different cues. RT was first measured for actual trials, as the duration between the imperative signal and the time when the electromyographic activity increased above baseline. TMS was triggered at different times during imagined trials: at rest, 50ms before imperative, and at ¼, ½, ¾ and 3/2 of individual actual RTs. Motor evoked potentials (MEPs) were recorded in the right first interosseous muscle. Similarly to our previous study, we observed a decrease of CS excitability during the preparation of the imagined movement (50ms before imperative) and an increase during MI (3/2 of RT) in comparison to baseline. The transition between inhibition and facilitation was progressive and dynamic. The decrease of CS excitability was maximum at half of the RT period, then CS excitability was progressively facilitated. Similarly, SICI increased until half of the RT period then it was reduced when participants imagined the movement. The increase of SICI during the preparation may be responsible for the decrease of CS excitability, and inversely. We could consider that the modulation of CS excitability during the transition between preparation and mental simulation would reflect the balance between inhibitory and excitatory processes, similarly to actual movements.

Title: Transcranial magnetic stimulation measures of intrinsic motor system excitability and task-based inhibition exhibit intra-subject stability across weeks

Authors: *I. GREENHOUSE, M. KING, R. B. IVRY;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Individual differences in resting corticospinal excitability are highly reliable. For example, the resting motor threshold (rMT) for single-pulse transcranial magnetic stimulation (TMS) and the motor evoked potential (MEP) recruitment curve are stable across days. However, it is unknown whether task-based measures of corticospinal excitability show similar reliability. To explore this question, we examined TMS signatures of preparatory inhibition across two test sessions. . At two visits (13.7 ± 2.5 days apart), 26 participants performed a choice RT, delayed response task. On each trial of the task a cue signaled the preparation of a lateral flexion of either the left or right index finger followed 900 ms later by an imperative stimulus. Catch trials were included to limit anticipatory responses. TMS intensity during the task was set to 115% of rMT, as determined on an individual basis. The TMS coil was positioned over right M1, with MEPs measured from the left first dorsal interosseous muscle. Single TMS pulses were applied during a baseline intertrial interval or 800 ms into the preparatory delay. . The rMT was highly reliable across visits ($R = .92$, $p < .001$), as were baseline MEP amplitudes ($R = .60$, $p < .005$). Replicating earlier work, MEPs were inhibited relative to baseline when the left hand was selected (Visit 1: $t = 5.1$, $p < .001$; Visit 2: $t = 6.3$, $p < .001$) or not selected (Visit 1: $t = 3.2$, $p < .005$; Visit 2: $t = 5.4$, $p < 0.001$) for the forthcoming response. Inhibition was also greater for the selected than the non-selected hand (Visit 1: $t = 3.0$, $p < .01$; Visit 2: $t = 2.0$, $p < .05$). The degree of inhibition in the selected hand was reliable across visits ($R = .53$, $p < 0.005$) and was marginally reliable in the non-selected hand ($R = .35$, $p = .08$). Importantly, baseline MEP amplitudes did not predict the amount of task-based inhibition (all p's > .16). . The results demonstrate that processes underlying preparatory inhibition of corticospinal excitability are stable across weeks within individuals (albeit marginally for the non-selected hand). The fact that these dynamic, task-based measures were not predicted by resting static measures of excitability suggests that preparatory inhibition reflects the recruitment of a distinct neural mechanism.

Title: The relationship between neural and muscle synergies investigated with common decomposition methods

Authors: *R. L. HARDESTY, JR[1], W. J. TALKINGTON[1], E. OLESH[2], V. GRITSENKO[1]; [1]Neurosci., [2]West Virginia Univ., Morgantown, WV

Abstract: Limb dynamics, defined as the sum of non-linear forces that arise directly or indirectly from muscle contractions, requires complex control by the neural motor system. Some of these forces are caused by the effect of gravity on the moving limb, others are caused by mechanical coupling between limb segments, termed interaction torques. Healthy motor control involves the generation of coordinated muscle contractions, or muscle synergies, that are appropriately scaled to overcome or take advantage of limb dynamics for any given movement. We investigated whether common decomposition methods can provide accurate representations of neural synergies that underlie muscle synergies engaged during arm movements of humans. Subjects performed three reaching tasks that consisted of pointing to spherical targets in virtual reality. The locations of targets were chosen so that movement to them is accompanied by varying directions of interaction and gravitational torques. Neural synergies were assessed using single-pulse transcranial magnetic stimulation (TMS) of the primary motor cortex at varying time points during movement. Motion capture and electromyography of 12 muscles spanning the shoulder, elbow, and wrist were recorded synchronously. Data analysis was carried out in MATLAB (Mathworks). To normalize TMS responses to the background motoneuronal excitability, the integration of inputs by motoneurons and the contribution of spindle afferents were mathematically modeled. The relationships between TMS responses, background muscle activity, and kinematic and dynamic variables of limb motion were investigated using non-negative matrix factorization (NNMF) and principal component analysis (PCA). Results indicate that during movement the TMS responses are modulated together across several muscles in agreement with muscle synergies extracted with NNMF from background muscle activations. These synergies also showed relationships with kinematic or dynamic components of movement. These results support the use of NNMF to extract neural synergies and suggest that these synergies may represent specific variables of limb dynamics.

Title: Short interval intrahemispheric inhibition (SICI) in a shoulder girdle muscle in humans

Authors: *K. MUDGAL[1], C. ALEXANDER[2];
[1]Imperial Col. London, Staines-Upon-Thames, United Kingdom; [2]Physiotherapy, Imperial Col. Healthcare NHS Trust, London, United Kingdom

Abstract: In order to control the hand in space the muscles of the scapula are required to help position the arm. Indeed it is clear that without appropriate positioning and stability of the shoulder region, manipulation of the hand becomes difficult (Levin 1996). Consequently, control of the shoulder region muscles is relevant to upper limb function. Surprisingly, little is understood about the mechanisms enabling modulation of activity of these muscles, which is in contrast to the understanding of control of hand muscles. To investigate control of shoulder region muscles we have examined short interval intrahemispheric inhibition (SICI) in both upper and lower fibres of trapezius. With ethical approval and informed consent and using standard techniques, the surface EMG of the dominant side of upper trapezius (UTr), lower trapezius (LTr) as well as the first dorsal interosseous muscle of the hand (FDI) were recorded from 16 healthy subjects. A figure of eight coil from a magnetic stimulator was positioned over the motor cortex upon the hotspot for the muscle under investigation. All stimuli were conditioned at a test condition interval of 2.5ms. The aim was to deliver a test stimuli at an intensity to evoke MEPs in the upper and lower trapezii between 0.5mV and 1mV. The conditioning stimulus was varied by 10% increments from 50-90% of the resting motor threshold. Conditioning and test stimuli were randomly interleaved such that 10 stimuli at each conditioning intensity were delivered and 10 test stimuli were delivered alone. Any effect upon the test stimulus was measured as a percentage modulation of the amplitude of the test MEP. In addition, the experiment was repeated with the test muscle active at 5% of MVC using 10 of the subjects with the conditioning stimuli intensity ranging from 50-90% of active motor threshold. As has been previously described, SICI could be evoked at rest in the right FDI (inhibition 32% ±21%; p =0.00). SICI at rest was strongest at a conditioning stimulus of 70% (49% ± 38% UTr; 60% ± 29% LTr). Interestingly we were unable to evoke SICI when the test muscle was active at only 5% of MVC in either FDI or UTr. However, SICI could be evoked in LTr (p=0.008) with a conditioning intensity of 70% and 80% of active motor threshold (82% and 80% respectively). Abstract: Our movements are initiated more efficiently when prepared in advance. This facilitation effect has been considered to arise from brain states during a preparatory period before motor execution. However, the precise properties of the neural network that induces a prepared state are unknown. Here, we show that sparse and low activity in cortical circuits facilitates the reaction time for subsequent behavior in mice performing a delayed reaching task that we have developed. Unlike previous behavioral paradigms such as licking or whisking tasks, our reaching task has incorporated variable delay periods and thus enabled us to study the network state specifically when mice prepared for an intended movement. Using *in vivo* two photon imaging with a highly-sensitive calcium sensor (GCaMP6), we monitored simultaneously the activity of up to hundreds of neurons in the motor cortex and decoded it using machine-learning algorithms. The reaction times of forepaw movements were significantly shorter when the cortical network exhibited a characteristic pattern of spatially sparse and low activity. Our results indicate that shifting the motor cortex network to a state in which a majority of neurons are inactive facilitates effective initiation of motor behavior, and highlight the importance of sparse activity with low noise for efficient cortical processing.

Title: Enhancing acquisition of classical eyeblink conditioning by non-invasive transcranial direct current stimulation (tDCS) in alert rabbits

Authors: *C. AMMANN, A. GRUART, J. M. DELGADO-GARCÍA, J. MÁRQUEZ-RUIZ; Univ. Pablo de Olavide, Seville, Spain

Abstract: Transcranial direct-current stimulation (tDCS), a non-invasive brain stimulation technique, has been successfully applied for modulation of cortical excitability. The aim of this study was to investigate whether the application of tDCS on primary motor cortex (M1) could modulate the acquisition of an associative learning. Additionally, to rule out that thermal effect underlies the observed changes, a second experiment was carried out. For the first objective six male rabbits were prepared for classical eyeblink conditioning and simultaneous tDCS on M1. tDCS was applied on M1 through a disk electrode (0.5 cm2) over the skull, with a saline-soaked sponge attached to the contralateral ear serving as a counterelectrode. We applied a delay paradigm using a 350 ms tone as CS followed 250 ms from its onset by a 100 ms air puff directed to the left cornea as US. The presence of conditioned responses (CRs) was determined by recording the EMG activity of the ipsilateral orbicularis oculi muscle. Anodal and cathodal tDCS (1 mA, ± 2 mA/cm2, ~ 30 min) were applied during conditioning day 3 (C3) and day 8 (C8), respectively. Sham stimulation implicated the same electrode placement and conditioning protocol, except for tDCS duration, consisting of a 30 s application. The results showed that the presence of anodal tDCS during C3 potentiated the acquisition of the classical eyeblink conditioning, whilst cathodal tDCS during C8 did not present a significant effect on the percentage of CRs, nevertheless this tDCS polarity reduced magnitude and increased latency of the CRs. To discard a potential thermal effect associated to tDCS, three male rabbits received anodal and cathodal tDCS on M1 during 60 or 120 min through the disk electrode over the skull. An epidural NTC thermistor was implanted on M1 for brain temperature measurement before, during and after tDCS. Different current densities of tDCS were applied (±0.029, ±0.29, and ±2.9 mA/cm2). No significant changes of the epidural temperature were detected for any of the different current densities neither with anodal nor with cathodal tDCS application. The present work highlights the potential use of anodal tDCS on M1 to enhance the acquisition of an associative motor learning and the modulating capability of cathodal tDCS on motor responses. On the other hand, the results established that no thermal effect was induced over the brain

cortex when density currents two orders of magnitude higher than those applied in humans were used. These findings confirm that the prolonged application of tDCS can be considered safe from a thermal point of view, suggesting that tDCS effects are not related to an induced variation of brain temperature.

Title: Kisspeptin cell-specific deletion of PTEN results in sex- and nucleus-specific trophic effects in the adult mouse brain

Authors: *A. L. NEGRON[1], U. BOEHM[2], M. ACOSTA-MARTÍNEZ[3];
[1]Stony Brook Univ., Stony Brook, NY; [2]Pharmacol. and Toxicology, Univ. of Saarland Sch. of Med., Homburg, Germany; [3]Physiol. and Biophysics, Stony Brook Univ. Med. Ctr., Stony Brook, NY

Abstract: In mammals, kisspeptin and its receptor Kiss1R, play an important role in the control of gonadotropin-releasing hormone and are necessary for normal reproductive function and pubertal development. There are two principal hypothalamic kisspeptin-expressing neurons in rodents: one in the anteroventral periventricular nucleus (AVPV) and a second in the arcuate (ARC) nucleus. Kisspeptin protein and mRNA expression in the AVPV is sexually dimorphic (greater in females than males), which partly explains the ability for females and not males to produce a luteinizing hormone (LH) surge. During specific periods of development, hormone-dependent and -independent pathways are responsible for shaping the sexually dimorphic expression of kisspeptin. However, the molecular mechanisms underlying the hormonal and non-hormonal organizational actions on kisspeptin expression and function remain unknown. Phosphatase and tensin homolog (PTEN) is a dual protein/lipid phosphatase that regulates neuronal cell survival, size, and proliferation. Using adult Kiss-Cre PTEN$^{flx/flx}$ mice (Kiss-PTEN KO) and DAB immunostaining, we found that male Kiss-PTEN KO mice had more kisspeptin-immunoreactive (ir) cells compared to WT littermates, whereas female KOs had less compared to WT. The intense kisspeptin fiber density in ARC and the increased peptide content in AVPV make accurate cell counting and cell area measurements difficult. Therefore, we crossed Kiss-PTEN KO mice with a R26-YFP reporter mouse (Kiss/YFP-PTEN KO). In the AVPV, male

Kiss/YFP-PTEN KO mice had a higher number of Kiss-ir cells/section compared to WT, confirming our previous findings using DAB staining. In contrast, neither significant genotype effects in AVPV Kiss-ir cell number was observed in females, nor any differences in the ARC Kiss-ir cell numbers of either sex. In addition, compared to Kiss/YFP-WT littermates, Kiss/YFP-PTEN KO females showed increased cell area of AVPV Kiss neurons. Because PTEN deletion can activate mammalian target of rapamycin (mTOR) signaling, which regulates cell size and protein synthesis, we co-labeled Kiss/YFP with pS6, a marker of mTOR activity. A significant increase in the percentage of co-labeled cells in both the AVPV and ARC of female KO mice compared to WT was observed. Our findings suggest that PTEN signaling in kisspeptin neurons participate in the hormone-dependent and independent organizational events leading to sex-specific hypothalamic kisspeptin expression. Kisspeptin neurons exhibit hypertrophy in postmenopausal women and in ovariectomized monkeys. Thus, decreased PTEN signaling may also lead to premature kisspeptin cellular senescence.

Title: Effects of estrous cycle on fear conditioning and extinction, and on single prolonged stress induced extinction recall deficits

Authors: *C. V. CHEN, I. LIBERZON;
Univ. of Michigan, Ann Arbor, MI

Abstract: Post-traumatic stress disorder (PTSD) is a deleterious mental health condition with a lifetime prevalence of 6-9% in the US, affecting twice as many women as men. Since gonadal hormones play a crucial role in many sex differences, they may contribute to sex differences in susceptibility to PTSD. Using a PTSD rodent model - Single Prolonged Stress (SPS), our lab has shown that SPS in male rats leads to a deficit in retention of fear extinction, a postulated key deficit in PTSD. Here, we sought to determine how fluctuating hormone levels throughout the estrous cycle in female rats affect various aspects of fear associated learning like fear conditioning, fear extinction, and SPS induced extinction recall deficits. Adult female rats' vaginal impedance was measured daily for twelve days to determine their estrous stage. Four groups of animals were then exposed to SPS during proestrus, estrus, diestrus 1, or diestrus 2. As previously described, SPS consisted of restraint, forced swim and ether anesthesia, followed by a

7-day quiescent period. Control animals were left undisturbed during the 7-day quiescent period. Following the undisturbed time, all rats were tested for fear conditioning (FC), fear extinction (FE) and extinction recall (ER). Preliminary data indicate that, in female controls, hormone levels on the day of learning affect memory performance . When hormone levels are high during FC, animals show higher levels of initial freezing the following day. Conversely, rats with high hormone levels during FE show the stronger evidence of extinction during ER. However, SPS exposure interacted with the hormonal effects on fear and extinction memory. When SPS was performed during proestus, it subsequently enhanced conditioning, showing higher freezing during FE and ER, as compared to animals undergoing SPS under other estrous stages. When matched with controls on the same estrous stage, females in proestrus on the day of SPS showed SPS-characteristic ER deficits. Low hormonal levels during FC, FE and ER, did not interact with SPS effects and animals showed SPS-induced ER deficits compared to stage matched controls. Future studies will seek to clarify whether estrogen, progesterone or both are responsible for these effects. These results, however, indicate that cycling hormones may explain the differential susceptibility to PTSD in the female population.

Title: Progesterone receptor immunoreactivity in the brains of neonatal PRA knockout (PRAKO) or PRBKO mice

Authors: *D. LALITSASIVIMOL[1], K. D. ACHARYA[2], S. NETTLES[2], M. J. TETEL[2], O. M. CONNEELY[3], C. K. WAGNER[1];
[1]Psychology, Univ. At Albany, Albany, NY; [2]Neurosci. Program, Wellesley Col., Wellesley, MA; [3]Mol & Cell Biol., Baylor Col. of Med., Houston, TX

Abstract: During critical developmental periods, progesterone receptor (PR) is expressed in neural structures that influence sexually dimorphic behaviors in adulthood, including the ventrolateral subdivision of the ventromedial nucleus of the hypothalamus (VMN), and the medial preoptic nucleus (MPN). There is a significant sex difference in the expression of PR in the MPN, in which perinatal males express higher levels of PR immunoreactivity (PR-ir) in the MPN compared to females, suggesting a developmental window during which the male brain is more sensitive to progesterone than the female brain. The two PR isoforms, the full length PRB

and the truncated PRA, can differentially regulate the expression of specific genes. In the present study, we investigated the differential expression of PRA and PRB in the VMN and MPN during development by comparing PR-ir in neonatal male and female PRA knockout (PRAKO) and PRBKO mice and their wildtype (WT) counterparts. In both the MPN and the VMN, there was a significant main effect of sex, a main effect of genotype, and a significant interaction between sex and genotype. Levels of PR-ir were higher in WT males than in WT females ($p<0.001$) consistent with previous results from the developing brain. However, this sex difference was abolished in both PRAKO and PRBKO mice, with PR-ir levels in knockout males significantly lower than WT males, but similar to WT females. Knockout females did not differ from WT females in either region. These findings suggest that the sex difference in PR-ir in the neonatal MPN and VMN can be attributed to the expression of both PR isoforms and implicate PR in the sexual differentiation of these regions and the behaviors they regulate in adulthood.

Title: Role of microglia in sexual differentiation of the amygdala

Authors: *J. W. VANRYZIN[1], M. M. MCCARTHY[2];
[2]Dept. of Pharmacol., [1]Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Microglia are the dominant resident immune cells of the brain and function in multiple ways outside their traditional capacity of responding to insult. During development microglia regulate tissue homeostasis, neuronal precursor populations, and synaptic circuitry. We recently implicated microglia as an integral component of sexual differentiation of the preoptic area and control of male copulatory behavior, suggesting these immune cells also function to organize sex-specific brain structure and function (Lenz et al. J Neurosci 33(7), 2013). The amygdala is also a sexually dimorphic brain region that regulates social behaviors known to differ in males and females. We reported a sex difference in the number of newly born cells in the developing rat medial amygdala (MeA) that is mediated by endocannabinoids, with females having higher numbers of newly born cells than males and a lower endocannabinoid tone. These differences in newly born cells correlated to behavioral changes, as newborn females treated with the CB1/2 agonist WIN55,212-2 exhibited masculinized juvenile social play behavior and reduced cell

genesis in the developing amygdala (Krebs-Kraft et al. PNAS 107(47), 2010). Further investigation suggests microglia may be central in establishing the observed sex difference in newly born cells, as males have more Iba1+ microglia exhibiting phagocytic morphology compared to females in the medial amygdala during the sensitive period for sexual differentiation. Treatment with minocycline, a tetracycline derivative and inhibitor of microglial activation, increased male BrdU+ cell counts to female levels, but did not alter the number of female BrdU+ cells in the MeA. We are now deciphering the relative contributions of microglia phagocytosis and trophic signaling in the regulation of newly born cells using methods that selectively deplete microglia or prevent phagocytosis. Ultimately, these studies will provide valuable insight into new facets of immune regulation of brain sexual differentiation and development. This work was supported by RO1 MH52716-018 to MMM.

Title: Sex difference in microRNA-124 in neonatal hippocampus and impact on NKCC1

Authors: *K. E. KIGHT[1], M. M. MCCARTHY[2,3];
[1]Program in Mol. Med., [2]Dept. of Pharmacol., [3]Program in Neurosci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Neurogenesis is regulated by numerous intrinsic factors, and varies among brain regions and across the lifespan. We have previously reported that developmental cell genesis in the hippocampal formation of the Sprague Dawley rat is greater in the dentate gyrus of males compared to females during the first week of life, but not the second (Bowers et al., Bio Sex Diff 2010). We have also found a sex difference in the amount of several microRNAs known to be functionally involved in neuronal cell genesis, differentiation, and maturation. Female rat pups have higher baseline expression of several mature microRNAs in the dentate gyrus during the first postnatal week, including miR124, which promotes cell-cycle exit and neuronal maturation. One of the predicted targets of miR124 is the SLC12A2 transcript, which encodes the bumetanide-sensitive Na-K-2Cl cotransporter, NKCC1. As the primary channel facilitating chloride ion influx in immature neuronal cells, NKCC1 is critical for conferring the depolarizing actions of GABA on neuronal precursors and immature neurons, and its expression is downregulated in maturing neurons. Here we report that males had higher levels of NKCC1

mRNA compared to females in the neonatal dentate gyrus. This positively correlates with the male-biased proliferation and is inversely related to the sex difference in miR124 expression. Antagonism of miR124 via i.c.v. infusion of locked-nucleic acid-modified oligonucleotides downregulated NKCC1 expression. The higher levels of miR124 in females and the inhibitory effect of miR124 on NKCC1 expression suggest a mechanism for the earlier developmental shift to hyperpolarizing GABA seen in the hippocampus of females during the first postnatal week (Nuñez and McCarthy, Dev Neurobiol 2007). These results also suggests that differential expression of microRNAs between males and females, particularly miR124, may direct the sex difference in early postnatal neurogenesis through downstream effects on depolarizing GABA.

Title: CB1 and CB2 endocannabinoid receptors act in concert to modulate sex differences in the developing amygdala and social play behavior

Authors: *K. J. ARGUE[1], J. W. VANRYZIN[2], M. M. MCCARTHY[1];
[1]Pharmacol., [2]Program in Neurosci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Males of most species display higher levels of juvenile social play behavior compared to females. In rats, this sex difference is negatively correlated with cell proliferation in the developing amygdala. Both sex differences in play behavior and cell proliferation are mediated by the endocannabinoid system (PNAS 107; 2010). Further investigation into involvement of the endocannabinoid receptor types revealed surprising evidence of cooperation between the two receptors. Neonatal activation of either CB1 or CB2 alone between postnatal days 0-3 was not sufficient to increase female play behavior, however dual-agonist treated newborn females displayed increased levels of social play when tested as juveniles during postnatal days 27-38 (ANOVA $p < 0.05$), and activation of either CB1 or CB2 was sufficient to decrease the number of BrdU+ cells in the female developing amygdala (ANOVA $p < 0.001$). Dual-agonist treatment had no effect on play in males. Antagonizing both receptors in females reduced play behavior (ANOVA $p < 0.05$). Both CB1 and CB2 are known to mediate cell proliferation, however traditionally they were thought to be expressed on different cell types. We used a flow cytometry approach to identify newly proliferating cells in the developing amygdala, and found that neonatal females contain more newly proliferating cells coexpressing CB1 and CB2 compared to

males (t-test $p < 0.05$). Together with our behavioral analyses, these data suggest that developmental sex differences in endocannabinoid receptor expression mediate effects on juvenile social play behavior. Currently we are performing further characterization of the newly born cells that coexpress CB1 and CB2, and assessing how sex differences in neuronal morphology in the juvenile amygdala correspond to endocannabinoid-mediated effects on social play behavior. This study was funded by RO1MH52716-018 to MMM.

Title: High-throughput identification of sexual and developmental dimorphisms within the hypothalamus and pituitary gland

Authors: *K. L. GRUCHALLA, T. RHEN;
Dept. of Biol., Univ. of North Dakota, Grand Forks, ND

Abstract: The hypothalamus is the main control center of the endocrine system in vertebrates, and the pituitary gland acts as an intermediary between the hypothalamus and peripheral endocrine organs. The hypothalamus is a sexually dimorphic region that requires precise organization during development for proper sex-specific function throughout life. Yet, few high-throughput analyses have been performed to identify sex differences in gene expression during early development. We therefore isolated total RNA from hypothalami and pituitary glands of male and female snapping turtles during embryogenesis and at hatch. We used the Illumina platform to sequence all expressed genes at each time point and in each sex. We combined reads from hypothalamus/pituitary, gonads, and intestine to assemble a complete transcriptome for the snapping turtle. We then used CLC Genomics Workbench to map hypothalamus/pituitary reads to the transcriptome, calculate gene expression values, and test for differences in gene expression between the sexes and across developmental stages. We identified differentially expressed genes

using a false discovery rate of $p<0.05$. We annotated differentially expressed genes by BLASTing snapping turtle sequences against proteomes from human, chicken, and Chinese softshell turtle. We are using BLAST2GO, DAVID, and GeneMANIA to assign Gene Ontology terms for further analyses. Relatively few genes are differentially expressed between the sexes at either time point. At mid-embryonic development, 180 genes are differentially expressed between males and females, and at hatching, 164 genes are differentially expressed between the sexes. Many more genes exhibit developmental changes in expression between embryonic and hatch time points, with 1533 and 3170 differentially expressed genes in males and females, respectively. This suggests major neurological changes occur during the second half of embryonic development. Genes differentially expressed between male and female hatchlings include chromogranin A, the alpha chain of glycoprotein hormones, proopiomelanocortin, prolactin releasing hormone, and somatostatin. Expression of these genes was 1.7 to 3 fold higher in females than in males, mirroring well-documented physiological and behavioral differences between the sexes (reviewed in Rhen and Lang, 2004). High-throughput studies like this will expand our knowledge of gene networks important for sexual differentiation of the hypothalamus. Identification of genes underlying morphologic and physiologic differences will allow a better understanding of the developmental causes of neuroendocrine dysfunction.

Title: The role of microglia and mast cells in sculpting the sexually dimorphic nucleus (SDN) of the POA

Authors: *L. A. PICKETT[1], K. M. LENZ[2], M. M. MCCARTHY[1];
[1]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Psychology, The Ohio State Univ., Columbus, OH

Abstract: The first neuroanatomical sex difference detected in the mammalian brain was reported in 1978 and named the sexually dimorphic nucleus (SDN) due to its larger size in males compared to females (Brain Res. 148:333, 1978). The SDN is a dense collection of calbindin-expressing neurons (J. Neurobiol. 42:315, 2000) located within the central division of the medial preoptic nucleus (MPNc) of the preoptic area (POA), a critical brain region for the control of

partner preference and maternal behaviors (Horm. Behav. 55:611, 2009; Neurosci. Bull. 30:863, 2014). Previous studies have established that both sexes generate the same number of neurons in the SDN and they selectively die off early in development in females due to a lack of the endogenous survival factor, estradiol (Brain Res. 353:7, 1985; Brain Res. Dev. Brain Res. 52:17, 1990). This system is an excellent model for naturally occurring cell death versus neuroprotection in the developing brain but the involvement of non-neuronal cells in this model system has been largely ignored. We have previously established that innate immune cells of the brain, microglia, and inflammatory mediators such as prostaglandins direct the development of sex-specific synaptic patterns in the neonatal POA that correlate with sexual behavior in the adult rat (Nat. Neurosci. 7:643, 2004; J. Neurosci. 33:2761, 2013). We now turn our attention to an additional inflammatory cell type, mast cells, which like microglia are of myeloid cell lineage with origins outside the nervous system. We determined there are more mast cells in the POA of neonatal males than females and this sex difference was mediated by estradiol. We have also found that pharmacological activation of mast cells in newborn females induces a male-typical microglial morphology, with higher numbers of ameboid microglia and lower numbers of ramified, phagocytic microglia. We are currently investigating whether mast cells modulate microglial primary phagocytosis (phagoptosis) and whether this contributes to the sexual differentiation of SDN volume by phagoptosis of neurons in the female SDN. Collectively these results indicate non-neuronal cells are crucial and unappreciated factors shaping brain development and sex-specific physiological and behavioral outcomes. Understanding the role of these cells in apoptotic and neuroprotective cascades during normal brain development will allow for further studies of novel therapeutic strategies and potential sex differences in efficacy of estradiol and/or immune cell inhibitors as neuroprotective agents.

Title: Organizational influences of sex steroid hormones on glucocorticoid receptor responses in male and female Long Evan rats

Authors: ***L. INNALA**, L. HILL, Y. YANG, A. ANONUEVO, V. VIAU;
Cell. and Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The sex steroid milieu during the neonatal period in the rat exerts marked effects on the development of the hypothalamic-pituitary-adrenal (HPA) endocrine axis, including programming the decline in stress HPA axis responses to repeated stimulus exposure (i.e. habituation). In Long Evan rats, neonatal ATD (aromatase inhibition) in males did not alter corticosteroid responses under acute or repeat restrain exposure, while neonatal testosterone propionate (TP) in females resulted in decreased corticosteroid output under acute conditions, and prevented corticosteroid habituation after 5 days of repeated restraint exposure. This organizational effect could involve changes in glucocorticoid-mediated negative feedback efficacy. Using Western blot analysis, we assessed hippocampal glucocorticoid receptor protein responses to single and repeated restraint exposure in adult male and female bearing postnatal implants of the aromatase blocker ATD or testosterone propionate, respectively. Analysis of receptor distribution revealed a trend towards a reduced percentage of GR in the nucleus in neonatal testosterone treated females under naïve conditions, and no effect of ATD on GR localization in males. Prompted by these findings to suggest potential interactions between stress-HPA axis habituation and the sex steroid milieu during the neonatal period on adult GR responses in the hippocampus, we are currently expanding our analysis to include other brain regions known to mediate negative feedback regulation of the HPA axis.

Title: Stress-induced hypothalamic pituitary adrenal axis responses in male and female Long-Evans and Sprague-Dawley rats

Authors: ***Y. YANG**, L. INNALA, A. ANONUEVO, L. HILL, V. VIAU;
Cell. and Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Male and female rodents show different capacities for coping with stress-induced threats to homeostasis, including stress hypothalamic-pituitary-adrenal (HPA) axis habituation. Moreover, within-sex variability in behavioral and neuroendocrine responses has also been identified in different rodent strains. To provide a framework for studying how genotype and sex may come to interact on stress HPA axis habituation, we examined plasma corticosterone and

central corticotropin-releasing hormone (CRH) mRNA responses of adult male and female Sprague-Dawley and Long-Evans rats exposed to repeated restraint (2 h day/5 consecutive days). Females in general showed higher plasma corticosterone concentrations than males under acute and repeat restraint conditions. Assessment of corticosterone output between the first and last bout of restraint indicated comparable declines in total corticosterone responses in both male and female Sprague-Dawley rats (68 % and 77%, respectively). Significant declines in corticosterone (50%) occurred in Long-Evans males (50%), but not females (109%). Repeated restraint increased CRH mRNA in the paraventricular nucleus of hypothalamus in both strains of female rats. Whereas CRH mRNA decreased in Long-Evans males, there was no change in Sprague-Dawley males. Taken together, the interactions revealed here continue to underscore the importance of sex and strain in modeling individual differences in neuroendocrine habituation and stress vulnerability.

Title: Effects of DNA methyltransferase inhibition on sexually dimorphic cell groups in the preoptic area

Authors: *M. MOSLEY, J. M. WEATHINGTON, A. CASTILLO-RUIZ, N. G. FORGER; Neurosci., Georgia State Univ., Atlanta, GA

Abstract: Gonadal steroids act perinatally to orchestrate the formation of sex differences in the brain. In some cases, such sex differences are due to differential cell death, but other differences persist even when cell death is prevented. For example, the sexually dimorphic nucleus of the preoptic area (SDN-POA) is larger in males than in females in many species. Calbindin immunoreactivity (ir) defines the SDN-POA in mice (referred to as the CALB-SDN), and the sex difference in the CALB-SDN persists in Bax knockout mice, in which cell death is prevented (Gilmore RF et al., 2012). We hypothesized that sexual differentiation of the CALB-SDN is due to the hormonal control of cell phenotype. Epigenetic modifications can lead to lasting changes in gene expression and are likely candidates for such steroid-dependent, cell fate “decisions.” The best-studied epigenetic modification is the methylation of DNA, catalyzed by DNA methyltransferases (DNMTs) and usually associated with gene repression. To test whether a

disruption of DNA methylation during the neonatal critical period alters the development of the CALB-SDN, mice were injected, i.c.v., with the DNMT inhibitor zebularine, or saline alone, on the day of birth (P0) and P1. Brains were collected on P27 and immunohistochemically stained for calbindin. We find a two-fold increase in the number of CALB-SDN cells in mice neonatally treated with zebularine ($p= 0.01$). Zebularine increased CALB-SDN cell number in females to that in saline males, although zebularine-treated males had even more calbindin+ cells than control males or zebularine-treated females. We also found more calbindin+ cells just lateral to the CALB-SDN ($p< 0.04$) in zebularine-treated mice, but no effect of zebularine on calbindin+ cell number in the cortex. To determine whether other sexually dimorphic cell groups in the POA were affected by neonatal DNMT inhibition, adjacent sections were stained for estrogen receptor (ER) α ir. As expected, control females had more ERα+ cells than males in the medial POA ($p<0.01$). Neonatal zebularine treatment increased the number of ERα+ cells ($p<0.03$) and eliminated the sex difference in the medial POA: ERα+ cell counts were low in control males, and elevated to a similar level in control females and males and females treated with zebularine. In a more lateral region of the POA there was no effect of sex or zebularine treatment on ERα+ cell number. Thus, a transient disruption of DNA methylation during the neonatal period causes long-term changes in at least two sexually dimorphic markers in the mouse POA. We are currently examining other markers and brain regions, and determining possible critical periods for these effects.

Title: Excitatory synaptic input differs by sex in the nucleus accumbens core but not shell in prepubertal rats

Authors: J. CAO, J. A. WILLETT, C. A. HAUSER, T. R. WILL, D. M. DORRIS, *J. MEITZEN;
Biol. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Sex differences exist in how the brain mediates motivated behavior and reward, both in normal and pathological contexts. Investigations into the underlying neural mechanisms yield

accumulating evidence of sexually different dendritic spine morphology and neuromodulator and steroid sex hormone action in the striatal brain regions, including the nucleus accumbens core and shell. How these sex differences influence the electrophysiological properties of neurons in the nucleus accumbens to ultimately modulate this region's function is an area of active research. One current hypothesis is that the excitatory synaptic input onto medium spiny neurons (MSNs), the primary output neurons of the nucleus accumbens, differs by sex. Here we test this hypothesis by performing whole-cell recordings of MSNs in acute brain slices from pre-pubertal male and female nucleus accumbens core and shell. We assess intrinsic neuronal electrophysiological properties through the application of current stimuli in current-clamp and excitatory synaptic input through recording of miniature excitatory post-synaptic currents (mEPSCs) in voltage-clamp. mEPSC frequency is higher in female than in male MSNs in the core but not shell. No sex difference was found in mEPSC amplitude or time of decay. MSN intrinsic excitability and action potential properties are stable across sex in both the core and shell. This data implicates excitatory synaptic input as a potential mechanism underlying sex differences in nucleus accumbens-mediated behaviors, and that sex differences in excitatory synaptic input is generated before puberty.

Title: Disruption of conditioned sexual inhibition in male rats: role of dopaminergic VTA neurons in alcohol- and cue-induced dopamine release in the nucleus accumbens core

Authors: *K. GERMÉ, L. R. GOSSIP, J. ALVAREZ-BARKHAM, N. WATSON, J. G. PFAUS;
Dept. of Biol. / Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: When male rats are given access alternatively to a sexually nonreceptive female scented with a neutral odor (almond) and an unscented receptive female, they display a conditioned avoidance of the scented female on a final copulatory test, with two receptive females, one scented and one unscented. An acute treatment with a low dose of alcohol (0.5g/kg) before the final test disrupts this inhibition. We have shown previously that this does of alcohol

alone increases dopamine (DA) concentrations in the nucleus accumbens (NAc) compared to saline. Although almond odor alone had no effect on DA in saline-treated males, it increased DA in alcohol-treated males. Because the ventral tegmental area (VTA) sends large DA inputs to the NAc, we examined the role of VTA dopaminergic neurons in cue and alcohol-induced DA release in the NAc core. Sexually naive male Long-Evans rats were conditioned for sexual inhibition to an odor (almond) using our established paradigm and injected with saline or alcohol (0.5g/kg) before the final choice test. The retrograde tracer Fluoro-Gold (FG) was then infused into the NAc core. Male rats were exposed to alcohol and to the inhibitory odor or a novel odor for an hour. Then fluorescence immunohistochemistry was performed on VTA slices to determine the numbers of cells expressing Fos, TH and FG so the numbers of DA cells that are activated and that have axons in the NAc core. Preliminary results suggest that VTA activation may not be necessary for alcohol and cue-induced DA increase in the NAc core.

Title: Both populations of kisspeptin neurons are involved in the stimulation by rams of LH secretion in anestrous ewes

Authors: C. FABRE-NYS[1], *L. DUFOURNY[1], S. MARTINET[1], O. LASSERRE[2], R. P. MILLAR[3], S. OKHURA[4], Y. SUETOMI[4];
[1]INRA-CNRS-Univ Tours-Haras Nationaux, Nouzilly, France; [2]INRA UEPAO, Nouzilly, France; [3]Univ. of Pretoria,, Pretoria, South Africa; [4]Nagoya Univ., Nagoya, Japan

Abstract: Sheep are seasonal breeders and are sexually quiescent during spring. However, ovulation can be induced in these females by sudden exposure to a sexually active ram a phenomenon known as “the ram effect”. The first endocrine change observed is an immediate stimulation of LH pulsatile secretion. Several studies have shown that Kisspeptins (Kiss) are potent stimulators of LH secretion. Kiss is present in 2 populations of neurons, in the arcuate nucleus (ARC) and in the preoptic area (POA). Our aim was to understand whether one or the 2 populations of Kiss neurons were implicated during the “ram effect”. Using a double immunofluorescent detection of Kiss (Kiss IR) and cFos (Fos IR) we identified Kiss neurons

activated by exposure to a sexually active ram for 2h (M2=7) or 12h (M12=12) compared to a control situation (exposure to females for 2h, n=5). Density of labelled cells were compared using Kruskall and Wallis test followed by Mann and Whitney U test. The density of Kiss IR also Fos IR and the proportion of KissFos IR differed significantly among the groups both in the ARC ($p<0.002$) and the POA ($p<0.002$) and the proportion of double labelled cells was higher in ewes exposed to males than to females but did not differ between ewes exposed to M2 and M12. Median and interquartile were respectively 1.86 ±2.45 (Cont ARC) , 21.74±2.24 (Cont POA), 26.32 ±10.49 (M2 Cont), 71.43 ± 13.53 (M2 POA), 38.36 ± 20.44 (M12 ARC), 66.65 ± 15.85 (M12 POA). By contrast the density of Kiss IR neurons or Fos IR neurons did not differ between groups. We then tested whether local administration by retrodialysis of a Kiss antagonist (P234 10-6M given for 3 h starting 1h before male introduction) either in ARC or POA would affect the LH response of anoestrus ewes to rams compared to infusion of solvant. Data were analysed as % change of LH concentration compared to the mean level during the hour before male introduction and compared using GLM ANOVA followed by Fisher post-hoc test. LH concentration changed with time in all groups. ($p<0.003$ in the POA and $p< 0.0001$ in the ARC). In the POA, there was a significant effect of treatment ($p<0.01$) and an interaction between treatment and time ($p<0.01$). Treatment differed from solvant 1 to 4 hours after male introduction ($p<0.001$ 1 to 3h after male introduction, $P<0.026$ 4 h after). In the ARC treatment had no significant effect and there is no interaction between time and treatment but post-hoc comparisons showed a significant difference between treated and control at 1h ($p<0.026$) 2h ($p<0.0016$) and tended at 3h ($p=0.038$). These results show that both populations of Kiss neurons are involved in the early stimulation of LH secretion by the “ram effect”.

Title: Non-ovarian aromatization regulates sexual motivation and receptivity in female quail

Authors: C. DE BOURNONVILLE[1], C. A. CORNIL[2], G. F. BALL[3], *J. H. BALTHAZART[2]; [1]Res. Group in Behav. Neuroendocrinology, Univ. of Liège, Liege, Belgium; [2]Univ. of Liege, B-

4000 Liege 1, Belgium; [3]Col. of Behavioral and Social Sci., Univ. of Maryland, College Park, MD

Abstract: Although aromatase is expressed in both male and female brains, its functional significance in females remains unclear. In male Japanese quail, we found that brain aromatase regulates both motivational and performance aspects of sexual behavior but that the latency of action of locally produced estrogens is different for the two responses. In female quail, sexual receptivity is activated by estrogens. However it is not known whether sexual motivation is similarly estrogen-dependent and whether estrogens locally produced in the brain contribute to these behavioral responses. 18 ovariectomized (OVX) females received a 20 mm long Silastic implant filled with crystalline testosterone (T) while 8 OVX females and 12 SHAM-operated females received an empty implant of the same size. Half of the T-treated females were also chronically treated with the potent aromatase inhibitor Vorozole and all other birds were injected in parallel with the vehicle solution. All birds were then tested for their motivation to approach a male sexual partner or a congener of either sex (sexual vs. social motivation) and for sexual receptivity. Ovariectomy induced a significant decrease of time spent in close proximity to the male. Treatment with testosterone partially restored this response and this effect was prevented when estradiol synthesis was inhibited by Vorozole. The total time spent near the male or the female (social motivation) was not affected by these treatments. Sexual receptivity (composite score including crouches and avoids) of OVX females did improve following T treatment and this effect was blocked by the aromatase inhibitor. These changes in receptivity reflected mostly effects on male avoidance behavior rather than on sexual crouches. Serum estradiol concentration was significantly higher in SHAM females than in all OVX groups and serum E2 was significantly higher in OVX+T than in OVX or OVX+T+Vorozole females. Together these data demonstrate that treatment of OVX females with T increases sexual motivation and aspects of sexual receptivity and that these effects are mediated at least in part by non-gonadal aromatization of the androgen. Crouching behavior was not significantly affected by T suggesting that this behavior requires exposure to higher doses of estrogens or is only activated after longer latencies. Brain aromatization likely contributes to the behavioral effects observed here following T treatment but alternative sources of estrogens (e.g. adipose tissue) should also be considered.

Title: Depressive-like behavior in same sex preference male rats with prenatal letrozole

Authors: *A. HERNANDEZ-GONZALEZ[1], A. FERNANDEZ-GUASTI[2];
[2]Farmacobiologia, [1]CENTRO DE INVESTIGACION Y ESTUDIOS AVANZADOS DEL I, mexico city, Mexico

Abstract: Commonly there is a sex preference difference: usually males select females, while females in estrus choose male sex partners. However, in all species studied there is a subpopulation that shows same sex preference. Prenatal administration of the aromatase inhibitor, letrozole, induces same sex preference in male rats. This effect is mediated by letrozole´s-induced decrease in brain estradiol levels along development, essential to organize the structures that mediate male sexual behavior in adulthood. In addition, there is a larger incidence in depressive symptoms in homosexual men in comparison with heterosexuals, apparently due to social factors. In this work we aim to explore the putative biological component of this difference. The experimental group received a daily prenatal letrozole (0.56µg/kg) injection to mothers from gestation day 10 to term (during 10 days) to induce same sex preference in some male rats' offspring. A control group received oil. The male offspring were left undisturbed until 3 months of age, when they were evaluated for sex preference (a box where the experimental male could choose to interact with a receptive female or a sexually experienced male) and time interacting with either stimuli. After the sex preference test all animals were subjected to the forced swim paradigm (FST) where immobility, swimming and climbing were recorded. The results showed an increased immobility (depressive-like behavior) in male rats with same sex preference as compared to males with female preference. Results also showed that there was a males' subpopulation that had a higher interaction with males (even sexual, lordosis or proceptivity), despite they spent more time with the female. In these males there was also an increased immobility in the FST. These results suggest that our method permits to discern at least two populations of males oriented to other males that consistently displayed higher levels of depressive like behavior.

Title: Hormonal response in enforced interval of copulation and copula add libitum in male rats

Authors: *T. M. MEDINA[1,2], M. ARTEAGA-SILVA[3], H. BONILLA-JAIME[3], M. HERNÀNDEZ-GONZÀLEZ[4];

[1]Univ. De Guadalajara, Guadalajara, Jalisco, Mexico; [2]Physiotherapy, Univ. Politecnica de la Zona Metropolitana de Guadalajara, Tlajomulco de Zuñiga, Jalisco, Mexico; [3]Reproductive Biol., Univ. Autonoma Metropolitana, Mexico, D.F, Mexico; [4]Behavior Neurophysiol., Univ. de Guadalajara, Guadalajara, Jalisco, Mexico

Abstract: Mating behavior is under the regulation of two main axis, it is activated by the hypothalamus-pituitary-gonadal axis (HPG) and inhibited by hypothalamus-pituitary-adrenal (HPA). An increase of Corticosterone (C) and Testosterone (T) after masculine sexual behavior has been reported in several mammal species, suggesting that both axes are activated simultaneously by sexual behavior. After sexual activity, plasma levels of C and T increase in sexual experienced male rats. Enforced Interval of Copulation (EIC) was described by Larsson (1956), this model consist of interruption of mating by means of the female withdrawal during one minute each time, until ejaculation. With this approach, it has been observed that this repeated interruption of copulatory interaction in experienced male rats decrease the time needed to achieve ejaculation. The aim of this study was to investigate what response in levels of T and C are caused by different intensities of sexual stimulation in sexually experienced and inexperienced male rats. Two groups of male rats, with and without sexual experience, were divided into four subgroups according to the copulatory scheme: copula *ad libitum* until ejaculation (CAD-E); Enforced Interval of Copulation up to 3 intromissions (EIC-3I); Enforced Interval of Copulation up to ejaculation (EIC-E); copula *ad libitum* up to 3 intromissions (CAD-3I) and in presence of receptive female during 20 min physically separated by a grid between them to prevent physical contact (GRID). The different sexual conditions correlated to higher plasma levels for C in both groups. Males with prior sexual experience had higher C concentration in plasma for all sexual conditions. The greater C levels was observed for EIC-E, they were significantly higher than the levels observed for CAD-E. The animals from EIC-3I and CAD-3I had the lowest levels among all groups; also we found differences between them. Plasma levels for T increased both, in experience and naïve group, after exposure to a receptive female, but only experienced males had significant differences compared with control group. In experienced males, T levels increased significantly in all the sexual conditions as compared with naïve males, no differences between subgroup were found. Males allowed to ejaculate showed an increase in plasma levels both for C and T. Altogether, these data showed that the increase of T and C levels strongly depends on sexual experience, which corroborate the simultaneous activation of HPA and HPG axes, interaction of both axes depends on the sexual conditions which can modulates the intensity and patterns of hormonal response following sexual activity.

Title: Neural circuits in the medial preoptic area associated with appetitive female sexual behaviour are modified by steroid hormones

Authors: *J. W. PAYNE, M. GRAHAM, K. GERMÉ, J. G. PFAUS;
Concordia Univ., Montreal, QC, Canada

Abstract: The medial preoptic area (mPOA) is critical for the control of appetitive sexual behaviours in the female rat, and dopamine (DA) receptor activation has been shown to mediate the display of these behaviours. We have also shown previously that DA receptors in this region are themselves dependent on the hormonal priming of the female. Specifically, in female rats primed with estradiol benzoate (EB) alone, activation of D2 receptors (D2R) in the mPOA increases appetitive behaviours, whereas in females primed with both EB and progesterone (EB+P) these behaviours increase after D1 receptor (D1R) activation (Graham & Pfaus, 2010; 2012). Modulation of DA receptors by estradiol and progesterone has been further demonstrated using Western blots, and females treated with EB alone had reduced D1R protein levels in the mPOA, whereas females treated with EB+P had increased D1R protein in the mPOA. D2R protein levels showed the reverse pattern. To further understand how ovarian steroids might affect the neural circuits in the mPOA associated with appetitive female sexual behaviour, the present experiment used fluorescence immunohistology to map pathways projecting from the mPOA to either the ventral medial hypothalamus (VMH) or the ventral tegmental area (VTA), areas known to regulate lordosis. Ovariectomized rats were infused with FluoroGold (FG), a retrograde tracer, into either the VMH or VTA 10 days prior to sacrifice. Rats were randomly assigned into one of three steroid treatment groups: EB+P (10µg and 500µg, respectively), EB+Oil, or Oil+Oil; with hormone injections administered 48h and 4h prior to sacrifice. Fluorescent immunohistology was conducted on mPOA slices to label either glutamate or GABA neurons, and neurons expressing D1R or D2R. Thus, in combination with the autofluorescence of FG-positive cells, we were able to quantify neuronal type, type of DA receptor expression, and if the neurons project from the mPOA to either the VMH or VTA. Preliminary results indicate that the administration of EB increased the number of GABA cells that expressed D2R. These data support previous findings demonstrating that ovarian steroids modulate the expression of DA receptors in the mPOA, and extend those findings to the identification of neurochemical systems that might be altered by mPOA DA release in the facilitation of appetitive sexual behaviour in the female rat. Title: Naloxone blocks neurogenesis in the olfactory bulb induced by paced mating in the female rat

Authors: *M. SANTOYO ZEDILLO, R. G. PAREDES, W. PORTILLO MARTÍNEZ;
Inst. de Neurobiologia, INB-UNAM, Queretaro, Mexico

Abstract: Previous research from our group, demonstrated that in the female rat a paced mating encounter increases the number of newborn cells in the accessory olfactory bulb (AOB). On the other hand, when female rats are allow to pace the sexual interaction they develop a positive affective (reward) state, evaluated by the conditioned place preference paradigm. This reward state is mediated by opioids because the intraperitoneal injection of naloxone (opioid receptor antagonist) blocks the change of preference induced by paced mating. In the present study we evaluated if blocking the opioid receptors could reduce the number of new cells that incorporate to the AOB generated during the first session of paced sexual contacts. Sexually-naïve female rats, bilaterally ovariectomized and hormonally supplemented were randomly assigned to one of five groups: 1) without sexual contact, 2)without sexual contact injected with naloxone, 3) females that mated without pacing the sexual interaction, 4) females injected with saline before paced mating and 5) females injected with naloxone before paced mating. An increase in newborn cells, BrdU inmunoreactive (BrDU IR), in the AOB of the females treated with saline that paced the sexual interaction was clearly observed when compared to the other groups. Naloxone administration before paced mating blocked the increase in the number of BrdU IR cells. These data support that opioid peptides have a fundamental role in the production of new cells in the olfactory bulb induced by paced mating in the female rat. Further research will need to determine the role of these newborn cells in the physiology of reproduction.

Title: Effects of the endocrine disruptor 2-4 dichlorophenol in male rat sexual behavior

Authors: *H. A. HURTAZO[1], F. QUINTANILLA[1], J. P. MAC GREGOR[2], M. CRUZ-SOTO[1]; [1]Univ. Del Valle De Mexico, Queretaro, Mexico; [2]Univ. Politecnica de Santa Rosa Jauregui, Queretaro, Mexico

Abstract: Chlorophenols present in the food chain and aquatic environment have been of great concern due to their potential endocrine disrupting effects on human health and wildlife. 2,4-Dichlorophenol (2,4-DCP) is a chemical substance primarily used as an intermediate in herbicide and dye manufacture. It has also been reported that 2,4-DCP can be formed as a degradation product of another herbicide component, 2,4-Dichlorophenoxyacetic acid. Phenols and chlorines naturally react with each other to form 2,4-DCP on disinfection of drinking water or on deodorization of polluted water processes. The administration of 2,4-DCP to female rats via drinking water during the pre-mating, mating, gestation and lactation periods at a concentration of 300 ppm caused a decrease in litter size and increased liver and spleen weights of F1 pups, although 2,4-DCP is suspected of having endocrine disrupting effects, there is still a lack of understanding on whether these endocrine responses can be manifested by an impairment of sexual behavior. In the present study, the endocrine disrupting effects of (2,4-DCP) on male sexual behavior were investigated. Sexually naïve male Wistar rats (300-350 g) were kept under a reversed 12-h light/dark cycle with free access to food and water. The animals were divided into two groups, one control and one administrated with 1.25 mg/day for 45 days. After 45 days of administration male sexual behavior was evaluated. The following parameters were recorded: 1) latency to the first mount and intromission; 2) number of mounts and intromissions; 3) ejaculation latency. The results demonstrated that 2,4-DCP affected male sexual behavior. We found a decrease of mount, intromission and ejaculation latency compared with control animals. Further studies are required to find out the neural mechanism involved in the sexual behavior effect and also, an analysis of aromatase expression in areas such as the olfactory bulb and medial preoptical area in response to 2,4 DCP administration.

Title: The role of experience and testing arenas on the ejaculatory threshold in male rats

Authors: *J. OLAYO-LORTIA, A. MORALES- OTAL, A. CRUZ-BENITES, A. FERREIRA- NUÑO;
Biologia de la Reproduccion, Univ. Autonoma Metropolitana - Iztapalapa, Mexico, Mexico

Abstract: The Multiple Partner-Choice Arena (MPCA) is a device developed in our laboratory, consisting of four acrylic cylinders arranged in a circle, with a small door located at the base of each cylinder where only the female can cross. Inside of each compartment, a sexually expert male rat (SEM) left, while in the central compartment a hormone-primed receptive female is allowed to choose the male to copulate with. Under these competitive conditions, in a previous study we demonstrate that all SEM ejaculate faster in comparison when they were tested in a standard arena (SA, a closed acrylic cylinder), since the parameters of the ejaculatory threshold (number of intromissions, and ejaculation latency), shown a significant reduction. To analyze the role of experience and testing arenas in the reduction observed on ejaculatory threshold in the MPCA, we compare two groups of sexually naïve male rats (n = 12) evaluated in both arenas (MPCA and SA) during four successive weekly sexual tests of 30-min. During the first 2 copulatory series of each test, the number of mounts (NM) and intromissions (NI) preceding each ejaculation, as well as mount (ML), intromission (IL) and ejaculation (EL) latencies, post-ejaculatory interval (PEI), ejaculation frequency (EF) and the hit rate (HR) were recorded. For the record of ML, IL, EL and PEI in the MPCA, only time those females spent in the compartment of each male considered. In comparison with the males tested in the SA, in the MPCA males shown a significant increase in ML and IL. However, a significant reduction in NM and NI on both copulatory series in most of the four tests obtained and consequently this provokes a significant reduction in the EF. No significant differences observed on EL, PEI and HR parameters in both groups of males. In conclusion, our results shown that the reduction obtained in the NI when male rats are tested in the MPCA depends on the competitive conditions, while the reduction observed in EL when SEM are tested in the MPCA depends on sexual experience.

Title: Investigating the role of ghrelin in male rat sexual behavior

Authors: *L. M. HYLAND[1], S. ROSENBAUM[2,3], B. WOODSIDE[3], J. PFAUS[3], A. ABIZAID[2];
[2]Neurosci., [1]Carleton Univ., Ottawa, ON, Canada; [3]Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: The physiology of reproduction in animals depends on the organism`s metabolic state and energy availability. The orexigenic peptide hormone ghrelin plays an integral role in energy metabolism and is known to have an inhibitory effect on reproductive physiology. In contrast, ghrelin and its receptor, the GHSR-1a, is also key for generating motivated behaviors, including sex behaviors. The aim of the current study was to investigate the effects of a GHSR knock out genetic manipulation animal model on appetitive and consummatory male sexual behavior using bi-level chambers. Male wild type (n=10) and GHSR KO rats (n=7) were exposed to sexually receptive females for 30 minutes inside bi-level chambers and were allowed to copulate. This protocol was followed every four days for a total of five sessions. During these sessions we measured appetitive (locomotor activity in anticipation of a female) and consummatory behaviors (latency to mount, intromissions, latency to ejaculate, and number of ejaculations). Results show that GHSR KO rats have a shorter latency to approach a female during the initial exposure to the female, and this effect disappears by the fifth session. Interestingly, male GHSR KO rats displayed less anticipatory locomotor activity in the bi-level chambers than their WT littermates. These data suggest that ghrelin has a modulatory effect on male rat sexual behavior, and may differentially affect appetitive and consummatory behavior.

Title: Sexually dimorphic brain nuclei in female rats that undergo same-sex preference conditioning

Authors: *M. B. TECAMACHALTZI-SILVARÁN[1], M. BARRADAS-MOCTEZUMA[2], L. I. GARCÍA[2], P. CARRILLO[2], J. MANZO[2], G. A. CORIA-AVILA[2];

Abstract: We have previously shown that under the effects of quinpirole (QNP a D2-type agonist) male rats can be easily conditioned to develop a same-sex partner preference. In a drug-free final test our conditioned males displayed a social and sexual preference towards the male partner over a sexually-receptive female. In addition, there was an increase in the area size of the supraoptic nucleus (SON), but no changes were observed in the preoptic area (SDN-POA) Behavioural Brain Research 283 (2015) 69-77. In the present study we assessed the area size of the SON and SDN-POA of female rats with conditioned same-sex preference. We used ovariectomized Wistar females, primed exclusively with estradiol benzoate (EB) 48 h prior to every conditioning trial. On the day of conditioning they received 1.25 mg/kg of QNP (i.p.) and 1 min later they were allowed to cohabitate during 24 h with a lemon-scented female, also primed with EB. Females were returned to their single home cages and this was repeated every four days, for a total of three trials. A first QNP-free preference test occurred four days after the last conditioning. Females were primed with EB+P and chose between two female partners (lemon-scented vs. unscented). The results indicated that females preferred the lemon-scented female as observed with more body contacts, sexual solicitations, and hops and darts. Females were reconditioned for two more sessions, and four days later were tested again for partner preference between one stud male and the lemon-scented female. The results indicated that QNP females displayed a similar preference for males over females, whereas control females preferred males. Four days later their brains were obtained and processed for the Nissl dye technique to assess the area size of SON and SDN-POA. Taken together, these results indicate that female rats primed exclusively with EB can be conditioned to develop a same-sex preference under the effects of enhanced D2-type receptor activity. The preference is observed with social and sexual behaviors when females are fully primed with EB+P. Such conditioning process appears not to affect the area size of SON and SDN-POA.

Title: Hypothalamic and peripheral oxytocin in the female rat and the effect of mating experience

Authors: M. L. LANGETT, *N. CAMERON;
Dept. of Psychology, Binghamton Univ., Binghamton, NY

Abstract: Sexual activity is known to affect the oxytocin (OT) neuron populations within the paraventricular nucleus (PVN) and the supraoptic nucleus (SON). However, specific factors influencing each nuclei's activation remain unknown. In addition, the effect of mating on plasma OT levels has not been consistently shown. We hypothesize that OT production in the brain and plasma levels are linked to the type of sexual experience, as assessed by pacing and vaginal cervical stimulations (VCS) received. To test this hypothesis Experiment 1 examined baseline OT levels in brain and plasma of proestrus or metestrus female rats. In Experiment 2, sexually-experienced ovariectomized steroid-primed females were used to study the effects of VCS and paced mating on OT levels. These females were either paced or not paced, and vaginally masked or unmasked during a 30 minute trial. For both studies, OT levels in the brain and plasma were analyzed with an enzyme-linked immunosorbent assay. In experiment 3, proestrus or metestrus females received an intraperitoneal injection of fluorogold five days prior to brain collection. OT peripheral projections from the PVN and SON were examined using immunofluorescence of the retrograde tracing of fluorogold and OT positive cells. Our results show a significant effect of estrous cycle on the SON, where OT concentrations were higher at proestrus ($p=0.02$). Estrous cycle did not affect OT concentration in PVN or plasma levels. Additionally, no significant correlation between the PVN, SON and plasma OT levels was found. In experiment 2, VCS significantly increased PVN OT concentration ($p=0.03$) but had no effect on SON or plasma OT levels. Paced mating had no effect on brain or plasma OT levels. In experiment 3, estrous cycle had no effect on the average number of dual labeled neurons in either nuclei suggesting that both the SON and PVN have the capacity to contribute equally to plasma OT levels. These results indicate the importance of VCS in PVN OT activation. However, the lack of correlation between PVN OT and plasma levels during mating suggest the PVN may not be releasing OT into the periphery. Interestingly, OT production in the SON did not increase during the two mating conditions and is not associated with sexual behavior in the experienced female rat. Additionally, only the SON OT levels are affected by estrous cycle. In conclusion, the lack of correlation between brain and plasma OT levels may imply a quick release of OT following the initiation of sexual activity that was not captured. Our findings demonstrate that in the rat the PVN and SON equally project to the periphery, and VCS only influences PVN OT production during mating in experienced female rats.

Title: Effect of sexual behavior on the prevention of testosterone-induced precancerous prostate lesions

Authors: *D. HERRERA-COVARRUBIAS[1], M. B. TECAMACHALTZI-SILVARAN[2], M. BARRADAS-MOCTEZUMA[2], J. MANZO[2], G. E. ARANDA-ABREU[2], N. ISMAIL[4], M. HERNÁNDEZ[3], G. A. CORIA-AVILA[3];

Abstract: Prostate cancer has been classically associated with androgens like testosterone (T) because they induce cell division and spontaneous mutations that could result in more abnormal cells within the gland. In previous studies we showed that rats treated with subcutaneous (s.c.) implants of T (100 mg/kg) during four weeks expressed precancerous prostate lesions such as dysplastic epithelium, apolarity of the nucleus, and abnormal Nucleus:Cytoplasm ratio (N:C 1:1). Because some studies suggest that the lack of sexual activity may be a risk factor for the development of prostate cancer, we explored such posibility in rats under the model of testosterone-induced lesions. A total of twenty wistar rats (250 g) were divided in two groups. One group received a s.c. implant of T, while the other, the control group, received an empty implant. Both groups bore the implant during 5 weeks. During that time the two groups were further divided into two subgroups. The first subgroup was allowed to have sex for 10 trials, while the second subgroup was only exposed to a receptive female for 10 trials without access to copulation. Sexual behavior occurred twice a week and was videorecorded and scored. After 5 weeks, animals were sacrificed with a lethal dose of sodium pentobarbital and the prostates were extracted and processed for H&E dye. Results showed that rats treated with T presented precancerous histological abnormalities in the dorsolateral and ventral portions of the prostate. Moreover, compared to controls, males treated with T displayed poor sexual performance during the first few trials. Sexual activity modulated the malignancy of the prostate lesions. In conclusion, five-week exposure to a high dose of T is sufficient to induce pre-cancerous lesions in the prostate. The lesions are modulated by sexual behavior, but the latter is also affected by high levels of T.

Title: Development of a conditioned ejaculatory preference in male rats is determined by their first sexual experiences

Authors: *G. R. QUINTANA ZUNINO, L. PRIMEAU, J. PFAUS;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Estrous odors of female rats are salient appetitive cues for male rats that compel them to move towards females in heat during their first sexual experiences. However, after baseline rate of sexual responding has been achieved, the importance of these cues tends to diminish, and at this stage learning becomes pivotal on the establishment of new associations. We have shown previously that male rats develop a conditioned ejaculatory preference (CEP) for females scented with a neutral odor like almond or lemon (ScF) that is paired with the male's post-ejaculatory reward state during repeated sexual experiences. The present study evaluated the behavioral and neural components of CEP for a neutral odor cue after manipulating the very first sexual experience(s) of male rat. Sexually naïve males were divided into two groups that received one or five trials of copulation to ejaculation with sexually receptive females either scented with almond odor (ScF) or not scented (UnScF). Following this training, half the animals in each group were given 10 subsequent copulatory trials with the other type of female (ScF for males trained first with UnScFs, or UnScF for males trained first with ScFs). On a final test, males were placed into a large open field with two sexually receptive females, one ScF and one UnScF. Males that had their first five experiences with either ScFs or UnScFs did not show a CEP for either female, nor did males that had their first sexual experience with the ScF followed by 10 trials with UnScFs. However, males that had their first sexual experience with an UnScF followed by 10 trials with ScFs displayed significant CEP for the UnScF in the open field, indicating that the odor conditioning had been inhibited by the first experience with the UnScF. Exposure to the scent cue before perfusion revealed different patterns of Fos-IR (neural marker for general neural activation) in regions of the nucleus accumbens and medial preoptic area. Altogether, these findings show a differential role of conditioned and unconditioned cues during a male rat's first sexual learning experiences on the development of CEP.

Title: Conditioning heterosexual preference in male rats with unconditioned same-sex preference

Authors: ***M. BARRADAS**, M. B. TECAMACHALTZI-SILVARAN, L. I. GARCÍA, P. CARRILLO, J. MANZO, G. A. CORIA-AVILA;
Neurosci., Ctr. De Investigaciones Cerebrales, Xalapa, Mexico

Abstract: Several studies in the last 50 years indicate that sexual dimorphism of the brain depends on the exposure (or not) during critical periods of development to testosterone (T) or its metabolite estradiol (E). Accordingly, demasculinized males are likely to display unconditioned same-sex preference when they reach adulthood. In addition, our group has shown that partner preference can be conditioned in adulthood when males cohabitate with males under the effects of the D2-type agonist quinpirole (QNP, 1.25 mg/kg, i.p.). In the present study we assessed the unconditioned same-sex preference of demasculinized males and then we conditioned them to prefer females. Male rats were divided in five groups, depending on whether or not they were to be demasculinized: Intact (I), sham castration at postnatal day 1 (ShPN1), castrated at PN1 (CXPN1), castrated at PN30 (CXPN30) and sham castrated at PN30 (ShPN30). At PN60 the unconditioned sexual preference was assessed before a male and a sexually-receptive female as potential partner choices. The results indicated that groups I, ShPN1 and ShPN30 displayed unconditioned sexual preference for the female. However, the group CXPN1 preferred the male, and the group CXPN30 showed a low interest towards the female but no indication of same-sex preference. Males from group CXPN1 were organized into three subgroups to undergo conditioning: a) cohabitation with a receptive female, b) cohabitation with a receptive female + QNP and c) QNP without cohabitation. Conditioning occurred every 4 days, for a total of three trials. For days after the last conditioning trial there was a second preference test to assessed conditioned preference. Male rats under the effects of QNP that cohabitated with a female did develop a heterosexual preference. However, neither cohabitation alone nor QNP alone induced a preference for the female. The results indicated that heterosexual partner preference can be conditioned in demasculinized males with unconditioned same-sex preference.

Title: The role of female sexual components on mate choice of the male rat in a multiple- partner choice arena

Authors: *A. FERREIRA-NUNO[1], A. CRUZ-BENITES[2], J. OLAYO-LORTIA[2], A. MORALES-OTAL[2];
[1]Univ. Autonoma Metropolitana, 09340 Mexico, DF, Mexico; [2]Biología de la Reproducción, Univ. Autónoma Metropolitana, México D.F., Mexico

Abstract: Rat is a polygamous species, since males and females mate with multiple partners simultaneously. To evaluate mate choice in the rat, our laboratory develop a Multiple Partner Choice Arena (MPCA), formed by 4 transparent acrylic cylinders (40 x 50 cm) placed in a circular fashion with a sexually expert male rat (MSE) in each. In the central area, an ovariectomized receptive female rat primed with estradiol benzoate and progesterone (OVX+EP) was placed, allowing the opportunity to choose the male to copulate with, entering in small doors which has the cylinders at its base. Under these conditions, we demonstrate that female rat copulate longer and receives more ejaculations from one of the four males. In order to demonstrate whether the male rat is also capable of preferring a particular female and evaluate the importance of female sexual components of attractivity (female odor), proceptivity (hopping, ear wiggling and darting) and receptivity (lordosis) in this selection, two groups of MSE (n = 7) were tested in a 6-cylinder MPCA. In the first 5-min olfactory test, in which the entries were sealed with wire mesh, sawdust from housing cages of 6 OVX+EP female rats were placed behind each door and the time spent investigating the female odor by each group of males were recorded. After the test, we selected the 2 most preferred females and 2 females less preferred by smell. Subsequently, in a second 5-min. olfactory test, we evaluated again the time spent investigating the female odor of the sawdust bedding of the 4 selected females. Finally in a third 30-min. sexual contact test, in which the wire meshes were removed and the sawdust was replaced by the corresponding female, we recorded: the time spent by male in front of each cylinder, the number of intromissions and ejaculations that each female received from each male, the number of proceptive and receptive female behaviors displayed during the visit of each male, and the order in which the 4 females were visited. The three tests were performed weekly, 3 times. Considering the most preferred female, the female that received more ejaculations, the number of ejaculations were correlated with the aforementioned parameters of the female sexual components: attractivity, proceptivity and receptivity. Males showed a significant preference for one of the females in 83% of tests and this preference was correlated with the characteristics of the female in the following order: lordosis (r = 0.76), ear wiggling (r = 0.74), darting (r = 0.62), hopping (r = 0.34), time spent in the male compartment (r = 0.21) and visitation order (r = 0.15). Therefore, male rats prefer significantly those female rats showing more lordosis and ear wiggling.

Title: Biphasic effects of intra-VTA anandamide administration on sexual behavior expression of the male rat

Authors: A. CANSECO-ALBA, *G. RODRIGUEZ-MANZO;
Cinvestav-Sede Sur, IPN, Mexico City, Mexico

Abstract: Male sexual behavior, like other rewarding behaviors, is modulated by the dopaminergic mesocorticolimbic system (MSL). The dopaminergic neurons of the MSL system originate in the ventral tegmental area (VTA) and project mainly to the nucleus accumbens and the prefrontal cortex. Endocannabinoids (eCN) are retrograde transmitters that modulate MSL activity by regulating GABA and glutamate release both at the VTA and the nucleus accumbens. VTA eCN receptors have been suggested to play a key role in the regulation of motivation, therefore eCN play an important role in the regulation of rewarding behaviors through the modulation of MSL activity. We recently reported that the systemic administration of the eCN anandamide (AEA) exerts dose-based biphasic effects on copulation, facilitating its expression at low doses. On this basis we hypothesized that AEA might exert its effects on male sexual activity by acting at the MSL system. The objective of this work was to determine if intra-VTA AEA administration to sexually experienced male rats reproduced the biphasic effects on copulatory behavior observed after its systemic administration. To this aim, independent groups of sexually experienced male Wistar rats were bilaterally infused with different AEA doses (0.1 - 3.0 μg/rat) into the VTA and subjected to a 60-min sexual behavior recording with a sexually receptive female. Results showed that the lower AEA doses (0.3 and 1.0 μg/rat) facilitated sexual behavior expression, while the highest dose tested (3.0 μg/rat) had inhibitory effects on copulation. None of the tested doses significantly modified the animals' spontaneous ambulatory behavior. It is concluded that AEA exerts its modulatory effects on male rat sexual behavior expression by interacting with the MSL dopaminergic system.

Title: The effects of acute prenatal exposure to valproic acid on sociosexual behaviors and anxiety in female rats

Authors: *S. M. HARDING, J. A. CAPUTO, S. R. BARRETT, E. C. MASTERS, M. M. MCDONOUGH;
Psychology Dept, Fairfield Univ., Fairfield, CT

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that is characterized by enhanced anxiety, social impairments, and deficits in communication. In rodents, exposure to the antiepileptic drug valproic acid (VPA) has been linked to ASD-like behavioral changes in males, although studies using females have been limited and inconsistent. Therefore, the present study was conducted to examine long-term effects of early exposure to VPA on social behaviors and anxiety in female rats. Pregnant Long Evans rats were injected s.c. with saline (Control, n=1), Low VPA (350mg/kg; n=2), or High VPA (600 mg/kg; n=2) on gestational day 12.5. In adolescence, the female offspring were tested for social interactions with female conspecifics using a social preference test, and anxiety was assessed with an emergence test. Preliminary data analysis suggests that prenatal VPA exposure had no effect on social preference. In the emergence test, females exposed to High VPA spent less time in the closed portion of the apparatus compared to Low VPA ($p < .02$) and Control groups ($p < .08$), suggesting heightened anxiety. These findings were consistent with what we have reported with male rats. In adulthood, all female rats were ovariectomized and received injections of estradiol benzoate and progesterone before undergoing tests for sociosexual behavior with male rats, including test for copulation, partner preference, and 50kHz vocalizations. VPA groups were compared to saline Controls and a separate group of sexually experienced females. Preliminary data analysis reveals that High VPA and Low VPA groups showed significantly fewer ear wiggles than sexually experienced females ($p < .03$ and $p < .002$, respectively), suggesting reduced proceptivity. In addition, lordosis was observed less frequently in the High VPA group compared to Sexually experienced females ($p < .05$) suggesting reduced receptivity. After a single sexual encounter, both Low VPA and High VPA groups showed increased preference for an intact male vs. a castrate compared to Controls ($p < .05$), suggesting enhanced sexual motivation. Surprisingly, no differences between groups were seen in 50kHz vocalizations. These results suggest that acute exposure to VPA during development may be sufficient to induce anxiety in female rats, but that the effects of VPA exposure on social interactions vary based on dose and type of interaction, i.e. same sex conspecifics vs. sexual partners. These findings will be discussed in comparison to what we have reported with males, and have important implications for the study of ASD in females.

Title: One of these things is not like the other: Sign-tracking for sucrose does not predict sign-tracking for sex

Authors: ***L. M. SPARKS**, V. BOUZO, V. PALLIKARAS, D. DI GREGORIO-RIFIORATI, A. SHARMA, S. KANTHASAMY, J. G. PFAUS;
Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Repeated pairings of a conditioned stimulus (CS) with an unconditioned stimulus (US) result in individual differences in Pavlovian-conditioned approach (PCA) toward the CS (sign-tracking; ST) or US (goal-tracking; GT). Furthermore, such differences extend across different types of reward; animals that exhibit ST for food reward also ST for drug reward. Studies have yet to examine whether these differences extend to sexual reward. Objective: The present study examined whether rats identified as ST or GT following sucrose conditioning would continue to exhibit ST or GT when an ejaculatory reward state served as the US. Method, Phase 1: Sexually-naïve, male, Long-Evans rats received 16 autoshaping sessions in operant chambers, where a lever (CS) predicted the availability of sucrose (US; 10% w/v) delivered into a fluid port. Phase 2: Rats received 13 Pavlovian conditioning trials in an individualized compartment of an open field chamber, where an orange cone (CS; 2-min/presentation) predicted the opportunity to copulate to ejaculation in a separate compartment with a receptive female (US). Pavlovian-conditioned approach toward the CS (ST) and US (GT) was measured by the proportion of time spent in an area located around the CS or door to the female compartment, respectively, in the absence and presence of the cue. Preliminary Results, Phase 1: Sign-trackers displayed significantly greater lever contacts, significantly shorter latency to the first lever contact, and significantly longer latency to the fluid port compared to goal-trackers. Phase 2: On trials 1 and 7, rats did not display CS- or US-directed behavior; no differences were observed in the proportion of time spent in the CS- and US-designated areas. On trial 13, individual differences in PCA were detected; a subset of rats spent significantly more time in the CS-designated area (ST), another subset spent significantly more time in the US-designated area (GT), and others were identified as intermediates. For rats displaying ST and GT using sucrose reward, only one-third maintained their phenotype following sexual conditioning. Conclusions:

These results provide further evidence that conditioned cues acquire incentive motivational properties through Pavlovian conditioning using sucrose or sexual reward. Importantly, our preliminary findings suggest that individual differences in PCA responses might not extend to all types of reward. Instead, such differences are dependent on the nature of the reward itself.

Title: Investigation of glutamate neurotransmission during sex behavior in female Syrian hamsters

Authors: *K. M. MOORE, L. E. BEEN, R. L. MEISEL;
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Female sexual behavior is a fundamental motivated behavior for which there is an extensive literature on its underlying neurobiology. Despite this wealth of information, there is surprisingly little known regarding the neurotransmission associated with different components of the female's ongoing sexual interactions with the male. While dopaminergic signaling has traditionally been examined in this area, glutamate is the major excitatory neurotransmitter in the central nervous system, and is well known for its involvement in long-term potentiation and synaptic plasticity in both learned and motivated behaviors. Nonetheless, glutamatergic neurotransmission has been largely understudied in naturally motivated behaviors, particularly sex behavior, partially due to technical limitations in measuring glutamate release in real time. Classic electrochemistry based on oxidation/reduction such as fast scan cyclic voltammetry for dopamine was not possible as glutamate is non-electroactive. Our study utilized a technique involving enzymatic biosensors to elucidate the effects of male copulatory behavior on glutamate release in multiple regions of the female brain. Our goal is to determine how this patterning of glutamate release is associated with various components of sexual behavior, including its motivation and termination. Our results suggest that the pattern of glutamatergic neurotransmission in different brain regions in the female hamster may be responsible for

encoding distinct properties of the female's copulatory interaction with the male. Specifically, the prefrontal cortex appears to encode overall bouts of male copulatory behavior, which we hypothesize may be responsible in signaling to downstream regions responsible for copulatory reward. In contrast, recordings restricted to the ventrolateral portion of the ventromedial nucleus of the hypothalamus appear to encode individual vaginal cervical stimulations, which we hypothesize may be involved in signaling termination of sexual receptivity. We aim to continue to advantage of this biosensor technology and mating patterns in female Syrian hamsters to further characterize the regions examined in this study, as well as other regions of interest such as the medial amygdala, an area implicated in the endocrine cascade to set up the progestational state. These studies will develop a comprehensive picture of the relation of *in vivo* glutamate release in the female brain to individual components of sex behavior.

Title: Using fast-scan cyclic voltammetry to measure dopamine release from the nucleus accumbens of female hamsters during sex behavior

Authors: *L. E. BEEN, S. R. EBNER, B. T. HIMMLER, R. L. MEISEL;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: In many mammals, reproductive success depends on a female receiving an optimal pattern of vaginal stimulation during mating. Despite the evolutionary importance of this species-specific "vaginal code", the neural mechanisms underlying the female's regulation of vaginal stimulation during mating are poorly understood. Previous research in our lab suggests that dopamine release in the nucleus accumbens is an integral component of how female hamsters control the receipt of vaginal intromissions by a male. Using fast-scan cyclic voltammetry we can measure dopamine release from the nucleus accumbens of female hamsters during mating behavior to track the receipt of vaginal intromissions during mating behavior with sub-second temporal resolution. Adult female hamsters were ovariectomized and implanted with a unilateral cannula dorsal to the nucleus accumbens core. A chlorinated silver reference electrode was implanted in the contralateral forebrain and a stainless steel stimulating electrode was implanted the ipsilateral ventral tegmental area. Following recovery, females were hormone-

primed to induce sexual receptivity and an acute carbon-fiber electrode was lowered into the nucleus accumbens using a micromanipulator. Females were paired with a stimulus male and background-subtracted dopamine transients were recorded during a 10-minute sex behavior test. Voltammetry recordings were time-stamped to video recordings of behavioral tests so that dopamine transients could be correlated with individual behavioral events. Our preliminary results suggest that dopamine transients are time-locked to the receipt of vaginal stimulation by the male. Future experiments will test the hypothesis that sexual experience can shift the pattern of dopamine release such that dopamine transients anticipate the receipt of vaginal intromission by the male. These data provide the first example of measuring dopamine release in real time during female sex behavior and are the first steps in uncovering the neural mechanisms by which females regulate the timing of mating behavior.

Title: A single dissociation: Intranasal oxytocin alters affiliative but not sexual cues

Authors: *N. M. Y. KUEK[1], J. C. J. LIU[2];
[2]Div. of Social Sci., [1]Yale-Nus Col., Singapore, Singapore

Abstract: A common assertion amongst theories of love is that there exist distinct systems of love. More recently, anthropologist Helen Fisher suggested that these systems may have dissociable underlying mechanisms: lust is regulated by estrogens and androgens; attraction by dopamine, norepinephrine, and serotonin; and attachment by oxytocin and vasopressin. In support of this notion, one study found that natural variations in plasma oxytocin levels correlate with non-verbal expressions of attachment (affiliation cues), but not with non-verbal expressions of lust (sexual cues). To the extent that this suggests separate systems dissociable at the neuroendocrine level, we sought to investigate whether administration of oxytocin would selectively alter the expression of affiliation but not sexual cues. 102 healthy young adults were administered either intranasal oxytocin or a placebo, and were paired with an unfamiliar participant of the opposite gender. Participants were given discussion questions that induced varying degrees of intimacy (low, medium, high), and were video-taped during their discussions. Subsequently, two trained coders independently coded the video for displays of sexual cues (lip bite, lip suck, lip lick, tongue protrusion, lip pucker) and affiliation cues (nod, Duchenne smile,

gesticulation, lean). We found a significant three-way interaction between the type of non-verbal cue (affiliation vs. sexual), drug condition (oxytocin vs. placebo), and intimacy level of the discussion (low vs. medium vs. high; $F(2, 99) = 3.39$, $p = .04$). Namely, for affiliation cues, oxytocin participants displayed fewer cues than placebo participants when discussing medium and high intimacy questions. However, for sexual cues, there were no main or interaction effects involving participants' drug condition. Our finding of a single dissociation supports the idea that different love systems are independently regulated by different hormones. We note, however, that *within* the affiliation system, our findings suggest a complex, context-dependent relation between oxytocin levels and the expression of cues.

Title: Acute postnatal phthalate exposure results in both an immediate and long-term deficit in the masculinization of crucial neural circuits in the male rat brain

Authors: *M. R. HOLAHAN, A. WEIR, C. SMITH;
Dept Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Phthalates are synthetically-derived chemicals used to soften and provide malleability for a variety of common household and personal care products. Because they are not chemically bound to these products, they are easily released into the environment and, due to their high oil solubility, they readily infiltrate biological systems. Studies examining the biological impact of phthalate exposure on developing organisms are critical given that estimates of phthalate exposure are considerably higher in infants and children compared to adults. In this regard, phthalate exposure has been shown to disrupt Sertoli and Leydig cell function during sensitive developmental periods. A reduction in the number or in the functioning of Sertoli and Leydig cells can lead to reduced testosterone and estradiol levels in the brain which may interfere with the organizational effect of these sex steroids resulting in long-lasting changes in the nervous system and behavioral outcomes. Our published data (to be re-illustrated) has shown that post-natal exposure to phthalates (PND16 - PND22) has an immediate (but not readily apparent long-term or organizational) impact on the masculinization of hippocampal CA3 axonal inputs and CA3 spine density arrangements. Spine density on third and fourth order basal dendritic branches and second, third and sixth order apical dendritic branches of CA3 neurons was reduced in male

rats to control levels seen in female rats following exposure to phthalates. New data have revealed that post-natal exposure to phthalates during the same timeframe (PND16-PND22) resulted in persistent, long-term deficits in the masculinization of dopamine cell densities in the ventral tegmental area and, to a lesser extent, in the substantia nigra. These data indicate that phthalate exposure during sensitive post-natal developmental periods may impede both the activational and organizational effect of sex steroids on the masculinization of critical memory- and reward-related brain circuits in the male brain. Phthalate-induced interruption of these organizational effects may have consequences on the frequency of sexually-dimorphic behaviors in males such as courtship displays, territorial aggression, mating, and parental care.

Title: Hypothalamic modulation of mesolimbic reward circuitry: a functional tracing study

Authors: *O. IYILIKCI[1], J. BALTHAZART[3], G. F. BALL[2,4];
[2]Psychological and Brain Sci., [1]Johns Hopkins Univ., Baltimore, MD; [3]GIGA Neurosciences, Univ. of Liege, Liege, Belgium; [4]Dept. of Psychology, Univ. of Maryland, College Park, MD

Abstract: There is ample evidence indicating that the medial preoptic nucleus (POM), Lateral Hypothalamus (LHA), paraventricular nucleus PVN and the mesolimbic reward circuitry are implicated in regulating sociosexual behaviors in vertebrates. However, there is a paucity of studies investigating the potential interplay of hypothalamic and mesolimbic reward systems, particularly in the case of male sexual behaviors. We argue that projections originating from POM, LHA and/or PVN may play a modulatory role on the mesolimbic reward circuitry related to sexual behavior. The present study, therefore, aimed to elucidate whether cells in POM, PVN and LHA that have projections to VTA are activated during sociosexual interactions. To this aim, we stereotaxically injected a biotinylated dextran amine (BDA) into VTA as a neuroanatomical tracer. At low molecular weights (3kDa), BDA retrogradely labels cell bodies that send projections to the injection site. One week after the injections, male quail in the experimental group interacted freely for 15 minutes and demonstrated stereotypical appetitive and consummatory sexual behaviors. Animals in the control condition were placed in same experimental apparatus without a female stimulus for the same amount of time. 90 minutes after testing, subjects' brains were prepared for triple immunohistochemical labeling of BDA, FOS

and Orexin. Our results demonstrated a significant increase in Fos-immunoreactivity (ir) in POM in response to sociosexual interactions, similar to the previous findings. More interestingly, among the retrogradely labeled BDA cells in POM, we found significantly more FOS labeled associated with sociosexual interactions. Our results, so far, indicate that cells with direct projections from POM to VTA exhibit enhanced Fos-ir while the birds are engaging in appetitive and consummatory sexual behaviors. These data are consistent with the known role of the POM in regulating sociosexual behaviors, especially for appetitive sexual behaviors.

Title: The neurobiology of reproductive competition

Authors: S. M. BOWDEN[1], M. H. FERKIN[2], G. J. DE VRIES[1], *A. PETRULIS[1]; [1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Dept. of Biol. Sci., Univ. of Memphis, Memphis, TN

Abstract: To optimize reproductive fitness, brains control timing of ejaculation as well as amount of sperm per ejaculate. The latter happens when males compete to fertilize the eggs of a single female, a condition termed sperm competition. When competition is high, males can increase the amount of sperm per ejaculate, a phenomenon called sperm loading (SL). For example, meadow voles double the amount of sperm per ejaculate within 30 minutes after exposure to the odor of a competing male; they do so without changing reproductive behavior. Although the neural circuits underlying SL have not been identified, the paraventricular and supraoptic nuclei of the hypothalamus (PVN and SON) are well positioned to mediate these effects. They could do so in two ways: via hormonal release of vasopressin (AVP) and oxytocin (OT), both of which increase contractions of the myoepithelium in reproductive ducts that propel sperm, or by actions on the autonomic nervous system via descending PVN projections to the spinal cord. Our preliminary data suggests that peripheral blockade (via Manning compound) of AVP receptors significantly decreases, but does not eliminate, SL in meadow voles. This suggests that magnocellular AVP neurons in the PVN and SON are involved in SL. We are bolstering this hypothesis by using immunohistochemistry to co-localize odor-induced cFos protein expression and OT or AVP in the PVN/SON of male voles exposed to odors signifying high sperm competition (male + female odors) or low sperm competition (male only or female only).

Title: Dopamine signaling in the nucleus accumbens is necessary for sexual preference in male mice

Authors: ***Y. BENY**, T. KIMCHI;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Sexual preference to opposite-sex individuals is an innate, essential behavior for successful reproduction and propagation of all animal species. Males' sexual preference and motivation to approach female stimuli are triggered by female pheromonal signals and depends on the animals' endocrine state and internal drive. Here we tested the hypothesis that the innate attraction of males to females pheromones and sexual preference are mediated by dopamine release within the nucleus accumbens (NAc). Male mice with a mutation in the TrpC2 gene, a crucial component expressed in sensory neurons of the vomeronasal organ (VNO), fail to detect pheromones through the VNO, do not express olfactory preference for female over male odors, and exhibit sexual behavior indiscriminately toward both sexes. We applied a conditioned olfactory aversion (COA) paradigm on adult wild-type (WT) and TrpC2-/- mutant male mice. According to this paradigm, mice were exposed to female pheromones, followed by either lithium-chloride (LiCl) or saline IP injections and were tested for their sexual preference, motivation and consummatory sexual behaviors. We show that TrpC2-/- mutant males are capable of learning a specific-aversion to female pheromones and thus to discriminate between sex odors, in a similar manner to WT males. Next, we quantified dopamine release in the NAc during interaction with an alien female and male conspecifics, using an in-vivo microdialysis assay. We found that in WT males, exposure to a female conspecific, but not to a male, lead to a significant elevation in dopamine levels in the NAc. In contrast, in TrpC2-/- males, exposure to female stimuli failed to induce elevation in accumbens dopamine levels. Finally, we show that WT males bilaterally injected with D1R antagonist in the NAc failed to develop conditioned place preference for female pheromones, and lost their sexual preference. In summary, our study demonstrates that the representation of the intrinsic rewarding value of female pheromones driving the innate sexual preference of males to females is coordinated by NAc dopamine, possibly via D1 receptors and is VNO-mediated.

Title: Spargel overexpression in dopaminergic neurons induces male-male courtship

Authors: *K. WU[1], J. QIAO[1], C. QIAN[2], Y. KE[1];
[1]Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Hong Kong, China; [2]Sch. of Pharm., Fudan Univ., Shanghai, China

Abstract: Peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α) is well-studied in muscle and liver, and has been regarded as the master regulator of mitochondria. Its functions include mitochondrial biogenesis, regulation of cellular energy metabolism and reactive oxygen species suppression. Recently, dopaminergic (DA) neurons, which control locomotor ability, arousal, rewards and courtship, have been found to be selectively sensitive to sustained PGC-1α overexpression. In our study, we overexpressed the PGC-1α fly homolog, spargel, in DA neurons to investigate the effect of spargel on DA neurons and fly behaviors. Our results indicated that spargel overexpression did not significantly affect survival rate and locomotor ability. However, increased inter-male chain activity, which usually reflects changes in courtship behavior, was observed in spargel overexpressing flies 10 days post-eclosion. Paired courtship assays revealed that courtship towards males was significantly enhanced upon spargel overexpression but not in courtship towards female. Immunohistochemical analysis on whole-mount brain did not indicate any significant changes in DA neuron number and morphology. Increased mitochondrial DNA copy number, which indicates mitochondrial biogenesis, was detected in fly heads with spargel overexpression. To conclude, our findings showed that spargel overexpression in DA neurons could selectively upregulate male-male courtship and such behavioral change might be associated with increased mitochondrial biogenesis in DA neurons.

Title: The incentive value of multisensory stimuli in male rats

Authors: *E. M. SNOEREN, A. ÅGMO;
Univ. of Tromso, Tromso, Norway

Abstract: Male rats prefer a hormonally primed female rat over a male rat in a sexual incentive motivation test. Since approach to a conspecific must depend on distant stimuli, the modalities involved can be vision, movement, olfaction or audition. Previous studies have shown that the playback of 50 kHz ultrasonic vocalizations (USV) have no incentive value, while the odor of a receptive female induces approach behavior. In this study, we investigated what stimulus or what combination of stimuli (multisensory) is required to induce approach behavior in males. Male rats (n=12) were placed in a sexual incentive motivation test for 10 minutes and presented with two incentives: a male rat and 'another stimulus'. The following stimuli were used in a randomized order: an empty box, a receptive female, the odor of a receptive female, an anesthetized receptive female, a devocalized receptive female or the playback of USV. The different stimuli were sometimes presented together in different combinations as multisensory stimulus. All possible combinations of stimuli were presented. When a multisensory stimulus excluded odor, an anosmic subject male rat was used. The results show that the modality of only olfaction, moving, or vision (but not audition) is enough to remove the preference for social contact with a male. Both incentives were approached equally. A multisensory stimulus of at least 2 modalities, however, was sufficient to induce approach behavior towards the stimulus. One of these modalities needed to be the smell of a receptive female. The multisensory stimulus of smell and USV, though, failed to have an incentive value over the male rat. In conclusion, the modalities moving, vision and olfaction are important for the attraction of conspecifics. But a multisensory stimulus of 2 modalities is necessary to induce preference for the stimulus over social contact with a male rat. The playback of USV, however, seems to decrease the incentive value of the different stimuli.

Title: Comparing the efficacy of maternal fluoxetine and exercise in a rodent model of postpartum depression: outcome of both mother and male and female offspring

Authors: *A. R. GOBINATH[1], R. J. RICHARDSON[2], C. CHOW[2], J. L. WORKMAN[2], S. E. LIEBLICH[2], A. M. BARR[3], L. A. M. GALEA[2];
[1]Neurosci., [2]Psychology, [3]Anesthesiology, Pharmacology, & Therapeut., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Postpartum depression (PPD) affects approximately 15% of mothers and can have negative effects on the mother-infant dyad. Pharmacological antidepressants such as fluoxetine (Prozac) are commonly used to treat PPD. However, fluoxetine can remain active in breast milk and potentially impact offspring development. For this reason, non-pharmacological therapies, such as exercise, may be more agreeable. Unfortunately, it is unclear whether exercise is efficacious for treating PPD while preserving normal offspring development. To investigate this, we treated dams daily with high levels of corticosterone (40 mg/kg), to induce a depressive-like phenotype, or oil during the postpartum. Within the oil and corticosterone conditions, four additional antidepressant groups were created: 1. Fluoxetine (Prozac; 10 mg/kg) + exercise (voluntary access to running wheel); 2. Fluoxetine + no exercise; 3. Saline (vehicle for fluoxetine) + exercise; 4. Saline + no exercise. Male and female offspring were weaned and then tested in adulthood for anxiety-like behaviour using the novelty suppressed feeding task and for stress reactivity using the dexamethasone suppression test. Preliminary findings indicate that maternal postpartum fluoxetine reversed corticosterone-induced disruptions in maternal care, regardless of exercise condition. Additionally, preliminary findings indicate that exercise had a greater antidepressant-like effect than fluoxetine for the dams. For this reason, we predict that exercise will result in a protective effect particularly in the adult male offspring. Our findings will shed light on how the postpartum antidepressant treatments (Prozac, exercise) differentially affect the well-being of the mother as well as the male and female offspring. Title: Estrogen receptor alpha expression in the auditory cortex changes across motherhood

Authors: *A. MORENO[1], K. K. CHONG[3,2], T. N. IVANOVA[2], R. C. LIU[2];
[2]Biol., [1]Emory Univ., Atlanta, GA; [3]Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Maternal response to infants requires sensitivity and detection of infant specific sensory cues, yet how these social cues are processed to enhance responsiveness is not fully understood. It is hypothesized that changes in sensory neural encoding are responsible for enhanced processing of social cues (Miranda, 2009). Mouse mothers quickly learn to respond to pup-calls and display long-term neural plasticity in the auditory cortex (AC) for those calls. Because estrogen treatment enhances pup-call responsiveness in non-mothers (Koch, 1989), parturition related estrogen exposure might be responsible for the enhancement of social auditory cue processing in the AC. To determine estrogen's role in pup-call representation enhancement in the AC, it is important to determine if estrogen can have a direct effect on AC neurons. To achieve this, we characterized the distribution of the most common auditory cortical estrogen receptor, estrogen receptor alpha (ERα), over the course of parturition and motherhood. Age matched animal groups included female virgin pup-naive, late pregnancy pup-naïve, early and late mother mice. ERα immunohistochemistry was performed on 40μm thick brain sections containing the primary AC. Our results indicate a large number of ERα immunoresponsive (IR) neurons throughout the AC across motherhood. There was no change in ERα -IR density moving from rostral to caudal in the AC. Comparing across conditions using a one-way ANOVA, there is a significant difference in the density of ERα-IR neurons between conditions ($F_{3,9} = 5.9$ $p < .001$). Density of ERα-IR neurons peaked in pregnant females, similar to the endogenous estrogen peak during late pregnancy (Miranda, 2009). Not only are AC neurons sensitive to estrogen but also estrogen concentration might alter AC ERα expression. ERα-IR density in late mothers was significantly lower than pregnant females ($p = .001$), and dropped below virgin pup-naïve levels. Because late mothers are known to retain maternal responsiveness (Ehret, 1989), this suggests that AC ERαs might not be necessary for mothers to maintain enhanced neural responses to pup-calls. Our findings are consistent with previous work hypothesizing that estrogen acts as a priming mechanism, preparing the AC for social auditory learning of pup-associated cues (Banerjee, 2013). Estrogen associated molecular mechanisms are a fertile area for social auditory communication research and can determine how sensory encoding fits into the picture of maternal response.

Title: Effects of reproductive state on the expression of oxytocin receptor mRNA and protein in the midbrain raphe nuclei of female rats

Authors: *Z. GRIEB, J. LONSTEIN;
Neurosci. Program, Michigan State Univ., East Lansing, MI

Abstract: The female brain undergoes tremendous neurochemical changes across different reproductive states, which during the peripartum period facilitate females' ability to adjust to the increased investments of motherhood and properly care for offspring. This facilitation of maternal behavior is, in part, achieved through changes in central oxytocinergic systems. For example, oxytocin signaling is upregulated in forebrain regions important for the display of maternal behaviors, including the medial preoptic area. This is functionally relevant, as antagonizing oxytocin receptors in the medial preoptic area interferes with normal maternal behaviors. This area of research, though, has largely ignored the midbrain. Given some recent evidence demonstrating an interaction between the oxytocinergic and serotonergic systems in mediating social reward, we are investigating the expression of oxytocin receptors in the midbrain raphe nuclei (the source of most central serotonin) in female rats across different reproductive states. To accomplish this, we are using qRT-PCR to examine oxytocin receptor mRNA expression in the raphe nuclei across four different reproductive states: diestrus virgin, pregnancy day 10, ~3 hours of parturition, and postpartum day 7. We are also conducting autoradiography using a highly-selective oxytocin receptor ligand to quantify the density of oxytocin receptor binding in the raphe at these same time points. We predict that oxytocin receptor mRNA and protein will be upregulated in the raphe nuclei soon after parturition, which would be consistent with what is found in some forebrain regions regulating maternal behavior. We also predict that while the pregnancy day 10 and postpartum day 7 groups will have lower oxytocin receptor expression compared to the day of parturition group, both groups will have higher expression than the virgin controls. This research will contribute to the growing literature examining how interactions between the oxytocinergic and serotonergic systems influence social behavior, and as far as we are aware, the first to investigate the expression of oxytocin receptors in the midbrain raphe nuclei across numerous reproductive states in the brain of any female animal.

Title: Ultrasonic vocalizations and parenting in a rat model of postpartum depression

Authors: *M. PEREIRA;
Dept. of Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Postpartum depression is a serious psychiatric condition that has deleterious effects on the mother, and poses a risk for the mother-infant relationship and ultimately the infant's development. Maternal anhedonia is a major clinical feature central to postpartum depression and likely contribute to deficits in parenting. The present study used Wistar Kyoto (WKY) mother rats, an animal model of depression-like symptomatology which we have developed to examine the postpartum disorder (Pereira et al. 2012), to investigate the relationship between depressive-like symptoms and parenting disturbances. WKY and Sprague Dawley (SD) postpartum females were examined for their affective responses to the cues and behaviors of the pups, as measured by their ultrasonic vocalizations (USVs) during a maternal behavior test. Both WKY and SD mothers predominantly produced ~50 kHz USVs when interacting with the pups in the maternal behavior test. Preliminary analysis of results indicates that WKY mothers exhibited fewer vocalizations in response to social cues from pups as compared with SD mothers. Similarly, WKY mothers exhibited substantial disturbances in their maternal behavior. Taken together, these results provide evidence for the presence of maternal USVs during mother-litter interactions, and further suggest that variations in USVs produced by mothers during social interaction with their pups may function as an index of their positive maternal affect. Rat USVs may be used for to study the neurobiological mechanisms underlying maternal affect in animal models of postpartum disorders.

Title: Immediate early gene activation in post parturient oxytocin receptor forebrain knockout mice

Authors: *S. K. WITCHEY[1], K. GERBIG[1], H. K. CALDWELL[1,2];
[1]Biol. Sci., Kent State Univ., Kent, OH; [2]Sch. of Biomed. Sciences, Kent State Univ., Kent, OH

Abstract: In females, the oxytocin (Oxt) system is not only important to parturition and milk ejection but plays a role in the initiation of maternal behavior. Previous work from our lab has shown that disruption of Oxt signaling in total body Oxt receptor knockout (Oxtr−/−) mice and forebrain-specific oxytocin receptor knockout (OxtrFB/FB) mice results in significant increases in the abandonment of first litters relative to control mice. These data suggest that Oxt, signaling through the Oxtr, lowers the threshold for the initiation of maternal care. To determine where Oxt may be acting in the brain to affect maternal care in our mice, we examined immediate early gene activation, i.e. cFos, in OxtrFB/FB and wildtype brains that were collected approximately one hour after parturition. We hypothesized that there would be differences in cFos immunoreactivity in brain areas known to be important for the onset of maternal care, such as the paraventricular nucleus, the supraoptic nucleus, the medial preoptic area, the bed nucleus of the stria terminalis, and the lateral septum. We predicted that OxtrFB/FB would show reduced c-Fos activation in some of these brain areas. We found that c-Fos differed between the genotypes in only one brain area, the nucleus accumbens shell (NAcS)- with OxtrFB/FB mice having increased c-Fos immunoreactivity compared to wildtype controls. The NAcS, which expresses the Oxtr, is important for the rewarding properties of motivated behaviors, including maternal behavior. In rats and voles, Oxt in the NAcS has been implicated in the consolidation of maternal memory and the regulation of "spontaneous" maternal behavior, respectively. Our data suggest that at least in mice, Oxt signaling in the NAcS may also impact the responsiveness of dams to pups, perhaps altering the rewarding properties of their interaction, which could alter the likelihood that a dam will initiate maternal care.

Title: Child executive functioning is predicted by parent hypothalamic pituitary adrenal (hpa) function in both cancer survivors and healthy control children

Authors: *R. RIEGER[1], S. M. DINCES[1], S. N. HILE[1], L. N. ROWELL[1], J. F. L. PINNER[1], N. C. MOSS[1], R. S. ALLEN[1], M. EMERY THOMPSON[2], A. C. TANG[1,3,4], R. D. Fndn., Arlington, VA; [5]Dept. of Pediatrics, Univ. of Colorado Denver, Denver, CO

Abstract: Exposure of infant rats to mild stress associated with a relatively novel non-home environment can modify the influence of maternal HPA function on offspring cognitive function. To determine whether the impact of these converging early life influences generalize to humans, we investigated whether experience of cancer, a major chronic stressor, can change the influence of parent HPA function on child executive function (EF). Eighty-one children, ages 5-18, from 63 families (Healthy Controls=32, Cancer Survivors=31) were included in a nested-design study. To identify major dimensions underlying EF, principle component analysis was performed on 9 measures of EF (NIH Examiner). The first three components accounted for 78.47% variance with the first interpreted as attention control, the second as responsivity to stimuli, and the third as response inhibition. Parent HPA function was indexed by normalized evoked salivary cortisol response (CORTne=PreStress -PostStress)/PreStress) to the Trier Social Stressor Task (TSST). Multilevel modeling was applied to each of these three components with cancer experience and parental cortisol as predictor variables controlling for child age, showing a significant main effect of parent CORTne on the component of child attention control ($F(1,51.35)=4.08, p=.049$)---parents with higher rise in cortisol response to the TSST had children with higher levels of attention control. This result suggests that parent ability to increase cortisol output in response to a stressful event can predict child attention control across different stress conditions. Therefore improving parent self-stress regulation may positively contribute to cognitive development in children experiencing different levels of stress.

Title: The role of sensitization and stress on maternal behavior and neuronal activation in lactating mice

Authors: *M. CHAVEZ[1], D. MERCADO[1], L. JAQUES[1], M. MCCREARY[2], K. D'ANNA-HERNANDEZ[1];
[2]Psychology, [1]California State Univ. San Marcos, San Marcos, CA

Abstract: Lactating dams display a reduction in the hormonal and behavioral response to stress relative to virgin dams. However, it is unknown whether these effects are driven by perinatal hormonal changes or exposure to pups. As maternal behavior is vital for offspring survival and sensitive to the effects of stress, this study proposes to answer this question by analyzing the effect of a stressor on maternal behavior in lactating dams compared to sensitized virgins mice (virgins females exposed to pups). The mice were divided into two groups; lactating dams (LD; n=10) and sensitized virgins (SV; n=10). From PND 1-4, virgin mice were sensitized to four donor pups that were scattered along with the nesting material in the home cage for two hours/day. On the last day of sensitization, the virgins and lactating dams underwent a 15 minute pup retrieval and maternal behavior test. On PND 5, LD and SV were placed on the elevated zero maze to induce a mild stressor. Maternal behavior was again analyzed for 15 minutes immediately after the EZM. After the maternal behavior test and ninety minutes following the stressor, dams were perfused and are being assessed for c-Fos as an indirect marker for neuronal activity to address brain differences in response to the stressor. For the behavioral results, two way repeated measures ANOVAs revealed differences in maternal behaviors between sensitized virgins and lactating dams following the EZM mild stressor. Overall, lactating dams were quicker to retrieve pups and spent less time nursing than sensitized virgins. However, following the stressor, sensitized virgins displayed shorter latencies to both self-groom and lick and groom pups compared to the lactating dams. There is also a strong trend towards increased cFos activation in the paraventricular nucleus of the hypothalamus in SV vs. LD, suggesting altered neuronal activation in response to stress in brain regions important for stress regulation. This work suggests pregnancy hormones rather than pup exposure may underlie an adaptive maternal behavioral and neural response to stress as high levels of licking and grooming, as seen in SV, has previously been shown to reduce pup stress reactivity and may have adverse consequences for offspring raised in adverse conditions.

Title: Absence of the father during pre-weaning does not impact adult offspring anxiety, social recognition or parental care in C57Bl/6J mice

Authors: *S. WILLIAMS[1], W. S. YOUNG[2];
[1]Section on Neural Gene Expression, NIMH, Bethesda, MD; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Variations in neonatal and pre-weaning environments have important and enduring effects on neurobiology and behavior throughout life. Rodent studies have shown that changes in maternal care received can result in altered stress responses and anxiety, as well as social behaviors including parental care of offspring. The presence or absence of the father in the pre-weaning environment has had mixed effects of adult offspring, likely dependent on the species and/or strain. Since parental care is a major contributor to the early environment, the neurobiology underlying the transition to and maintenance of parental behavior has been investigated for several decades. Studies investigating the genetic basis of parenting have used mice primarily from the C57Bl/6J background strain. The breeding of genetic mutants often occurs from permanently co-housing heterozygous male and female breeder pairs, resulting in the presence of the father during rearing. Our observations show that the male contributes to the care of pups in this procedure. However, maternal behavior studies typically remove the male prior to the birth of the pups, resulting in a novel parenting environment for the females to transition to maternal care compared to what they experienced as pups. Here we investigated the adult behavior of offspring reared with their fathers (WF) or without theirs fathers (NF) present during the pre-weaning phase of development. Male and female C57BL/6J mice were paired and once pregnancy was confirmed divided into 2 groups: WF and NF. The NF group had the male removed 1 week prior to birth, and in the WF group fathers remained with the mothers throughout gestation and weaning. Adult male and female offspring were tested for anxiety using an elevated O maze. Pup retrieval was assessed in both male and female offspring in the first postpartum week. Social recognition was measured using a 30 minute 2-session habitation test in males only. We found no differences between WF and NF groups on anxiety-like behavior, social recognition or likelihood to retrieve pups. These results indicate that the presence or absence of the father does not have major effects on baseline behaviors in offspring of the C57Bl/6J strain. Importantly, these results suggest that differences in parental care observed in genetic mutants from the C57BL/6J background most likely result from the genetic disturbance and not from the female rearing young in a different social environment than she was reared, especially when the heterozygous parents are behaviorally normal. This research was supported by the NIMH (Z01-MH-002498-24).

Title: The experience of cancer affects the relationship between parent and child hypothalamic pituitary adrenal (hpa) function

Authors: *S. M. DINCES[1], S. H. HILE[1], L. N. ROWELL[1], J. F. L. PINNER[1], R. E. RIEGER[1], N. C. MOSS[1], R. S. ALLEN[1], M. EMERY THOMPSON[2], A. C. TANG[1,3,4], R. D. ANNETT[5]; [1]Dept. of Psychology, [2]Dept. of Anthrop., [3]Dept. of Neurosciences, Univ. of New Mexico, Albuquerque, NM; [4]Intl. Sci. and Engin., Natl. Sci. Foundatation, Arlington, VA; [5]Dept. of Pediatrics, Univ. of Colorado, Denver, Aurora, CO

Abstract: Rodent studies show that offspring experience of moderate stress can modify the association between the infant's and the mother's HPA function. Therefore, having a mother with poor HPA function does not mean that her offspring will necessarily have similarly poor function. Here we examine whether this modifiability of the relation between parental and child HPA function generalizes to humans. HPA function was examined in parents and their children from healthy control (HC) and pediatric cancer survivor (CS) families. Multilevel modeling was applied to data from a nested-design study (85 children, 5-18 years old, from 64 families, HC:n=32; CS:n=32) to characterize the relation between parent (baseline and post-stress salivary) and child (hair) cortisol measures within HC and CS groups, controlling for child age, sex and parent ethnicity. A second analysis was performed; examining whether corticosteroid exposure as part of cancer treatment affects the association between parent and child cortisol. The interaction effect between cancer experience and parental cortisol on child HPA function was significant (Baseline:$F(1,46.23)=4.53$,p=.039; Post-Stress:$F(1,47.21)=8.99$,p=.004) with a more positive association between parent and child cortisol in HC compared to CS families. The interaction effect between child corticosteroid exposure and parent cortisol was significant (Baseline:$F(1,61.02)=4.76$,p=.033; Post-stress:$F(1,61.42)=6.04$,p=.017) with a more positive association between parent and child cortisol in the non-exposed (N=67), compared to the exposed group (N=11). Parallel to findings from the rodent model, these results reveal a modifiability of the relation between parent and child HPA function by child corticosteroid exposure and indicate plasticity of HPA function beyond infancy.

Title: Effects of maternal 5-HT2C inhibition and mouse pup handling on maternal behavior

Authors: *D. V. WIDZOWSKI[1], D. S. AMPOFO[2];
[2]Biol. & Psychology, [1]Indiana Univ. of Pennsylvania, Indiana, PA

Abstract: Many genetic, physiological and environmental factors have an impact on maternal behavior including care for offspring and on subsequent structural and functional development of the offspring. For example, pharmacological manipulation of serotonergic systems can alter numerous aspects of rodent maternal behavior including retrieval, nursing, and licking of pups. In rodents, the quantity and quality of maternal care can influence resilience to stress and cognitive performance of the offspring as adults. Despite recent studies focusing on the role of serotonin in maternal behavior, the function of specific receptor subtypes in maternal behavior remains unclear. Selective activation of 5-HT2C receptors has been reported to impair maternal behavior but few studies have focused on the effects of selective 5-HT2C receptor antagonists on maternal behaviors. Since activation of 5-HT2C receptors by an agonist impairs aspects of maternal behavior (e.g., pup retrieval, nursing) we hypothesized that selective inhibition of these receptors would have an opposite effect. To test this hypothesis, in this pilot study we evaluated the effects of two factors on mouse mothers' allocation of behavioral time: 1.) Sub-chronic selective 5-HT2C inhibition (SB242084 1 mg/kg ip) or vehicle/placebo during the days one to seven post-natal and 2.) Transient (5 minute) handling or no-handling of pups on the same days. Daily ten-minute behavioral observations were made approximately 30 minutes before administration of drug (baseline) and 15 minutes after (acute drug effect). Outcome measures included quantification of time of various maternal behaviors (e.g., nursing, licking and grooming) as well as other maternal behaviors (e.g., self-grooming, nest building) following drug administration. Results showed a significant effect of handling and postnatal day on maternal licking and grooming but no main effect of 5-HT2C inhibition and no interactive effect at the dose tested. A marginally significant ($p = 0.054$) effect of 5-HT2C antagonism was noted on maternal self-grooming. No effect of 5-HT2C antagonism or handling was noted on baseline behaviors. These results do not support the hypothesis that 5-HT2C inhibition increases maternal licking and grooming of pups.

Title: Biparental behavior in the burying beetle, Nicrophorus orbicollis: a role for dopamine?

Authors: J. P. SPEER[1], J. W. YAEGER[2], K. J. RENNER[2], *S. C. PANAITOF[1];
[1]Biol., Univ. of Nebraska at Kearney, Kearney, NE; [2]Biol., Univ. of South Dakota, Vermillion, SD

Abstract: Burying beetles, *Nicrophorus orbicollis*, exhibit facultative biparental care of young. While the ecological and evolutionary factors that have helped shape the remarkable plasticity of their reproductive behavior are well characterized, the neuromodulation of biparental care in this species remains poorly understood. Male-female beetle pairs bury a small vertebrate carcass as food for its altricial young. During a breeding bout, male and female behavior changes synchronously at appropriate times and is coordinated to provide effective care for offspring. Previous studies show that juvenile hormone (JH) levels rise dramatically at the time beetle parents first accept and feed larvae and stay elevated during the period of active larval care. Levels of JH then fall abruptly when parental care is terminated. However, fluctuations in reproductive hormone levels alone cannot account for the elaborate control of *N. orbicollis* reproductive behavior. The biogenic amines octopamine (OA), dopamine (DA) and serotonin (5-HT) mediate a wide range of insect behaviors, including a plethora of reproductive social behaviors. Thus, these neurotransmitters represent potential candidates for the neuromodulation of burying beetle reproductive behavior. In this study, we measured whole brain monoamine levels in individual insects, and established the OA, DA and 5-HT profiles of male and female burying beetles during a breeding bout. Remarkably, after 24 hr of parental care, when parental feeding rates begin to peak, levels (pg/μg protein) of DA (mean ± SEM) increase in breeding beetles (19.8 ± 2.6) compared to nonbreeding, unmated controls (16.5 ± 2.1) matched for age and colony background ($P<0.05$). In contrast, OA and 5-HT levels remained unchanged. These findings provide the first evidence for a potential role of DA in the modulation of burying beetle parental care. To better understand the effect of these central monoamines on beetle reproductive behavior, we have set out to clone and characterize several subtypes of OA, DA and 5-HT receptors. Additional studies will take advantage of the experimental tractability of this invertebrate model of biparental care and use *in vivo* pharmacological approaches to alter brain monoamine function via receptor antagonists or agonists and assess behavioral changes associated with the onset, maintenance and termination of care.

Title: Bubble nesting behavior is disrupted in male Betta splendens exposed to sub-toxic levels estradiol

Authors: *A. J. VELKEY[1], K. WOOLWINE[2], H. KAY[2], N. KHAN[2], A. EDWARDS[2], K. GUDYKA[2], K. CARTER[2], H. PREMO[2];
[1]Psychology, [2]Neurosci., Christopher Newport Univ., Newport News, VA

Abstract: Bubble nesting is an important component of the reproductive cycle of Betta splendens. Many environmental factors can influence bubble nesting behavior and nest construction, including exposure to xenoestrogenic substances. As nest size is an indicator of mate quality, and nest density is an important factor that influences the viability of eggs, endocrine disruption of nesting behavior can have substantial impact on the life cycle of exposed organisms. The present study examines the effect of low-level estradiol exposure on the size of bubble nests formed and maintained by adult male Betta splendens. Males housed in solitary conditions were exposed to varying estradiol levels (0 µg/L, 30 µg/L, or 60 µg/L). Images of nest sizes were taken three times a day (9 AM, 12 PM, and 3 PM) for one week pre-exposure and one week post-exposure. The nest areas were quantified using grid counts. Results indicate reduced bubble nest area and maintenance in animals exposed to the low, but not the high, dose of estradiol. These findings can have important ramifications in the determination of environmental liability of xenoestrogenic substances.

Title: Hypocretin receptors 1 and 2 differentially regulate materal motivation and maternal depressive behavior in lactating dams

Authors: *Y. CABRERA, H. NORRIS, N. GRENIER, A. KENT, E. LANE, K. D'ANNA-HERNANDEZ;
California State Univ. San Marcos, San Marcos, CA

Abstract: Postpartum depression is a serious illness that contributes to disruptions in maternal care. Postnatal neuromechanistic changes in the arousal and reward systems may contribute to the onset of this disorder. This study will address the role of both hypocretin (HCRT) receptors (HCRTR) 1 and 2, both activated by the neuropeptide HCRT-1, which is related to both arousal and reward, on depressive behavior in the postpartum period. HCRT is associated with general wakefulness in rats and humans and also enhances signaling in the mesolimbic pathways associated with increased motivation and reward-seeking behavior. During lactation, there is an increase in HCRT-1 neuronal activity in both rodent and human mothers associated with time awake caring for offspring, a rewarding behavior. This study will administer varying doses of HCRTR1 antagonist SB-334867 (n=10 each group, vehicle and 30 mg/kg) as well as HCRT-2 antagonist EMPA (n=8-9 each group, vehicle and 30, 75 mg/kg) on postnatal day 4. Separate groups of dams were tested for depressive-like symptoms on the forced swim and tail suspension test after which they underwent a 20 min test for pup retrieval and initiation of maternal behavior. An additional group of dams were tested for pup retrieval on the Tmaze as a proxy for maternal motivation. Parity was also considered as an additional factor. There was no effect of parity or HCRTR1 antagonism on depressive-like symptoms in the forced swim or tail suspension tests. However, primiparous dams that received 75 mg/kg of the HCRT-2 antagonist floated more and swam less than 30 mg/kg dams ($p=0.036$), suggesting blocking HCRTR2, but not HCRTR1, facilitates postpartum depressive symptoms. In addition, in the Tmaze, multiparous dams that received the HCRTR1 antagonist increased time to approach pups relative to primiparous dams ($p<0.05$) and HCRTR1 receptor antagonist decreased overall maternal behaviors, including time licking and grooming pups ($p<0.05$) and latency to retrieve pups ($p<0.001$). Together this work suggests that depressive symptoms in the postpartum period may be regulated via the HCRTR2 receptor while pup-directed behaviors may be driven by changes in the HCRTR1 system.

Title: Trait anxiety is associated with medial prefrontal cortex GABA system protein expression in postpartum rats

Authors: *C. M. RAGAN, J. S. LONSTEIN;
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Typically, early postpartum females have lower anxiety compared to nulliparous females, but some postpartum women (and laboratory rats) experience elevated anxiety after giving birth that interferes with mother-infant interactions and socioemotional development of offspring. This peripartum anxiety is strongly predicted by previous high anxiety in humans and maternal rats. Although the neurobiological mechanisms associated with differences in anxiety among mothers is unclear, central GABA neurotransmission has been implicated in anxiety in nulliparous and randomly-selected postpartum females. In the current study, we selected 8 low-anxious and 8 high-anxious female rats based on the time spent in the open arms of an elevated plus maze on postpartum day 7. We then analyzed protein expression of GAD65 (responsible for synthesis of GABA released from terminals), and the vesicular GABA transporter (vGAT; responsible for uptake and storage of GABA into vesicles) in the medial prefrontal cortex (mPFC), an area associated with emotion regulation. We found a negative correlation between vGAT expression in the mPFC and the number of open arm entries driven by the high-anxious females. We also found a trend suggesting a positive correlation between GAD65 expression and open arm time in the low-anxious females. There was no relationship between vGAT expression and open arm entries, nor between GAD65 expression and anxiety, in the high-anxious females. There was no association between vGAT expression and open arm time nor GAD65 and anxiety in the low-anxious females. These data suggest that differential cortical GABA regulation may contribute to behavioral differences between high- vs. low-anxious mothers.

Title: Gestational stress impairs maternal motivation and induces anhedonia: role of dopamine signaling in the nucleus accumbens shell

Authors: *B. LEUNER[1,2,3], A. HAIM[3], C. ALBIN-BROOKS[1], M. SHERER[1], E. MILLS[1]; [1]Dept. of Psychology, [2]Behavioral Neuroendocrinology Group, The Ohio State Univ., Columbus, OH; [3]Dept. of Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Postpartum depression is a common complication following childbirth experienced by as many as 20% of all new mothers. Mothers diagnosed with postpartum depression often experience anhedonia and impaired mother-infant interactions which can compromise infant development and yet the underlying neural mechanisms mediating these symptoms of postpartum depression remain unspecified. Maternal care is a goal-oriented, highly motivated behavior, which in conjunction with increased anhedonia suggests that deficits in reward and motivation processing might play a role. Here, we investigated whether gestational stress, a risk factor for postpartum depression, would similarly induce anhedonia in postpartum rats using the sucrose preference test. We also evaluated the extent to which gestational stress disrupted maternal motivation as assessed in both a pup retrieval test and the conditioned place preference test. Lastly, we investigated the impact of gestational stress on various components of dopamine signaling in the nucleus accumbens (NAc) shell, a critical component of the brain's reward circuit. Specifically, immunohistochemical staining and densitometry were used to detect and quantify tyrosine hydroxylase (TH; rate limiting enzyme of dopamine synthesis), dopamine D1 receptor (D1), dopamine D2 receptor (D2), and the dopamine transporter (DAT; protein responsible for DA reuptake and termination of dopamine signaling). Our results demonstrate that gestational stress induces anhedonia in postpartum rats and leads to deficits in maternal motivation. These behavioral effects in gestationally stressed mothers were accompanied by decreased density of TH, D2 receptor, and DAT in the NAc shell but no change in D1 receptor density. Overall, gestational stress represents an important translational risk factor that can be used to investigate the neurobiological mechanisms underlying postpartum depression which as suggested by our results may involve altered DA signaling in the NAc.

Title: Effects of the environmental context on the maternal behavior of early undernourished rats

Authors: M. REGALADO, *M. GIORDANO, N. SERAFIN, L. RUBIO, C. TORRERO, M. SALAS;
Univ. Nacional Autónoma De México, Querétaro, Qro., Mexico

Abstract: The complex maternal motivational state occurring during the early postpartum not only promotes the expression of nursing and care of the offspring, but also the display of vigorous pup-seeking behavior when the pups are spread out of the nest or under unfamiliar conditions. In this study we assess the long-term effects of perinatal undernutrition (PU) on the behavioural performance of lactating dams, versus the well-fed mothers to a new nest environmental signals that may interfere with the maternal care of the progeny. The unfamiliar paradigm, consisted of two chambers connected by a horizontal tunnel (10 cm in diameter) as a device to provoke maternal novelty. The day before testing the litter was separated 12h from the pups and thereafter, the maternal behavioral tests were evaluated at 4, 8, and 12 days of the lactating period. In all subjects the frequencies of approaching to the young, sniffing and licking pups, digging sawdust, rearing, and self-grooming bouts were sampled. Early underfed mothers reduced ($p<0.05$) the approaching and their licking to the pups, digging sawdust, and increased the number of pups sniffing, and self-grooming bouts on day 8 ($p<0.05$) vs. the control dams. The results indicated that PU interferes with the maternal responsiveness to novel cues elicited by the pups in a non-familiar conditions. These findings, suggest that the motivational response of PU dams to the pups is poorly focused to protect and give care to the progeny, and presumably results in newborn careless and delayed brain development.

Title: Postpartum lesions targeting serotonergic neurons in the dorsal raphe alter various aspects of maternal behavior

Authors: *M. A. HOLSCHBACH[1], E. M. VITALE[2], J. S. LONSTEIN[1,2];
[1]Neurosci. Program, [2]Psychology, Michigan State Univ., East Lansing, MI

Abstract: The survival and wellbeing of mothers and their young require high levels of maternal care, aggression toward conspecifics, and low anxiety. These behaviors are affected by pharmacological manipulation of serotonin signaling, but no experiments have analyzed in detail the effects of serotonin-specific lesions of the midbrain on all of these postpartum behaviors. We performed serotonin-specific lesions of the dorsal raphe using a saporin-conjugated toxin targeting the serotonin transporter. After dorsal raphe infusion of the toxin or an inactive control conjugate on postpartum day 2, undisturbed maternal behavior was observed daily and retrieval of scattered pups observed every other day for one week after surgery. Anxiety-like behavior was measured in an elevated plus maze and light dark box on postpartum days 8 and 9, respectively, followed by tests of aggression toward a male intruder in the home cage. Serotonergic lesions of the dorsal raphe altered numerous postpartum behaviors. During undisturbed observations, lesioned animals groomed themselves less and showed more crouching over and less licking of pups. Lesions did not greatly affect pup retrieval or anxiety-like behavior, but did reduce the average duration of attack bouts during aggression testing. This experiment indicates new roles for DR serotonin in the suite of behavioral changes occurring during the postpartum period.

Title: Impacts of perinatal oxytocin exposure on maternal behavior, physiology, and epigenetic regulation

Authors: *A. M. PERKEYBILE[1], W. M. KENKEL[1], J. R. YEE[1], T. S. LILLARD[3], T. ROSENSTEIN[1], C. F. FERRIS[1,2], C. S. CARTER[4], J. J. CONNELLY[3];
[1]Psychology, [2]Ctr. for Translational Neuroimaging, Northeastern Univ., Boston, MA; [3]Psychology, Univ. of Virginia, Charlottesville, VA; [4]The Kinsey Inst., Indiana Univ., Bloomington, IN

Abstract: The use of synthetic oxytocin (OXT) in the birth process is very prevalent in obstetric practices today as a way to induce or augment labor. The long-term consequences for mother and offspring, however, are not fully understood. Here we investigate the post-birth impacts of this birth intervention on behavior, autonomic functioning, and epigenetic regulation in the mother using the prairie vole (Microtus ochrogaster). The prairie vole is uniquely suited to answer these.

This species engages in biparental care of offspring, with the father displaying the same suite of parental behaviors as the mother aside from lactation, and also has a human-like pattern of autonomic system regulation. In addition, there are 4 identified CpG sites in the promoter region of the OXT receptor (OXTR) in prairie voles that are conserved from human OXTR and these sites are not homologous in mice or rats. In this study, pregnant females were injected with one of three doses of OXT (0.05, 0.25, or 0.5 mg/kg) or saline vehicle or were not injected on the day of expected delivery of the litter. Ninety minutes after injection, the female was sacrificed and brains were collected to examine changes in methylation of the OXTR at several CpG sites. A second cohort of adult females was implanted with radiotelemetry devices prior to mating. On the expected day of birth of the first litter, females were injected with either OXT (0.25 mg/kg) or saline vehicle, with the other drug injected just prior to the expected birth of the second litter. Order of injection was counterbalanced across subjects. Parental behavior was observed four times between postnatal days 1-3 after the birth of each litter. During each of these four observations, autonomic functioning of the mother was also recorded. Methylation changes in OXTR were seen in regions of the brain involved in maternal behavior, including an increase in methylation levels following the low dose of perinatal OXT exposure in the medial preoptic area and following the high dose of OXT in the amygdala compared to treatment with saline vehicle. Preliminary behavioral results indicate that treatment with OXT compared to saline vehicle prior to birth does not affect maternal care of offspring in the first postnatal days. Maternal autonomic function data will also be presented. Results here indicate peripartum exposure to OXT may have consequences for maternal methylation of the OXTR but does not appear to impact care of offspring and adds to our understanding of the impact of birth intervention on the mother.

Title: A little extra push: exploring the consequences of oxytocin administration on neonatal physiology, behavior and epigenetics

Authors: ***W. KENKEL**[1], A. M. PERKEYBILE[1], J. R. YEE[1], T. ROSENSTEIN[2], C. F. FERRIS[2], C. S. CARTER[1], J. CONNELLY[3];
[1]Indiana Univ., Bloomington, IN; [2]Psychology, Northeastern Unniversity, Boston, MA; [3]Virginia Univ., Charlottesville, VA

Abstract: The majority of births in the U.S. now involve the administration of exogenous oxytocin (OXT) to induce and/or augment labor. There is evidence that such OXT can cross the placenta and reach fetal circulation, but the long-term effects on brain, body and behavior remain to be explored. Given that direct OXT exposure in early life can produce brain and behavior changes in adulthood, we sought to evaluate whether OXT administered to the expectant female can influence offspring development. Here, we present data from our model of peripartum OXT administration, using the monogamous prairie vole (Microtus ochrogaster). In this paradigm, pregnant female voles were treated with one of three doses of OXT (0.05, 0.25, or 0.5 mg/kg) or saline vehicle on the expected day of delivery. Effects on the neonate were evaluated in terms of: prenatal heart rate, epigenetic regulation and transcription of the OXT receptor, and several aspects of postnatal behavior including ultrasonic vocalizations and anxiety-related behavior in the open field test. Peripartum OXT administered to the expectant dam results in dose-dependent decreases in prenatal heart rate in both sexes and increases in OXT receptor methylation in females. Following cross-fostering, the analysis of behavioral changes brought on by peripartum OXT will contribute to a growing body of knowledge concerning the consequences of this commonplace obstetric practice.

Title: Changes in maternal behavior due to fetal ethanol exposure and stressed environment

Authors: *V. A. DONAHUE;
Viterbo Univ., La Crosse, WI

Abstract: Early-life trauma, such as exposure to drugs or maternal maltreatment, leave lasting imprints which can cause behavioral deficits. Maternal maltreatment during development can cause physical deformities, behavioral and social deficiencies, problems with executive functioning, and various molecular changes, including changes to neurotrophic factors. Brain-derived neurotrophic factor (BDNF) acts in the central and peripheral nervous system to increase the survival of neurons. Increased signaling or decreased signaling can interfere with proper neuronal development. Through the use of aUsing a Long-Evans rat model, the effect of maltreatment and ethanol exposure during development on maternal behavior, cognition and the epigenetic effects on the BDNF gene. Previous studies have indicated that Pre-impregnated dams were placed in either a stressed or non-stressed environment. aA stressfuled environment causes

dams to exhibit poor maternal behavior. Ethanol treatments were given to neo-natal rat pups which were separated into three treatment groups, ethanol-treated, intubation-control, and non-treated control. An ethanol/milk mixture was given to the ethanol-treated group, whereas the control groups received only intubation or no treatment. Ethanol treatments were administered on post-natal days 4 through 9. Dam maternal behavior such as licking and grooming, nursing posture and pup retrieval time were recorded on post-natal days 2, 4, 6, 8, and 10. On day 25, pups underwent pup drop testing to view differences in maternal behavior, a stress test, to view fear response, and a radial arm maze to view processing capacity in a new environment. RT-PCR was done to look at the levels of BDNF mRNA. In pup drop tests, there was no significant differences in retrieval time between ET and Control groups, however pups from stressed dams showed less time to retrieve than the non-stressed counterparts. In the stress test and radial arm maze, ET rats showed less fear and were quicker to choose an arm than the other treatment groups.

Title: Parental environment affects social behaviors and neurochemical systems in the offspring of socially monogamous prairie voles

Authors: *M. TABBAA[1], K. LEI[2], Y. LIU[1], Z. X. WANG[1];
[1]Florida State Univ., Tallahassee, FL; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Although it has been well documented in humans that paternal absence has detrimental effects on offspring development and wellbeing, the underlying mechanism is still unknown. In the present study using the socially monogamous, bi-parental prairie vole (Microtus ochrogaster), we examined the effects of father absence during early development on the offspring's social and anxiety-like behaviors as well as neurochemical systems in adulthood. Paired voles were checked daily. On the day of litter birth, fathers were either continuously housed with the mother and offspring to create bi-parental group (BP) or were removed to create single mother group (SM). Three times a day during the entire 20 day postnatal period, ten spot checks were conducted with a 5 minute interval between each spot check. SM offspring were licked, groomed, and carried less by a parent, and were left alone in the nest more frequently than BP offspring. At weaning (21 days of age), SM and BP offspring were housed in pairs with

a same sex and treatment sibling until 90 days of age and then tested for parental, affiliative, and anxiety-like behaviors. More SM subjects displayed parental behaviors than BP subjects. Interestingly, SM subjects engaged in more huddling behaviors compared to BP subjects. SM subjects also engaged less in non-parental behaviors, such as self-grooming, compared to BP subjects. Further, SM males, but not females, engaged in more side by side contact with a stimulus conspecific, compared to PB males, during the social affiliation test. In the elevated plus maze (EPM) test, SM subjects entered the arms of the EPM less frequently than PB subjects. Brain tissues were processed for neurochemical marker labeling. Western blot analysis revealed that SM subjects had lower levels of oxytocin receptor as well as alpha and beta glucocorticoid receptor expression in the hippocampus than BP subjects. Together, our data indicate that lack of paternal exposure during early development has long-lasting effects on the behavior and brain of this socially monogamous rodent species. The effects on other neurochemical systems, including BDNF and histone acetylation, are currently under investigation.

Title: Individual differences in maternal care associate with variations in dendritic morphology and Rem2 within the medial preoptic area of rats

Authors: ***T. ZHANG**, C. I. PARENT, X. WEN, S. K. DHIR, R. RYAN, J. DIORIO, M. J. MEANEY;
Douglas Mental Hlth. Univ. Institute, Sackler Program for Epigenetics & Ps, McGill Univ., Verdun, QC, Canada

Abstract: The medial preoptic area (MPOA) mediates maternal behavior and is implicated in the expression of individual differences in maternal behavior such as the frequency of pup licking/grooming (LG). We sought to determine if variations in maternal behavior were associated with underlying MPOA morphology. We examined phosphorylated cyclic adenosine monophosphate (cAMP) responsive element-binding protein (pCREB) expression and dendritic

morphology within the MPOA of lactating mothers. We found a significantly higher number of pCREB-immunoreactive cells in the MPOA of high-LG mothers compared to low-LG mothers immediately after a nursing bout on postnatal day 5 (PND 5). High-LG mothers also displayed a significantly reduced population of greater dendritic complexity index (DCI) neurons compared with low-LG mothers in the MPOA. Rem2, a small GTPase, that reduces dendritic complexity while enhancing glutamatergic synapse formation was significantly increased in the MPOA of high-LG mothers compared to low-LG mothers. CREB overexpression in MPOA neuronal cultures increased the expression of genes implicated in dendritic pruning including brain-derived neurotrophic factor (BDNF) exon IX and Rem2 gene expression. CREB overexpression also reduced the DCI of cultured MPOA neurons. The enhanced expression of Rem2 following CREB overexpression in cultured MPOA neurons is a novel finding that suggests CREB's ability to regulate neuronal dendritic growth by enhancing the expression of a negative regulator of dendritic complexity. The enhanced expression of pCREB and Rem2 in the MPOA of high LG mothers compared to low-LG mothers associates with a reduced DCI and suggests enhanced glutamatergic excitatory synapses in the MPOA of high-LG mothers.

Title: Heightened medial orbitofrontal cortex activity in mothers' responses to infant vocal cues: an fMRI comparison of women with and without young infants

Authors: ***C. PARSONS**[1,2], K. YOUNG[4], E.-M. JEGINDØ[3], A. STEIN[1], M. KRINGELBACH[1,2];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Ctr. for Functionally Integrative Neurosci., [3]Aarhus Univ., Aarhus, Denmark; [4]Psychology, UCLA, L.A., CA

Abstract: Becoming a mother is assumed to bring about a profound change in a woman's capacity to respond to an infant. The neural mechanisms underlying such a change are not well understood in humans. This study investigated differences in how women with and without young infants respond to salient infant vocal cues. Twenty-nine mothers of young infants and twenty-nine non-mothers participated in this study. Participants were scanned using fMRI while

they performed a task designed to ensure auditory attention (tone detection), with infant and other sounds played incidentally. The infant cues consisted of negative (cry) and neutral ('babble') sounds produced by infants aged between 6 and 8 months. Participants also listened to adult negative and neutral vocalisations. Mothers showed heightened activity relative to non-mothers in the left medial orbitofrontal cortex (mOFC) when listening to infant sounds compared to adult sounds. Among the mothers, the magnitude of the mOFC response was positively correlated with the age of their own infants. Other regions that showed differential patterns of activity in the maternal and non-maternal groups included the left inferior frontal gyrus and the right middle frontal gyrus. We propose that this differential neural activity is an important aspect of the changes associated with becoming a mother. For mothers, activity in the medial OFC appeared to be important in differentiating infant from adult vocal cues. These findings further suggest that caregiving experience may be important in shaping the extent of medial OFC activity. Heightened responsiveness to infant cues in a key reward region in mothers may support early parenting behaviours.

Title: Maternal care and oxytocin secretion are controlled by a sexually dimorphic hypothalamic circuit

Authors: N. SCOTT, M. PRIGGE, O. YIZHAR, *T. KIMCHI;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Parental care is a complex stereotypic behaviour toward offspring that is shared by numerous species. In laboratory mice, there are profound differences in offspring directed behaviours between the sexes. At their first encounter, nulliparous females behave maternally toward alien pups while males will usually ignore the pups or attack them. Here we show that tyrosine hydroxylase (TH)-expressing neurons in the anteroventral periventricular nucleus (AVPV) of the mouse hypothalamus are more numerous in mothers than in virgin females and males, and govern parental behaviours in a sex-specific manner. In females, ablating the AVPV TH+ neurons impairs maternal behaviour whereas optogenetic stimulation or increased TH expression in these cells enhance maternal care. In males, however, this same neuronal cluster has no effect on parental care but rather suppresses adult-directed aggression. Strikingly, optogenetic activation or increased TH expression in the AVPV TH+ neurons of female mice

increases circulating oxytocin, whereas their ablation reduces oxytocin levels. Using neuroanatomical tracing and optogenetic stimulation, we found that AVPV TH+ cells relay a onosynaptic input to oxytocin-expressing neurons in the paraventricular nucleus. Our findings uncover a previously unknown role for this neuronal cluster in the control of maternal care and oxytocin secretion, and provide a causal relationship between sexual dimorphism in the adult brain and sex differences in parental behaviour.

Title: Individual differences in male mice ultrasonic vocalizations to females are correlated with sexual motivation and neuronal activity in the ventral tegmental area

Authors: *K. KOUTA[1], T. KIKUSUI[2];
[2]Companion Animal Res., [1]Azabu Univ., 1-17-71 Fuchinobe, Sagamihara, Kanagawa, Japan

Abstract: Individual differences in male mice ultrasonic vocalizations to females are correlated with sexual motivation and neuronal activity in the ventral tegmental area Sexually dimorphic displays are observed in various animals, which are thought to be shaped in the process of evolution. In rodents, male mice emit ultrasounds when encountering females as courtship vocalizations. The ultrasonic vocalizations (USVs) contain song-like structure and recent studies have focused on the detail analysis of the characteristics of the songs, such as syllable compositions or temporal sequence of syllables, which are regarded as a biolinguistic model of syntax and models of social behaviors. However, biological or behavioral significance and neural mechanisms of the USVs has been poorly understood. Here, we demonstrate that amount of emission in the USVs in male mice reflected sexual motivation. That is primarily because the amount of the emission was negatively correlated with mount latency; males that emitted more showed mounting on a female with a shorter latency. In addition, comparing males before and after castration, USVs was significantly decreased after castration and testosterone replacement restored the USVs. Furthermore, males exhibited almost no vocalizations after ejaculation. Next, we screened the responsible brain regions for the USVs emission using immunohistochemistry for neuronal activity maker c-Fos. As a result, the number of c-Fos immunoreactive (ir) cells in the lateral amygdala, ventral tegmental area (VTA), and dorsal raphe nucleus were significantly higher in the males that exhibited USVs than that in exhibited no USVs. Finally, we further

investigated cell type of the c-Fos-ir cells in the VTA. Approximately 25 % of the c-Fos-ir cells were dopaminergic in mice which exhibited the USVs on average, and the dopaminergic c-Fos-ir cells were correlated with amount of the USVs. The present study suggests that courtship vocalization is expression of sexual motivation related to sex hormones rather than general sociality, and that the dopamine-related systems in the VTA is responsible for the USVs emission and its individual differences.

Title: Male mice ultrasonic vocalizations enhance female reproductive function

Authors: *A. ASABA, K. MOGI, T. KIKUSUI;
Azabu Univ., Kanagawa, Japan

Abstract: Male-female vocal communication is important for selecting a suitable mating partner and we previously suggested that ultrasonic vocalizations (USVs) from male mice, which were emitted when encountering females, were contributed to kin recognition and used to avoid inbreeding, on the basis of concomitant presentation with a male pheromone, ESP1 (Asaba et al, 2014). On the other hand, there have been reported that male vocalizations could promote female fertility in some animals. However, there have not been intensive studies about it in mice USVs. In the present study, we first investigated the relationship between the numbers of delivery in breeding pairs for 4 months and of USVs syllables emitted from those paired males during 3 minutes of sexual encounter with unfamiliar females. Interestingly, there was a positive correlation between these two indices, suggesting a possibility that male USVs could promote female's fertility. Next, we examined the effect of male USVs on sexual behavior in females. As results, females showed more approach behavior towards vocalizing-males than devocalized-males. Finally, to examine whether male USVs could activate neural system governing reproductive function in females, the activation of Kisspeptin neurons, key neurons to drive gonadotropin-releasing hormone neurons in the hypothalamus, were examined using dual-label immunocytochemistry with cAMP response element-binding protein phosphorylation (pCREB). In the anteroventral periventricular nucleus (AVPV), there tended to be increased in the number of Kisspeptin neurons expressing pCREB after simultaneous exposure to male-USVs and ESP1 as compared with other groups; male-USVs and vehicle, background noise and ESP1, or

background noise and vehicle. In conclusion, we suggest here that male USVs could promote fertility in female mice, by activating both their sexual motivation and central Kisspeptin neurons. It is also suggested that multisensory integration with pheromonal cue is involved in this putative function.

Title: Non-breeder's alloparenting behaviors are enhanced by coprophagy in eusocial rodents, the naked mole-rats

Authors: ***A. WATARAI**[1], N. ARAI[2], S. MIYAWAKI[3], K. MIURA[3], K. MOGI[1], T. KIKUSUI[1];
[1]Companion Animal Res., Azabu Univ., Kanagawa, Japan; [2]IPCR, Saitama, Japan; [3]IGM, Hokkaido Univ., Hokkaido, Japan

Abstract: Naked mole-rats have eusociality. Their colonies consist of a single breeding female (the queen) and some breeding males. All the other adults in a naked mole-rat colony are sexually immature (non-breeders). Non-breeders are altruistic and support parturition of the queen and nursing pups. It has also been found that naked mole-rats frequently perform coprophagy, which is a habit of eating both their own and other's feces. Hamilton's rule explains why non-breeders perform altruistic alloparenting behaviors. On the other hand, physiological mechanism promoting alloparenting behaviors of non-breeders has not been discovered. In the present study, we examined how non-breeders acquired motivation of alloparenting behaviors towards the pups. First, we assessed preference to pups and measured fecal and urinary gonadal steroid hormone concentrations of non-breeders in each reproductive stages of the queen; pregnancy, postpartum and non-lactating. Non-breeders showed preference to pups in the postpartum stage of the queen. We also found that fecal and urinary estradiol concentration increased in the pregnancy stage of the queen. Secondly, to confirm whether coprophagy was involved in motivation of alloparenting behaviors, we assessed preference to pups of non-breeders after they ate feces of the pregnant queen or impregnating with estradiol of the non-pregnant queen. As result, their preference to pups was facilitated by both the treatments. These results suggest that non-breeders acquire motivating of alloparenting behaviors by coprophagy, eating feces including estradiol from the pregnant queen.

Title: Fumbling the maternal-fetal microbial handoff: maternal stress reprogramming of the developing gut-brain axis

Authors: ***E. JAŠAREVIC**, C. D. HOWARD, A. MISIC, D. P. BEITING, T. L. BALE; Univ. of Pennsylvania, Philadelphia, PA

Abstract: Prenatal stress is associated with an increased risk for neurodevelopmental disorders. In our established mouse model of early prenatal stress (EPS), long-term programming effects on offspring development have been demonstrated, including reprogramming of the hypothalamic-pituitary-adrenal (HPA) axis, dysregulation of HPA stress axis responsivity, cognitive dysfunction, and post-pubertal growth. Mounting evidence points to a likely influence of maternal stress experience on reprogramming of the gut-brain axis via the maternal vaginal microbiome. As the neonate acquires its founding population of gut microbes during passage through the birth canal, changes in the vaginal microbiome produced by stress during pregnancy alters the composition and function of the microbiota colonizing the neonate gut. Such programming exerts lasting effects on the neonate brain by metabolically altering the neonate gut environment, and ultimately contributing to aspects of our EPS phenotype. We have found that EPS changes in the microbiome composition are paralleled by plasma and gut metabolite profiles related to impaired energy metabolism and availability, and sex- and brain region-specific changes in amino acid transport by postnatal day 2 (PN2). This early life disruption in neonate microbiota composition is associated with long-term and sex-specific impact on microbial composition, metabolism, and gastrointestinal barrier deficits into adulthood as well. To provide a causal link of the stress-altered vaginal microbiota with reprogramming of the developing gut-brain axis, we used cesarean delivery (CD) of neonate mice colonized with vaginal microbiota from either control or EPS dams, and assessed microbial composition, the gut metabolome, and the developing hypothalamic translatome at PN2. We confirmed that colonizing CD offspring with maternal vaginal microbiota restored microbial diversity and abundance similar to vaginally

delivered offspring, providing validation that vertical transmission of maternal vaginal microbiota is a critical source of microbial diversity in the neonate gut. To determine whether colonization by a stress-altered microbiota recapitulates key features of our EPS phenotype, gastrointestinal barrier function and HPA stress responsivity in these offspring was assessed in adulthood. Remarkably, aspects of the EPS phenotype are transferrable by colonization of a stress-altered vaginal microbiota, validating the importance of the vaginal microbiome in neurodevelopmental programming. Together, these studies provide valuable insight into the novel role of maternal stress in driving the developing gut-brain axis.

Title: Placental OGT serves as an epigenetic dispatcher of prenatal stress signals to the developing fetal brain

Authors: B. M. NUGENT[1], C. L. HOWERTON[1], *T. L. BALE[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Dept Animal Biol, Univ. Pennsylvania, Philadelphia, PA

Abstract: Prenatal stress is a risk factor for several neurodevelopmental disorders, including schizophrenia and autism, which display marked sex differences in age of onset, severity, and prevalence. In our mouse model of early prenatal stress (EPS), stress exposure during the first week of gestation imparts long-term neurodevelopmental programming deficits in male offspring resulting in hypersensitivity to stress, cognitive impairments, and alterations in metabolic programming. The placenta acts as an arbitrator between the mother and fetus, providing all necessary nutrients and gasses needed for fetal growth and is now widely regarded as an important contributor to healthy neurodevelopment. Previously, we identified O-linked-N-acetylglucosamine transferase (OGT) as a sex-specific placental biomarker of prenatal stress. OGT acts as a nutrient sensor that modifies numerous proteins to alter various cellular signals,

including major epigenetic processes like histone methylation and DNA demethylation. OGT is an X-linked gene with dramatically higher expression in the female placenta compared to males and expression is further decreased in males following EPS. Importantly, placental-specific knockout of OGT recapitulates the EPS phenotype, validating the important role of OGT signaling in the placenta for neurodevelopmental programming. To determine the mechanistic contributions of OGT in the placenta, we quantified expression levels of important epigenetic regulators following placenta-specific knockout of OGT and found large changes in histone modifiers and modifications associated with epigenetic repression. In addition, we used Chip-Seq to analyze activational and repressive chromatin marks to compare and contrast gene sets impacted by changes in histone methylation following placental OGT knockout. These studies provide further mechanistic insight into the importance of OGT signaling in epigenetic gene regulation in the placenta in response to stress. *Supported by MH091258, MH087597, MH099910, MH104184*

Title: Maternal and fetal exosomes: a message in the bottle for neurodevelopmental programming

Authors: *B. M. NUGENT, T. L. BALE;
Dept. of Biomed. Sci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Maternal and fetal exosomes: a message in the bottle for neurodevelopmental programming Bridget M. Nugent & Tracy L. Bale Department of Biomedical Sciences, University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA, 19104, USA. Understanding how maternal stress affects the maternal and fetal milieu is important for identifying mechanisms involved in perturbations of brain programming, which are often associated with neurodevelopmental disorders. In our well-established mouse model, male offspring exposed to early prenatal stress (EPS) have altered hypothalamic pituitary axis (HPA)

programming, resulting in increased stress sensitivity and dysregulation in hypothalamic metabolism, similar to endophenotypes identified in boys with autism and men with early-onset schizophrenia. Previously, our lab found that gene sets important for endo- and exosomal cellular processes are down-regulated in the male placenta in response to EPS, suggesting that EPS alters maternal and fetal exosome signaling. Exosomes are small vesicles secreted locally and into the bloodstream by most tissues transferring proteins, microRNAs (miRNAs), and other signaling factors between cells and tissues as a means of short and long-distance communication. Importantly, exosomes can cross the blood-brain barrier to impact neural gene expression, and potentially alter brain development. To explore the effect of EPS on exosome signaling, we collected maternal and fetal serum and tissues on embryonic day 18.5, and isolated proteins and miRNAs for 'omics analyses. Using proteomics and small RNA-Seq, we found that maternal stress during the first week of pregnancy produced lasting and robust effects on exosome signaling, as well as sex differences in the overall number of exosomes in fetal and neonatal circulation. Our proteomics data suggest that EPS induces long-term changes in exosome production and cargo from a variety of maternal sources, including maternal immune cells and the placenta. Since miRNAs have the potential to broadly impact gene expression by targeting mRNAs for degradation, and exosomes can have widespread targets throughout the body, stress-induced alterations in exosomal miRNAs may produce extensive changes in tissue function including changes in the fetal brain. *Supported by MH091258, MH087597, MH099910, MH104184*

Title: Lasting and dose-responsive reprogramming of sperm microRNA content by paternal stress

Authors: *J. CHAN, A. B. RODGERS, T. L. BALE;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Epidemiological studies suggest that epigenetic inheritance of paternal lifetime experiences can influence neuropsychiatric disease risk in subsequent generations. Rodent models examining transmission via the paternal lineage, where males do not participate in offspring rearing, provide an exciting model for examining the unique epigenetic germ cell contribution to offspring development. Recent studies have demonstrated that paternal exposure to a variety of perturbations can impact offspring behavior and physiology, and have identified changes in histone modifications, DNA methylation, and/or microRNA (miRs) populations as potential mechanisms of transmission. We have developed a paternal stress model in which both male and female offspring show a significantly hyporesponsive HPA stress axis. . Paternal sperm analyses detected a significant increase in 9 specific miRs following stress. Zygote microinjection of these miRs was able to recapitulate the blunted stress response seen in paternal stress offspring. However, the timing by which sperm epigenetic marks can respond to environmental perturbations such as stress and how long these changes last is not known. Our current studies examined the maintenance and specificity of stress-sensitive sperm miRs following chronic stress exposure and their ability to reprogram offspring stress responsivity. Sires were exposed to stress either once or twice per day for four weeks, and were then bred multiple times over a 3-month period to examine the acute and long-term programming effects of paternal stress on offspring neurodevelopment. Interestingly, offspring exhibited differences in stress regulation and body weight, with the magnitude of offspring body weight differences increased with greater paternal stress experience, suggesting that germ cells can encode specific information about stress severity. miR-sequencing was used to identify the total miR population altered in sperm following stress, and to assess the relationship between stress severity and offspring phenotypic reprogramming. Ongoing studies examining the temporal responsiveness of sperm miRs following stress experience promise insight into the dynamic regulation of germ cell epigenetic marks in response to environmental perturbations, and will provide novel and exciting insight into how the paternal environment can impact offspring neurodevelopmental disease risk.

Title: Placental insulin receptors as novel orchestrators of sex-specific neurodevelopmental programming

Authors: *S. L. BRONSON, T. L. BALE;
Sch. of Vet. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Adverse prenatal experiences remodel the developing brain and confer lifelong neuropsychiatric disease susceptibility. Males are uniquely vulnerable to intrauterine perturbations such as maternal stress and metabolic dysfunction, which predispose them to neurodevelopmental disorders including autism, attention-deficit hyperactivity disorder, and schizophrenia. The mechanisms by which prenatal adversity produces sex differences in vulnerability to disease remain largely unclear. Recent studies have emphasized the emerging role of the placenta as an orchestrator of sex-specific fetal programming. Human studies and animal models examining the effects of maternal stressors have pointed to disruption of key homeostatic pathways within the placenta, including that of insulin. We hypothesize that impaired insulin receptor signaling within the placenta in response to diverse perturbations of the maternal milieu drives sex-specific neurodevelopmental reprogramming. To demonstrate the importance of placental insulin in neurodevelopment, we utilized the conditional Cre-Lox transgenic mice to selectively target insulin receptors (InsR) in trophoblastic cells of the placenta. Sex specificity and behavioral stress phenotypes were then examined in wildtype and placental-knockout mice as adults. Intriguingly, placental InsR deletion significantly increased the hypothalamic-pituitary-adrenal axis stress response and impaired sensorimotor gating in males, thereby recapitulating endophenotypes of sex-biased neurodevelopmental disorders. Lack of these programmatic changes in females suggests distinct vulnerability of the male placenta. To determine the changes in placental function related to InsR deletion, we conducted a transcriptomics analysis comparing genotype x sex by Affymetrix microarray. Consistent with the heightened behavioral vulnerability of males, InsR deletion elicited dramatic changes in gene expression in male placentas, indicative of vascular dysfunction and impaired lipid transport. As the fetus relies on placental transfer of maternally derived lipids, we assessed lipid composition in the fetal brain. Extensive shifts in fetal brain phospholipid and fatty acid composition were associated with enduring changes in myelination in placental InsR deficient mice, and suggest that preservation of placental lipid transfer may contribute to female resilience. Together, these data provide compelling evidence demonstrating the programmatic capacity of the placenta and reveal the emerging role of placental insulin signaling in sex-specific reprogramming in response to intrauterine adversity.

Title: Father: An essential element The impact of preconception paternal experience on offspring neurodevelopment and behaviour

Authors: *A. F. HARKER, S. RAZA, K. WILLIAMSON, B. KOLB, R. GIBB;
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: A rich literature has been amassed demonstrating the impact of early life events on the structure and function of the developing brain. While a plethora of research has shown that maternal experience during the prenatal period of life has the ability to alter neurodevelopment and behavioural outcomes of offspring, far less in understood regarding the impact of preconception paternal experience on developing brain architecture. The goal of this research was to examine the effect of two independent preconception paternal experiences on subsequent neurodevelopment and behaviour of male and female offspring. Research has shown that stress during the prenatal period can alter brain morphology in the developing brain, and is thought to be a factor in the development of some adult psychopathologies. Our first experiment examined the impact of preconception paternal stress on offspring brain and behaviour. Our hypothesis was that paternal stress in the preconception period would negatively impact brain development in offspring, leading to behavioural abnormalities. While stress and environmental enrichment have been shown to have opposing effects on brain architecture and behavioural outcomes in offspring, we decided to explore the impact of environmental enrichment provided to fathers during the preconception period. We hypothesized that preconception paternal enrichment would alter brain development and positively impact behaviour of offspring. Both experiments followed the same experimental design. Male Long Evans rats were exposed to either a stressing paradigm or a complex environment for 27 days prior to mating. Developmental assays, anatomical measurements, and brain morphology analyses were conducted throughout offspring lifespan.

Title: Whole genome response of developing baboon fetal hypothalamus to the effects of maternal nutrient restriction (MNR) in late gestation

Authors: *T. NURMAMAT[1], L. A. COX[1], P. W. NATHANIELSZ[2], S. YANG[2], C. LI[2], J. GLENN[1];
[1]Genet., Texas Biomed. Res. Inst., San Antonio, TX; [2]Univ. of Wyoming, Laramie, WY

Abstract: Introduction: Moderate malnutrition during pregnancy is widespread around the world and it impacts large number of pregnancies in both developing and developed countries. Maternal nutrient restriction (MNR) can lead to programming of the fetal hypothalamic-pituitary-adrenal (HPA) axis, predisposing offspring to obesity and psychiatric diseases in later life (Reviewed by Matthew SG, Nature Rev Endo 2014). We have developed a baboon nonhuman primate (NHP) model of MNR and previously reported up regulation of the fetal baboon HPA axis (Li et al., 2013). Hypothalamus is one of the most sensitive regions of the brain to the effect of environmental stimuli, but the hypothalamic response to nutritional stress induced by MNR at the whole genomic level is lacking. In this study, our aim was to determine the whole genome response of fetal baboon hypothalamus to MNR in late gestation (0.9 G). Methods: Randomly selected pregnant baboons were fed either ad libitum (control; CTR; n=5) or a globally reduced diet (70% of CON; n=5) from 0.16 G through 0.9 G that produces IUGR (14% reduction in fetal weight). Fetuses were removed by Cesarean section at 0.9 G, and fetal hypothalamus samples were collected for genomic analysis. Gene arrays were performed for determining the whole genome profiles and the Ingenuity Pathway Analysis (IPA) software was used for data analysis. Results: We detected total of 10400 genes expressed in the fetal baboon hypothalamus and 745 genes accounting for 7.1% of the total genes expressed were differentially expressed in CON vs. MNR. Of those 745 differentially expressed genes, 425 genes were up regulated ($P < 0.05$) and 320 genes were down regulated ($P < 0.05$) in MNR fetuses. Canonical pathway analysis results revealed that multiple cellular growth pathways, including IGF-1, Akt, CREB, PDGF, STAT3, etc. were up regulated. Cellular stress response pathways, including p38 MAPK and EIF2 were also up regulated. Further, several metabolic pathways (Noradrenalin and adrenalin degradation and TCA cycle II) and apoptosis signaling pathways were dysregulated in response to MNR. Network analysis results show that gene networks involved in cell death and survival, embryonic development and organ development were affected Conclusions: The results show that non-human primate hypothalamus is widely susceptible to the impact of MNR in late gestation. The increase in multiple cell growth and stress response related pathways indicate highly activated fetal hypothalamic response to MNR at the molecular level, which may

contribute to the programming of HPA axis. These results need further validation by immunohistochemistry to determine the effect at the protein level.

Title: Birth: an overlooked event in brain development?

Authors: ***A. CASTILLO-RUIZ**, M. MOSLEY, N. G. FORGER;
Georgia State Univ., Atlanta, GA

Abstract: Birth involves dramatic changes in a newborn's environment and the processes associated with birth (labor and parturition) trigger an 'adaptive stress' response which prepares key peripheral organs for the transition to postnatal life. However, little is known about how birth influences the brain. Cell death is an important feature of nervous system development. In mice, there is increased cell death across many brain regions around the time of birth. Whether cell death is induced by parturition has not been addressed. In addition, mode of birth might be important for the normal course of cell death in the brain, because 19 days post-conception, Cesarean (C) born mice show decreased cell death in several brain regions (e.g., dentate gyrus, oriens layer of the hippocampus, and suprachiasmatic nucleus) relative to mice born vaginally (V) the same day. To systematically study how birth influences cell death, we manipulated birth mode (V vs C) in timed-pregnant mice and collected the brains of male and female offspring *in utero* at embryonic day (E)18.5 and E19 and *ex utero* (V and C birth carefully matched for time of delivery) at postnatal day (P)0 (3h after birth), P1, P3, and P23 (the latter three groups were cross-fostered to unrelated dams). We monitored the morphometric development (body weight and eye-opening) of these mice and assessed affective state by measuring ultrasonic vocalizations in an isolation test at P9. Birth mode did not affect gross development of newborn or juvenile mice. We did observe slightly increased body weight in C mice at weaning, which is consistent with clinical reports of higher body mass index in humans born by C-section. We also found that birth mode may alter neurobehavioral/affective development because C mice had significantly softer (lower amplitude) calls than V mice in the isolation test. Interestingly, call amplitude is reported to be the most salient feature of an infant's call for eliciting maternal

behavior in mice. We are currently processing the brains for the histochemical detection of cell death (activated caspase-3) and microglia (Iba1) markers. Microglia, the brain's resident immune cells, may play an active role in neuronal cell death. Parturition activates the peripheral immune system and birth mode influences the degree of this activation. Whether the immune activation at birth extends to the brain it is not known and will be investigated here. Taken together our work (previous and current) suggests that birth may be an important event for brain development and deviations from the natural mode or timing of birth may alter brain development and behavior.

Title: Chronic CRH stunts cortical neuron dendritic arborization: A basis for reduced cortical thickness in children exposed to high CRH *in utero*?

Authors: *M. M. CURRAN, C. SANDMAN, E. DAVIS, L. GLYNN, A. ANDRES, T. Z. BARAM;
Univ. of California Irvine, Irvine, CA

Abstract: Rationale: Hypothalamic corticotropin releasing hormone (CRH) initiates neuroendocrine responses to stress. CRH levels are low to undetectable in human plasma, but increase during pregnancy when primate placenta uniquely produces large amounts of CRH and releases it into maternal (and fetal) circulation. Placental CRH production and consequent maternal plasma levels are augmented by stress during pregnancy. We measured plasma CRH levels in a group of pregnant women every 5 weeks during gestation weeks 15-35 and correlated them to structural brain MRI scans of their children at 6-9 years. A 12% reduction in whole brain cortical thickness was found in the group of children who were exposed to higher levels of maternal CRH throughout gestation. How might increased maternal CRH levels lead to cortical thinning in children? Is gestational CRH merely a marker of stress and other stress hormones affect cortical development? Or might CRH directly influence cortical integrity and growth? Here we probed a potential causal role of CRH in decreased cortical thickness. We reasoned that: 1) cortical thickness is largely comprised of neuronal dendritic branches (Paus 2009); 2) chronic exposure to CRH reduces dendritic branching of hippocampal neurons (Chen 2004, 2008). Here we tested the biological plausibility of CRH-induced dendritic impoverishment as a direct

mediator of reduced cortical thickness. **Methods**: Sprague Dawley rat primary cortical cultures were used. Cortical neurons were isolated within 36h of birth and grown for 7d followed by 7d of CRH. Three experiments were performed with CRH concentrations of 0.01, 0.1, 1, 10 & 100nM. Cultures were fixed and stained for the dendritic marker MAP2 and individual neurons imaged by confocal microscopy without knowledge of treatment groups. Dendrites were manually traced, and dendritic arbors were compared using Sholl analysis. Statistical comparisons employed 2-way repeated measures-ANOVA, followed by Šídák's *post-hoc* multiple comparisons test. **Results:** Exposure to nM CRH levels decreased dendritic branching of cortical neurons in a dose dependent manner. Higher CRH concentrations (10nM, 100nM) reduced arborization significantly at 40-80µm from somata. Lower CRH levels (≤1 nM) had no significant effect. **Conclusions:** These results are consistent with a direct contribution of CRH to impoverished dendritic branching which may underlie reduced cortical thickness in children exposed *in utero* to higher peptide levels. Together with the imaging data, the results provide a novel potential mechanism for the influence of high maternal stress during pregnancy on the developing brain of her child.

Title: Prenatal stress induces epigenetic changes in the rat offspring brain

Authors: *M. C. ANTONELLI[1], M. C. MONTELEONE[2], M. E. PALLARES[1], E. ADROVER[1], A. C. FRASCH[2], M. A. BROCCO[2];
[1]Inst. de Biologia Celular y Neurociencia, Buenos Aires, Argentina; [2]Univ. de San Martin, Inst. de Investigaciones Biotecnologicas, Buenos Aires, Argentina

Abstract: The period of intrauterine development represents a sensitive window during which disruption or modification of the environment can influence fetal development and might lead to altered health throughout life course. Moderate to severe stressful life-events, in combination

with inadequate social network, are closely associated with increased child morbidity, neurological dysfunction, attention-deficit hyperactivity disorder (ADHD) and sleep disturbance during infancy, which if persist in adulthood might result in depression and vulnerability to psychotic disorders. The process of 'fetal programming' is mediated by the impact of prenatal experience on the developing hypothalamic-pituitary-adrenal (HPA) axis, a dynamic metabolic system that regulates homeostatic mechanisms, including the ability to respond to stressors, and which is highly sensitive to adverse early life experiences. Several studies support the hypothesis that parental programming is mediated by epigenetic mechanisms that stably alter gene transcription affecting physiology and behavior. In this study, we analyzed the effect of prenatal stress (PS) on gpm6aexpression and the epigenetic mechanism involved.gpm6aencodesthe neuronal glycoprotein M6a involved in filopodium extension. Hippocampus and prefrontal cortex (PFC) samples were analyzed for gene expression (qPCR for mRNAs and microRNAs), methylation status (bisulfite conversion) and protein levels in male offspring at postnatal days 28 and 60.Hippocampal neurons in culture were used to analyze microRNAoverexpression effects. Prenatal stress induced changes in gpm6alevels in both tissues and at both ages analyzed, indicating a persistent effect. Two CpG islands in the gpm6agene were identified. Variations in the methylation pattern at three specific CpGs were found in hippocampus, but not in PFCsamples from PS offspring. MicroRNAs predicted to target gpm6awere identified in silico. qPCR measurements showed that PS modified the expression of several microRNAs in both tissues, being microRNA-133b the most significantly altered. Further studies overexpressing this microRNAin neuronal cultures showed a reduction in gmp6amRNAand protein level. Moreover filopodium density was also reduced, suggesting that GPM6afunction was affected. Gestational stress affected gpm6agene expression in offspring likely through changes in methylation status and in posttranscriptional regulation by microRNAs. Thus, our findings propose gpm6aas a novel target for epigenetic regulation during prenatal stress.

Title: Involvement of the serotonergic and orexinergic systems in the antidepressant effects of light of maternally separated male Sprague-Dawley rats

Authors: *J. J. DIMATELIS[1], A. MTINTSILANA[2], D. J. STEIN[3], V. A. RUSSELL[2];
[2]Human Biol., [3]Psychiatry and Mental Hlth., [1]Univ. of Cape Town, Cape Town, South Africa

Abstract: Depression is a debilitating mood disorder that requires more effective treatment strategies because conventional treatment does not relieve depressive symptoms in all affected individuals. Maternal separation (MS) is a well-established rodent model of depression/anxiety. Chronic light exposure during adolescence has been shown to reverse the depression-like behavior induced by the early life trauma of maternal separation. We aimed to further delineate the molecular machinery involved in the anti-depressant effect of light exposure. Specifically, we investigated the involvement of the dopaminergic (DA), serotonergic (5-HT) and orexinergic systems as they have been suggested to be involved in depression. The MS paradigm (removal of the dam from the litter for 3 h/day from postnatal day (P) 2-14) was used to induce behavioral changes in male Sprague-Dawley rats, some of whom were also treated with chronic constant light (CCL) for 3 weeks during adolescence. At P80 (adulthood), rats were decapitated and brain tissue collected for analysis of glutamate- and potassium-stimulated [3H]DA release in the nucleus accumbens (NAc) using an *in vitro* superfusion technique. Enzyme-linked immunosorbent assays were employed to measure 5-HT levels in the hypothalamus and prefrontal cortex (PFC). Polyacrylamide gel electrophoresis and Western blotting was used to measure orexin receptor 1 (OXR-1) and 2 (OXR-2) in the PFC. MS rats had significantly reduced glutamate-stimulated [3H]DA release in the NAc in comparison to non-MS animals. CCL exacerbated the MS-induced reduction of [3H]DA release in the NAc. CCL increased hypothalamic 5-HT levels and reduced 5HT levels in the PFC of MS and non-MS rats. MS rats had increased OXR-1 and OXR-2 protein levels in the PFC compared to non-MS rats, an effect that was reversed by CCL. Therefore, this study has demonstrated that the antidepressant effect of CCL treatment of MS animals may be attributable to alterations in the serotonergic system and reversal of the MS-induced up-regulation of orexin receptors in the PFC.

Title: Maternal separation during breastfeeding affects eating behavior by generating a greater preference for sweetener products consumption, increase body weigh and alters locomotion activity

Authors: L. B. AYA-RAMOS[1], C. A. CONTRERAS-VARGAS[2], *Z. DUENAS[1];
[2]Med. Sch., [1]Univ. Nacional De Colombia, Bogota DC, Colombia

Abstract: It has been shown that disruption mother-breeding interaction has adverse effects on regulating physiological, neuroendocrine and behavioral systems; thus, by generating phenotypic adjustments in the eating behavior structure that alters intake patterns, especially for the highly palatable food. The aim of this study was to determine whether maternal separation during lactation (MSDL) in Wistar rats influences the sweeteners consumption, body weight gain, blood glucose level and behavioral responses such as locomotion. MSDL protocol was performed from 1 to 21 postnatal days during of 360 minutes per day, 180 in the morning and 180 in the afternoon, under the dark phase. Control group corresponds to animals that had no MSDL. On postnatal day 22 animals were distributed by sex and treatment. On postnatal day 26 experimental process started with sweeteners (sucrose, stevia, sucralose and aspartame). Sweetener consumption was taken every 24 hours, body weight gain every four days, blood glucose every five days and, on postnatal day 50 rats locomotion was tested in an open field. It was found that the maternal separation protocol generates a preference for sucrose consumption in both females and males $p<0.05$. Related with stevia and aspartame the preference was find in the females group; likewise, neonatal stress protocol generated a greater body weight gain in males with sucrose and in females with aspartame, as well as higher blood glucose levels in females with sucralose and stevia; finally, it was determined that MSDL affects locomotion in both males and females. These results indicate that neonatal stress as MSDL affects eating behavior by generating a greater preference for sweetener products consumption; besides, it may becomes a risk factor for developing chronic diseases such as diabetes and obesity.

Title: Long term consequences of maternal separation on integration of postnatally generated granule cells

Authors: M. LÓPEZ-VARGAS, A. ROQUE, L. TORNER, E. OLVERA - CORTÉZ, *N. LAJUD;
Inst. Mexicano del Seguro Social, Morelia, Mexico

Abstract: Early life stress (ELS) increases hypothalamus - pituitary - adrenal (HPA) axis reactivity and programs for psychopathology later in life. Periodic maternal separation (MS180) is widely used ELS rodent model that mimics long term consequences observed in humans, increases basal glucocorticoid levels, depressive like behavior and impairs memory and learning. MS180 decreases survival of developmentally generated granule cells at postnatal day 15 (P5); however the long term effects on these cells have not been evaluated. Therefore, the aim of this study was to test the hypothesis that maternal separation affects granule cell integration and hippocampus development. Control (CONT) and maternally separated pups (3 hours a day from P1 -14) were injected twice with BrdU at P5 (25 mg / kg) and left to survive for 2 months. At P60 animals were perfused, brains were dissected and we performed a systematic random sampling of 40μm slices (240μm apart) for Immunostaining. We estimated the number of BrdU+ cells within the granular (GC) and sub granular (SGC) layers of the hippocampal dentate gyrus. Different sets of animals were tested in the object recognition test (ORT) and the Morris water maze (MWM). MS180 decreased GC and SGC layers volume but had no effect on total BrdU+ nuclei number; however we observed a highly significant effect of MS180 on BrdU+ nuclei density wen data were plotted along the septo - temporal axis ($F_{1,125}$:26.6 $p \leq 0.0001$). Moreover, a significant increase of BrdU+ nuclei density was observed in the temporal but not the medial and septal thirds of the dorsal hippocampus. MS180 had no effect on the ORT test or the acquisition phase of the MWM but impaired memory on the probe trial. In conclusion, MS180 selectively increased integration of granule cells originated during the postnatal period and impaired memory retrieval. The work was supported by FIS (Fondo de Investigacion en Salud) grant to N.L. No: FIS/IMSS/PROT/G13/1223

Title: Alterations in learning of C7BL/6 mice following daily maternal separation

Authors: *J. D. KARP[1], N. RINALDI[2], M. FRIEDFELD[2], C. ROACH[2];
[2]Biol., [1]Rider Univ., Lawrenceville, NJ

Abstract: Interactions between young rodents and their mother can influence the physiology and behavior of the offspring when they become adults. Many studies indicate that early life experiences can predispose animals to potential anxiety-related maladaptive behaviors later in life. Early life experiences that alter reactivity to the environment may also influence the ability

of animals to learn. To investigate this possibility, we separated litters of C57BL/6 mice from their mothers daily for short periods before weaning. We evaluated the behavior of both male and female mice in two learning tasks, namely a stressful step-down test and a non-stressful novel object recognition test, after the mice became adults. We observed maternally separated male and female mice displayed longer learned step-down latencies in the stress-learning task than non-maternally separated mice. This showed maternal separation increased context-dependent anxiety. Among the same animals, maternal separation increased the amount of time male and female mice would explore a novel object in a non-stressful learning task. This showed manipulation of mother-pup interactions increases the motivation of mice to interact with their environment. Together, the results of these behavioral tests suggest that maternal separation makes both male and female mice more emotionally reactive to their environment as adults and those alterations in reactivity can influence learning both non-stressful and stressful situations. In addition, we collected brain tissue samples of the mice and assayed their prefrontal cortex, striatum, and hippocampus for dopamine and norepinephrine levels using high-pressure liquid chromatography with electrochemical detection. We found a tendency for baseline brain dopamine to norepinephrine ratios to be elevated in the prefrontal cortex of maternally separated mice. These results suggest interactions between mother mice and her pups influence long lasting neurochemical and behavioral responses presumably through epigenetic mechanisms. We are currently examining the possibility that these behavior phenotypes and/or brain neurochemical attributes can permanently influence bidirectional communication between the nervous system and other systems of the body.

Title: Characterizing Bdnf DNA methylation in the mPFC throughout development in healthy and early-life stressed rats

Authors: ***J. BLAZE**, T. L. ROTH;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Negative experiences with a caregiver during infancy can result in long-lasting changes in brain function and behavior. Victims of child abuse have increased incidences of

cognitive abnormalities and psychiatric disorders correlating to aberrant neural development, but underlying mechanisms are not well-understood. It is our central hypothesis that brain and behavior changes are conferred by early childhood adversity through epigenetic changes such as DNA methylation. DNA methylation is an epigenetic modification that alters gene transcription without changing the DNA sequence. Using a rodent model of early-life caregiver maltreatment (involving exposure to an adverse caregiving environment for postnatal days [PN]1-7), we have previously demonstrated abnormal methylation of DNA associated with the Brain-derived neurotrophic factor (Bdnf) gene in the medial prefrontal cortex (mPFC) of developing and adult male and female rats along with changes in gene expression of epigenetic regulators. BDNF is crucial for neuroplasticity and development, and aberrant Bdnf regulation has been implicated in several psychiatric disorders linked to early-life adversity. The current study aimed to more fully characterize Bdnf DNA methylation (cite-specific and 5-methylcytosine vs. 5-hydroxymethylctyosine) across multiple time-points during development in the healthy and stressed mPFC. Using a within-litter design, pups were exposed to an adverse (maltreatment condition) or nurturing (cross-foster condition) caregiving environment outside the homecage for 30 minutes each day during the first postnatal week. Remaining pups in a litter were left with the biological mother during each session (providing normal care controls). Brains were removed at postnatal day (PN) 8, 30, or 90, and bisulfite-sequencing PCR was used to quantify percentages of methylation at each CG site within Bdnf exon IV. Data indicate that early-life stress alters the normal trajectory of Bdnf methylation and confirm previous findings that methylation patterns are age- and sex- specific. We are also investigating cell-type specificity to identify methylation patterns in neurons vs. non-neurons in rats that experienced early-life maltreatment. Title: Neonatal maternal separation modifies vasopressin receptor Va1 and V1b expression during development in rat amygdala and cerebellum: it possible role in anxiogenesis and alcohol intake

Authors: *A. T. NAVA KOPP, L. ZHANG;
Dept. of Physiology, Fac. of Medicine, Natl. Autonomous Univ. of, Mexico City, Mexico

Abstract: During ontogenesis, vasopressin (VP) contributes to the regulation of proliferation and morphogenesis of the target cells and organs (brain, pituitary, kidney and liver. VP system is known to be activated around birth when VP contributes to the establishment of a new equilibrium in the body fluids and the adaptation of the fetuses to the stress of the labor. Following birth, VP induces a redistribution of the blood flow via the cardiovascular system in order to increase blood volume in the vital organs and those responsible for stress reaction (brain, pituitary gland, heart, adrenals), while reducing the blood flow in other peripheral organs. Afterwards, the physiological role of VP extends to the regulation of the cardiovascular system, water re-absorption in kidney and glucogenolysis in liver. Vasopressin's effects on the central nervous system are being extensively investigated. On the other hand, using neonatal maternal separation (MS), a well-validated rodent model used to assess the effect of early postnatal stress on cognition and emotionality in adulthood, we have previously reported that in response MS, the rat hypothalamic vasopressin system becomes up-regulated, showing increased expression of mRNA and enlarged volume of the hypothalamic paraventricular and supraoptic vasopressin nuclei. The sensitivity to acute stressors of these subjects is also increased in adulthood. In order to further investigate the mechanisms underlying this stress hyper-responsiveness, we devised a series of experiments to evaluate the expression dynamics of the VP's two major receptor types, V1a and V1b, in the MS's rat brains, compared with control, using the newly available method RNAscope (ACD, San Francisco, CA). Our preliminary data indicate a down regulation of V1a expression on the GABAergic neurons in the centro-medial nucleus of the amygdala and an up-regulation of V1b in the cerebellar cortex. The role of this modification on alcohol preference and Fos expression during anxioigenic behavioral tests will be discussed.

Title: Prenatal exposure to ethanol and early maternal separation alters HPA axis responsiveness and emotional state in young adult rats

Authors: *F. BIGGIO[1], V. LOCCI[2], M. G. PISU[3], M. C. MOSTALLINO[3], M. SERRA[1]; [1]Univ. of Cagliari, Cagliari, Italy; [2]Univ. of Sassari, Sassari, Italy; [3]Inst. of Neuroscience, Natl. Res. Council, Cagliari, Italy

Abstract: It's wide reported that adverse stress events during pregnancy as well as in early or adolescence period may fall in long-term effects on developement and emotional/behavioral states inducing deep, and sometimes irreversible changes in the adulthood (Weinstock ., 2008). Thus, the quality of prenatal environment and postnatal experiences has been shown to predict vulnerability to psychopathologies in the adult. We studied whether a moderate dose of ethanol (1g/kg,), during the pregnancy (GD17-20) and stress induced by daily maternal separation (MS 3h, PDN 3-15) alters emotional behavior and sensitivity to acute stress in adult offspring. Because maternal separation stimulates HPA activity of the dams and changes of corticosterone levels influence maternal care (Rees et al., 2004), we evaluated if exposure to ethanol during pregnancy may influence maternal behaviour. Thus, dam corticosterone levels and maternal care level were assessed during at weaning and at the first two postnatal weeks, respectively. The responsiveness of the HPA axis to stressful conditions was evaluated in young adult male rats by measuring the basal and foot shock-stimulated plasma levels of corticosterone as well as allopregnanolone. We found that prenatal treatment with ethanol and subsequent maternal separation (EtOH-MS) induced a decrease in plasmatic corticosterone and allopregnanolone content respect to counterpart not subjected to maternal separation (EtOH-NMS). Moreover, the enhancement of corticosterone and allopregnanolone levels induced by foot-shock stress in EtOH-MS was markedly increased compared to that observed in EtOH-NMS group. In addition, elevated plus maze test revealed an increase in anxiety state in EtOH-MS group respect to EtOH-NMS. As expected, (Biggio et al., 2014) we found that maternal separation induced an increase in arched-back nursing and pup-licking in mothers not exposed to ethanol. Interestingly, the exposure to ethanol during late pregnancy did not affect the maternal care of pup-separated dams. This results suggests that the alteration in emotional state and stress response in animals subjected to prenatal stress and subsequent maternal separation is not related to the quality of maternal care received. In conclusion, these results suggest that stressful experiences during pregnancy and childhood may change the programming stress-responsiveness of HPA axis involved in emotional regulation in adulthood. Title: Effects of maternal separation and post-weaning housing on social and depressive-like behaviors and neuronal oxytocin expression in rats

Authors: Y. GILLES[1], A. NTIM-ADDAE[1], L. APOLONIO[2], K. F. MANAYE[1], *E. K. POLSTON[1];
[1]Dept. of Physiol., Howard Univ. Col. of Med., Washington, DC; [2]Col. of Computing, Georgia Inst. of Technol., Atlanta, GA

Abstract: Maternal separation (MS) is a well-established rodent model for depression. The adverse effects of MS can be ameliorated by environmental enrichment. We investigated whether social enrichment in the form of group housing could also mitigate the effects of MS. Male and female Sprague-Dawley rats were assigned to two neonatal groups, MS or non- MS. MS pups were separated from their mothers for four hours each day for the first 21 days of life. Non-MS pups remained undisturbed with their mothers. On postnatal day 21, half of the animals from each treatment group were weaned into either single or same-sex group housing conditions to yield four experimental groups: maternal separated/single housed (SSH), maternal separated/group housed (SGH), non-separated/single housed (NSH), and non-separated/group housed (NGH). A social play test was performed at 5 weeks of age, followed in adulthood by two tests for depressive-like behaviors, the forced swim test (FST), and the sucrose preference test (SPT). The FST measures helplessness and the SPT tests for anhedonia, traits associated with depression in humans. All animals were euthanized and brains were removed. Sections through the hypothalamus were immunostained for oxytocin (OT), a neuropeptide that is implicated in social bonding and depression. Numbers of OT-positive neurons in the paraventricular and supraoptic nuclei of the hypothalamus (PVN, SON) were quantified stereologically. A significant main effect of post-weaning housing was observed in almost every behavioral measure. Single housed animals exhibited more social behaviors than group housed animals, irrespective of whether the behaviors were categorized as ‘prosocial’ (sniffing grooming, approach) or ‘antisocial’ (boxing, pinning, rejecting). Effects of sex and MS on social behaviors were relatively minor. Results from the FST and SPT were similar. Post-weaning housing exerted the most dominant effect on depressive-like behaviors, while the effects of sex and MS were less significant. OT cell numbers in the main cell groups of the PVN and SON did not reflect the behavioral findings; no group differences were observed in either of these regions. However, in the anterior parvocellular division of the PVN, there was a significant interaction between housing and MS treatment. In both sexes, SGH animals had significantly more OT cells than any other group. Our results show that while sex and MS treatment can influence social and

depressive-like behaviors in this model, social isolation in adulthood plays a more significant role. The effects of MS and social isolation may be related to a change in OT neuronal number in the anterior parvocellular division of the PVN.

Title: Maternal separation reduces NFKB1 and miRNA-155 expression in hippocampus of female adolescent mice with no effect of physical training

Authors: *L. WEARICK-SILVA[1], T. W. VIOLA[1], L. A. AZEREDO[1], A. CENTENO-SILVA[1], T. W. BREDY[2], R. GRASSI-OLIVEIRA[1];
[1]Biomed. Res. Inst., Pontifical Univ. of Rio Grande Do Sul, Porto Alegre, Brazil; [2]Univ. of California Irvine, Irvine, CA

Abstract: MicroRNAs belong to a family of non-coding RNAs that regulates the expression of their target mRNAs post-transcriptionally, playing important roles in development, differentiation and autoimmunity. Recent identifying identified that miRNA-155 can transcriptionally control NFKB1 gene expression in brain tissues. In addition, immune re-programming has been related to early life stress (ELS) exposure, impacting neurodevelopment. Moreover, evidences suggest that ELS activates intracellular pathways of NF-kB. Here, we investigate the expression of NFKB1 and miRNA-155 in the hippocampus of female mice exposed to maternal separation (MS). We also investigate whether physical training during infancy and adolescence could impact the expression of these targets. Newborn BALB/c litters were randomly assigned to MS or Standard Rearing (SR - Controls) at birth and were exposed to daily 3-h maternal separation from post-natal day (PND) 2 to PND15. Another set of mice were assigned to exercise group that run 60 min/day in a treadmill for 3 weeks from PND31 to PND52. At PND52 mice were tested in the Open Field Test (OFT) for anxiety-like behavior and immediately sacrificed to hippocampus extraction and NFKB1 mRNA and miRNA-155 assessed by qPCR. We found that adolescents female mice exposed to ELS exhibited lower expression of

NFKB1 mRNA and miRNA-155 in hippocampus when compared to animals not exposed to MS. Furthermore, we found that anxiety-like behavior was positively correlated with NFKB1 expression. In addition, we conducted another experiment using a moderate-intensity physical exercise during infancy and adolescence as intervention in both MS and SR animals, but we did not find any effect on those parameters previously described. Taking into account the role of that NFKB1 and miRNA-155 in immune response, our results suggests MS can modify immune-related genes expression and this could not be reverted by physical training.

Title: Effects of maternal care on amygdala, prefrontal cortex, and hippocampal development in infant rhesus monkeys

Authors: C. L. FU[1], V. K. WING[1], D. L. PADMANABHAN[1], B. R. HOWELL[3], D. G. GUZMAN[1], J. R. GODFREY[1], Y. SHI[4], M. STYNER[4], *M. SANCHEZ[2,1];
[2]Yerkes Natl. Primate Res. Ctr., [1]Emory Univ., Atlanta, GA; [3]Univ. of Minnesota, Minneapolis, MN; [4]Univ. of North Carolina, Chapel Hill, NC

Abstract: Childhood maltreatment is a detrimental experience with neurobehavioral consequences. Using a naturalistic rhesus monkey model of infant maltreatment, we have reported long-term socioemotional alterations (e.g. low affiliation; high levels of aggression, anxiety, and fear), elevated levels of stress hormones (cortisol) and brain structural alterations during adolescence (effects on brain white matter (WM) using diffusion tensor imaging and

bigger amygdala volumes) linked to poor emotional regulation. In this study we examined the unfolding of brain structural effects during infancy and the juvenile period (6-12 months of age), focusing on the amygdala, prefrontal cortex (PFC), and hippocampus, due to their critical roles in emotional and stress regulation. We also examined whether exposure to maltreatment-induced elevated cortisol levels predicted structural changes. To disentangle the effects of experience from those of inheritance on brain development, we used a cross-fostering experimental design with random assignment of infants to control or maltreating foster mothers at birth. This resulted in 42 infants (20 Control -11 females, 9 males; 22 Maltreated -8 females, 14 males-) balanced by biological mother group, sex and social rank. Structural magnetic resonance imaging (MRI) scans were acquired at 6 and 12 months of age, and rhesus infant atlases and AutoSeg software were used to generate automatic tissue segmentations (i.e. WM, gray matter -GM, cerebrospinal fluid -CSF-). These segmentation outputs were manually adjusted by 3 raters blind to group. Total volumes of the hippocampus, amygdala, and PFC GM and WM were calculated and correlated with hair cortisol prenatal exposure (from hair shaved from the back of the neck at birth) and postnatal accumulation (from birth-6 months). Smaller amygdala and PFC GM volumes were detected in maltreated animals than in controls at 12 and 6 months of age, respectively. Significant correlations were also found between amygdala and PFC volumes and levels of the stress hormone cortisol during infancy and pregnancy, respectively. No significant maternal care effects were found in the hippocampus, though, but these could emerge later in life. Our findings suggest that the neurodevelopmental effects of maltreatment emerge during infancy, but the directionality, magnitude and timing differ among brain regions, potentially due to their different developmental trajectories.

Title: Impacts of maternal stress and high fat diet on hpa axis programming in offspring

Authors: *S. ABUAISH[1,2], C. M. W. LUM[1,2], P. O. MCGOWAN[1,2,3,4];
[1]Biol. Sci., Univ. of Toronto, Scarborough, ON, Canada; [2]Cell and Systems Biol., [3]Psychology, [4]Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: The hypothalamic pituitary adrenal (HPA) axis is a neural system responsible for maintaining endocrine homeostasis, including during psychosocial stress. This system is known to be highly impacted by early life cues that later shapes the organism's response to stress, consequently modulating mental health. Early life environments, including maternal stress and overnutrition, have been independently reported to program the HPA axis, however there are no reports of their joint effect on the development of the HPA axis. This study investigated the effects of maternal stress using a chronic variable stress exposure during the last half of gestation and maternal overnutrition in the form of high fat diet (HFD) exposure during gestation and lactation on HPA-related behavioural and physiological measures in rat adult offspring. Preliminary results show that maternal chronic variable stress and maternal HFD induced an increase in HPA axis reactivity in dams during pregnancy, as indicated by increased corticosterone levels in response to a restraint challenge. In addition, HFD increased maternal behaviour, a known mediator of HPA programming in offspring. Adult offspring showed sexually dimorphic alterations in anxiety-like behaviour. Male offspring from HFD litters showed decreased anxiety-like behaviour on the elevated plus maze test regardless of their exposure to prenatal stress. Female offspring from prenatally stressed HFD litters showed increased anxiety-like behaviour in the open field test. This was comparable to the increased anxiety-like behaviour exhibited by female offspring from either maternal stress or HFD litters. In addition, anxiety-like behaviour on the elevated plus maze test and corticosterone levels in response to a restraint challenge were significantly correlated with the amount of maternal care provided to the male offspring. These behavioural changes could be mediated through differential gene expression and underlying epigenetic modification of HPA-related genes in limbic regions, which will be examined in ongoing studies.

Title: Impact of Early Life Stress during Stress Hyporesponsive period (SHRP) attenuates both fear retention and extinction in rats

Authors: *P. K. MISHRA, JR, L. T. RAO, B. M. KUTTY;
NIMHANS, Bangalore, India

Abstract: Purpose: The long-term impact of 10-days of maternal separation stress on the fear memory and fear extinction was evaluated in male Wistar rats. **Methods:** Early maternal separation and isolation stress (EMS) were carried out in rat pups during the Stress Hypo Responsive Period (SHRP) for 6 hours daily for 10 days, while effects on fear retention and extinction were ensured 2 months later. 2 months after EMS, rats were exposed to cued fear conditioning session. 24 hours, 48 hours and 72 hours after fear conditioning, both normal control and EMS groups of rats were received extinction training sessions respectively. Percentage freezing was assessed during all stages of fear retention and fear extinction training including session of retention of fear extinction. **Results:** The retention of fear memory was stronger in EMS rats than controls. 10 days after extinction training session, EMS rats showed increased freezing to the conditioned stimulus than controls. **Conclusions:** Our data suggested that EMS causes a long-term behavioural disposition that is activated by acute stressors like fear conditioning. **Affiliation:** CSIR, ICMR and NIMHANS, Government of India for the financial support. **Key Words:** Maternal separation stress, SHRP, Fear conditioning, Extinction

Title: A blend of dietary prebiotics and the probiotic LGG modulate behavioral and cognitive responses to maternal separation stress

Authors: R. V. WAWORUNTU[1], K.-A. M. NEUFELD[2], *B. M. BERG[1], S. M. O'MAHONY[3], T. G. DINAN[4], J. F. CRYAN[3];
[1]Mead Johnson Nutr., Evansville, IN; [2]Alimentary Pharmabiotic Ctr., [3]Dept. of Anat. and Neurosci., [4]Dept. of Psychiatry, Univ. Col. Cork, Cork, Ireland

Abstract: Maternal separation (MS) of rat pups is a robust and reliable model of early life stressed-induced alterations in behavior. Changes in the gut microbiota of MS rat pups have also been found, suggesting gut-brain axis signaling to be an important mechanism of action. Since certain dietary factors are known to impact composition and diversity of the gut microbiota, this study assessed the impact of consuming prebiotics polydextrose (PDX) and galactooligosaccharide (GOS) with or without the probiotic Lactobacillus rhamnosus GG (LGG) during early development on cognition, social- and anxiety-related behaviors in rodents. Rats were separated from their mothers between postnatal day (PD) 2 to 12. Both MS and non-

separated (NS) rats (N=5-9 each) were fed control or prebiotic diet (7 g/kg PDX-GOS) with or without LGG (108 cfu/ml) in drinking water from PD 21 throughout behavioral testing to PD 100. Overall there were no differences in body weight or food intake across diets. However, the open field test revealed that MS rats traveled a shorter distance with reduced velocity than NS rats ($p<0.05$). These MS effects were ameliorated by prebiotic feeding ($p<0.01$) and LGG ($p<0.01$), but interestingly not when combined. MS rats displayed deficits in spatial memory in the Morris water maze ($p<0.05$) while rats fed prebiotic plus LGG showed a reversal of this impairment ($p=0.05$). In conclusion, these results demonstrate that both prebiotics and LGG ameliorate early life stress-induced changes in adult behavior and when combined can improve memory performance.

Title: Cross-fostered high-yawning dams increased stress responses in the outbred Sprague-Dawley rats: a base of atypical maternal care

Authors: *C. URIBE[1], C. CORTES[1], J. R. EGUIBAR[1,2];
[1]Inst. De Fisiología BUAP, Puebla, Mexico; [2]Res. Office-VIEP, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico

Abstract: Maternal care in rats determined stress responses in adulthood. So, lower maternal licking-grooming (LG) and arched-back nursing (ABN), increase the responses in the hypothalamic-pituitary-adrenal (HPA) axis after middle-stress maneuvers. Anxiety-like responses also dependent on the maternal care received. Pups that receive less maternal care showed epigenetic changes that can be transfer from the mothers to daughters. In our laboratory, we selectively bred a high-yawning (HY) subline with a mean of 20 yawns/h that showed lower nest quality, lower latency to retrieve the pups but showed atypical retrieving and re-retrieving. The aim of this study was to analyze the effect of maternal care on stress responses using the cross-fostering technique. The subjects (Ss) were maintained under standard conditions. In the first 12 h after delivery we adjusted the litters to eight pups and culled by sex and exchange all the litter between HY and Sprague-Dawley (SD) dams, and in-fostering used as a control group. At 90 of age, all Ss were tested in light-dark box and in the open-field arena. Twenty min later we obtained blood in a tube by decapitation. Plasma was recovered by centrifugation (3500 r.p.m.) during 10 min. Plasma was separate using Pasteur pipettes, stored in freezer at -20oC until ELISA assays were done. Corticosterone and adrenocorticotropic hormones were measured using ELISA kits (Corticosterone ELISA Kit Catalog No. ADI-900-097, Enzo®; Adrenocorticotropic Hormone ELISA Catalog No. 21-ACTHU-E01 ALPCO®). Results were summarized in the table 1. Results show that HY subline showed less anxiety levels, but SD offspring raised by HY dams showed higher anxiety levels and more HPA activation after open field test. Therefore, HY dams are likely model of maternal maltreatment because mimics human inadequate maternal care that is elevated anxiety responses and higher responses in the HPA axis.

Title: Effect of VNS-paired extinction of conditioned fear in a VPA-induced animal model of autism

Authors: ***A. ALVAREZ-DIEPPA**, K. GRIFFIN, S. CAVALIER, P. SEKAR, C. MCINTYRE; Univ. of Texas At Dallas, Richardson, TX

Abstract: Administration of vagus nerve stimulation (VNS) during trials of fear extinction reduces expression of conditioned fear faster than extinction training alone. Our preliminary studies show that VNS pairing with extinction training affects expression of markers of synaptic plasticity in the basolateral complex of the amygdala (BLA), an area of the brain that is important for extinction learning, leading to an increase in P-CaMKII and GluN2B expression and a decrease in Arc protein levels. Although we've shown that VNS can enhance extinction of fear and affect plasticity in the BLA of healthy rats, the ability of VNS to rescue impaired extinction learning is yet to be tested. Rats prenatally exposed to VPA on day 12.5 of gestation

(VPA-exposed rats) are used as an animal model of autism, and they exhibit impaired extinction of conditioned fear. This study was designed to test the potential of VNS to reverse extinction impairments in the VPA-exposed rat model of autism. VPA-exposed and saline-control rats were subjected to auditory fear conditioning followed 24 hours later by extinction training that was paired with either VNS or Sham stimulation. During a conditioned fear response test on day 3, VPA-exposed rats that received VNS during extinction training showed freezing levels that were similar to those of saline-control rats, and significantly lower than those of VPA-exposed rats that received sham stimulation during extinction training. Results suggest that VNS-paired extinction can rescue impaired extinction learning in the VPA-exposed animal model of autism.

Title: *In vivo* imaging of vagal afferent neurons to decode internal senses

Authors: *E. K. WILLIAMS, D. E. STROCHLIC, R. CHANG, B. D. UMANS, S. LIBERLES; Harvard Med. Sch., Boston, MA

Abstract: The vagus nerve controls diverse physiological processes, including feeding behavior, respiration, blood pressure, heart rate, nausea, and cough. However, little is known about the repertoire of sensory mechanisms residing in vagal sensory neurons, or the diversity of vagal cell types that transmit signals from the periphery to the brain. We developed an *in vivo* imaging technique involving genetically encoded reporters of neural activity that enables a massively parallel analysis of individual vagal sensory neuron responses. We found discrete vagal sensory neuron subsets responsive to different physiological stimuli. Furthermore, using genetic tools, we have identified molecular marks for subsets preferentially responsive to particular stimuli. These molecularly defined subsets exhibit specific peripheral and central projection patterns, and control specific physiological functions. These studies provide the first direct insights into single-neuron receptive fields, and the molecular identities of functional subsets in this key body-

to-brain sensory system. Determining response properties of individual neuron types is a critical first step towards understanding sensory transduction mechanisms.

Title: Lipolysis activates sensory nerves in white fat

Authors: ***J. T. GARRETSON**, V. RYU, L. A. SZYMANSKI, T. J. BARTNESS;
Biol., Georgia State Univ., Atlanta, GA

Abstract: Background: White adipose tissue (WAT) lipolysis is principally initiated by central signals via the sympathetic nervous system (SNS). Sensory circuits innervating fat multisynaptically connect into central feedback loops back toward WAT and elsewhere throughout the CNS in areas dense with metabolic function (e.g. nucleus of the solitary tract, rostral ventral lateral medulla, paraventricular hypothalamus) yet the physiological role of WAT afferents in metabolism is still unknown; therefore, we tested if lipolysis triggers increases in WAT sensory nerve activity. Method: Siberian hamsters were anesthetized, nerves innervating left and right inguinal WAT (IWAT) were resected, cut, and decentralized distal trunks attached to electrodes for afferent nerve electrophysiological multiunit measures. CL316,243, a specific β3 receptor agonist, was unilaterally infused into IWAT simultaneously with saline into the contralateral fat pad to test if β3 agonism-induced lipolysis increases IWAT afferent nerve activity using each animal as its own control. Glycerol (0.13mM) and eicosopentanoic acid (EPA, 0.29mM), products highly released during natural lipolysis, also were tested to answer which specifically affect IWAT afferents. Fat pad-specific spike frequency was assessed and analyzed as percent change from baseline activity over time compared with saline vehicle-injected contralateral recording. Results: CL316,243 (a dose and injection method confirmed to cause lipolysis as indicated by increased WAT phosphorylated hormone-sensitive lipase (pHSL)) trigged rapid (<10 min) increases in IWAT afferent nerve multiunit activity nearly 2-fold versus the saline vehicle control in the contralateral IWAT. Glycerol and EPA caused similar patterns of activation. Conclusions: These results indicate that β3-induced lipolysis and products of this process are sensed by IWAT sensory nerves rapidly. Afferent transduction of lipolysis likely

feeds back though spinal and central circuits to affect SNS drive. Future studies will elucidate the physiological role of this activation.

Title: Differential distribution of adiponectin receptors 1 and 2 in olfactory bulb and hippocampus in the rat and insulin receptor induction by adiponectin

Authors: *A. MIRANDA-MARTINEZ[1], R. GUEVARA-GUZMÁN[2];
[1]Fisiologia, Univ. Nacional Autonoma De Mexico, Mexico, Mexico; [2]Fisiologia, Univ. Nacional Autonoma de Mexico, Mexico, Mexico

Abstract: Introduction: Adiponectin (APN) is an adipocyte-derived hormone that has peripheral beneficial effects as anti-inflammatory, cardioprotective, anti-atherogenic, also as metabolism modulator and insulin pathway sensitizer. Even though there is evidence of the presence of adiponectin and its receptors in the brain, little is known about its influence in Central Nervous System. Furthermore, brain is an insulin-sensitive organ with wide expression of insulin receptor (InsR) particularly in areas related to cognitive processing and feeding regulation, however there are no reports about the induction of this receptor by means of APN. Objective: The aims of this work were to describe the presence and distribution of Adiponectin Receptor 1 and 2 (AdipoR1 and AdipoR2) in the olfactory bulb (OB) and hippocampus (HIPP) of rats and evaluate the effects of APN administration in brain over InsR expression in these two brain structures. Methodology: Intact male Wistar rats weighting 250-300 grs were used for immunofluorescence

and PCR assay. For Western Blot, animals were injected in OB or HIPP with 1µg of APN (1µg/µl); control animals followed the same procedure receiving only isotonic saline solution. OB and HIPP were dissected, homogenized and supernatants collected. 60 micrograms of protein was electrophoresed for InsR protein content. Results: Our data have showed presence of AdipoR1 and AdipoR2 in periglomerular, mitral and granulose cell layers in OB; also in pyramidal cells of CA1 and CA3 and granular cells of dentate gyrus in HIPP. Moreover, a significant increase in the amount of InsR in the OB of APN hippocampal treated group versus control was observed. Histological analysis shown that there are more InsR positive cells in OB and HIPP in animals treated with APN compared with control. Conclusion: Our results indicate that AdipoR1 and AdipoR2 are expressed in different cellular groups in OB as well as in HIPP in rat brain. These receptors correspond with those described for skeletal muscle and liver respectively. In addition, we also showed that APN regulates InsR content mainly in the OB than in HIPP.

Title: Effects of long-term estrogen replacement in the ventromedial nucleus of the hypothalamus on ovariectomy-induced changes in body weight, fat distribution and bone mass in rats

Authors: Z. ZHANG[1], *A. KALSBEEK[3], E. FLIERS[1], A. BOELEN[1], J. LIU[2], Y. SU[1], E. FOPPEN[1], B. C. J. VAN DER EERDEN[4], N. BRAVENBOER[5], P. H. BISSCHOP[1]; [1]Dept. of Endocrinol. and Metabolism, [2]Academic Med. Ctr. (AMC), Amsterdam, Netherlands; [3]Academic Med. Ctr. (AMC), Dept Endocrinol & Metab, Amsterdam, Netherlands; [4]Dept. of Intrnl. Med., Erasmus MC, Rotterdam, Netherlands; [5]Dept. of Endocrinol. / Clin. Chem., VU Univ. Med. Ctr., Amsterdam, Netherlands

Abstract: Estrogens play an essential role in energy and bone metabolism. In rodents, ovariectomy (OVX) causes increased body adiposity and bone loss which is reversible with systemic estradiol (E2) treatment. Recent studies have indicated that within the brain the hypothalamus, in particular its ventromedial nucleus (VMH) is involved in the effect of E2 on energy homeostasis. Moreover, the VMH regulates bone metabolism via the sympathetic

nervous system. In our study we aimed to determine in rats: 1) the effect of chronic intracerebroventricular (icv) administration of E2 on white adipose tissue (WAT) metabolism after OVX, and 2) the effect of E2 in the VMH on WAT metabolism, calorie ingestion, energy expenditure and bone mass. Icv E2 for 4 weeks decreased body weight and reduced visceral but not subcutaneous fat, confirming that central E2 administration affects body fat distribution. Next we administered E2 into the VMH for 3 hours by bilateral microdialysis. E2 in the VMH increased LPL and HSL gene expression in gonadal WAT, indicating a role for the VMH in peripheral WAT metabolism. Finally, we administered E2 into the VMH of OVX rats for 4 weeks by using slow-releasing E2 containing beeswax pellets. Food and water intake during the light period were reduced by E2 administration in the VMH. Metabolic cages data showed a lower respiratory exchange rate (RER) in the E2 group during the light period indicating increased fat oxidation in the E2 treated group. Although, total food intake was not significantly different, food efficiency (gram body weight gain per gram chow) was decreased in the E2 VMH group compared to the control group. The effect of E2 administration on bone metabolism was determined 8 weeks after E2 containing pellets were implanted in the VMH. Femur bone mass and structure was evaluated by high resolution micro CT scanning. Both trabecular bone number and bone thickness were decreased after OVX. However, E2 administration in the VMH did not change total or trabecular bone number. In conclusion, we showed that chronic E2 administration in the VMH of ovariectomized rats affects body fat distribution and energy balance, but does not prevent bone loss.

Title: The combination phentermine + 5hydroxytryptophan/carbidopa showed a synergistic effect on food intake and weight loss in rats: a new drug combination therapy for obesity

Authors: ***C. PEREZ DIAZ**[1], B. KALYANASUNDAR[1], M. G. MORENO[1], A. LUNA[1], S. A. SIMON[2], R. GUTIERREZ[1];

[1]CINVESTAV, MEXICO CITY, Mexico; [2]Dept. of Neurobio., Duke Univ. Med. Ctr., Durham, NC

Abstract: Obesity is a major public health problem. Although the main treatment for obesity should be diet and exercise, for some people these activities are frequently supplemented with the use of appetite suppressants. Recently Hendricks et. al. 2009 reported that physicians frequently prescribed a new drug combination of appetite suppressants for the treatment of overweight: phentermine(PHEN) plus 5hydroxytriptophan/carbidopa(5HTP/CB). 5HTP is a precursor of serotonin, carbidopa is a peripheral L-aromatic decarboxylase inhibitor, leading to more 5HTP available to enter the brain; and PHEN acts inhibiting recapture of dopamine, norepinephrine and serotonin. Despite that this seems to be a common practice, the use of this combination has not extensively study and currently it is not authorized by the FDA. Furthermore, it is not known if this combination is synergistic at the behavioral level(body weight-loss, food suppression and locomotor activity) and modulating single-unit activity in the nucleus accumbens shell(NAcS). The main goal is to determine the efficacy of this combination at the behavioral and electrophysiological level in rats. To address this issued, we used i.p injections of PHEN and 5HTP/CB either alone or in combination for 7 days daily treatment. For PHEN and 5HTP/CB the ED50 for weight loss was 15 and 31 mg/kg, respectively. We then combined the ED50 of 5HTP31 and CB75mg/Kg against the ED25, ED50 and ED75 of PHEN(10, 15 and 20 mg/kg, respectively). We found that the combination significantly produced a larger increase in weight-loss, strongly decreased food intake and a reduction in locomotor side effects relative to its compounds by themselves. This data demonstrate at the behavioral level that the combination PHEN+5HTP/CB are synergistic. Now we record single-unit activity of the NAcS in order to shed light of the neuronal correlates of this synergism(only CB75+5HTP31+PHEN15). We found that PHEN15 alone exerts a strong inhibitory imbalance towards inhibition(n=74, inh 62%: act 9%), whereas PHEN15 in the presence of 5HTP/CB induced a quite similar inhibition in 57% inhibited neurons (out of 140) and 7% was activated. These data indicates that the combination do not interfere with the ability of PHEN15 to inhibits the NAcS activity. Our pilot studies indicated that PHEN+5HTP/CB combination exhibits synergism of its pharmacological effects and reduced their adverse effects. Hence this preclinical evidence demonstrated for the first time a synergistic combination with its possible neuronal mechanism in the brain reward region(NAcS) supporting the use of this combination as future therapy for the treatment of obesity.

Title: Genetic ablation and pharmacological blockade of FKBP51 in mice reduces obesity and metabolic dysfunction

Authors: *G. BALSEVICH[1], N. C. GASSEN[1], A. HÄUSL[1], C. W. MEYER[2], X. FENG[1], C. DOURNES[1], A. URIBE[1], M. THEODOROPOULOU[1], M. PAEZ-PEREDA[1], T. REIN[1], F. HAUSCH[1], A. CHEN[1], M. H. TSCHÖP[2], M. V. SCHMIDT[1];
[1]Max-Planck-Institut für Psychiatrie, Munich, Germany; [2]Inst. for Diabetes and Obesity, Helmholtz Ctr., Munich, Germany

Abstract: FKBP51 is an immunophilin protein best known as a regulator of the glucocorticoid receptor and consequently the physiological stress response. Additional functions of FKBP51 include the regulation of AKT signaling, which represents a central node within the insulin signaling pathway and a key pathway found to be deregulated in type 2 diabetes (T2D) and obesity. In mice, genetic ablation of FKBP51 furthermore results in a reduced body weight phenotype. Nevertheless, whether FKBP51 plays a critical role in whole body energy and glucose homeostasis remains to be elucidated. We aimed to characterize the role of FKBP51 in energy and glucose homeostasis using FKBP51 knockout (51KO) mice. We found that 51KO mice were protected from high fat diet-induced weight gain and glucose intolerance. In addition 51KO mice showed a prolonged response to insulin examined in an insulin tolerance test. At a molecular level, we found that insulin signaling was enhanced specifically within skeletal muscle of 51KO mice. In line with these findings, glucose uptake was significantly increased by FKBP5 knockdown in differentiated myotubes. In order to assess whether pharmacological blockade of FKBP51 may serve as novel therapeutic possibility, we treated mice with a highly selective FKBP51 antagonist (SAFit2) for either 10 or 30 days. We report that systemic treatment with SAFit2 lowered body weight gain and glucose tolerance. Finally, in C2C12 myotubes, SAFit2 treatment increased glucose uptake. These data directly implicate FKBP51 in metabolic regulation and provide evidence for the therapeutic potential of FKBP51 in the treatment of obesity and T2D.

Title: Central GLP-1 signaling contributes to cancer anorexia and body weight loss in hepatoma tumor bearing rats

Authors: *T. BORNER, T. A. LUTZ, T. RIEDIGER;
Inst. of Vet. Physiology, Univ. of Zurich, Zurich, Switzerland

Abstract: The cancer-anorexia-cachexia syndrome (CACS) negatively affects therapy success and quality of life in cancer patients. The area postrema (AP) and the nucleus of the solitary tract (NTS) are involved in the control of food intake and implicated in the mediation of emesis and nausea. Neurons in the AP/NTS are activated in tumor-bearing (TB) animals. In our recent study, a specific surgical lesion of the AP attenuated anorexia and body weight loss induced by tumor growth in rats. While this clearly supported a role of the AP in the mediation of CACS, the exact mechanism still needs to be elucidated. In the brainstem, the neuropeptide glucagon-like peptide-1 (GLP-1) mediates food aversions and anorexia induced by toxins and endotoxins. Therefore, we hypothesized that GLP-1 signaling could also play a role in tumor-dependent anorexia. Using a rat hepatoma tumor model, we investigated if a pharmacological blockade of brainstem GLP-1 receptors (GLP-1R) ameliorates cancer anorexia. In addition, we tested if tumor growth was paralleled by a conditioned food aversion. Chronic fourth ventricular administration of the GLP-1R antagonist exendin-9 (100 µg/day, $n = 8$) partially reversed the anorexia in TB rats leading to a significantly higher mean daily food intake compared to vehicle-treated TB animals (16.3 ± 0.4 vs. 13.9 ± 0.6 g, $n = 8$, $p < 0.01$). Furthermore, exendin-9 treatment attenuated tumor-induced body weight loss in these animals (-16 ± 2.4 vs. -27.4 ± 4.7 g, $p < 0.05$). In non-tumor-bearing (NTB) rats, the same exendin-9 treatment did not affect food intake or body weight. Hence, the anti-anorectic effect of GLP-1R blockade in TB animals appears to be unrelated to alterations of baseline food intake. To examine the presence of tumor-induced food aversion, a two diet choice paradigm was used. Food preference for two flavored diets was tested before tumor induction. During tumor growth, animals received their preferred diet for 8 days; non-tumor-bearing rats were included as controls. A second preference test was conducted for 5 consecutive days during the anorectic phase. While diet preference was preserved in NTB rats ($n = 7$), the preference for the previously preferred diet decreased from 83 to 8% in TB rats ($n = 8$, $p < 0.001$). The conversion of diet preference into diet avoidance in hepatoma tumor-bearing rats suggests the development of a tumor-induced food aversion. This study provides first evidence for a role of central GLP-1 signaling in the mediation of cancer-anorexia and body weight loss. Tumor-induced food aversion might be a contributing factor to cancer anorexia in this tumor model. GLP-1R antagonists may be therapeutically useful for the treatment of CACS.

Title: High fat diet results in activation of microglia and reorganization of the nucleus of the solitary tract as well as a change in the intestinal microbiota

Authors: *K. CZAJA[1], A. VAUGHN[2], E. M. COOPER[2], P. M. DILORENZO[3], L. J. O'LOUGHLIN[2], M. E. KONKEL[2], J. H. PETERS[2];
[1]VCAPP, Univ. of Georgia, Athens, GA; [2]Washington State Univ., Pullman, WA; [3]Binghamton Univ., Binghamton, NY

Abstract: In the current study, we studied whether high fat diet results in microglia activation and reorganization of nucleus of the solitary tract (NTS) and alters gut microbiota in Sprague Dawley rats. One group of rats was fed regular rodent diet (RD; Teklad F6; 3.1 kcal/g; 6.4 % fat) for the entire experiment and a second group received RD for two weeks followed by a high fat diet (HFD; Open Source D12492; 5.24 kcal/g; 34.9 % fat) for four weeks. Body weight and food intake were monitored three times a week. Fresh fecal pellets containing the intestinal microbiota were collected from all rats before introducing the HFD at day 7 and again at day 28. Body fat composition was determined by Dual-Energy X-ray Absorptiometry (DEXA) scans before and after introduction of the HFD. At the completion of the study (animals demonstrated diet-induced obesity), rats were perfused (4% paraformaldehyde) and the hindbrains were collected, sectioned, and stained using standard immunofluorescence methods. Additionally, sections of the cecum, duodenum, and jejunum were collected for microbiome analysis. Microglia activation was determined using an antibody against Isolectin 4 to label vagal afferents and by quantifying changes in the density of fluorescent staining with an antibody against ionizing calcium adapter binding molecule 1 (Iba1). We found that HFD-induced obesity triggered a shift in the intestinal microbiota. Specifically, we observed an increase in Streptococcus mitis in the distal jejunum and an increase in Proteus mirabilis, Lactobacillus animalis, and Enterococcus faecalis in the caecum, as determined by 16S ribosomal sequencing. In addition, HFD-induced obesity resulted in withdrawal of vagal afferents as well as microglia activation in the intermediate NTS of rats. Neural damage was also observed when neurons were treated *ex vivo* with each of the bacteria, as judged by fluorescence staining with Beta III-tubulin antibody. The alteration in intestinal microbiota, degeneration of vagal neurons innervating the gut, and inflammation with reorganization of the hindbrain feeding centers in response to diet-induced obesity is consistent with a previous report of neuroanatomical alterations in the gut-brain communication following damage to the peripheral vagal nerve. This model system provides a foundation to investigate the relationship between microbiota and neural damage in animals with diet-induced obesity and sets

the stage to address whether specific bacterial species contribute to the disruption of vagal signaling and obesity.

Title: Effects of ethanol administration on energy homeostasis in male Long Evans rats

Authors: ***N. NELSON**[1], N.-C. LIANG[2];
[1]Neurosci. & Psychology, Univ. of Illinois At Urbana-Champaign, Champaign, IL;
[2]PSYCHOLOGY, Univ. of Illinois- Urbana Champaign, Champaign, IL

Abstract: Ethyl alcohol is an energy-containing (7 kcal/g) beverage widely consumed for its relaxing and mood elating effects. In developed countries, alcohol-derived energy comprises 10-15% of total energy intake by adults. Many epidemiological and laboratory studies with humans have often reported opposing findings regarding the relationship between alcohol and energy balance. Reports from rodent studies are also inconclusive. The inconsistencies necessitate well-controlled animal studies. Here, we hypothesized that the effects of alcohol on food intake and body weight (BW) are dose-dependent. Male *Long Evans* rats were first habituated to i.p. injections of saline every other day for one week (3 injections total). All injections occurred 2hrs before light onset. Then they received either ethanol (EtOH) or saline (SAL) injections. The SAL group received only saline injections at the same time when the EtOH rats were injected with ethanol. The EtOH group received the dose of 1 g/Kg every other day for 2 weeks (6 injections total), followed by the dose of 3 g/Kg administered once per week for 4 weeks (4 injections total). Initially, rats had *ad lib* access to standard laboratory chow and tap water, and subsequently a 45% high fat (HF) diet was introduced on the second week of 1 g/Kg EtOH injections. The data indicated that SAL and 1 g/Kg EtOH injections had no effect on food and water intake. When both chow and HF diets were available, the SAL and EtOH treated rats all preferred the HF diet and did not differ in their diet preference. However, EtOH at the dose of 3 g/Kg significantly suppressed food and water intake up to 85% and 36%, respectively ($P<0.001$). Food intake suppression lasted for at least 72h post-injection. As a result of reduction in food intake, weight gain in the EtOH group was suppressed, and thus the BW of EtOH rats (382.5±6.7 g) was significantly lower than that of the SAL controls (511.7±17.3 g) after the last injection ($P<0.05$). The lower BW of the EtOH group was sustained even after two weeks without EtOH treatment (SAL 503.8±17.0 g vs EtOH 413.1±8.4 g; $P<0.05$). At the end of the experiment,

visceral fat was dissected and weighed. Compared to the SAL controls (4.3±0.5%), the EtOH rats (1.7±0.3%) had less percent visceral fat composition (P<0.05). Overall, these results indicate that 3 but not 1 g/Kg EtOH suppress appetite and weight gain and support the hypothesis that the effects of ethanol on energy homeostasis are dose dependent.

Title: Effects of Roux-en-Y gastric bypass surgery on lingual fatty acid receptor expression in high fat diet-induced obese female rats

Authors: ***A. HAJNAL**[1], A. M. ROGERS[2], S. D. PRIMEAUX[3,4];
[1]Dept Neural & Behav Sci., [2]Surgery, Penn State Univ., Hershey, PA; [3]Dept. of Physiology, Joint Diabetes, Endocrinol. & Metabolism, LSUHSC, New Orleans, LA; [4]Pennington Biomed. Res. Ctr., Baton Rouge, LA

Abstract: The fatty acid receptor, CD36, on the circumvallate papillae of the tongue has been implicated in the preference for and intake of dietary fat. CD36 knock-out mice exhibit a reduced preference for linoleic acid and selective decreases in CD36 expression on the circumvallate papillae attenuates the preference for linoleic acid in rats (Chen et al., 2013; Sclafani et al., 2007). Lingual CD36 expression is hypothesized to alter fat intake and fat preference, thereby leading to changes in body weight. Roux-en-Y gastric bypass (RYGB) surgery has been successfully used as a treatment for obesity. Following gastric bypass surgery, the preference for and sensitivity to dietary fat, as well as other tastants, is altered. The goal of the current experiment was to assess fatty acid receptor mRNA levels on the circumvallate papillae following RYGB in female rats. All rats undergoing surgery were fed a high fat diet (HFD, 60%kcal of fat) for 14 weeks prior to surgery. Five months following RYGB or sham surgery, rats were sacrificed following an overnight fast. A control group fed a standard chow diet was included. CD36 mRNA levels were assessed by Real Time PCR. Sham-operated rats consuming the HFD weighed more than RGYB rats fed HFD and control rats, at the time of sacrifice. CD36 mRNA levels were increased by the consumption of the HFD in the sham-operated rats

compared to the control rats. RYGB attenuated the HFD-induced increase in CD36 mRNA expression on the circumvallate papillae. Decreased expression of CD36 on the circumvallate papillae following RYGB suggests that this mechanism may play a role in the reduced preference for dietary fat in these individuals. Analyses of the fatty acid receptors, GPR40 and GPR120 on the circumvallate papillae are underway. Supported by NIH Grants DK080899 and DC000240 to AH and LSUHSC to SDP.

Title: Obese rats induced by high-sucrose diet promote a stage of hypoalgesia: Antinociceptive effects of ketoprofen

Authors: *O. A. JARAMILLO-MORALES[1], J. V. ESPINOSA-JUAREZ[1], J. N. CORONA-RAMOS[2], F. J. LOPEZ-MUNOZ[1];
[1]Cinvestav, DF, Mexico; [2]CINVESTAV, Mexico, Mexico

Abstract: BACKGROUND.Obesity is a risk factor associated with alterations in the pain perception, however, it is unclear what mechanisms underlie this association. NSAIDs are the most commonly used drugs in the treatment of pain, for example, ketoprofen. However, there are no studies evaluating the analgesic response to ketoprofen in patients obese. The aim of this study was to analyze the nociceptive pain in Wistar rats obese hypoestrogenic with high sucrose diet and to compare the antinociceptive response using ketoprofen. METHODS.The hypoestrogenism was induced by bilateral ovariectomy. Animals received hypercaloric diet (30% sucrose in drinking water) or water ad libitum for 17 weeks. At the end of treatment were measured thermal nociception, body weight, tolerance to oral glucose, weight of abdominal fat and it was evaluated differents dosis of ketoprofen (10, 31.6 or 100 mg/Kg p.o) in both groups. The nociception was assessed using the “Plantar test” method. RESULTS.The hypoestrogenic Wistar obese rats with high sucrose diet had significantly higher body weight and abdominal fat weight than the control groups. Also, it was observed significantly increased in thermal latency compared to their control group. There were no differences in basal blood glucose levels, however, showed altered oral glucose tolerance. The administration of ketoprofen showed dependent effect of dose in both groups, nevertheless, the antinociceptive efficacy was not different but potency showed statistical differences. CONCLUSIONS. Our data suggests that

obesity may contribute stage of hypoalgesia, as well as changes in the antinociceptive potency of ketoprofen in Wistar rats obese hypoestrogenic.

Title: A role for vitamin D in diet-induced obesity and dopamine-related behaviors

Authors: *J. R. TRINKO[1], B. B. LAND[1], W. B. SOLECKI[1], R. J. WICKHAM[1], L. A. TELLEZ[1,2], J. G. MALDONADO-AVILES[1], I. E. DE ARAUJO[1,2], N. A. ADDY[1], R. J. DILEONE[1];
[1]Ribicoff Res. Facilities, Dept. of Psychiatry, Yale Univ., New Haven, CT; [2]The John B Pierce Lab., New Haven, CT

Abstract: Human obesity rates have increased over the past two decades. Interestingly, vitamin D3 deficiency rates have also increased within a similar timeframe and clinical research has identified an inverse relationship between circulating vitamin D3 levels and body mass index (BMI). However, a causative role for this deficiency in the development of obesity has not been explored. Using mice, we assessed the effect of this deficiency on diet-induced obesity (DIO). A high-fat diet was modified to have reduced dietary vitamin D3 (HF-D, containing 9-11% of the control HF vitamin D3). At day 50 of ad libitum feeding, HF-D mice were found to have significantly reduced circulating levels of vitamin D3. From days 50 to 100, the HF-D mice began to display a persistent gain in body weight (BW), demonstrating that deficiency can contribute to obesity, as well as increased food intake (FI). Alternatively, we explored the effects of exogenous treatment of fully active vitamin D3 (calcitriol) on mice that were made leptin-resistant by previous ad libitum consumption of the HF diet. Calcitriol caused a reduction in FI and BW after an acute treatment with fully active exogenous D3 (calcitriol, 10 μg/kg). These effects were enhanced in mice that received both calcitriol and leptin (3 mg/kg). Chronic calcitriol (1.0 μg/kg daily) also reduced FI and BW in mice previously exposed to 1 yr of HF diet. Because similar alterations in dopamine (DA) signaling have been observed in the brains of both obese individuals and drug addicts, and since evidence exists supporting vitamin D3 effects on DA neurons in rodents, we explored the possible role for D3 in regulating the DA system and

associated behaviors. Vitamin D3 receptor (VDR) protein, which functions as a transcription factor, was detected in DA neurons of the midbrain and striatum of mice. Acute calcitriol caused upregulation of tyrosine hydroxylase and dopamine transporter in the midbrain, and upregulation of dopamine receptor type 2 in the ventral striatum. Treatment also enhanced amphetamine-induced (2.5 mg/kg) dopamine release as assessed by microdialysis and fast scan cyclic voltammetry, suggesting a role in DA signaling. In the deficient state, HF-D mice showed attenuated locomotor responses to acute amphetamine, but compensatory increases of oral amphetamine intake consistent with a state of "reward deficiency". In contrast, naïve mice treated with calcitriol showed enhanced locomotor responses, but decreased consumption of oral amphetamine. These data suggest a causative role of dietary vitamin D3 deficiency in the development of obesity and drug consumption, and that DA centers may be therapeutic targets for exogenous calcitriol.

Title: The effects of obesity and type-2 diabetes on performance in open-field and light-dark box tasks

Authors: *J. A. HICKS[1], J. A. SEGGIO[2];
[2]Biol. Sci., [1]Bridgewater State Univ., Bridgewater, MA

Abstract: Previous studies have shown that animal models with type-2 diabetes or obesity either through genetic modification or access to high-fat diets have shown deficits in learning and memory, anxiety, and explorative behaviors. On the other hand, voluntary exercise has been known to reduce anxiety and increase explorative behaviors and learning. This study investigated the effects of obesity and type-2 diabetes C57BL6/J (B6) mice were placed into running-wheel cages - half were locked and thus no wheel-running could occur, while the other half were unlocked, and given either 60% high-fat diet or regular chow. These mice were then exposed to both the open field and light-dark box tests to test for anxiety- and explorative-like behaviors, using the AfaSci(™) system. Additionally, TallyHo/JngJ (TH) mice were also assessed in order to allow us to assess the behavioral capabilities of a mouse selectively bred for type-2 diabetes and obesity without the need of a high-fat diet. In an open-field test, obese mice exhibited reduced rearing, indicating a possible reduction in explorative behaviors. However, obese mice

did not show deficits in other parameters of an open field task (total distance traveled, total active time, or time spent in the center). In the light-dark box test, the amount of time spent in the darkened area or the latency of entry to the darkened area were not different, however, obese mice exhibited an increase in the number of light-to-dark area transitions. As previously shown, wheel-running did produce a slight decrease in high-fat diet preference, but did not produce differences in body weight. Access to a running-wheel did not significantly reduce the adverse effects of high-fat diet on these behavioral tasks. These results indicate that exercise can only slightly restore the behavioral problems caused by obesity and type-2 diabetes, indicating an overall healthy lifestyle which includes good diet and exercise are both necessary to overcome these deficits. This study contributes to the body of evidence that diabetes and obesity are linked with neurobehavioral deficits.

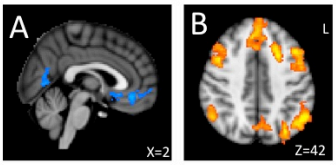
Title: Brain self-control networks and weight loss in humans

Authors: *S. NESELILER[1,2], W. HU[3], M. ZACCHIA[2], K. LARCHER[1], S. SCALA[2], M. LAMARCHE[3], S. STOTLAND[4], M. LAROQUE[4], E. MARLISS[3], A. DAGHER[1,2];
[1]McConnell Brain Imaging, Montreal Neurolog. Inst., Montreal, QC, Canada; [2]Integrated Program in Neurosci., [3]McGill Nutr. and Food Sci. Ctr., McGill Univ., Montreal, QC, Canada; [4]Motivation Weight Mgmt. Clin., Montreal, QC, Canada

Abstract: While for most adults, dieting does not result in sustainable weight-loss, successful weight losers can be predicted by the initial weight loss at 1 month. We used fMRI to investigate how the neural response to food cues changes as weight-loss progresses over three months. 24 adults enrolled in a three month weight loss program based on calorie restriction (mean BMI: 30.1±3.2, range: 25-37). The average BMI of the participants decreased over the 3-month period from 30.1 to 28.6 ($F(1.2, 21.4)=32.7$, $p<0.001$). Subjects underwent fMRI prior to dieting, at 1 month, and at 3 months, while viewing and rating food and scenery images. fMRI response for food cues was contrasted to scenery cues. Compared to the baseline, at 1 month, participants showed reduced activation in the ventromedial prefrontal cortex, a brain region that has been implicated in encoding stimulus value. In addition, there was a correlation between weight lost

and increased activation in a fronto-parietal network that has been implicated in cognitive control. Despite continuous weight loss, at three months the activity of the brain regions associated both with the reward value and with cognitive control returned to baseline. Behavioral results followed a similar pattern: at 1 month participants rated food cues, but not scenery cues, as less wanted. At 3 months, the rating for food cues returned to baseline ($F(2,42)=6.9$, $p=0.002$). The initial weight-loss is associated with greater activity in regions implicated in cognitive control and reduced activity in regions associated with stimulus value. This response returns to baseline at 3 months despite continuous weight-loss. This change may contribute to reduced control over food intake and to subsequent weight regain in long-term.



Brain activation measured by fMRI to food pictures at 1 month during weight-loss.
A) Reduced activation in regions associated with reward value.
B) Increased activation in the fronto-parietal network is correlated with increased weight loss.

Title: Short photoperiods reduce hippocampal blood vessel density in white-footed mice (Peromyscus leucopus)

Authors: *J. C. BORNIGER[1], S. TEPLITSKY[2], R. J. NELSON[1], C. RINK[2];
[1]Neurosci., [2]Surgery, The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Organisms living outside the tropics need to adjust their behavioral and physiological repertoires throughout the year to adapt to the changing seasons. Winter and summer provide vastly different environmental challenges, and animals must predict and alter their phenotypes to survive and reproduce. Specifically, white-footed mice (Peromyscus leucopus) display reduced hippocampal volume, hippocampal-dependent spatial memory function, long-term potentiation (LTP), and altered neurogenesis in response to short (winter-like) photoperiods. During winter, these mice putatively shunt energy away from the brain to maximize peripheral thermogenesis and immune capacity. Whether these reductions in hippocampal function are accompanied by alterations in brain vasculature remains unknown. We maintained white-footed mice in short (8 h light:16 h dark) or long (16:8) photoperiods for 8 wks. Mice were then perfused with fluorescein isothiocyanate (FITC)-conjugated tomato (Lycopersicon esculentum) lectin to visualize endothelial cells in the brain. Specific FITC+ hippocampal blood vessels were isolated via laser capture to assess gene expression. Mice exposed to short days reduced hippocampal and cortex blood vessel density (FITC+ area) and vessels isolated from short-day exposed mice expressed high levels of the gelatinase MMP2, which may contribute to the vascular remodeling we observed. These changes occurred prior to gonadal regression, indicating that changes in brain vascularity precede measureable reproductive regression in P. leucopus.

Title: Effects of ambient temperature and hypothalamic temperature manipulations on thermoregulatory yawning in rats

Authors: *M. L. SHOUP-KNOX, K. GAFFNEY, L. GAMBRILL, K. PONDER, R. PRUETT; Psychology, James Madison Univ., Harrisonburg, VA

Abstract: Recent evidence suggests that yawning functions to cool the brain during times of mild central nervous system hyperthermia. According to this thermoregulatory hypothesis a yawn could only effectively cool the brain if air temperatures are low enough to assist in evaporative and convective cooling of blood and the mucosal surfaces of the nasal cavity. At higher ambient temperatures yawning would be replaced by more effective methods of thermoregulation. The current study explores this thermal window prediction by recording

yawning in rats under four different air temperature conditions: 27oC, 29 oC, 32 oC, and a continuously decreasing phase. During testing we also directly measured brain temperature in the pre-optic area (POA) of the hypothalamus and the prelimbic cortex (PRL). We found a strong relationship between air temperatures and brain temperature for both brain areas (rPOA = 0.61, $p < 0.01$; rPRL = 0.64, $p < 0.01$). In a second study we directly manipulated POA temperature between 33 and 38 oC to examine its effects on yawning frequency. Preliminary evidence suggests that yawning occurs most frequently during the cooling phase following heat stress, but less during the highest hypothalamic and ambient temperature conditions.

Title: Huperzine-A in clinical concentrations does not block sympathetic nAChR-mediated nitrergic neurogenic dilation of porcine basilar arteries

Authors: *T. J.-F. LEE[1,2,3], M.-F. CHEN[2,4], C.-C. SHIH[5], P.-Y. CHEN[2,5];
[1]Southern Illinois Univ. Med. Sch., Springfield, IL; [2]Dept of Med. Res, Buddhist Tzu Chi Gen. Hosp, Hualien, Taiwan; [3]Dept of Life Sci, Coll of Life Sci, Tzu Chi Univ., Hualien, Taiwan; [4]Tzu Chi Coll of Technol., Hualien, Taiwan; [5]Dept of Pharmacol & Toxicol, Coll of Med, Tzu Chi Univ., Hualien, Taiwan

Abstract: Several cholinesterase inhibitors (ChEIs) are known to block nicotinic acetylcholine receptors (nAChRs) located on perivascular sympathetic nerves innervating the basilar arteries, leading to diminished vasodilation in the brainstem. This vascular side-effect may decrease brainstem blood flow and their efficacy in clinical therapy. Huperzine A (Hup-A), a naturally-occurring ChEI, is indicated for treating Alzheimer's disease (AD). We examined if Hup-A inhibited nAChR-mediated nitrergic vasodilation in porcine isolated basilar arteries, using blood-vessel myography technique. Transmural nerve stimulation (TNS) of perivascular parasympathetic nerves and activation of sympathetic nAChRs by nicotine (100 μM) induced nitrergic dilation of basilar arteries. Nicotine-induced vasodilation was inhibited by Hup-A (30-

300 μM) and donepezil (1-30 μM) concentration-dependently with the former being 20 folds less potent than the latter. Hup-A, but not donepezil, in low concentrations (3-10 μM) significantly increased nicotine-induced vasodilation. Both ChEIs, however, equally decreased TNS-elicited neurogenic nitrergic vasodilations which, unlike those induced by nicotine, were reversed by atropine. Similarly, donepezil was significantly more potent than Hup-A in inhibiting nicotine-elicited calcium influx in rat superior cervical ganglion (SCG) neurons and inward currents in α7- and α3β2-nAChR- expressing *Xenopus* oocytes. Although both ChEIs in high concentrations inhibit sympathetic α7- and α3β2-nAChRs leading to blockade of parasympathetic nitrergic vasodilation, Hup-A in clinical concentrations increases neurogenic nitrergic vasodilation. Hup-A may have advantages over donepezil and other ChEIs in maintaining brainstem blood flow during AD therapy.

Title: The effects of anodal tDCS on neurovascular coupling in rat somatosensory cortex

Authors: ***C. THOMAS**[1], T. F. D. FARROW[2], C. MARTIN[3];
[1]Psychology, [2]Academic Clin. Neurol., [3]Psychology, Neurovascular and Neuroimaging Res. Group, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Background: Transcranial direct current stimulation (tDCS) is a non-invasive stimulation technique that holds great promise in the modulation of cortical excitability and behavior in clinical and experimental applications. The polarity-specific effects on neuronal firing thresholds are most clearly seen towards the end of stimulation and shortly afterwards. This alludes to a long-term change resulting from the low-level DC stimulation. It is likely that this type of stimulation mechanistically modifies both spontaneous firing rates and responsiveness to afferent synaptic inputs (Stagg & Nitsche 2011). However, the actual mechanism by which these effects arise is unknown. Neuronal activity can be indirectly measured by hemodynamic changes (cerebral blood flow, CBF). We aim to gain a mathematical and physiological handle on the effects of anodal tDCS on neurovascular coupling by examining the relationship between somatosensory neural activity and CBF responses, following whisker pad stimulation. We hypothesise that anodal tDCS will modulate neuronal responses and that changes will also be observed in cerebral blood flow in the rodent somatosensory cortex

(whisker barrel). These changes are anticipated to occur both during and after a short period of DC stimulation concurrent with whisker stimulation, peaking at the end of stimulation then declining overtime. Methods: Anesthetized Hooded Lister rats will be prepared with a thin cranial window over somatosensory cortex to enable laser speckle imaging of cortical blood flow and optical imaging of cerebral blood volume and oxygenation. Neuronal responses will be measured from barrel cortex using a multichannel electrode probe. 15 minutes of anodal tDCS (400μA, anode 7mm2) will be applied through a circular electrode positioned rostral to the cranial window (~15mm2 surface area), with the cathode positioned on the animals back. Before, during and after tDCS, the contralateral whisker pad will be electrically stimulated to evoke neuronal and hemodynamic responses. In accordance with our hypotheses, initial data indicates tDCS increases baseline and stimulus-evoked CBF compared with pre-tDCS measures.

Title: Cortical and subcortical modulations of neurovascular coupling by serotonin

Authors: A. SPAIN[1], C. HOWARTH[1], J. BERWICK[1], *C. J. MARTIN[2];
[1]Neurovascular and Neuroimaging Res. Group, Dept. of Psychology, [2]The Univ. of Sheffield, Sheffield, United Kingdom

Abstract: The rapid and local adjustment of brain hemodynamics in relation to changing neuronal activity is termed neurovascular coupling. Our understanding of the physiological mechanisms underpinning neurovascular coupling has advanced substantially in recent years, including the roles played by the cells that comprise the neurovascular unit and associated inter- and intra-cellular signalling mechanisms. Whilst empirical work to date has focussed on the role for excitatory, glutamate-mediated neurotransmission in neurovascular coupling, little research has addressed whether and how important modulatory neurotransmitters such as serotonin (5-HT), which are known to have (a) a range of vasoactive properties and (b) altered functionality under many pathological conditions, might affect neurovascular function. To address this, we investigated the cortical and subcortical effects of pharmacological manipulation of the 5-HT

system upon neurovascular coupling *in vivo*, by applying a range of concurrent measurement techniques including fMRI, tissue oxygen fluorescence, laser speckle and laser Doppler blood flow measurement, optical imaging spectroscopy and electrophysiological recording. Under anaesthesia, the skull overlying somatosensory cortex was thinned to translucency for cortical imaging whilst burr holes were made to allow for the insertion of tissue oxygen or laser Doppler probes and recording or stimulating electrodes. Hemodynamic and neuronal data were acquired in cortical (barrel cortex) and subcortical (striatum) structures under baseline and stimulation conditions (via whisker stimulation or trans-callosal cortical stimulation). Data were acquired both before and after the administration of 5-HT modulating drugs (or control substances) including the 5-HT releasing agent fenfluramine (10mg/kg), the 5-HT 2A receptor agonist (and metabolite of the hallucinogen psilocybin), psilocin (2mg/kg), and the 5-HT 1B/1D receptor agonist (and anti-migraine drug) sumatriptan (2mg/kg). Initial data indicate alterations in the relationship between stimulus evoked neuronal activity and hemodynamic responses attributable to pharmacological manipulation of the 5-HT system. For example in the case of psilocin and sumatriptan, hemodynamic responses were augmented by the drug whereas neuronal responses were reduced (psilocin) or unaltered (sumatriptan). Alterations in neurovascular coupling by changes in the function of the 5-HT system may have important implications for the application of functional MRI to investigate drug action or disease mechanisms that involve 5-HT systems in both humans and animal research models.

Title: Does vasomotion alter functional connectivity; a multi-modal study using optical imaging spectroscopy, multi-channel electrophysiology and bold fmri

Authors: ***P. PATEL**, A. KENNERLEY, L. BOORMAN, M. JONES, J. BERWICK;
Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Perturbations in brain connectivity is often inferred by examining correlations in the spontaneous fluctuations in Blood Oxygenation Level Dependent (BOLD) functional magnetic resonance imaging (fMRI) signals in the absence of stimuli or tasks. However, systemic parameters and neurovascular coupling are known to affect cerebral hemodynamics which may also be altered in disease states; therefore, inferring connectivity changes from the BOLD fMRI and the underlying hemodynamics may be problematic. To investigate this issue, we employed the following techniques: two-dimensional optical imaging spectroscopy (2D-OIS) for the

underlying changes in blood volume and oxygenation and multi-channel electrophysiology recording to measure the cortical neural activity in the somatosensory and motor cortex of anaesthetized rodents. A low frequency cerebral hemodynamic oscillation (0.1Hz) was examined following the manipulation of systemic blood pressure (BP) in order to part emulate physiological conditions in disease states. This 0.1Hz oscillation known as vasomotion is a spontaneous oscillation in the small vessel lumens observed in many microvascular beds and is unrelated to cardiac rhythm (Hudetz et al, JCBFM, 1992). Despite a significant amount of literature on the vasomotion signal, its physiological function and pathophysiology are not yet clear. One hypothesis is that vasomotion rhythms are significant for its ability to increase optimal delivery of oxygen to the tissue (Hudetz et al, Advn Exp Med Bio, 1998). A series of experiments to manipulate the size of vasomotion by altering the levels of BP and the level of inspired oxygen were conducted. Data suggested that when there is low BP there is a presence of vasomotion and when BP is increased to normal physiological levels the magnitude of vasomotion is significantly reduced; suggesting that this signal is present when blood flow in the brain becomes compromised. To further understand if the vasomotion signal is dependent on the amount of tissue oxygen tension in the brain, we increased levels of oxygen in the inspired air during the periods of lowered BP. This resulted in an increase in the oxygen saturation levels in the blood which were associated with reduced magnitude of vasomotion. A further experiment making direct measurements of tissue oxygen tension confirmed that this manipulation increased tissue PO2. To investigate the spatial extent of vasomotion in these physiological perturbations, similar whole brain measurements were made with BOLD fMRI.

Title: Cholinergic modulation of neurovascular coupling and neuroimaging signals

Authors: *G. BREZZO, A. SPAIN, J. BERWICK, C. MARTIN;
Univ. of Sheffield, Sheffield, United Kingdom

Abstract: In recent years a number of brain diseases, such as Alzheimer's disease (AD), have become associated with pathological changes in blood flow regulation and the neurovascular

apparatus that supports it, the neurovascular unit. This has led to research into how interventions to improve neurovascular function could provide a degree of neuroprotection from neurodegenerative diseases. Several central nervous system (CNS) penetrating cholinergic drugs such as donepezil have been developed for the treatment of AD and have been shown to reduce disease symptoms. A recent study (Kocsis et al., JCBFM, 2014) suggested that cognitive enhancement effects of CNS cholinergic drugs were mediated by vascular and not neuronal actions. An important question is whether and how these vascular effects are manifested in the brain's neurovascular coupling response, in terms of the rapid and local adjustment of cerebral blood flow (CBF) to changing neuronal and metabolic demands. To investigate this, we used a rodent model in which CBF and neuronal activity were measured across a range of sensory stimulation parameters, in order to identify the effects of pharmacological manipulations of brain acetylcholine on neuronal, hemodynamic and neurovascular coupling measurements. In anaesthetised animals, a thin cranial window was prepared over the somatosensory barrel cortex to enable recording of CBF using laser speckle contrast imaging. A burr hole was made in the thin cranial window for insertion of a multichannel electrode for electrophysiological recording of neuronal activity. Whisker stimulation protocols included a mixed frequency design (1-40Hz range, 2s duration) and long duration stimulation (5Hz, 16s). Data were acquired at baseline and following the administration of the anticholinergic drug scopolamine (2mg in 1ml, IV). Results indicate that scopolamine decreased baseline blood flow and stimulus-evoked hemodynamic response magnitude, although electrophysiological data show little alteration in concurrently measured neuronal responses. The study is currently being extended to include the non-CNS penetrating anticholinergic drug neostigmine and the current AD drug, donepezil. Initial findings indicate a cholinergic modulation of neurovascular coupling which may have important implications for (i) our understanding of how drugs which modulate vascular function can impact upon neurovascular coupling (ii) the interpretation of functional brain imaging (fMRI) signals acquired in the context of cholinergic manipulations, (iii) our understanding of the physiological mechanism underpinning the effectiveness of cholinergic drugs for the treatment of AD.

Title: NMDA-dependent neurovascular dysregulation in mice overexpressing mutated human tau

Authors: *L. PARK, K. KOIZUMI, P. ZHOU, C. IADECOLA;
Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: The microtubule-associated protein tau is present in neurons, wherein stabilizes microtubules at the synapses. In Alzheimer's disease and in brain diseases associated with tau mutations, such as frontotemporal dementia (FTD), tau becomes hyperphosphorylated (p-tau), detaches from microtubules, and aggregates in paired helical or straight filaments disrupting synaptic function (Neuron, 82:756-71, 2014). Although its deleterious neuronal effects are well established, it is not known if p-tau also disrupts neurovascular regulation, which, in turn, could contribute to brain dysfunction in tauopathies. To address this question, we examined neurovascular regulation in transgenic mice expressing mutated human tau. Cerebral blood flow (CBF) was assessed using laser-Doppler flowmetry in anesthetized rTg4510 and PS19 mice (n=5/group) equipped with a cranial window and with controlled blood pressure and blood gases. The increase in somatosensory cortex CBF evoked by neural activity (whisker stimulation, WS), a critical response coupling energy supply and demand in the active brain, was suppressed in both strains (WT: 23±2%; rTg4510: 11±2%; PS19: 14±1-%; $p<0.05$; mean±SE), which was not related to reductions in the field potential evoked by electrical whisker pad stimulation (WT: -5.1±1.8; PS19: -4.4±2.1 mV; $p>0.05$). Furthermore, the increase in CBF produced by neocortical application of acetylcholine, a response mediated by the endothelial NO, was not attenuated (WT: 24±2%; rTg4510: 24±1%; PS19: 22±1%; $p>0.05$). Since glutamatergic synaptic activity is a key contributor to the increase in CBF evoked by WS, we examined the CBF increase induced by glutamate receptor activation. The CBF response to neocortical application of NMDA (40 μM) was attenuated (WT: 26±3%; rTg4510: 13±2%; $p<0.05$), whereas the response to AMPA (10μM) was not (WT: 31±4%; rTg4510: 36±3%; $p>0.05$). To determine whether the attenuation in the CBF increase produced by WS in p-tau mice was a consequence of failure of the NMDA-dependent component of the vasodilatation, we examined neurovascular coupling in the presence of the NMDA receptor inhibitor MK801, superfused on the neocortex. MK801 (10 μM) attenuated the CBF increase evoked by WS in WT mice (-51±1%; $p<0.05$), but did not reduce the response in rTg4510 mice ($p>0.05$). The data provide the first demonstration that p-tau impairs neurovascular regulation. The effect is specific for the increase in CBF evoked by neural activity and reflects a deficit in NMDA receptor-mediated vasodilatation. Overall, the findings unveil a previously unrecognized aspect of tau pathobiology with potential diagnostic and therapeutic implications.

Martinos Ctr. for Biomed. Imaging, Dept. of Radiology, Massachusetts Gen. Hosp. and Harvard Med. Sch., Charlestown, MA

Abstract: Neurovascular coupling, the regulation of cerebral blood flow (CBF) and oxygen supply to match neuronal functional activity, is regulated by synchronous action of different cell types comprising the neurovascular unit - neurons, vascular cells such as vascular smooth muscle cells and endothelium, and glia. Pericytes, first described by Rouget in 1873 as mural cells of the capillary vessel wall, are critical for the stabilization of the capillary wall, maintenance of the blood-brain barrier and have recently been implicated in the regulation of capillary diameter. However, their role in regulation of neurovascular coupling remains debatable. Using pericyte-deficient mice, we show that pericyte reduction *in vivo* leads to delayed capillary dilation in response to neuronal stimulus, and reduced red blood cell flow velocity in capillaries carrying oxygen to activated brain sites. Furthermore, we show diminished local oxygen supply to cortex in response to stimulus in pericyte-deficient mice in spite of an intact arteriolar response and vasoactivity. Together, these data imply that pericytes play an important role in neurovascular coupling and oxygen supply to the brain, and that pericyte degeneration contributes to neurovascular uncoupling. Degeneration of pericytes, as is seen in neurological disorders including Alzheimer's, likely contributes to neurovascular dysregulation, leading to neurovascular dysfunction and eventually neurodegeneration.

Abstract: In order to investigate living brain functions, we need a chronic cranial window.. Here, we introduce a transparent and flexible silicone based material for chronic animal cranial window. This soft material is used as a substitute for the skull for longitudinal study of rat and mouse brains. This cranial window ensures good physiological states because it can maintain intracranial pressure and cerebrospinal fluid flow within a normal range demonstrated by a computer simulation. This cranial window was utilized for several chronic *in vivo* experiments such as laser-speckle imaging, optical recording of intrinsic signal of cortex, and multi-photon microscopic imaging. Also, this soft cranial window allows repeated penetration of electrodes for drug delivery and neuronal signal recording without any cerebrospinal fluid leakage and inflammation. Thus, our soft cranial window technique might facilitate effective longitudinal studies of living brain function in conjunction with electrophysiological recording, drug delivery, and imaging.

Title: The local cerebral blood flow in the dorsal hippocampus of rats during initial and deep stages of informational pathology of behavior

Authors: *M. NEBIERIDZE[1], I. KVACHAKIDZE[2], L. GUMBERIDZE[2], L. DAVLIANIDZE-GOBECHIA[2], M. MANTSKAVA[2], N. MOMTSELIDZE[2], N. SIKHARULIDZE[2];

Abstract: Introduction, materials and methods. The local cerebral blood flow (LCBF) was studied by the hydrogen clearance technique in the dorsal hippocampus (DH) of rats with initial and deep stages of informational pathology of behavior (IPB). The initial stage of IPB was induced by the negative emotional stress developed during the short period of delayed testing (indirect version, 2-3s delay), in I group of animals, while the deep stage of IPB was induced by the chronic negative emotional stress developed during the long period of testing delayed reactions (indirect version, 2-3s delay) in II group of animals, under conditions of the time shotage between the signals (30s) and the existence of high level of motivation. Results. A significant increase in the LCBF level was observed in I experimental group in comparison with the control one, while in II experimental group a significant decrease in the LCBF level in comparison with the control group was demonstrated. Conclusion. It is supposed, that this alteration of LCBF in I group may be caused by the strengthening of DH functional activity as result of short time negative emotional stress, thus being a form of the cerebral self-regulation activity. In II group 1) the decrease in the LCBF may have a secondary character as a result of suppression of functional activity of the DH by exposure to the chronic negative emotional stress; 2) It is not inconceivable that the LCBF decrease is of a primary character and may account for dysfunction of this structure facilitating the emotional stress and its acquisition of pathogenic properties, thus being an important factor of the IPB formation.

Title: Evidence that resting-state functional connectivity is mediated via arteriole vasomotion

Authors: *C. MATEO[1], P. KNUTSEN[1], P. S. TSAI[1], A. Y. SHIH[3], D. KLEINFELD[1,2]; [1]Physics Dept, [2]Neurobio., UCSD, La Jolla, CA; [3]Neurosciences, Med. Uni. of South Carolina, Charleston, SC

Abstract: Neural activity leads to changes in metabolism that are reflected in a blood oxygen level dependent (BOLD) signal in functional magnetic resonance imaging (fMRI) and an intrinsic optical signal (IOS) in reflection imaging. In the absence of stimulation or a cognitive task, infra-slow oscillations (~ 0.1 Hz) of the BOLD fMRI signal correlate between regions with mirrored functionality across hemispheres (Biswal et al. MRM 1995), as well as with spontaneous fluctuations in the envelope of gamma-band (~ 30-80 Hz) neural activity (Schölvinck et al. PNAS 2010). Correlations in the infra-slow BOLD fMRI signal between brain regions form the basis of functional connectivity studies in human and nonhuman primate. We hypothesize that entrainment of the infra-slow vasomotor oscillations in cortical arterioles could provide a bridge between spontaneous fluctuations in neural activity and the BOLD signal. To address this hypothesis, we employed imaging, electrophysiology, and optogenetic manipulation of neural activity and hemodynamics in awake, head-fixed mice, in which arterioles exhibit vasomotion near ~ 0.1 Hz (Drew et al. PNAS 2011). First, we observe strong spectral coherence between the envelope of the gamma rhythm of neural activity and changes in the diameter of nearby arterioles (n = 20) measured with two-photon microscopy. Changes in the envelope of the gamma rhythm lead the dilation of arterioles by about 2 s. Next, optogenetic activation of cortical neurons (PV-Cre x Ai32 and Thy-1:Chr2) reveal that induced infra-slow oscillations in the gamma-envelope cause concurrent oscillations in arteriole diameter (n = 10). In contrast, optogenetic-induced dilation of cortical arterioles at these frequencies fails to change field activity. Lastly, concurrent IOS imaging and measures of arteriole diameter show that arteriole dilation leads the local increase in pO2 in the parenchyma (n = 6). These data establish a sequence: gamma-band fluctuations drive arteriole dilations that in turn drive an increase in tissue oxygenation. As a means to directly relate the entrainment of vasomotion to functional connectivity, we performed simultaneous bilateral measurements of arteriole diameter with ultra-wide scale two-photon microscopy (Tsai et al. OE 2015). We find that infra-slow changes in diameter are strongly coherent between mirrored regions across hemispheres, but less so between functionally distinct regions (n = 4). The correlations are consistent with axonal connections via the corpus callosum and support the notion that entrainment of vasomotion by neural activity is responsible for correlations in blood oxygenation that underlie functional connectivity.

Title: Coupling of spontaneous and sensory evoked hemodynamic signals to neural activity in the barrel cortex of awake mice

Authors: *A. WINDER, P. J. DREW;
Ctr. for Neural Engin., Penn State Univ., University Park, PA

Abstract: Spontaneous hemodynamic signals are used as indicators of neural activity in resting-state MRI experiments. However, it is not clear whether spontaneous hemodynamic signals reflect ongoing neural activity in the same way that sensory evoked hemodynamic signals do. To determine if the coupling of neural activity and hemodynamic signals is the same for both sensory-evoked and spontaneous activity, we examined neurovascular coupling in the barrel cortex of awake, head-fixed mice during several behaviors. We simultaneously measured local neural activity, CBV, and behavior in awake, head-fixed mice. Blood volume changes were measured using intrinsic optical signal imaging in the vibrissae cortex. The local field potential (LFP) and multiunit activity (MUA) were measured from the same location. Whisker position was tracked to determine when volitional motions occurred. The vibrissae were also stimulated with brief puffs of air. The data were categorized into three behaviors: sensory evoked, volitional whisking, and rest. Neural and CBV increases to whisker stimulation were substantially stronger than during volitional whisking. During rest, neural activity and CBV were weakly correlated. Neurovascular correlations during spontaneous behavior were not disrupted by transection of the facial nerve, indicating that they were not due to sensory input during whisker movement. We calculated the hemodynamic response function (HRF), the linear kernel that relates the measured CBV to the local neural activity for each behavior. We found the HRFs obtained for each behavior condition to be similar, indicating that neurovascular coupling was conserved across behavioral state. We then used these HRFs to determine what fraction of the spontaneous and sensory evoked changes in CBV could be explained by local neural activity. Here there were substantial differences among behaviors in the variance of the hemodynamic signal captured by the HRFs. Sensory evoked hemodynamics, on average and during individual trials, were better predicted by local neural activity than those measured during volitional whisking or resting behaviors. The prediction error, for all behaviors, could be accounted for by the presence of ongoing CBV fluctuations that were not associated with any measured neural activity. This uncorrelated signal obscures neurally-evoked hemodynamic changes to a greater degree during

volitional whisking and resting behaviors since these behaviors drive smaller increases in neural activity and CBV. These results highlight the need to investigate additional sources of spontaneous hemodynamic fluctuations in alert subjects in order to better interpret fMRI.

Title: Strong blood flow undershoot induced by brief stimulation in the human brain

Authors: *D. RESS, J. KIM;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Brief neural activation creates a hemodynamic response function (HRF), a stereotypic manifestation of neurovascular coupling. A recent theory (Kim et al., JCBFM, 2013) predicts that the flow response underlying the HRF has an underdamped oscillatory behavior. This hypothesis was tested and confirmed by arterial spin-labeling MRI experiments, which also produce simultaneous BOLD HRF measurements. **Methods**: Subjects ($N = 6$) view a 2-s duration full field of flickering black & white dots on a gray background. These impulses were separated by a 32-s inter-stimulus interval, and repeated 16 times per run for 5—6 runs to create a total of 80—96 measurements per session. Combined flow and BOLD HRF data were obtained using the standard (PICORE) sequence on a Siemens 3T scanner with 2-mm voxels and TR = 4 s, using 2× GRAPPA acceleration on 14 quasi-axial slices. Stimulus presentations were jittered relative to the TR to increase temporal sampling to 1 s. The flow and HRF data were transformed into a high-resolution (0.7-mm) reference anatomy so that they could be averaged within visual areas V1—3, predefined for each subject. **Results**: All subjects show a significant flow undershoot (Figure), and some show a more complex oscillatory return to baseline. Standard errors across the many measurements, shown by dotted lines, demonstrate the high quality of the quantification. Flow response peaks ~4 s earlier than the BOLD HRF. BOLD signals also show a significant undershoot that is always later than the flow undershoot, and can also persist substantially longer. **Discussion**: The flow induced by brief stimulation has a strong undershoot and complex late time behavior consistent with underdamped oscillation. HRF responses are substantially delayed from the flow response, consistent with convective time delays as the flow propagates into downstream venous microvasculature that dominates the BOLD signal. The

ability to perform these combined measurements, coupled with the theoretical model, will enable the quantification of oxygen metabolism ($CMRO_2$) consequent to brief neural stimulation.

Title: Regional cerebral blood flow in pediatric post-traumatic headache

Authors: *D. J. HODKINSON[1], P. SERRANO[1], M. O'BRIEN[2], A. LEBEL[1], L. BECERRA[1], D. BORSOOK[1];
[1]Dept. of Anesthesiology, Perioperative & Pain Med., [2]Div. of Sports Med., Boston Children's Hospital, Harvard Med. Sch., Boston, MA

Abstract: Introduction: Post-traumatic headache (PTH) is a common outcome of mild traumatic brain injury (mTBI) and concussion. The consequences of PTH in children can be severe, and may result in the interruption of normal healthy development [1] and increased risk of pain chronification [2]. **Aims & Objectives:** To determine whether PTH onset and progression is related to the dysregulation of cerebral blood flow (CBF) in brain regions involved in autonomic function that may occur as a result of closed head injury. **Methods:** *Participants:* 12 PTH patients and 22 healthy controls were recruited for the study (age range 14-18 years). PTH patients were identified at Boston Children's Hospital (Emergency Medicine Department, Division of Sports Medicine, and Chronic Headache Clinic) and scanned on average 133.2/4.4 days/months post-concussion/mTBI. *Image acquisition:* Participants were scanned on a 3T MRI scanner. High-resolution T1-weighted anatomical scans were acquired for image registration. Quantitative regional cerebral blood flow (rCBF) measurements were performed using pseudo-continuous arterial spin labeling (pCASL) [3] [PLD=1.3sec, LD=1.5sec, GE-EPI, TR/TE= 3870/12, FOV=220mm, matrix=64x64, 26 slices, slice thickness = 5mm]. *Image processing:* Data were pre-processed using SPM8. Group-wise changes in regional CBF (rCBF) were calculated using a random effects two-sample t-test. **Results:** Quantitative CBF maps were calculated for controls and PTH patients. Ratio between the CBF in the controls and PTH groups shows an approximate 10-20% global CBF increase in the PTH group. Statistical comparisons between healthy controls and PTH patients revealed significant regional CBF increases in the forebrain, including basal ganglia and limbic system. **Discussion:** Regional CBF is closely coupled with glucose utilization, oxygen consumption, and aerobic glycolysis in the resting human brain [4,5]. Increased CBF in PTH patients may potentially reflect disruptions in autonomic function [6]. This experimental technique may be used for reliable identification of successful brain recovery or potential long-term neurological impairments, and could help to determine whether and when it is safe for patients to return to activity. **References:** [1] Kirk et al., (2008). *Dev Med Child Neurol*, **50**(6): p. 422-5 [2] Gavett et al., (2011). *Clin Sports Med*, **30**(1): p. 179-88 [3] Dai et al., (2008)., *Magn Reson Med*; **60**: 1488–1497 [4] Raichle et al., (2001). *PNAS*. **98**: 676–682 [5] Vaishnavi et al ., (2010). *PNAS*. **107**: 17757–17762 [6] Cambron et al., (2014). *Headache.* **54**(4): p. 655-62.

Title: Role of 20-HETE in the development of hypertension-related cerebral vascular disease

Authors: *F. FAN[1], L. RICK[2], M. R. PABBIDI[1], E. GOMEZ-SANCHEZ[1], R. J. ROMAN[1]; [1]Pharmacol., [2]Neurobio. and Anatom. Sci., The Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: We have reported that a reduction in the expression of CYP4A and the production of 20-HETE contributes to development of impaired myogenic response and autoregulation of cerebral blood flow (CBF) in Dahl salt sensitive (SS) rats. The present study examined whether this impaired myogenic response in the cerebral circulation promotes the development of cerebral vascular disease after the induction of hypertension. 20-HETE production was 6-fold higher in cerebral arteries of CYP4A1 transgenic and SS. 5BN consomic rats (in which chromosome 5 from Brown Norway was transferred into SS background) than in SS rats. The diameter of the middle cerebral artery (MCA) decreased to 70 ± 3 % and 65 ± 6% in CYP4A1 and SS. 5BN rats when pressure was increased from 40 to 140 mmHg. In contrast, the myogenic response of the MCA isolated from SS rats did not constrict. Administration of a 20-HETE synthesis inhibitor, HET0016, abolished the myogenic response of MCA in CYP4A1 and SS. 5BN rats, but had no effect in SS rats. Autoregulation of CBF was impaired in SS rats in comparison to CYP4A1 and SS. 5BN rats. Blood brain barrier leakage was 5-fold higher in the brain of the SS rat than in SS. 5BN and SS.CYP4A1 rats. Neurodegeneration and vascular remodeling was observed in neocortex and CA3 area of hippocampus in hypertensive SS rats in comparison to CYP4A1 and SS. 5BN rats. The SS rats exhibited a cognitive impairment and took 4 times longer time to escape from an eight-arm water maze in comparison with SS.CYP4A1 rats after induction of hypertension with a high salt diet for 4 weeks. These findings indicate that a genetic deficiency in the formation of 20-HETE contributes to an impaired myogenic response in MCA and autoregulation of CBF in SS rats and this may contribute to cerebral vascular disease and a vascular cognitive impairment following the onset of hypertension.

Title: Role of gamma-Adducin in cerebral vascular disease

Authors: *R. J. ROMAN[1], A. M. GEURTS[4], R. LIN[2], M. R. PABBIDI[1], E. GOMEZ-SANCHEZ[1], G. RAJKOWSKA[3], D. R. HARDER[5], F. FAN[1];

Abstract: We recently identified a K572Q mutation in Add3 in FHH rats in comparison with FHH.1BN congenic rats in which chr. 1 from the BN rats containing 15 genes including Add3 was transferred into FHH genetic background. The present study examined the contribution of this mutation to cerebral vascular function. Expression of Add3 is lower in FHH than in FHH.1BN rats. The diameter of the middle cerebral artery (MCA) decreased to 80 ± 2 % and 71 ± 4% in FHH.1BN and in our newly generated FHH.Add3 transgenic rats, respectively, when perfusion pressure was increased from 40 to 140 mmHg. In contrast, the MCA isolated from FHH and SD. Add3 knockout rats did not constrict. Moreover, we observed that the myogenic response is also impaired in MNS rats that share the same mutation in Add3 as the FHH rat and this phenotype complemented in a F1 cross of FHH and MNS rats. CBF rose by 99 ± 7%, 64 ± 5% and 42 ± 4% in FHH, FHH.1BN and FHH.Add3 rats, respectively, when MAP was increased from 100 to 190 mmHg, demonstrating that the impaired autoregulation of CBF in FHH rats was rescued when replacement with wildtype Add3. BBB leakage was greater in FHH rats than in FHH.1BN and FHH.Add3 rats after induction of hypertension with DOCA/salt. In contract to FHH.1BN and FHH.Add3 rats, hypertensive FHH rats exhibited marked neurodegeneration and vascular remodeling of the neocortex and hippocampus with a 33% reduction of both neuronal density and the size of neuronal cell bodies. Gap junctions between endothelial cells were larger in hypertensive FHH rats with neuronal, mitochondrial and myelin degeneration in the vacuolated area around the leaky capillaries. The hypertensive FHH rats took 2.5 times longer time to escape from an eight-arm water maze in comparison with FHH.1BN rats. These findings suggest that the K572Q mutation of Add3 contributes to the impaired myogenic response in the MCA and autoregulation of CBF in both FHH and MNS rats and that this may contribute to cerebral vascular disease and vascular cognitive impairments following the onset of hypertension.

Title: Exploring the neuronal population responses in the human intraparietal sulcus during real life speech processing

Authors: *X. YANG[1,2], A. DAITCH[2], J. SCHROUFF[2], S. GATTAS[2], S. DEHAENE[3], H. KOOPMAN[4], J. PARVIZI[2];

(LBCN), Stanford, CA; [3]INSERM-CEA Cognitive Neuroimaging Unit, Collège de France, Paris, France; [4]Dept. of Linguistics, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: We recorded electrocorticography (ECoG) signals in three human subjects implanted with intracranial electrodes in the lateral parietal lobe. We analyzed high-frequency broadband (HFB) or high gamma activity during an experiment, which required retrieval of autobiographical and arithmetic knowledge, and employed ROC curves to select optimal amplitude and duration parameters to identify the suprathreshold events as 'HFB peaks'. We then applied the same parameters to capture HFB peaks in the ECoG data during a condition in which participants listened to natural narrative stories and recalled the story facts with as many details as possible. Behavioral events of interest were determined as numerical words (numerals, ordinals, and quantifiers) in the stories heard or spoken by the participants. Electrodes that had shown significant increase of HFB activity during the experimental arithmetic condition exhibited only infrequent HFB peaks in the natural condition, most of which occurred at the times when the participants were processing numerical words in natural speech. Our analyses revealed that the IPS neuronal populations activated during the experimental arithmetic condition were also activated when participants were speaking or listening to numerical words in natural settings. Our findings also suggested that during speech comprehension the HFB responses in the IPS occurred after hearing numerical words, while most of the HFB peaks appeared early before the expression of numerical words during speech production. Our findings are in line with and confirm our previously reported findings in three other subject during spontaneous speech. Real life experience has a rich and constantly changing context that is shaped by the natural environment and human interactions, making it challenging to study the underlying brain dynamics during natural conditions. This study provides a means for both exploring the activity of a specific neuronal population in the human brain during a controlled experimental condition and the activity of the same population of neurons during real life settings.

Title: Dynamics within and between ventral temporal and parietal cortices during numerical processing

Authors: *A. L. DAITCH[1,2,3], I. KASIKCI[1,2,3], B. L. FOSTER[1,2,3], S. GATTAS[1,2,3], V. RANGARAJAN[1,2,3], J. PARVIZI[1,2,3];
[1]Neurol., Stanford Univ., Stanford, CA; [2]Lab. of Behavioral and Cognitive Neurosci. (LBCN), Stanford, CA; [3]Stanford Human Intracranial Cognitive Electrophysiology Program (SHICEP), Stanford, CA

Abstract: In every culture, arbitrary symbols are assigned specific meanings; for example numerals are associated with numerical quantities. While the ability to approximate and compare quantities is innate in infants and many other species, the ability to manipulate numerals to perform a computation is learned. Such computations likely engage a network of brain regions, from those processing visual features of each symbol, to those with more abstract numerical representations. Recent work from our lab has revealed an anatomical region within the human ventral temporal cortex (VTC) selective for visual numerals, compared to other morphologically, phonologically, or semantically similar stimuli. Additionally, human neuroimaging and animal electrophysiological studies have shown the involvement of the intraparietal sulcus (IPS) region in coding for a more abstract, amodal numerosity representation (i.e. “4” vs. “four” vs. “::”). To date, the fast temporal dynamics by which these regions interact with each other to interpret and manipulate visual numerals is not understood. In this study, we used direct cortical recordings in six human subjects (four with simultaneous VTC and IPS coverage), to track the fast temporal dynamics at and between VTC and IPS, as subjects read and manipulated visual numerals across several tasks, ranging from simple recognition to more complicated arithmetic computations, as well as during rest. We investigated the selectivity of each recording site to various stimuli (e.g. numerals vs. letters vs. false fonts), and their relative levels of engagement during different levels of numerical processing (e.g. reading versus active arithmetic). We computed the precise timing of activations at VTC and IPS to assess feed-forward versus feedback interactions. Finally, we measured resting state correlations between the VTC and IPS to see whether these regions are functionally correlated. We found that within VTC, there exist at least two distinct neuronal populations, both of which are engaged during active computations. One, more posterior region, exhibited an earlier latency response to numerals (~50-100 ms), but was less

selective for numerals relative to other similar visual stimuli. A slightly more anterior VTC region exhibited a later response to numerals (~100-200 ms), but was more selective for numerals relative to other stimuli, and exhibited higher activity during active manipulation of numerals than passive viewing. The activity at the anterior VTC region was also selectively correlated with that at IPS, both during task and rest conditions, highlighting in part the architecture of network interactions for numerical processing.

Title: How the visual system constructs perceptions of two- and three-dimensional manifolds (flat, corrugated and curved surfaces and volumes) from zero, one and two dimensional building blocks

Authors: *E. L. ALTSCHULER[1], H. J. KIM[2], S. RONCATO[3];
[1]Physical Med. and Rehabil., Temple Univ. Sch. of Med., Philadelphia, PA; [2]Sch. of Med., New Jersey Med. Sch., Newark, NJ; [3]Psicologia Generale, Univ. di Padova, Padova, Italy

Abstract: The principles of the emergence of planar figures from dots, lines and two-dimensional figures is much better understand than how dots, lines and planes are perceptually organized by the visual system into two-dimensional flat and curved surfaces (manifolds) and three dimensional volumes (manifolds). In particular we have been studying when assemblies of line and planar shapes are perceived as being flat vs. a corrugated surface or a shape with volume. We have found that when the Gestalt principles of good continuity and closure are put in conflict, e.g., by an X-junction they "conspire" to produce corrugation. Also we have found that contrast polarity preservation (Parlangeli & Roncato, 2010; McCormick et al. & Altschuler, 2012; Altschuler et al. & Roncato, 2013) influences whether a corrugated surface vs. 3-dimensional manifold is perceived. Equally spaced outlined diamonds are perceived as planes spaced in depth. But the orientation of this set of planes is ambiguous-the perception is reversible. T-junctions can be used to disambiguate the orientation of the set of planes. Another cue we find that disambiguates orientation is providing thickness to the planes (diamonds (perceived as squares)) by adding in the form of shading making the perceived flat planar regions as parallelepipeds with height small compared with their length and width. Consider an equally spaced array of such parallelepipeds: Let the plane of the page be the XY plane with the depth (small) dimension of the parallelepipeds be in the X direction and the spacing between

parallelepipeds also be in the X direction. The large dimensions of the parallelepipeds are then along the Y-axis and the perceived into the plane Z-axis. When the spacing between parallelepipeds is made unequal-so that there is alternately very small spacing and large spacing between pairs of parallelepipeds-we have made the most intriguing finding that the parallelepipeds are not perceived as being collinear with unequal spacing along the X-axis, but equally spaced now pairs of parallelepipeds with each pair consisting of two parallelepipeds aligned along the Y-axis. Interesting this is not perceived when the parallelepipeds are replaced by (two-dimensional) narrow rectangles (small dimension again along the X-axis). Our finding may be helpful in producing easily perceived higher dimension manifolds.

Title: The influence of color and vowel context on the perception of visual speech

Authors: *W. C. HOOKS, JR.[1], L. V. DEAL[2];
[1]OtoLing, Naperville, IL; [2]Communication Sci. and Disorders, Michigan State Univ., East Lansing, MI

Abstract: A premise of studies in speech perception has been targeted attention to the lips, teeth, chin, and cheeks. Yet, the amount of visually transmitted information has not been established for critical cues or their locations. Some individuals have distinguished /p, b, m/ visemes in different vowel contexts, but an explanation of the underlying visual characteristics has not been understood (Owens & Blazek, 1985). Anatomical and psychophysical evidence indicated clear subdivisions and parallel competition between magnocellular (magno) and parvocellular (parvo) cells (Livingstone & Hubel, 1987)—that is, magno neurons and the medial temporal (MT) cortex help us in the resolution of "where" we are looking for cues, whereas parvo neurons help in the identification of "what" cues we see. We know that the dual process theory partially describes how cone receptors respond in mutually opposite directions for red-green and blue-yellow. Our study probed whether interaction of opponent colors and vowel context would influence the recognition of /p, b, m/. Colors were scaled into Munsell notations and converted to Commission Internationale de L'Eclairage (CIE 1931) *y, x, z* coordinates for approximate wavelengths (λ) in nanometers (nm). A female talker with cosmetically applied opponent-colored lips [e.g., green upper/red lower (G/R) & blue upper/yellow lower (B/Y)] was videotaped in a television studio for broadcast quality playback in two experiments (Expt.). The talker spoke visually dissimilar vowel-consonant-vowel disyllables /ipi/, /ibi/, /imi/ in Expt. 1 and /apa/, /aba/, /ama/ in Expt. 2.

Six subjects viewed a mute video playback of the talker and generated 1,800 observations (per experiment) across five counterbalanced color conditions [R/G, G/R, B/Y, Y/B, and natural (NAT)]. The subjects' recognition of /p, b, m/ was assigned binary coding for logistic regression analysis. We assumed that the R/G and G/R would be influential because green ($\lambda = 565.8 \pm 0.2$ nm) approximated the human photopic luminosity peak ($\lambda = 555$ nm). Statistical significance was indicated for positive likelihood estimates in (R/G and B/Y), interaction effects for vowel (/i/), and phoneme (/b, m/). A composite analysis indicated statistical significance for (Y/B, B/Y, R/G, & NAT) and interaction effects between /p, b, m/, and the vowel /a/. We concluded that color interacted with vowel context as a relevant predictor for speech recognition. The data analysis suggested that specific colors could be used in the design of speechreading training. However, more research is needed to characterize eye movement and gaze patterns during speech recognition with opponent lip-color conditions.

Title: Multivariate decoding of numerosity-evoked fMRI activity patterns in human parietal cortex is reflective of individual differences in number discrimination performance

Authors: G. LASNE[1,2], M. PIAZZA[1,3], S. DEHAENE[1], A. KLEINSCHMIDT[1,4], *E. EGER[1]; [1]INSERM Cognitive Neuroimaging Unit CEA/NEUROSPIN, Gif/Yvette, France; [2]Univ. Pierre et Marie Curie, Paris, France; [3]Ctr. for Brain/Mind Sciences, Univ. of Trento, Trento, Italy; [4]Dept. of Clin. Neurosciences, Univ. Hosp., Univ. of Geneva, Geneva, Switzerland

Abstract: The importance of parietal cortex for numerical processing is supported by a variety of methods. Recently, we have shown that beyond overall recruitment during numerical tasks, human intraparietal cortex contains information discriminative of individual numbers which can be detected by fMRI pattern recognition, in similar subregions to those where number selectivity of individual neurons is observed in macaque monkeys. However, it remains open in how far such differences in activation patterns elicited by different numbers are behaviorally relevant, e.g., whether they can reflect the acuity with which numbers can be behaviourally discriminated. Here, we measured discrimination of non-symbolic numerosities in 12 healthy young adult subjects outside the scanner psychophysically in a delayed number comparison task, where a given sample numerosity had to be compared with a match numerosity appearing 3 or 6 s later, resulting in a measure of the precision of each subject's behavioral discrimination performance (Weber fraction) for the different sample numerosities (8, 13, 21, or 34 dots). We then scanned

the same subjects during a similar paradigm and tested for multivariate discrimination of activity evoked by the different sample numbers seen and held in mind, in ROIs within parietal and early visual cortex, as well as within parietal cortex in the human functional homologues of areas LIP and VIP, as determined by a previous study. The different sample numerosities could be decoded above chance in both early visual and parietal cortex with approximately the same average accuracy. However, in parietal but not early visual cortex fMRI decoding accuracies were negatively correlated across subjects with the psychophysically determined Weber fraction, indicating that subjects with a more precise behavioral discrimination measured prior to scanning showed a better discriminability of evoked fMRI activity patterns. Furthermore, within parietal cortex this relation was strongest in the right LIP area. Thus, we demonstrate for the first time that the discriminability of fMRI activation patterns for individual numbers in parietal cortex can be reflective of a subject's behavioural accuracy for discrimination of those numbers. Although information discriminative of numerosities was present in both early visual and parietal cortex, our results suggest a crucial role for the latter region in supporting a number representation which is explicitly accessed for behavior.

Title: Neural networks for pulse perception in musical rhythm

Authors: *E. W. LARGE[1], J. HERRERA[2];
[1]Dept. of Psychology, Univ. of Connecticut, Storrs Mansfield, CT; [2]Ctr. for Computer Res. in Music and Acoustics, Stanford Univ., Stanford, CA

Abstract: Entrainment of cortical rhythms to acoustic rhythms has been hypothesized to be the neural correlate of pulse and meter perception in music. Dynamic attending theory first proposed synchronization of endogenous perceptual rhythms nearly forty years ago, but only recently has the pivotal role of neural synchrony been demonstrated. Significant progress has since been made in understanding the role of neural oscillations and the neural structures that support synchronized responses to musical rhythm. Synchronized neural activity has been observed in auditory and motor networks, and has been linked with attentional allocation and movement coordination. Here we describe a neurodynamic model that shows how self-organization of

oscillations in interacting sensory and motor networks could be responsible for the formation of the pulse percept in complex rhythms. We test the model's prediction that pulse can be perceived at a frequency for which no spectral energy is present in the amplitude envelope of the acoustic rhythm. This model provides a theoretical link between oscillatory neurodynamics and the induction of pulse and meter in musical rhythm.

Title: Eeg based brain computer interfaces for numerical cognition

Authors: *V. MANIAN[1], O. NIEVES[1], J. CAMACHO[1], T. P. COLEMAN[2];
[1]Electrical and Computer Engin., Univ. of Puerto Rico, Mayaguez, PR; [2]Bioengineering, Univ. of California, San Diego, CA

Abstract: Electroencephalogram (EEG) is an effective tool for studying the complex dynamics of brain activities. It has been used widely to identify neuro cognitive problems. The goal of this work is to identify brain centers that show varied activity during the performance of a numerical cognitive task using a Brain Computer Interface (BCI). This will be used to identify subjects with cognitive problems. Cognitive problems have various causes such as side effects from prescription medication, alcoholism, emotions and stress, aging and cannabis abuse. In this work, we will investigate alterations in the EEG data collected when the subject performs a motor imagery (MI) based numerical cognition tasks. A 32 channel EEG cap will be used to acquire data during the performance of number comparison using MI. The goal is to identify the brain regions that have a probability of reduction in cognition. Different bandwidth will be investigated to see if they keep up sustained attention during the MI task. The BCI is implemented using Python and C++. It displays two random integers, the subject imagines left or right depending on which number is greater, the signals are collected over several trials. All the 32 EEG channels will be analyzed. Frequency domain and time-domain methods are widely used to assess EEG signals from varied subjects. Here, we will use time-frequency (TF) analysis methods by transforming time domain signal to a two-dimensional signal represented in time and frequency space. The short-time Fourier transform and Morlet wavelet transform are ways for

identifying characteristics at time and frequency (scale in case of Morlet) variations, and amplitude from EEG signal. The Energy and Entropy computed from the spectra will be used as indices to identify increased and slowly active regions. A threshold will be applied to discard signals with lower strength. The active centers will then be used for improving the subjects' performance in the BCI cognitive task. This in turn can lead to the use of BCIs for computer assisted cognitive behavioral therapy.

Title: The neural substrate of the Eureka effect

Authors: *Y. LU[1,2,3,4], W. SINGER[1,2,3];
[1]Dept. of Neurophysiol., Max Planck Inst. for Brain Res., Frankfurt, Germany; [2]Frankfurt Inst. for Advanced Studies, Frankfurt, Germany; [3]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany; [4]Dept. of Biology, Tech. Univ. of Darmstadt, Darmstadt, Germany

Abstract: For the segmentation of complex scenes and recognition of objects, sensory evidence has to be compared with Gestalt rules and acquired knowledge about objects (priors) stored in the functional architecture of sensory systems. However, it is unknown how the brain knows when the computations required for the solution of a perceptual problem have converged to a valid result. The latency of this convergence depends on the sensory evidence and its match with prior knowledge and hence is highly variable. Here we investigate the neural dynamics associated with the convergence towards the result state by analysing with high density Electroencephalography (EEG) recording the activity patterns preceding recognition and comparing them with conditions when convergence did not occur. Subjects had to detect figures in cluttered scenes while we manipulated both sensory evidence and prior knowledge in order to obtain trials that did or did not converge towards a perceptual solution and subjects had to signal the convergence with a manual response. We find that the "Eureka" effect is associated with the emergence of coherent oscillations in the alpha band. The corresponding network comprises

widely distributed regions of the cortical mantle with a marked lateralization over the right hemisphere. These results suggest that the signature of the transition towards the solution of a perceptual task is associated with a transient increase of alpha coherence within an extended network.

Title: Neural correlates of musical improvisation

Authors: *K. DHAKAL[1], M. NORGAARD[2], M. DHAMALA[3];
[1]Dept. of Physics and Astronomy, [2]Sch. of Music, [3]Physics and Astronomy, Georgia State Univ., Atlanta, GA

Abstract: Musical improvisation offers a unique model for the investigation of brain regions related to real-time creative behavior in which revision is not possible. Prior research shows contradictory results in which either activation or deactivation in the dorsolateral prefrontal region has been reported; thus, the role of this region in creative production is poorly understood. Because of confounding motor and perceptual variables in previous studies, this study incorporates a musical imagery task. Currently we are collecting and analyzing functional magnetic resonance imaging (fMRI) data from advanced jazz improvisers during an experimental improvisatory imagery task and comparing these results to a control task in which subjects imagine a pre-learned melody. The same contrast is investigated during vocalization of both improvised and pre-learned melodies allowing for behavioral data analysis. Four jazz melodies from the bebop era are used for vocalizing and imagining, as the complexity of these melodies is comparable to expected improvisations. We hypothesize that vocalizing and imagining an improvisation will produce similar patterns of activation. Our preliminary results show changes in activity that might be linked to improvisatory behavior, including the supplementary motor area, medial prefrontal cortex, dorsolateral prefrontal cortex, primary motor cortex, cerebellum, and premotor cortex. Brain activity during improvisation is distinctly higher and involving more regions than the performance of pre-learned melodies, both in the vocalization and imagine conditions. This suggests that musical improvisation is a complex creative behavior that may recruit a large network of brain regions. A deeper understanding of

the neural underpinnings of creativity could influence instructional strategies in both music and other domains.

Title: Dynamics of auditory cortex during internal speech

Authors: ***M. REGEV**[1], U. HASSON[2];
[1]Neurosci., [2]Princeton Univ., Princeton, NJ

Abstract: Does listening to and imagining auditory stimuli elicit similar activity in the brain? Auditory imagination of speech has previously been studied by looking for spatially overlapping neural responses while listening and imagining punctate stimuli such as isolated words or short sentences. In the present work, we take an alternative approach using continuous, complex linguistic stimuli. This approach allows us to explore beyond basic spatial localization of averaged signals to comparisons of the temporal response profiles of listened and imagined speech. Subjects learned to sing a 4-minute narrative song accompanied by a metronome, practicing until high reliability in content and timing across repetitions was attained. Next, using fMRI, we recorded neural responses from the trained subjects in three conditions: 1) listening to a recording of themselves performing the song ("external speech"); 2) silently imagining the song to the rhythm of the metronome ("internal speech"); and 3) listening to the metronome alone without imagining the song ("control"). We directly compared the response time courses in the three conditions within auditory cortex. Neural time courses during internal speech and during the metronome control were significantly different despite sharing the same external auditory information (the sound of the metronome). In contrast, response time courses were remarkably similar for the internal and external speech conditions ($R = 0.53$, $p < 0.0001$). These results indicate that the auditory cortex is not simply active in response to internally generated speech, but also that it shows highly similar neural dynamics during processing of external speech as when imagining the same content.

Title: Spelling with Color? An investigation into the Bidirectionality of Synesthesia

Authors: *B. HACKNEY, J. F. AWAD, J. BUENROSTRO, S. A. DREW;
California State University, Northridge, Northridge, CA

Abstract: Synesthesia is a condition in which a single stimulus elicits multisensory experiences. Many cases studying grapheme-color synesthetes have reported synesthetic perceptions as unidirectional experiences: graphemes inducing colors, but not vice versa. In what few studies have examined the phenomena of bidirectionality (that is, colors inducing a grapheme percept), the focus has been on inducing the perception of numbers from colors. We instead aimed to examine the induced perception of letter graphemes from color. Subjects for this study included three synesthetes with matched controls. Stimuli consisted of two sets of color patches; the colors corresponded with the colored photisms each synesthete associated with letter graphemes. One set of color patches was arranged to correspond with a word and the other with a non-word. As an example, for a synesthete that associates red with “U” and blue with “P”, a red square followed by a blue square would represent the word “UP” while a blue square followed by a red square would represent the nonword “PU.” Participants completed a series of forced-choice tasks, with the instruction to select the set of color patches that corresponded with a word. Two of three synesthetes performed significantly better than chance, with all 10 non-synesthetic controls scoring around chance. These preliminary results suggest possible bidirectional synesthestheic percepts associated with letter graphemes.

Title: Parietal cortex mediates perceptual grouping of dynamic stimuli independent of stimulus size

Authors: *P. R. GRASSI[1], N. ZARETSKAYA[1,2], A. BARTELS[1];
[1]Vision and Cognition Lab., Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]A. Martinos Ctr. for Biomed. Imaging, Boston, MA

Abstract: The perception of objects and scenes as unified structures is crucial for a meaningful interaction with the environment. To achieve this, the brain must interpret the retinal information received and combine local visual elements into coherent percepts. This process is referred to as grouping, spatial binding, or Gestalt perception. Despite the numerous approaches to study spatial binding, the neural mechanisms underlying this process are still largely unexplained. In a recent functional magnetic resonance (fMRI) and transcranial magnetic stimulation (TMS) study we showed that human parietal cortex was causally involved in mediating the conscious percept of global Gestalt from local moving elements [1]. We used a bistable motion illusion that causes spontaneous alternations between the perception of locally moving dots and of global planar motion of two illusory squares spanning all four visual quadrants. However, the local elements used in that study spanned a large visual space (about 10 visual degrees), which would potentially only be covered by the large receptive fields of parietal neurons. Here we asked whether other cortical regions with smaller receptive fields could also mediate spatial binding of moving elements when stimuli are sufficiently small. We used fMRI to measure activity over the whole-brain and in motion selective areas (V5/MT, MST, V3A and V6) in response to the bistable stimulus described above. The stimulus was presented in two sizes (large and small) to account for differences in receptive field sizes of neurons in the areas analyzed. Group whole-brain analysis revealed only two clusters in the parietal cortex involved in Gestalt perception. The results were indistinguishable for both, large and small stimuli, with no further regions involved. The analysis of independently localized motion responsive regions showed no differential response favoring global Gestalt perception. These results suggest that the posterior parietal cortex is exclusively involved in perceptual grouping of dynamic stimuli across both, large and small distances of visual space. Grouping is thus achieved by a receptive field size-independent mechanism mediated by the posterior parietal cortex. 1. Zaretskaya N, Anstis S, Bartels A. 2013. Parietal cortex mediates conscious perception of illusory gestalt. J Neurosci. 33:523-531.

Title: Familiar size relationships decrease size-contrast illusion

Authors: *M. MALTSEVA, K. STUBBS, M. A. GOODALE, J. C. CULHAM;
Western Univ., London, ON, Canada

Abstract: The image of a large dog beside a small cat is familiar to us because it is congruent with our knowledge of the real world sizes of these animals. The familiar size effect, which is characterized by slower reaction times when judging the size of objects that are incongruent with their familiar sizes, suggests that previous knowledge of an object's real world size can influence visual perception. But does familiar size also affect the perceived size? Here we examined the effect of familiar size on the classic Ebbinghaus illusion in which a central image surrounded by larger images is perceived as smaller than it actually is (and one surrounded by smaller images is perceived as larger). Participants used a keyboard to adjust the size of the target image on a computer screen so that it matched the perceived size of the central image in an Ebbinghaus illusion. The central image was identical throughout all trials (a 25-mm-wide dog), but the surrounding images (i.e., annuli) could differ according to physical size (12 mm vs. 37 mm), semantic category (animate vs. inanimate), and familiar size (cat vs. horse for the animate category; shoe vs. car for the inanimate category). Importantly, the physical size relationship between the central and surrounding images was either congruent (e.g., dog surrounded by small shoes or large cars) or incongruent (e.g., dog surrounded by large shoes or small cars) with their familiar size relationship. Illusion strength was defined by the difference in the perceived size of the central image between the conditions with physically small and physically large annuli. The strength of the illusion was significantly weaker in the congruent conditions than the incongruent conditions. For example, a dog of constant size was perceived as much smaller when surrounded by large shoes compared to small cars but the difference in perceived size was much attenuated for a dog surrounded by small shoes compared to large cars. These results show that perceived size is affected not just by retinal size but also by familiar size relationships.

Title: Neural oscillations and illusory rotatory motion: spatiotemporal analysis of neuromagnetic activities related to unusual visual perception

Authors: *A. TAKEDA[1], T. MAEKAWA[1], T. URAKAWA[2], T. OKAMOTO[3], K. OGATA[1], N. HIRONAGA[1], S. TOBIMATSU[1];
[1]Dept. of Clin. Neurophysiology, Neurolog. Inst., Fac. of Med. Sciences, Kyushu Univ., Fukuoka-shi, Japan; [2]Fac. of Science, Tokyo Univ. of Sci., Tokyo, Japan; [3]Div. for Arts and Science, Kyushu Univ., Fukuoka, Japan

Abstract: “Rotating Snakes (RS)” is a static picture that makes the observers perceive rotatory illusory motion. Previous studies have reported that luminance difference in the color arrangement of the image and microsaccades contribute to the production of the illusory motion perception. fMRI studies have also shown that area hMT/V5+ is activated when the participants perceive the illusory rotation. The aim of this study was to elucidate the spatiotemporal dynamics of neural activities related to the occurrence of the subjective unique illusory perception by magnetoencephalography (MEG). The RS image and control image without illusory motion were projected onto the screen in front of the healthy participants in a dim magnetic shield room for 5 s in a random order with 2 s inter-stimulus interval. Participants were required to report the perception of rotatory motion by pushing a computer mouse button as quickly as possible. Neuromagnetic activities were recorded by a 306-channel whole-head MEG system (Elekta Co. Ltd., Neuromag). The data were analyzed by time-frequency analysis with Wavelet transformation, and source localization was performed by a DICS beamformer method. We found that robust visual responses were elicited in the occipital region at around 150 ms after both stimulus onset, but there were no significant differences in the amplitudes and latencies between the two images. Regarding the results of the time-frequency analysis in grand-averaged data, α- and β-band oscillatory activities in the bilateral temporal regions tended to desynchronize beginning from around 400 ms before the participants reported the illusory motion. Furthermore, the sources of the desynchronized α- and β-bands were estimated in the areas including hMT/V5+ in each individual brain. Therefore, our results first demonstrated that neural activities related to the subjective recognition of illusory rotatory motion could occur at around 400 ms before reporting the perception. From our results and previous reports, this illusion could be related to the activation of area hMT/V5+.

Title: Effects of mechanical tactile noise on the amplitude of visual evoked potentials

Authors: *I. MENDEZ-BALBUENA[1], N. HUIDOBRO[2], M. SILVA[2], R. CORRIPIO[3], A. FLORES[2], C. TRENADO[4], L. QUINTANAR[1], O. ARIAS-CARRION[5], R. KRISTEVA[6], E. MANJARREZ[2];

Nacional Autónoma de México, México, Mexico; [6]Dept. of Neurol., Univ. of Freiburg, Freiburg, Germany

Abstract: The aim of the present study was to demonstrate the electrophysiological occurrence of multisensory stochastic resonance (SR) in the human visual pathway elicited by tactile noise. We examined whether a particular level of mechanical Gaussian noise applied to the index finger can improve the amplitude of the visual evoked potential (VEP). The VEP was elicited by checkerboard pattern reversal stimulation. The level of vibrotactile noise inducing multisensory SR varied between 30 and 200 mN. For all eight subjects, the highest amplitude of the VEP P100 occurred in occipital areas, particularly at Oz (4/8), O1 (2/8), and O2 (2/8). We compared the amplitude of the positive P100 VEP component between zero noise (ZN), optimal noise (ON) and high mechanical noise (HN). The percentage of change for the averaged P100 VEP amplitude (ON versus ZN) for all subjects was 50.7 ± 9.7 % (mean ± SE). We performed the nonparametric Friedman test to examine the statistical significance of the change in the P100 VEP amplitude, between the three conditions (ON, ZN and HN) in all subjects. The results showed significant differences between the three conditions ($p<0.002$, df 2). The post hoc Wilcoxon test revealed statistically significant differences between ZN and ON ($p<0.008$) and between ON and HN ($p<0.008$). In contrast, no statistically significant differences were found between conditions ZN and HN. We performed an identical analysis for the signals recorded from the C3 electrode placed on the region overlying the somatosensory area. In this region, we did not observe P100 evoked responses to the visual stimuli like those observed in occipital areas. For evoked potentials (EP) recorded at C3 we did not observe evidence of SR type behaviour and also no significant differences between the three conditions (ZN, ON and HN, $p>0.5$, df 2). Our electrophysiological study extends the psychophysical experiments by Lugo et al., (2012) and Mendez-Balbuena et al., 2012 in the context of an EEG paradigm. Our results

demonstrate that tactile noise could potentially modulate the amplitude of a relevant VEP component (P100) by following the principles of the multisensory SR phenomenon.

Abstract: Humans group color, a continuous perceptual attribute, into discrete categories. Evidence about the neural locus of color categorization is contradictory across different studies involving healthy participants. Here, we compare color categorization to other aspects of color perception and cognition in a patient with a focal brain lesion. RDS is a 51-year-old patient who, after a stroke in the left occipitotemporal region, presented with right-sided hemianopia, alexia without agraphia and signs of associative agnosia and color agnosia. His visual mental imagery for orthographic material and for object form and color was spared. We assessed RDS's color perception with the Ishihara and Fansworth-Munsell 100 Hue tests, and used a set of tailor-made behavioral tests to assess color naming, categorization and knowledge. RDS also underwent fMRI localizers with images of words, numbers, houses, tools, body parts, faces, colored and gray-scale Mondrians, as well as objects in gray-scale, or colored with typical vs. atypical colors

(eg a green frog vs. an orange frog). RDS had no substantial problems in tasks of color discrimination, color constancy or color contrast. His object color knowledge was virtually intact. In contrast, color categorization and naming were severely impaired. RDS was unable to name color patches, to group colors in categories and to judge colors on category membership. fMRI revealed that the lesioned left ventral visual stream did not hold any residual functional abilities. However, images of houses, tools, body parts and faces did activate the typical specialized regions in the right hemisphere. Colored Mondrians contrasted with gray-scale Mondrians activated the right hemisphere V4, which has been suggested to engage in passive color perception. Typically colored images compared to grayscale images revealed activations in the right fusiform gyrus, anatomically consistent with the localization of area V4α engaged in high-order color processing; in the left superior temporal gyrus and in the left middle frontal gyrus, areas active in language processing and recently shown to engage in color processing. Behavioural and neuroimaging results showed that the patient has spared color discrimination and object color knowledge, but disrupted color categorisation. These results suggest that color categorisation is dissociatied from those other processes of color perception, and is most probably guided by different neural mechanisms. As RDS' lesion is left-sided, we conclude that those mechanisms of color categorisation are most probably located in the left occipito-temporal areas.

Title: Visual cortex activity predicts subjective experience after reading books with colored letters

Authors: *O. COLIZOLI[1], J. M. J. MURRE[2], H. S. SCHOLTE[2], D. M. VAN ES[3], T. KNAPEN[3], R. ROUW[2];

Abstract: One of the most astonishing properties of synesthesia is that the evoked concurrent experiences are perceptual. Is it possible to acquire similar effects after learning cross-modal associations that resemble synesthetic mappings? In this study, we examine whether brain activation in early visual areas can be directly related to letter-color associations acquired by training. Non-synesthetes read specially prepared books with colored letters for several weeks

and were scanned using functional magnetic resonance imaging. If the acquired letter-color associations were visual in nature, then brain activation in visual cortex while viewing the trained black letters (compared to untrained black letters) should predict the strength of the associations, the quality of the color experience, or the vividness of visual mental imagery. Results showed that training-related activation of area V4 reflected the degree to which acquired letter-color associations had localizable color experiences, measured by the projector-associator dimension of grapheme-color synesthesia. In contrast, the strength of the acquired associations (measured as the Stroop effect) was not reliably reflected in visual cortex activity. The reported vividness of visual mental imagery was related to veridical color activation in early visual cortex, but not to the acquired associations. We show for the first time that subjective experience related to a synesthesia-training paradigm was reflected in visual brain activation.

Title: The effects of visual scene complexity on human cortex

Authors: A. J. BIES, J. B. WEKSELBLATT, C. R. BOYDSTON, R. P. TAYLOR, *M. E. SERENO;
Univ. of Oregon, Eugene, OR

Abstract: Complex natural forms (e.g., mountains, trees, clouds) exhibit fractal characteristics yet there has been little systematic, neuroscientific investigation of human responses to fractal stimuli. Fractals are patterns that repeat at increasingly fine magnifications, and have fractal dimensions (D) that fall between Euclidian dimensions (e.g., a fractal line has a D value lying between a smooth line, D = 1, and a filled plane, D = 2). The visual complexity generated by the repeating patterns increases with their D value. The horizon lines of natural landscapes have D values that fall in the low to middle portion of the range $1 < D < 2$. It has been hypothesized that humans are predisposed to prefer environments and scenes with a level of complexity near that of the landscapes in which we have evolved. In support of this idea, recent research has shown that individuals' preference for particular natural scenes depends on complexity, with greater preference for low-to-mid range complexity as characterized by a scene's fractal dimension (Taylor et al., 2011). Because natural scenes do not vary across the entire range of complexity without changing content, we produced a set of abstract scenes that sample the full range of complexity quantified by the fractal dimension (viz., D = 1.1, 1.3, 1.5, and 1.9 for each of 16

patterns). In the current study, human participants viewed these computer-generated fractal images and rated the aesthetic value of each, during functional magnetic resonance imaging. We used a subtraction paradigm to isolate brain areas that were more active when viewing a particular dimension than the others. Primary visual cortex fell within the region more activated by viewing images with D = 1.9, whereas lateral occipital cortex (LO) fell within the area more activated by viewing images with D = 1.1. We created masks for contrasts 1.1 > 1.9 and 1.9 > 1.1, and found that brain activity in early visual areas (1.9 > 1.1) shows a significant, linear increase in activity as complexity increases, whereas later visual areas (1.1 > 1.9) show a significant, linear decrease in activity in response to increased complexity. Meanwhile, preference ratings do not scale linearly with complexity. Ratings were high and exhibited little change in the low-to-mid range of D, but were considerably lower at high D values. Thus, visually appealing fractal patterns of low-to-mid range fractal D stimulate higher-level visual areas such as LO, regions known to be involved in processing objects. This activity in object-processing areas provides a putative explanation for why certain patterns naturally evoke object percepts (e.g., perceiving faces or animals in clouds, rock formations, ink blots).

Title: Attention and motion-induced position shifts: evidence from visual neglect

Authors: S. DE VITO[1,2,3,4,5], M. LUNVEN[1,2,3,4], C. BOURLON[6], C. DURET[6], P. CAVANAGH[7], *P. BARTOLOMEO[1,2,3,4,5];
[1]Inserm UMRS 1127, Brain and Spine Inst., Paris, France; [2]Sorbonne Universités, UPMC Univ. Paris 06, UMR S 1127, Paris, France; [3]CNRS, UMR 7225, Paris, France; [4]Inst. du Cerveau et de la Moelle épinière, Paris, France; [5]Dept. of Psychology, Catholic Univ., Milan, Italy; [6]Ctr. de Rééducation Fonctionnelle Les Trois Soleils, Boissise Le Roi, France; [7]Lab. Psychologie de la Perception, Université Paris Descartes, Paris, France

Abstract: When we look at bars flashed against a moving background, we see them displaced in the direction of the upcoming motion (flash-grab illusion). It is still debated whether these motion-induced position shifts are low-level, reflexive consequences of stimulus motion, or

high-level compensation engaged only when the stimulus is tracked with attention. To investigate whether attention is a causal factor for this striking position illusion, we evaluated it in six patients with damaged attentional networks in the right hemisphere and signs of left visual neglect and six age-matched controls. We presented a background motion of radial sectors centered at fixation, rotating at 180° per second and reversing direction every 660 ms. Importantly, the background was only visible in one half of the visual field, and was presented in different conditions in the top, bottom, right or left visual field. On each reversal of direction, two lines appeared briefly at the same location and both aligned horizontally (or vertically, depending on the condition) with the fixation point. However, due to the alternating background motion, they typically appeared shifted away from horizontal (or vertical) in opposite directions. Under instructions from the participants, the experimenter adjusted the locations of the lines to oppose any perceived offset until they again appeared to be superimposed, as the half-disk continued to rock back and forth. The amount of shift required to make the lines appear superimposed was the measure of the illusion strength. With stimuli in the top, right, and bottom visual fields, neglect patients experienced the same amount of illusion as controls. Strikingly, patients showed no significant shift when the test was presented in their left hemifield, even though they made equally precise judgments at this location. Thus, paradoxically, neglect patients perceived the position of the flash more veridically in their neglected hemifield. These results suggest that impaired attentional processes can reduce the interaction between a moving background and a superimposed stationary flash, and indicate that attention is a critical factor in generating the illusory motion-induced shifts of location.

Title: Dorsolateral prefrontal cortex, metacognitive awareness of emotional visual stimuli, and emotion regulation: a TMS/EEG study

Authors: *R. C. LAPATE, J. SAMAHA, B. ROKERS, A. AUSTERMUEHLE, H. HAMZAH, B. R. POSTLE, R. J. DAVIDSON;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Prior work suggests that awareness of emotional stimuli can benefit regulation of subsequent behavioral responses. For example, in the emotion misattribution paradigm, novel neutral faces are evaluated more negatively following unaware compared to aware exposures to negative facial expressions. Awareness is associated with the engagement of the prefrontal cortex, in particular dorsolateral prefrontal cortex (DLPFC), a region implicated in metacognitive awareness of simple visual stimuli, and in emotion regulation. Accordingly, less emotion misattribution during aware emotional processing correlates with DLPFC function. Here, we tested whether DLPFC causally promotes metacognitive awareness of emotional stimuli and prevents emotion misattribution by administering a transcranial magnetic stimulation protocol previously shown to inhibit cortical activation (theta-burst; tbTMS) to DLPFC, and to a control region (somatosensory cortex; S1). Following each application of tbTMS, 19 participants completed the emotion misattribution paradigm as well as assessments of face-stimulus awareness (face orientation & expression). Order of task and tbTMS target (DLPFC vs. S1) was counter-balanced across subjects. Using the method of constant stimuli at 6 contrast levels, we assessed both 'objective' (2-alternative forced choice stimulus judgments; 2AFC) and 'subjective' awareness (i.e., confidence ratings) of emotional faces, permitting the computation of an index of metacognitive accuracy, meta-d', at each contrast level, which reflects the correctness of subjective ratings given the accuracy of objective responses. To ascertain the effectiveness of the tbTMS protocol, we recorded resting state electroencephalography (EEG) before and after each tbTMS administration, and computed changes in power in the alpha frequency band (8-12 Hz). Alpha power at DLPFC electrodes increased following tbTMS to DLPFC (compared to S1), suggesting DLPFC inhibition. Critically, a valence by region interaction revealed that tbTMS to DLPFC (relative to S1) increased the influence of emotional faces on subsequent neutral-face judgments. While tbTMS did not significantly impact objective awareness metrics (2AFC performance or threshold), tbTMS region and contrast level interacted in predicting meta-d' for face orientation judgments, suggesting a reduction of metacognitive accuracy for faces shown at low contrasts. Collectively, these findings suggest that DLPFC plays a critical and causal role in promoting subjective awareness of complex emotional face stimuli and in attenuating their influence on subsequent behavior.

Title: Generic decoding of seen and imagined objects using hierarchical visual features

Authors: *T. HORIKAWA[1], Y. KAMITANI[1,2];
[1]ATR, Kyoto, Japan; [2]Kyoto Univ., Kyoto, Japan

Abstract: Brain decoding has achieved much success in neuroimaging analysis by reading out mental contents from fMRI activity patterns. However, the conventional classification-based approach has a fundamental constraint on the number of possible outputs: the outputs are limited to the number of the classes used in the training of a decoding model. While the image identification and reconstruction approaches enabled predictions about numerous states, including those not used for training the decoding model, they are designed for decoding retinotopically organized, image-level features. Here, we propose a method (termed generic object decoding) for decoding seen and imagined object categories including those that were not used in decoder training. Assuming that an object category can be represented by a set of mid-level visual features with invariances to position and/or rotation, we trained decoders to predict the features extracted by computer vision models or a deep neural network from fMRI signals measured while participants viewed natural images (150 categories). We examined whether a seen or imagined object that was not used for decoder training could be identified by comparing the predicted feature vector and object-specific feature vectors derived from annotated images in an online image database (15,322 categories). We performed this analysis for each combination of visual features (Convolutional Neural Network, HMAX, GIST, and SIFT) and brain regions of interest (V1-V4, LOC, FFA, and PPA). The trained decoders successfully predicted the values of individual features, making it possible to identify objects from fMRI signals with most of the feature-ROI combinations. Higher-order visual features tended to be better predicted from fMRI signals in higher than lower cortical areas (and vice versa). Mid-level features predicted from higher cortical areas were most useful in identifying object categories. Furthermore, imagining about an object category was sufficient to induce brain activity that was predictive of mid-level visual features and to perform object identification at a statistically significant level. Our results demonstrate that the decoding model trained on a limited set of object categories generalizes to decode arbitrary object categories. The successful identification with brain activity during imagery suggests that feature-level representations elicited in visual perception may also be recruited during top-down visual imagery. Our approach may provide a basis for a brain-based information retrieval system by translating brain activity into words/concepts.

Title: Progressive enhancement of phase synchronization in fronto-occipital regions during visual perception

Authors: *M. HAYAKAWA, K. AKIBA, Y. MORISHITA, Y. KAKIMOTO, O. ARAKI; Dept. of Applied Physics, Tokyo Univ. of Sci., Tokyo, Japan

Abstract: We can identify objects accurately from an incomplete picture involving them. To identify objects from limited information in the object perception process, visual disambiguation process is necessary. Success in the object identification should be guided not only by visual inputs but also by much top-down information. In many previous studies, degraded visual stimuli were used as insufficient visual inputs to induce the visual disambiguation process. These results showed that the cortical and subcortical areas were relevant to the visual disambiguation process. Moreover, electroencephalography (EEG) and fMRI data indicated the enhancement of functional connections between various cortical regions at the timing of cognition. However, it is still unknown about the dynamics in functional connections before and after the object recognition. We aimed to solve this issue by recording EEG of 14 subjects during a two tone (TT) image perception task. TT image might look meaningless at first sight, but the objects in it will gradually appear. Degradedness of the TT image presented to a subject was gradually changed over 10 levels from hard to easy by adjusting the threshold value. Each image of a level was presented once for 200 ms, and mask screen was presented for 1000 ms between each image. This intermittent presentation makes it easy for us to capture the timing of object recognition. Subjects were instructed to press a button as soon as possible, if they can identify objects in the presented TT images. We analyzed EEG data and calculated Phase locking value (PLV), which was used as an index of strength of functional connections. As a result, beta and gamma band PLV enhancement (increase of phase synchronization) between the frontal and occipital areas was observed in 100 ms after the onset of the TT image to which the subject has responded. Furthermore, the PLV enhancement was also observed in the previous presentation of an image which subjects have not recognized yet. The PLV in the block (B0) which the subject responded was more enhanced than that in the previous block (B1). Additionally, the PLV in the B1 block was more enhanced than the second preceding one (B2). The results suggest that beta and gamma band phase synchronization between fronto-occipital regions is correlated with visual disambiguation process. Furthermore, the phase synchronization enhancement may reflect a higher brain function accompanied by flow of information between cortical areas.

Title: The temporal sequence of cortical activity during probe-induced binocular rivalry

Authors: ***B. METZGER**[1,2], K. A. LOW[2], E. L. MACLIN[2], M. FABIANI[1,2], G. GRATTON[1,2], D. M. BECK[1,2];
[1]Dept. of Psychology, Univ. of Illinois, Urbana, IL; [2]The Beckman Inst. for Advanced Sci. and Technol., Urbana, IL

Abstract: Binocular rivalry occurs when highly dissimilar images are presented to the eyes. Perception alternates between the two images such that at times one image dominates awareness while the other is suppressed from awareness. Prior research has shown that brief, yet salient probes presented to the suppressed eye can cause a rapid switch in perceptual dominance. Previously we showed that these switches (i.e. reversals) are mediated by P1 and P3b ERP components (Metzger et al., VSS 2014) (Metzger et al., CNS 2015). In particular, we showed that P1 and P3b amplitudes increased monotonically as a function of reversal latency (from the suppressed-eye probe) such that faster reversals were associated with larger ERP amplitudes. These data suggest that the speed with which perception switches is determined by the degree to which the probe is initially processed (as indexed by the P1 amplitude) as well as the degree to which the probe forces a reallocation of attention (as indexed by P3b amplitude). Here, we used fast event-related optical imaging (recorded concurrently with EEG) to ask what cortical areas differentially respond to slow- and fast-switching suppressed-eye probes. Based on the observed ERP data, we would predict an early difference in a similar time window as the P1 and a later difference in parietal attention areas, in keeping with the P3b effects we observed. The EROS data showed greater activity for fast-switching suppressed-eye probes relative to slow-switching suppressed-eye probes in early visual cortex from 127-153 ms following the onset of the probe, a time frame that is comparable to the observed P1 ERP activity. In addition, activity in right superior parietal cortex was greater for fast-switching suppressed-eye probes in two distinct time windows that fell within the P3b window: at approximately 281 and 665 ms. following probe onset. Both time windows of activity precede the perceptual transition, which for the fastest switches occurred at approximately 900 ms. Taken together, the data suggest that the speed with which switches occur depends first on the saliency of the probe (as indexed by activity in early

visual cortex), which then influences the probability the probe will reallocate attention to the image in the suppressed eye (as indexed by activity in right parietal cortex).

Title: Differential cortical responses to high- and low-Level visual features of naturalistic movie stimuli

Authors: *S.-C. HUNG, K.-H. LU, H. WEN, Z. LIU;
Weldon Sch. of Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: Previous functional magnetic resonance imaging (fMRI) studies have shown that human cortical activity can be highly reliable within and across individuals while responding to complex and dynamic naturalistic stimuli. However, to what extent the cortical synchronization is evoked by different levels of visual features embedded in the natural stimuli still remains unclear. Also, whether or not the reliability of cortical response was affected by the eye movement is unknown. Here, we (i) scrambled a black-and-white movie by perturbing the high-level features of visual representations while preserving the low-level visual features, and (ii) employed the eye-tracking technique in fMRI experiments to assess the contribution of eye movement to blood-oxygen-level-dependent (BOLD) signals. Our results show that the cortical response to the low-level features of the movie is primarily revealed in the early visual cortex, while the intact movie evokes broader cortical response into higher-order association areas. These differential cortical patterns hold both across stimuli repetition and across subjects. Critically, the results are robust to the degree of coherence of eye movement under a free-viewing condition. Taken together, our data demonstrate reliable intra- and inter-subject synchronization of cortical activity in response to hierarchical levels of visual features during naturalistic stimulation. We suggest that the human cortical areas can reliably function in a hierarchical manner under a more realistic condition.

Title: Visually-responsive regions around the right TPJ and attentional reorienting

Authors: *L. DUGUÉ, E. P. MERRIAM, D. J. HEEGER, M. CARRASCO;
Dept. of Psychology and Ctr. for neural science, NYU, New York, NY

Abstract: Purpose: The right temporal-parietal junction (TPJ) has been proposed to play a central role in the attentional reorienting system (Corbetta et al., 2008). We tested the hypothesis that reorienting both endogenous (voluntary) and exogenous (involuntary) visual attention is mediated by visually selective regions within and around the TPJ. **Approach:** Cortical responses were measured using fMRI (8-ch phased-array surface coil, 2x2x2.5 mm, 28 slices covering temporo-parietal regions), while observers performed a two-alternative forced-choice orientation discrimination task. Two sinusoidal grating stimuli briefly appeared in the lower left and right quadrants of the visual field. A central response cue at the end of each trial indicated which of the two gratings was the target. Observers reported the orientation of the target stimulus (clockwise or counterclockwise relative to vertical) with a button press. In the endogenous attention task, a central precue instructed observers to attend to one of the two stimulus locations. In 75% of the trials the cue and target locations matched (valid), and in the remaining trials they did not match (invalid). In the exogenous attention task, a peripheral cue automatically attracted attention to one of the two stimulus locations. The cue was non-informative (valid in 50% of the trials). For both endogenous and exogenous visual attention tasks, based on the reorienting hypothesis, we predicted greater activity for invalid trials (that require reorienting at the end of each trial) than for valid trials (that do not require reorienting), in visually-responsive regions. **Results**: Three visually-responsive regions were identified within and around the right TPJ. The first matched a region called vTPJ (Horiguchi et al., 2014). The second region was located at the most caudal portion of the STS, just posterior to vTPJ and anterior to MST. The third region was located in posterior insula, just anterior to vTPJ. Each of these three regions was 0.5-1.0 cm^3 in volume, averaged across observers. Within each region, average activity was measured for valid and invalid trials, independently for endogenous and exogenous attention conditions. We found that in both the vTPJ and STS regions, activity was higher for invalid than valid trials, for both endogenous and exogenous attention tasks. In the insula region, there was no difference in activity between valid and invalid trials in either task. **Conclusion**: vTPJ and a visually-

responsive region within posterior STS participate in the reorienting of attention in both endogenous and exogenous visual attention tasks.

Title: Behavioral evidence that skin reflectance is used as an illumination cue for color constancy

Authors: ***R. LAFER-SOUSA**[1], K. L. HERMANN[1,2], B. R. CONWAY[1,2];
[1]BCS, MIT, Cambridge, MA; [2]Neurosci., Wellesley Col., Wellesley, MA

Abstract: The dress in #TheDress photograph is typically perceived as either blue/black (B/K), white/gold (W/G), or blue/brown (B/B) (Lafer-Sousa et al., Curr Biol, 2015). We hypothesize these percepts arise because the illumination cues in the image are ambiguous and individuals infer either a warm, cool, or neutral illuminant. By embedding the dress in a chromatically tinted scene on a model with chromatically tinted skin to make the color of the illuminant explicit (expt. 1), we found that regardless of how subjects initially perceived the dress' colors, their percepts conformed to a percept predicted by the color of the illuminant (warm illuminant: 77% of subjects report B/K; cool illuminant: 83% of subjects report W/G; N = 53). Could these results be attributed simply to chromatic contrast? We tested this hypothesis by probing percepts of the dress' color in images in which we surround the dress by a uniform field of average chromatic bias matching that used in the first experiment; we ran separate experiments in which the dress was presented on a model with skin tint or by itself. When presented without the model on a uniform chromatic background (expt. 2), less than 50% of subjects conformed to the percept predicted by the color of the background, significantly fewer than did in the first experiment (warm conditions: $p = 3*10^{-6}$, cool conditions: $p = 8*10^{-5}$; McNemar's chi-squared test). But when skin tint was the only cue (i.e. the dress and model presented on a white background, expt. 3), reports were predicted by the color of the skin tint (warm: 70% of subjects report B/K, cool: 79% of subjects report W/G). The extent to which subjects conformed to the percept predicted by the illumination did not differ between expt. 1 and 3 (the stimuli were equally effective) (warm conditions: $p = 0.6$, cool: $p = 0.1$), but did between expt. 2 and 3 (skin tint was more effective than color-contrast) (warm conditions: $p = 10^{-4}$, cool: $p = 10^{-4}$). These results suggest people use

skin chromaticity to recover the illuminant and compute object color, providing behavioral evidence to support modeling experiments showing that skin could be used as a cue to illumination for achieving color constancy— skin color may be useful for color constancy because the gamut of human skin has a distinctive profile in cone-contrast space (across skin types) that shifts predictably under varying illuminations (Crichton et al., CGIV, pp. 266, 2012; Bianco & Schettini, CVPR, pp. 65, 2012). People are likely to have a robust internal model of skin color and how it varies with illumination because we carry our skin with us wherever we go and skin color is a behaviorally relevant feature (e.g. face color signals emotional and health status).

Title: Neural coding of navigational affordances in visual scenes

Authors: *M. F. BONNER[1], J. RYAN[2], R. EPSTEIN[2];
[1]Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]Psychology, Univ. of Pennsylvania, Phiiladelphia, PA

Abstract: An essential component of visually guided navigation is the ability to perceive features of the environment that afford or constrain movement. For example, in indoor environments, walls limit one's potential routes, while passageways facilitate movement. Here we attempt to identify the cortical mechanisms that encode such navigational features. Specifically, we test the hypothesis that scene-selective regions of the human brain represent navigational affordances in visual scenes. In an fMRI experiment, subjects viewed images of artificially rendered rooms that had identical geometry as defined by their walls, but varied on the number (one to three) and position (left, right, center) of spatial passageways (i.e., open doorways) connected to them. The layout of these passageways defined the navigable space in each scene. Several versions of each layout were shown, each with the same set of passageways but different textures on the walls and floors. Furthermore, half of the rooms were empty except for the walls and passageways, while the other half included visual clutter in the form of paintings along the walls. The paintings were similar in size and shape to the passageways. Images were presented for two seconds while subjects maintained central fixation and performed an unrelated color-discrimination task on two dots overlaid on each scene. Using multivoxel

pattern analysis, we identified representations of navigational layout that were invariant to other visual properties of the images. This analysis revealed a consistent representation of navigational layout in the occipital place area (OPA), a scene-selective region near the transverse occipital sulcus. In this region, information about navigational layout could be decoded across changes in texture or visual clutter (i.e., paintings on the walls) even though the overall spatial geometry was the same for all scenes. These findings suggest a mechanism in the OPA for coding fine-grained information about the layout of navigational space.

Title: Neuroconnectivity in human fetuses subsequently born preterm

Authors: *M. E. THOMASON[1,4], D. SCHEINOST[5], J. H. MANNING[2], L. E. GROVE[2], P. K. JELLA[3], K. M. HERMEZ[2], J. L. HECT[2], S. JIRJIS[2], R. T. CONSTABLE[5], L. R. MENT[5], R. ROMERO[4];
[2]Merrill Palmer Skillman Inst., [3]Radiology, [1]Wayne State Univ., Detroit, MI; [4]Perinatology Res. Br., NICHD/NIH/DHHS, Detroit, MI; [5]Pediatrics, Radiology, Neurol., Yale Univ., New Haven, CT

Abstract: Many infants born preterm demonstrate mild to severe motor abnormalities. It is difficult to ascertain whether motor impairments result from altered neurological development *in utero*, as opposed to secondary injury. Functional connectivity mapping via resting state fMRI can measure fetal brain function before birth. It is thus possible to identify alterations in neural networks that present before birth to ascertain origins of neurological anomaly associated with preterm birth. We tested the hypothesis that altered motor network development precedes preterm birth. We enrolled pregnant women, some of whom were high-risk for preterm delivery, but who were experiencing otherwise healthy pregnancies. We compared 18 fetuses born prior to 37 weeks to 18 term-delivered fetuses matched on age, gender and motion during MRI. Postmenstrual gestational age (GA) at the time of the scan and sex of fetuses subsequently born preterm (PT) were 29+5 (weeks+days; SD=3+4), 11 males; age and sex of term-born control fetuses (TC) were 30+1 (SD=3+3), 10 males; study sample range was 22-36 weeks GA. We measured brain function *in utero* using non-invasive resting-state functional MRI. Functional data were co-registered to a 32-week gestational age fetal template. Seed-based connectivity

analyses were used to compute signal covariance maps from 5 regions in the left motor cortex and cerebellum, and in one control region. All analyses were conducted at uncorrected $p \leq 0.001$ and $k \geq 10$. We observed increased functional connectivity in TC compared to PT fetuses from motor and cerebellar seeds. Between group differences were greatest in distant brain regions, suggesting that PT fetuses lack long-range connectivity. In contrast, increased short-range connectivity was observed in PT fetuses, providing some evidence for a trade-off in local over distal connectivity in the PT fetus. Differences between groups were smaller in the parietal network that served as a control, indicating specificity in these observations. Here, we shift the timeline for discoveries about functional brain maturation to a time of exceedingly rapid change, the fetal period, when foundations for brain circuitry are being laid. For the first time we report altered neural connectivity in fetuses that will be born preterm. Reduced long-range and cross-hemispheric connectivity in PT fetuses indicates that deficient neuroconnectivity in the prenatal period precedes disturbances in motor learning in infancy. Scientific data that can non-invasively operationalize functioning of the fetal brain has the potential to transform our understanding of this sensitive and defining period in human life.

Title: Family nurture intervention alters relationships between preterm eeg coherence and 18 month neurodevelopmental outcome

Authors: ***M. G. WELCH**[1], R. STARK[2], P. GRIEVE[2], J. ISLER[2], R. LUDWIG[2], M. MYERS[3]; [1]Pathology & Cell Biol., Columbia Univ. Col. of Physicians & Surgeons, New York, NY; [2]Pediatrics, [3]Pedatrics and Psychiatry, Columbia Univ. Med. Ctr., New York, NY

Abstract: Background: Despite decreased mortality and morbidity, prematurely born infants remain vulnerable to a broad range of developmental disabilities, including increased risk for autism. A randomized controlled trial (RCT) of the Family Nurture Intervention (FNI) in the

NICU, designed to enhance the emotional relatedness between prematurely born infants and their mothers, demonstrated that FNI led to robust increases in EEG power and decreased coherence at term age in the frontal polar region of the brain when compared to infants receiving standard care (SC). Both findings are consistent with FNI promoting brain maturation. Objective: This analysis assessed the correlation between EEG coherence in preterm infants measured at term age and neurodevelopmental outcomes at 18 months. Design/Methods: Infants (26-34 weeks postmenstrual age) were enrolled in an RCT testing efficacy of FNI. FNI is delivered via nurture specialist-facilitated sessions between the mother and her infant. Activities include odor cloth exchange, vocal soothing, comfort touch and skin-to-skin and wrapped holding. At 18 months corrected age, Bayley's III and Modified Checklist for Autism in Toddlers (MCHAT) were used to assess cognition and language, and risk for autism, respectively. Results: In SC infants (N=17), term age EEG coherence was negatively correlated with 18 month cognition and language and positively correlated with risk for autism spectrum disorder (ASD). In FNI infants (N=34) there was no relationship between EEG coherence and outcome. Conclusion: The results from SC infants suggest that high coherence in brain regions involved in language, cognition and emotion regulation predicts poorer outcomes in these domains at 18 months. This indicates that in SC infants, measures of EEG coherence may provide an early marker to identify which preterm infants are in greatest need of intervention. Our prior studies showed that FNI infants have lower frontal coherence at term age and improved neurobehavioral outcomes at 18 months. Here we find that in contrast to SC, FNI appears to abrogates the impact of high coherence at term age on later outcomes. It may be that FNI promotes maturation of other processes that become more significant determinates of outcome than term age coherence. It may also be that the relationship between coherence and outcome in SC infants becomes less robust at later stages of development and that FNI has advanced infants into this more mature stage.

Title: Visual short term memory capacity in preterm born adults is associated with fractional anisotropy in posterior thalamic radiations and splenium of the corpus callosum

Authors: *A. MENEGAUX[1], C. MENG[2], J. NEITZEL[1], J. BAÜML[2], H. MÜLLER[1], D. WOLKE[3], A. WOHLSCHLÄGER[2], C. SORG[2], K. FINKE[1];

Abstract: Preterm birth is associated with increased risk for lasting cognitive impairments particularly in attention. It was shown recently that reduced visual short term memory (vSTM) capacity in preterm born adults was linked with changes in intrinsic functional connectivity in a way that suggested a compensatory reorganization of posterior intrinsic brain networks. However, the relationship to the severe white matter changes that are known to result from preterm birth is unknown. Thus, in the current study we related vSTM storage capacity functions in preterm and term born adults to white matter fractional anisotropy (FA) as assessed by diffusion tensor imaging. We used whole and partial report paradigms of briefly presented letter arrays based on the computationally specified Theory of Visual Attention (TVA) to assess the parameter visual short term memory capacity in 26 preterm and 21 full-term born adults. Based on the neural interpretation of TVA - the NTVA - the posterior thalamic radiations and splenium of Corpus Callosum (CC) were defined as regions of interest (ROI). Using tract-based spatial statisctics (TBSS) for these ROIs, we found that FA values in right posterior thalamic radiation were significantly reduced in preterm born adults. In both groups, vSTM capacity was significantly correlated with FA in right posterior thalamic radiation. In term born adults, the correlation was positive but in preterm born adults higher vSTM capacity was related to lower FA. In preterm born adults, furthermore, higher vSTM capacity was significantly correlated to higher FA in splenium CC. These results indicate that, in preterm individuals, an impairment of posterior thalamic radiations integrity might lead to the recruitment of splenium CC as a compensatory tract relevant for vSTM storage functions.

Title: Neural and behavioral markers of metacognititive sensitivity in infants

Authors: *S. KOUDIER, L. GOUPIL;
Ecole Normale Supérieure, Paris, France

Abstract: Responding optimally to the external world involves not only selecting among alternative options, but also reflecting upon one's own choices to evaluate their accuracy and adapt subsequent behaviour. Whether this capacity for metacognition is already present in infancy remains unknown. Past research showed a rather late development of metacognitive capacities. Yet, these studies were based on children's report about their own mental states. Here, we investigated the possibility that basic metacognitive mechanisms such as decision confidence and error detection are already present in infancy, although they would be discernible through implicit behavioural measures and neural signatures rather than explicit self-reports. Here, infants first performed a binary choice (i.e., pointing or fixating towards the correct/incorrect location of a hidden object). Next, infants were probed for differential overt behavior (e.g. persistence in their choice, change of mind) or electrophysiological responses (e.g., error-related negativity) following correct vs. incorrect decisions. A first study with 18 month-old infants (N = 29) showed that infants compute decision confidence in a manual search paradigm, by relying on post-decision search persistence as a proxy for metacognitive monitoring. A second study (N = 22) showed that they can use confidence to flexibly adapt their behavior, hence providing evidence of metacognitive control. Infants, after making a first choice, had to make a second decision which consisted either in persisting in their initial choice by asking for help, or in changing their mind towards the alternative choice. Crucially, this experiment revealed that their decision to ask for help vs. change their mind depends on the accuracy of their initial choice, revealing that they can not only evaluate their own performance, but also use this information to guide subsequent actions. In a third study relying on high-density electroencephalography (EEG), we show that 12 month-old infants (N = 55) evaluate the correctness of their anticipatory eye movements. Furthermore, we show that infants elicit the equivalent of an error-related negativity, an EEG component observed over fronto-central electrodes in human adults whenever they make an error. This demonstrates not only that infants can detect their own errors after making a decision, but also that they rely on the same mechanisms as those involved when adults detect their own errors. We propose that although explicit metacognition develops much later, it stems from implicit metacognitive abilities that are already present in infants.

Title: Neural dynamics of prediction and surprise in infants

Authors: ***S. V. GELSKOV**[1], B. LONG[2], L. LE STANC[1], S. CHARRON[1], L. S. BARBOSA[1], A.-C. FIEVET[1], S. KOUIDER[1];
[1]Dept. of Cognitive Studies, École Normale Supérieure, Paris, France; [2]Dept. of Psychology, Harvard Univ., Cambridge, MA

Abstract: Perception is not only determined by external stimulation, but also by our internal beliefs and predictions about the nature of upcoming events. In adults the neural mechanisms of predictive coding have been extensively studied. While behavioral studies have suggests that infants can also rely on probabilistic inferences, neural mechanisms underlying these computations have yet to be demonstrated during early development. To address this issue, we studied how the infant brain implements predictions. We combined high-density EEG recordings with a cross-modal cueing paradigm in which auditory cues acted as predictive signals to form expectations about upcoming visual events. Twenty-eight 12-month-old infants received one of two arbitrary sounds that were predominantly associated with one of two visual categories (i.e., faces vs. flowers). When collapsing across categories, scalp voltages over occipito-temporal sites revealed a series of well-known face-and object related components including the early P1, intermediate P400 and finally a Late Slow Wave (LSW). Consistent with Bayesian accounts of perception, we found an increased neural response for unexpected events. However, this effect of neural surprise was observed only during late processing stages. Interestingly, the LSW in infants has recently been found to share the same characteristics as neural markers of consciousness in adults. Early perceptual components, by contrast, revealed an amplification of neural responses for predicted rather than surprising events, suggesting that selective attention enhances perceptual processing for expected events. Taken together, our study shows 1) that cross-modal statistical regularities can bias sensory responses in the infant brain, revealing the neural mechanisms underlying the use of predictive signals by the end of the first year of life, 2) that the neural impact of predictive cues follows different dynamics depending on whether target stimuli were predicted or instead surprising, and 3) that there is a privileged link between infants' reaction to surprising events and conscious processing.

Title: Interactive Specialization and the development of functional systems support complex cognitive skills in children

Authors: *C. J. BATTISTA[1], T. NGOON[2], T. CHEN[2], L. CHEN[2], A. BAKER[2], J. KOCHALKA[2], T. EVANS[2], V. MENON[2];
[1]Psychiatry, Stanford Cognitive and Systems Neurosci. Lab., Palo Alto, CA; [2]Child Psychiatry, Stanford Univ., Stanford, CA

Abstract: Functional brain development is thought to involve cascading set of interactions between brain regions as they acquire new functional roles (Johnson, 2000; 2001; 2011), and studying this process requires a longitudinal design in order to avoid confounding effects from age and ability. To provide a more accurate characterization of development, we extended the framework of interactive specialization framework to investigate age-related changes in connectivity and activity that support mental arithmetic in children. We focus on the intraparietal sulcus (IPS), a region that plays a critical role in numerical cognition (Dehaene, 2003; Menon, 2014). Using data from 33 children between the ages of 8-14 (2-4 timepoints per child), we constructed hierarchical linear models of growth of task-based activity and connectivity (gPPI) during arithmetic problem solving to identify functional circuits undergoing change across our age range. We found linear decreases in left IPS connectivity with left prefontal cortex (dorsolateral PFC, ventrolateral PFC, and insula) and increases in connectivity with right superior parietal lobule, right IPS and right fusiform gyrus (FG). Activity in FG increased over time. To investigate the interaction between the formation of intraparietal, fronto-parietal, and dorso-ventral circuits, we constructed growth models of connectivity using bilateral IPS connectivity as a covariate. This revealed a link between changes in bilateral IPS connectivity and changes in fronto-parietal, but not dorso-ventral circuits. Specifically, individuals with higher left-right IPS connectivity also had higher fronto-parietal connectivity at the age of 8, which then decreased as left-right IPS increased over development. Brain-behavior relationships were also found: (a) bilateral IPS connectivity was related to gains in visuospatial working memory; (b) initial arithmetic ability (assessed by the Numerical Operations subtest of the WIAT-III) related to change in bilateral IPS connectivity, with high performers showing greater connectivity than low performers, with this difference decreasing with age. Taken together, these results suggest that development of the neural systems supporting cognitive skills requires the dynamic reconfiguration of several functional circuits, and that these changes reflect the result of multiple, rather than a single, maturational process. Critically, these changes relate to both arithmetic and working memory performance. Our findings provide new quantitative insights into interactive specialization and the development of functional brain systems supporting complex cognitive skills in children.

Title: Brain activity during expectation violation triggered by magic tricks

Authors: *A. H. DANEK[1], M. ÖLLINGER[2], T. FRAPS[3], B. GROTHE[1], V. L. FLANAGIN[4]; [1]Biol. II, Div. of Neurobiology, LMU München, Munich, Germany; [2]Psychology, LMU München, Munich, Germany; [3]Trick 17 Magic Concepts, Munich, Germany; [4]Univ. Hosp. Munich-Großhadern, German Ctr. for Vertigo and Balance Disorders, Munich, Germany

Abstract: Prior knowledge is essential to survive in a complex environment. Humans rely on their prior knowledge to predict the outcome of actions. This makes the case of magic so interesting: Magic tricks violate the expected action-outcome sequences. We aimed at identifying the neural correlates of such expectation violations by contrasting 24 video clips of magic tricks with 24 control clips in which the expected action-outcome relationship is upheld. Using fMRI, we measured the brain activity of 25 normal volunteers while they watched the clips in the scanner. Additionally, we measured the professional magician who had performed the magic tricks under the assumption that, in contrast to naïve observers, the magician himself would not perceive his own magic tricks as an expectation violation. As main effect of magic - control clips in the normal sample, we found higher activity for magic in the head of the caudate nucleus bilaterally, the left inferior frontal gyrus and the left anterior insula. As expected, the magician's brain activity substantially differed from these results, with mainly parietal areas (supramarginal gyrus bilaterally) activated, supporting our hypothesis that he did not experience any expectation violation. These findings are in accordance with previous research that has implicated the head of the caudate nucleus in processing changes in the contingency between action and outcome.

Title: Development of medial prefrontal cortex is related to statistical learning and inference

Authors: K. F. GUARINO[1], M. L. SCHLICHTING[1], A. C. SCHAPIRO[2], N. B. TURK-BROWNE[2], *A. R. PRESTON[1];
[1]The Univ. of Texas At Austin, Austin, TX; [2]Dept. of Psychology, Princeton Univ., Princeton, NJ

Abstract: Recent advances highlight the importance of a hippocampal-medial prefrontal (MPFC) circuit for memory integration across related experiences. Evidence suggests that abstracted representations in MPFC guide reactivation of related memories during encoding of new events, promoting hippocampal-mediated integration and generalization. For instance, both hippocampus and MPFC have been implicated in novel inference judgments that require consideration of the relationships among distinct episodes, and in a form of statistical learning, in which participants must extract temporal regularities from the environment by associating information across time. However, the protracted developmental trajectory of prefrontal cortex suggests that while hippocampus may support associative learning early in development, MPFC-guided integration may only reach maturity in adulthood. Here, we used high-resolution structural MRI to quantify developmental differences in MPFC structure, specifically cortical thickness of MPFC, in participants aged 6-30 years, further linking these differences to the development of memory integration. We aimed to identify the role of particular MPFC subregions in memory integration, as MPFC has largely been considered as a single region in prior work. Participants also completed two behavioral tasks, involving associative inference and statistical learning, respectively. Performance on both tasks improved into adulthood, suggesting that children do not integrate across events as effectively as adults. The cortical thickness of MPFC subregions decreased across the age range, consistent with protracted thinning of this region. Moreover, cortical thickness of MPFC was related to associative inference and statistical learning performance in the adult group, suggesting that this region plays an important role in memory integration when mature. This brain-behavior relationship was unique to posterior MPFC. These results suggest a fundamental shift in memory integration over development: Adults may integrate across events through the engagement of a hippocampal-MPFC circuit, but children may have to rely on hippocampal mechanisms alone and thus may be limited to encoding separate memories of related events.

Title: Neural correlates of spatial navigation in young children: Linking brain volumetry and performance on a virtual Morris Water Maze task

Authors: *Q. YU, A. SHAFER, D. ANDERSON, A. HEITZER, J. PIERCY, D. BRUSH, W. ANGELL, S. RAZ, N. OFEN;
Inst. of Gerontology, Detroit, MI

Abstract: Navigation through space is a complex cognitive task supported by a number of brain regions including the prefrontal cortex, hippocampus and cerebellum. Although spatial navigation ability develops with age, little is known about the neural correlates of this complex task in young children. Moreover, preterm birth may influence cognitive and brain development, and has specifically been associated with poor spatial cognition and alteration in brain regions important for spatial navigation. In the current study we tested whether, in young children, individual variability in brain volumes is related to individual variability in measures of spatial navigation ability. Forty-two children born either at term (n=19, age 6.11±0.14) or preterm (n=23, age 5.99±0.13) performed 15 repeated trials of a virtual Morris Water Maze (vMWM) task. Average time, distance, and fractal dimension (FD, a measure of path complexity) were calculated. High-resolution structural MRI was conducted in a subset of the participants (15 term, age 5.97±0.16; 13 preterm, age 6.09±0.18) and a semi-automatic method (FreeSurfer) was used to compute volumes of the prefrontal cortex (PFC), hippocampus (Hc), and cerebellar gray (CbGM) and white matter (CbWM). CbWM was related to both average time ($F(1,22)=4.86$, $p=.04$) and FD ($F(1, 23)=6.65$, $p=.02$), such that larger CbWM was associated with poorer spatial navigation ability as indicated by being slower in finding the target and using a more complex path. Hc volume was marginally related to average FD ($F(1,23)=3.72$, $p=.07$), such that larger Hc was associated with the use of a more complex path. Children born prematurely were faster in finding the target compared to term born children ($F(1,38)=4.39$, $p=.04$). Children born prematurely had smaller PFC volumes ($F(1,25)=7.39$, $p=.01$), however variability in PFC volume was not related to group differences in task performance. Term status, however, marginally interacted with CbGM in accounting for average time ($F(1,23)=3.14$, $p=.089$), such that in the preterm ($r=-.58$, $p=.06$), but not the term ($r=.15$, $p=.64$) group, larger CbGM was related to faster performance. Taken together, we demonstrate the feasibility of using the vMWM task to study the neural correlates of spatial navigation in young children. Moreover, our

findings suggest that variability in the volume of the hippocampus and the cerebellum relates to spatial navigation ability in young children.

Title: STSp functional connectivity in adults and children during biological motion perception

Authors: ***S. DASGUPTA**[1], Z. J. MCINTIRE[1], M. A. NGUYEN[1], J. X. LI[2], K. H. JAMES[2], E. D. GROSSMAN[1];
[1]Dept. of Cognitive Sciences, UCI, Univ. of California, Irvine, Irvine, CA; [2]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Background: Humans are quite adept in recognizing actions from the movements of the joints alone ("point-light" biological motion). Neuroimaging studies have identified neural signals selective for biological motion (BM) in the posterior part of the superior temporal sulcus (STSp) in both adults and children, a region that serves as an important hub for a larger network of ROIs that implicated in social perception more generally (Grossman et al., 2000; Carter & Pelphrey, 2008). The larger network includes parts of the ventral temporal lobe (Vaina et al. 2001), the lateral occipital gyrus (Grossman & Blake 2002; Beauchamp et al. 2002), as well as some regions within the prefrontal cortex (Grezes, J., 1998). The aim of this study is to map the neural communication between the STSp and other cortical regions during biological motion perception, and to assess how the connectivity pattern in this large-scale network changes developmentally. Thus, we computed task-based functional connectivity (FC) between the STSp and other brain regions during biological motion and non-biological motion-matched control tasks in both children and adults. Methods. Fifteen adults (all 18 years of age or older) and thirteen children (aged 4-6) participated in this study. Thirty-three bilateral ROIs, including the bilateral STSp, were identified from the conjunction of the children and adults whole-brain univariate analysis of biological motion selective brain signals. The timeseries from these regions were segmented into the blocks corresponding to the biological and non-biological experimental intervals, and then subjected to FC (Pearson's r) analysis. Significance was assessed via bootstrapping. Results. STSp FC in children has a pattern distinct from that found in

adults. STSp FC In the adults' brain was strongly bilateral, with more connections between STSp and visual cortex and between STSp and frontal cortex (particularly in the left hemisphere). In the children's brain, significant STSp connections were largely right lateralized, with the STSp-frontal connections absent. Instead, the STSp was more strongly connected to parietal cortex. These results are consistent with the notion that children using biological motion to engage social orienting cues, and have fewer long-range connections overall which are believed to develop later in life.

Title: Brain state flexibility predicts diverse cognitive functions during critical periods in neurodevelopment

Authors: J. D. MEDAGLIA, T. D. SATTERTHWAITE, M. YANG, S. GU, *Q. K. TELESFORD, R. C. GUR, R. E. GUR, D. S. BASSETT;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Adolescence is marked by several critical periods of rapid cognitive and social development, accompanied by alterations in brain dynamics across distributed cognitive circuits. Yet, exactly how these circuit dynamics relate to changes in cognitive function during normative neurodevelopment is unknown. Recent tools to quantify circuit organization have been drawn from graph theory, which traditionally ignores the time-dependent changes in the regional interactions and is therefore unable to quantify circuit dynamics. To address this gap, we develop a novel technique to assess the transition of the brain through cognitive states. We use this tool to

quantify brain state flexibility during early development and to test its relationship with effective cognitive function, as measured by a cognitive neuroscience based computerized battery which assesses accuracy and efficiency in executive function, memory, social cognition, and complex reasoning. In 780 youths aged 8-21 from the Philadelphia Neurodevelopmental Cohort, we acquired resting state functional magnetic resonance imaging (fMRI) data over the course of 6 minutes. We extracted 264 regional mean time series from functionally defined regions of interests in cortical and subcortical areas. We defined a temporal adjacency matrix A whose elements Aij give the similarity in regional BOLD magnitude across regions between time i and time j. We defined a brain state as a pattern of whole-brain activation that was frequently observed across the scanning session, and extracted such states in a data-driven fashion using community detection techniques applied to the temporal adjacency matrix. We defined brain state flexibility as the number of transitions among brain states observed in a single subject during the resting state scan. We observed that individual subjects visited approximately 15 brain states during the course of the 6-minute resting state scan, and the number of visited states remained constant over the full age range (8-21 yrs). Furthermore, we observed that brain state flexibility was positively correlated with cognitive performance in all cognitive measures during puberty and again in late adolescence. These results indicate that brain state flexibility may predict individual cognitive development over the life span during periods of rapid brain network consolidation. Effective transitions between states may drive developmental trajectories during these critical periods.

Title: Age predicts functional connectivity of the intraparietal sulcus during early childhood: implications for attention development?

Authors: *C. ROHR[1,2,3], S. VINETTE[1,2,3,4], K. PARSONS[1,3,4], S. BRAY[1,2,3,4];
[2]Dept. of Radiology, Cumming Sch. of Med., [3]Alberta Children's Hosp. Res. Inst., [4]Dept. of Paediatrics, Cumming Sch. of Med., [1]Univ. of Calgary, Calgary, AB, Canada

Abstract: Skills like visual-spatial attention mature rapidly in early childhood and lay the foundation for acquiring more complex skills such as reading. In many neurodevelopmental disorders, visual-spatial attention is impaired, suggesting that the underlying brain networks may have several distinct vulnerabilities. One promising site for investigation is the intraparietal sulcus (IPS), which has been implicated in visual sustained and selective attention, and is connected to prefrontal regions of the dorsal attention network and occipital visual regions. Our group recently demonstrated the effect of age on IPS functional connectivity in older children and adolescents (Vinette & Bray, 2015), however, an investigation of age effects in early childhood is lacking. To address this question, we examined the relationship between age, attention skills and IPS connectivity in 22 children between 4.14-6.67 years old (mean=5.26; sd=0.86). Attention measures were adapted from the Early Childhood Attention Battery (Breckenridge et al., 2013) and comprised sustained attention, selective attention and attention control measures. Following training in an MRI simulator, children freely watched clips from the TV show 'Elmo' in a 3T GE 750w scanner while undergoing functional magnetic resonance imaging. Data preprocessing included censoring of motion-corrupted volumes, specifically those which exceeded both framewise displacement 0.2mm and 0.3% change in BOLD signal intensity (Power et al. 2014). IPS connectivity was then assessed by regressing the average time-course of volumetric masks for IPS0-5 (Wang et al., 2014) against every voxel in the brain. At the group level, effects of age were assessed while controlling for IQ (mean=112.11; sd=11.25). Inferences were drawn at a $z>2.3$ voxel-wise threshold with cluster correction using Gaussian Random Field theory at $p<0.05$. Behaviorally, age correlated significantly with composite scores for both sustained and selective attention ($r=.59$ and $r=.65$, both $p<0.01$). On a functional connectivity level, age positively predicted IPS connectivity with visual areas (V2, V4) and supplementary eye fields (SEF), while negatively predicting IPS connectivity with thalamo-striatal regions. Our results suggest that IPS connectivity with dorsal attention and early visual regions increases with age in early childhood, while connectivity with subcortical areas decreases. IPS functional connectivity changes in early childhood may underlie the rapid development of children's visual-spatial attention skills.

Title: Resting state connectivity at 1st grade predicts math competence at 2nd grade

Authors: *G. PRICE, E. D. WILKEY, D. J. YEO, L. E. CUTTING;
Vanderbilt Univ., Nashville, TN

Abstract: Mathematical competence is critical for success in modern society, predicting academic success, rates of unemployment, physical and mental illness, arrest, and incarceration. Understanding of the neural mechanisms underlying math competence can aid the development of effective educational interventions. Previous research suggests that functional activation of the intraparietal sulcus (IPS) is related to individual differences in math competence (Bugden et al , 2012) and may be impaired in children with mathematical learning disabilities (Price et al, 2007). Information on connectivity between brain regions may yield important insights beyond traditional region-based analyses (Power et al, 2010). Previous studies report that functional connectivity during numerical and mathematical processing between frontal and parietal brain regions relates to math competence (Emerson & Cantlon, 2012; Rosenberg-Lee, Barth, & Menon, 2011). However, no studies that we are aware of have related math competence to connectivity while the brain is not engaged in an explicit task (i.e. 'resting state'). The present study related resting-state connectivity at the end of 1st Grade to math competence at the end of 2nd grade. Resting-state data from 42 1st grade children (Mean age 7.4 yrs) were correlated with standard scores on the Woodcock Johnson Arithmetic Fluency and Calculation subtests were collected one year later. Seed-based functional correlation analyses were used to assess connectivity across the whole brain with left and right IPS seed regions, regressing out signal from white matter and ventricles. Connectivity with the right IPS seed region was not correlated with math competence in any region. Connectivity with the left IPS region, in contrast, was correlated with math competence in the left precentral gyrus (-44, 2, 18), the left superior temporal sulcus (-39, -50, 25), and bilateral anterior cingulate cortex (5, 19, 29; -7, 19, 26). The present results reveal that spontaneous functional connectivity of a left lateralized network related to a left IPS seed region predicts math competence a year later. Task dependent functional connectivity of similar regions has previously been related to math competence, but the present data suggest that such connectivity may be intrinsically driven, as opposed to task dependent. Furthermore, the fact that connectivity strength in this network predicted math competence a year later suggests that this network is ontogenetically important, playing an meaningful role in the acquisition of math skills over critical early school years.

Title: Altered reading networks in young children with dyslexia

Authors: *J. WALTERS[1], J. MURTAGH[1], K. HALVERSON[1], A. CYR[1], T. K. PERRACHIONE[2], P. CHANG[1], P. HOOK[3], J. D. E. GABRIELI[1], J. A. CHRISTODOULOU[1,3]; [1]MIT, Cambridge, MA; [2]Boston Univ., Boston, MA; [3]MGH Inst., Boston, MA

Abstract: Despite considerable evidence for altered function of the brain's reading network in children with dyslexia, few (if any) studies have focused on children with dyslexia younger than 9. The earliest years of literacy instruction offer an important window to understand diverse reader performance. Here, we examined reading networks in early readers (ages 6-9) who are typically developing (n = 19) or who have dyslexia (n = 22). Children completed standardized behavioral assessments and a functional magnetic resonance imaging (fMRI) task using a 3.0T Tim Trio Siemens System. The fMRI task required children to view pairs of words sequentially and indicate by button push when subsequent words shared the same first sound. Activations in this first phoneme-matching task versus rest were compared between groups. Children with dyslexia exhibited reduced activation in three left-hemisphere regions associated with reading and language: frontal cortex (middle and inferior gyri; BA 44/45), fusiform cortex (BA 20/37), and temporal cortex (middle and superior gyri; BA 21/22). We provide evidence that reduced activity in the left-hemisphere reading network in children with dyslexia is apparent in early readers.

Title: Cortical maturation accompanying individual differences in longitudinal development of children's reading ability

Authors: *T. M. EVANS[1], M. SCHAER[2], J. KOCHALKA[2], T. J. NGOON[2], L. CHEN[2], C. BATTISTA[2], V. MENON[2];
[1]Stanford Cognitive Systems and Neurosci. Lab., [2]Stanford Univ., Palo Alto, CA

Abstract: Childhood is a time of extensive protracted neuroanatomical development accompanied by marked improvements in a number of cognitive domains. Behavioral research has identified core skills necessary for acquisition of reading ability, but little is known about neurobiological factors that contribute to long-term gains in children's reading ability. Previous work relating brain structure to impaired reading ability has implicated a temporoparietal and inferiotemporal network. However, these studies have, for the most part, focused on single time points. Consequently the neuroanatomical bases of individual differences in growth trajectories are unknown. This study employed longitudinal structural neuroimaging map individual differences in the development of reading skill onto corresponding maturation in brain structure. High-quality longitudinal brain imaging data were acquired from 24 children (13 females). Cognitive measures and high-resolution whole-brain structural images were obtained at 2 time points (time 1 = 8.6 ± 0.6 yrs, time 2 = 10.5 ± 1.4 yrs). Standardized scores adjusted for chronological age derived from the Word Reading subscale of the WIAT, which provides a measure of an individual's word reading abilities relative to their peers, were used to assess reading skills. Image processing and statistical analyses were carried out in Freesurfer. A GLM was used to assess the relationship between change in reading abilities and vertex-wise change in cortical thickness, with statistical thresholds of height $p < 0.01$ and cluster-corrected extent $p < 0.05$. Children showed considerable variation in the development of their reading abilities, with difference scores between two time points ranging from -9 to 30 (M = 2.1, SD = 8.6). A negative correlation between change in cortical thickness and change in reading skills was found in the right superior temporal sulcus, suggesting that increased cortical thinning in this region is associated with greater improvements in reading abilities. Our results demonstrate that growth in reading abilities in early childhood is associated with focal cortical thinning in the superior tempral sulcus, a region important for language processing, and previously shown to be abberent in struggling readers. This result is also consistent with previous longitudinal studies demonstrating an association between cortical thinning and individual performance gains in vocabulary, working memory, and executive function. This work extends previous findings by identifying a brain area where cortical thinning corresponds to individual differences in reading skills.

Title: The neural development of pragmatic inference-making in discourse comprehension

Authors: *F. SCHWARTZ[1], I. A. NOVECK[2], J. PRADO[2];
[1]Lab. Langage, Cerveau & Cognition, CNRS, Bron, France; [2]Lab. Langage, Cerveau & Cognition, CNRS Lab. Langage, Cerveau & Cognition, Bron, France

Abstract: Everyday verbal interactions often require people to make spontaneous inferences to understand implicit messages conveyed by speakers. A recent neuroimaging study suggests that such pragmatic inference-making in adults is supported by the interaction between brain regions involved in reasoning and mentalizing (i.e., processing other's intentions and emotions). To date, however, it remains unclear at what point of development this neural interaction emerges and supports pragmatic inference-making in children. The goal of the present functional Magnetic Reasonance Imaging (fMRI) study was to answer this question by investigating the neural development of pragmatic inference-making in typically developing children and adolescents from ages 8 to 14. Participants read short stories containing information (premises) that had to be integrated logically to understand the conclusion of the story. In half of these inference stories, premises were not sufficient to understand the conclusion made by the central character of the story. In these cases, participants had to make a pragmatic inference in order to understand the conclusion. We found that the ability make such inferences increases with age. We also found that such increases were associated with developmental increases of activity in regions typically associated with logical reasoning in the Rostrolateral Prefrontal Cortex (RLPFC). In contrast, stories in which conclusions required inference-making were associated with greater activity in the brain mentalizing system (i.e., right Temporo-parietal Junction and right Middle Temporal Gyrus) in both younger and older children, with no developmental increases. Therefore, our results suggest that children might detect the need for pragmatic inferences early on during development (i.e., 8-year-old). However, the ability to make these inferences might arise later in development (i.e., during adolescence) with the maturation of the RLPFC.

Title: TITLE: Investigating social initiation behaviors with strangers in different groups of children with developmental disorders

Authors: *N. WOO-VONHOOGENSTYN[1], P. LAI[1,2,3], J. REILLY[3], U. BELLUGI[1]; [1]Salk Inst., La Jolla, CA; [2]Univ. of California at San Diego, La Jolla, CA; [3]San Diego State Univ., San Diego, CA

Abstract: Children interact with strangers as a part of social development, but how do these children initiate social interaction? For this study, we used the Salk Institute Sociability Questionnaire (SISQ), a parental questionnaire that examines various aspects of social behaviors, to investigated how school-aged children (7-14) initiate social interactions. We specifically focused on one question from the SISQ - "Describe your child's typical reaction when meeting someone for the first time" - to evaluate the social initiation behaviors of different developmental groups. The groups included children with Focal Lesion (FL; n = 15), children with High Functioning Autism (HFA; n = 22), children with Williams Syndrome (WS; n = 14), and Typically Developing (TD; n = 21) children. We had adults' blind to each group's clinical diagnoses, rate randomly sorted parental responses on a spectrum from 1 (non-social) to 7 (high-social) with 4 being a neutral response. The question, regarding meeting someone for the first time, resulted in significant difference between the groups, $f(3,68) = 4.95$, $p = 0.003$. Follow up analyzes using post-hoc Tukey-HSD showed statistically significant group differences between the WS and FL groups, and the WS and HFA groups. In both cases, the WS group was rated as more social when compared to FL and HFA groups. The TD group did not differ significantly when compared to the three groups, and there was not a significant group difference between the FL and HFA group as their means were comparable to each other. Examples of these parental responses were: "Polite, quiet, minimal conversation but will answer questions. Takes a few moments and then will jump into a conversation" which was a response by a TD parent. Whereas a parent of an HFA child response was, "He is not always the first to make contact, does not always make eye contact. Sometimes he is not paying attention as to what is going on." Similarly, a parent of a FL child response was "Shy, doesn't make eye contact, and won't start a conversation. It takes him time to get comfortable with new people." And, one of the WS parental responses was, "Very interested in their name, what they like to do, where they live, do they like (whatever her current interest is). She will then sit with them, tell them after a few minutes she loves them if they are engaged in stuff she likes." Each of the developmental groups showed atypical initiation behaviors, the FL and HFA were less likely to exhibit social interactions, whereas WS were more likely to exhibit social engagement. By studying how different developmental groups initiate social interactions, we can better understand the social and behavioral phenotypes of these groups.

Title: Implicit learning in young children with autism

Authors: *R. M. JONES[1], C. CARBERRY[1], D. DELLARCO[2], A. HAMO[1], C. LORD[1];
[1]Weill Cornell Med. Col., White Plains, NY; [2]Weill Cornell Med. Col., New York, NY

Abstract: Implicit associative learning is an individual's ability to form connections between stimuli without conscious awareness. The literature is inconsistent whether individuals with Autism Spectrum Disorder (ASD) have difficulties with implicit learning compared to typically developing (TD) individuals. We hypothesize the discrepancy is not simply explained by methodological differences across studies, but reflects variability within ASD for implicit learning. To test our hypothesis, 50 children, 4-7 years of age completed the procedures, specifically 39 TD (Mean IQ = 112; 22M) and 11 with ASD (Mean IQ = 105; 10M). Building upon the implicit learning literature, we designed a child-friendly task that measures differences in reaction time (RT) behavior and accuracy to a target stimulus predicted by two cues at differing probabilities. In each trial, children were instructed to touch a target image presented on an iPad but to refrain from touching the cues and distractor image. Unbeknownst to the participants, one of the cues predicted the target image at a high probability (75%), while the other cue preceded the target at a low probability (25%); the distractor appeared when the target was not presented. Z-scored reaction times and percent accuracy were divided into thirds (early, middle and late trials) and by condition (high probability, low probability) and submitted to a 3x2 repeated measures ANOVA to assess learning. Due to an imbalance in sample sizes, TD and ASD analyses were performed separately. As expected, there were no significant differences in accuracy during the task or between groups (M = 84%; p's > 0.1), suggesting all children understood task instructions. TD children slowed in reaction times by the late trials to the target when preceded by the 25% cue compared to the 75% cue (time*condition: ($F(2,74)=6.6$, $p < 0.002$), suggesting TD children learned the contingencies with no difference in ASD (p's > 0.2). After the task, 10 of 39 TD children and 3 of 11 ASD children correctly matched the target image with the 75% cue image, with a trend of a higher IQ ($p = 0.1$) in those who made the conscious match in ASD, but not in TD ($p = 0.5$). Differences in conscious awareness suggest variability in the expression of learning. Future studies will explore the role of IQ in explicit understanding after learning in ASD. In a larger ASD sample, we will determine how variability in learning patterns may be important for predicting intervention success in children with ASD.

Behavioral findings will be the foundation for future research during functional Magnetic Resonance Imaging to understand the neural underpinnings of individual variability in implicit learning in ASD.

Title: Neural synchronization during different types of teaching

Authors: ***F. L. ZHENG**;
Sch. of Brain and Cognitive Sci., Beijing Normal Univ., Beijing, China

Abstract: Plenty of previous studies have focused on the neural mechanisms of learning. However, only a few studies have investigated the mechanism of teaching. Thus, the neural mechanism behind teaching is largely unknown. This study used fNIRS-based hyperscanning technique to examine the neural synchronization pattern between teachers and students in different types of teaching, i.e., lecture-style teaching and interactive teaching. Nine pairs of same-gender teachers and students were recruited (18 males and 18 females, mean age 22.56 years, range from 19 to 26). The content of teaching was numerical reasoning. Students were required to complete a numerical reasoning test both before and after the experiment. Wavelet Transform Coherence(WTC) was used to assess the relationship between fNIRS signals generated by teachers and students. The results showed a significant increase of the neural synchronization in the right temporo-parietal junction (TPJ) during interactive teaching, but not during lecture-style teaching. These results demonstrated that interactions between teachers and students are associated with higher-level interpersonal neural synchronization. This result will provide important insight into the neural mechanism of teaching.

Abstract: For most legal purposes, an individual is considered an adult at the age of eighteen; but sometimes, that age boundary shifts. Variations in the definition of "adult" exist in many legal and social policies. These distinctions between juvenile and adult are often based on political considerations and conventional wisdom rather than empirical evidence. Although developmental neuroscience research has shown that the brain continues to develop into the early twenties, behavioral and neural distinctions between adolescents and adults continue to be delineated, particularly in the eighteen to twenty-one age range. The present study implements a novel behavioral paradigm, together with psychophysiology and fMRI, to examine impulsivity under transient and sustained states of positive and negative emotion in 110 individuals. We show that 13 to 21 year olds show similar decrements in performance as compared to adults over the age of twenty-one in response to transient cues of potential threat and under sustained positive emotion (excitement). These behavioral results are paralleled by: 1) decreased activity in dorsolateral prefrontal cortex, implicated in emotion regulation, in teens and young adults relative to adults in response to fear cues; and 2) increased activity in medial prefrontal cortex, implicated in integration of self and affective information in decision making, in teens and young adults across the sustained excite context. Our findings suggest that, under transient threat and sustained excitement, 18 to 21 year olds may behave more similarly to younger adolescents than to older adults due to continued development of prefrontal circuitry. These results may have implications for age-related legal and social policies.

Abstract: As the use of modern digital technology has become an increasingly integral part of our everyday lives, concerns have been raised about whether the continuous fast-paced influx of information offered by modern media affects our ability to focus our attention. These concerns are especially relevant when it comes to the generation of “digital natives”. We investigated whether different information and communications technology (ICT) user profile groups show differences in performance or brain activity during attentionally demanding tasks. Participants were 173 healthy adolescents and young adults (aged 13-20 years) sampled from 3000 pupils and grouped according to their ICT use into three subgroups: computer gamers, social media actives, and controls. We measured brain activity with event-related functional magnetic resonance imaging (fMRI) in participants performing a sentence congruence judgment task in the auditory or visual modality (selective attention conditions), or both (divided attention condition). Performance deteriorated significantly during divided attention compared with selective

attention, and performance accuracy improved significantly with age in all conditions. There were no performance differences between the groups with different ICT profiles. fMRI analyses revealed a main effect of ICT group during all conditions in the left temporoparietal junction (which was associated with linguistic processing of the presented sentences), with the social media group showing less activity in this area than the other two groups especially during divided attention. In addition, the youngest social media users showed significantly smaller activity increases than the other two ICT profile groups within lateral and medial regions in the right frontal cortex that were activated specifically by divided attention. A correlational trend was observed between greater activity increases in these areas and better task performance. The results suggest that the type and extent of ICT use may have an impact on the functioning of brain networks involved in divided attention and language processing. More specifically, decreased activity in the left temporoparietal area was observed in the social media group, possibly reflecting insufficient recruitment of language processing areas during the experimental task. In addition, lower activation in frontal regions recruited by divided attention was observed in the youngest cohort of the social media group. This suggests that in this ICT user group, performing the experimental task placed more demands on brain networks related to attention and executive functioning.

Title: Cannabis use and adolescent neurocognitive development: a prospective fmri study

Authors: ***B. C. TERVO-CLEMMENS**[1], D. SIMMONDS[1], B. LUNA[2];
[2]Psychiatry, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cannabis has been associated with impairments in working memory (WM) (Varvel et al. 2001) which continues to improve through adolescence (Luna, Garver, Urban, Lazar, & Sweeney, 2004). As such, adolescents may be particularly vulnerable to the effects of cannabis on WM. To investigate the relationship between cannabis use and adolescent brain development, we are conducting a prospective longitudinal neuroimaging study where participants were

initially assessed at age twelve, before use, and then again at age fifteen. By the second time point, approximately 25% of the sample had begun using cannabis, early-onset cannabis use (EOC). At both visits, subjects performed a Sternberg-type visuospatial working memory task during fMRI acquisition. Reaction time and accuracy were recorded. A fast event-related design was used to distinguish encoding, maintenance, and response epochs of WM. Only correct trials were included in fMRI group analysis. For behavioral analysis, we used linear-mixed-effects modeling to examine differences between users and non-users at both time points. Thus, we examined potential risk factors for (time point 1), and consequences of (time point 2), adolescent cannabis use. Prior to use (time point 1), our preliminary results suggest that those who would go onto use cannabis (pre-EOC) have faster reaction times but do not differ in accuracy, compared to healthy controls. This behavioral difference was accompanied by greater maintenance period DLPFC activation in pre-EOC participants compared to controls. After use (time point 2), the groups no longer differed in reaction time but there was a statistical trend for more commission errors in EOC users compared to healthy controls. This post-use behavioral difference was accompanied by greater maintenance period activation in canonical WM regions including the ACC, IPS, and thalamus in EOC users compared to healthy controls. Together, these results suggest that there may be neurobiological risk factors for early cannabis , which may persist and interact with cannabis use, undermining WM development.

Title: The cognitive profile of early-onset obsessive-compulsive disorder. Does age matter?

Authors: *J. GOTTWALD[1,2], A. M. APERGIS-SCHOUTE[2], S. MOREIN-ZAMIR[3], M. KASER[2], A. SULE[2], A. CONWAY MORRIS[4], W. LIMMER[2], T. W. ROBBINS[3], B. J. SAHAKIAN[2];

Abstract: Obsessive-compulsive disorder (OCD) is a psychiatric condition characterised by recurrent distressing thoughts and acts. The majority of patients experience an onset of symptoms before the age of 18. However, most of the research has focused on adult patients, while adolescent OCD is rarely investigated. There are notable differences between juvenile and adult OCD. Teenagers generally have less insight into their disorder than adult patients and whilst there are no gender differences in adults, 2-3 times more boys than girls suffer from OCD. The aim of this study was to investigate the cognitive profile of adolescent OCD. Thirty juvenile OCD patients (22 females) without additional Axis I disorders and 30 healthy volunteers matched for age, gender, and intelligence were recruited. The Cambridge Neuropsychological Test Automated Battery (CANTAB) was used to assess visual memory (Pattern Recognition Memory), decision-making (Cambridge Gambling Task), and cognitive flexibility (Intra-Extra Dimensional Set Shift). Adolescent OCD patients took significantly longer to complete the memory task, yet their performance was worse. Patients also made less rational decisions in the Cambridge Gambling task, while they were slower and showed poor risk adjustment. Finally, cognitive flexibility was not impaired, though patients showed a general learning deficit. Follow-up analyses showed this effect to be driven by the younger subgroup. The older the patients were, the greater was their impairment of cognitive flexibility. This effect was significant when controlling for OCD, depression, and anxiety symptom severity, gender, and intelligence. An impairment in non-verbal working memory has previously been reported for adult OCD patients (Abramovitch et al., 2013); a similar impairment was observed in this sample. This suggests working memory to be a core deficit in OCD, irrespective of the patient's age. In contrast, the evidence for decision-making in adult patients is mixed (Cavedini et al., 2002, Watkins et al., 2005, Chamberlain et al., 2007), while this dataset shows a clear impairment for adolescents. Lastly, reduced cognitive flexibility is characteristic of adults with OCD (Chamberlain et al., 2006). The young patients did not show this impairment, perhaps due to a general learning deficit, which precluded formation of a stable attentional set and prepotent tendency. However, within this sample increased age correlated with a growing deficit in cognitive flexibility in OCD. Follow-up analyses will be necessary to investigate if adolescent and adult OCD should be treated as two different subtypes of the disorder, with possible implications for treatment.

Title: The combination of mk-801 and sch-23390 at sub-effective doses synergistically impairs attentional set-shifting in rats

Authors: *S. J. DESAI, B. L. ALLMAN, N. RAJAKUMAR;
Dept. of ACB, Univ. of Western Ontario, London, ON, Canada

Abstract: Contemporary research in the pathophysiology of cognitive deficits in schizophrenia has provided a multifactorial view, in which the neurotransmitters dopamine, gamma-Aminobutyric acid (GABA) and glutamate are disturbed in the prefrontal cortex (PFC) of schizophrenic brains. This view is supported by the fact that current antipsychotic drugs, which are primarily dopamine receptor blockers, are not effective in treating the cognitive symptoms of schizophrenia. We hypothesized that abnormality in dopamine and glutamate neurotransmissions act synergistically to cause certain cognitive symptoms of schizophrenia. We tested the effect of blockade of dopamine and glutamate neurotransmitter systems on executive function using an operant conditioning-based attentional set-shifting task to assess behavioral flexibility. In a series of dose-response studies, we determined the effective doses of the specific antagonists for dopamine D1 receptors (SH-23390) and NMDA receptors (MK-801). Next, sub-effective doses were administered subcutaneously 25 min before the set-shifting task. Our results indicate that while the single antagonist treatments did not impair set-shifting, combination of sub-effective doses of SH-23390 and MK-801 severely affected the performance. Present findings will help to elucidate mechanisms underlying cognitive deficits in schizophrenia.

Title: Testing sustained attention in rats in touchscreen operant chambers

Authors: *D. A. BANGASSER, B. WICKS, K. WHITE, N. DUNCAN, S. COHEN, J. BERGMANN, B. YEGLA, R. COLE, V. PARIKH, D. WAXLER;
Dept. of Psychology and Neurosci. Program, Temple Univ., Philadelphia, PA

Abstract: Sustained attention is the ability to detect rare and unpredictable events over a prolonged period of time, and this process is central to cognitive performance. To assess attentional capacities in the laboratory, a Sustained Attention Task (SAT) has been developed for rodents, in which they are trained to detect an unpredictably occurring signal (a brief light presentation) from non-signaled events. The traditional version of this task utilizes an operant chamber with a central panel light for the signal and two retractable levers on which the rats can respond to indicate whether the signal was present or absent. However, with the rise in popularity of touchscreen operant chambers, in which one side of the chamber is a touchscreen and no levers are present, the adaptation of SAT to this style of chamber could enhance the versatility of the task, making it easier to implement and more analogues to touchscreen automated testing procedures used to assess cognitive functions in humans. Here we developed a touchscreen version of SAT where the light signal is presented in the upper part of the touchscreen and rats respond by touching their nose to one of two touchscreen response areas below the light. The remaining parameters were kept similar between the traditional and touchscreen versions of SAT. Our results indicate that rats acquired touchscreen SAT at a similar rate to the traditional version. Additionally, the presence of a distractor (a flashing houselight) disrupted performance on the touchscreen version, which was similar to effects previously observed with the traditional SAT task. Another goal of the study was to validate this task in both male and female rats, given the growing interest of including female subjects in basic research studies. Interestingly, males acquired the task more rapidly than female rats, however most females did eventually master the task. Collectively, these data suggest that the touchscreen version is comparable to the traditional version of SAT, and is an equally valid way of measuring sustained attention. Thus, many researchers with touchscreen chambers could easily implement our modifications in order to study sustained attention.

Title: The effects of different pharmacological treatments on physiological signals in rats using implanted telemetry

Authors: *R. O. PUSSINEN[1], L. TOLPPANEN[1], A. NURMI[1], R. HODGSON[2];
[1]Charles River Discovery Res. Services, Kuopio, Finland; [2]Charles River Discovery Res. Services, Wilmington, MA

Abstract: Telemetry is a method of monitoring physiological functions in awake and freely moving laboratory animals, while minimizing stress and anaesthesia-induced artefacts. It allows for real-time remote recording of biological parameters such as core body temperature, locomotor activity and electrocardiogram (ECG), electroencephalogram (EEG) and electromyogram (EMG) that is cost-effective and minimally labor intensive relative to other methods. Continually evolving refinements in telemetry methodology will undoubtedly aid researchers in acquiring high quality, physiologically relevant data and contribute to groundbreaking discoveries that may, ultimately, lead to therapeutics. In the present studies, we use telemetry to describe the effects of five pharmacological agents on multiple physiological readouts. In the present study, telemetric transmitters (F40-EET, Data Sciences International) were inserted in the abdominal sac of six adult female CD rats (200-250 g) during inhalation anaesthesia of 2% isoflurane. In order to record ECG, the negative lead was guided subcutaneously to the upper left abdomen and attached to the pectoral muscle. The positive lead was attached to the abdominal tissue below the heart and the left diaphragm. Thereafter, subcutaneous pocket was made from the abdomen through the dorsal flank of the animal such that EEG leads could be guided through the pocket and taken out towards the base of the skull. After the EEG leads were guided through the pocket, abdominal cavity muscles and skin were sutured. The rat was then turned and small incision was made to expose the skull. Two trepanations were made in the skull at coordinates AP -1 mm, ML -1 mm and at AP +1 mm, ML +1 mm. The EEG electrodes were secured with dental acrylic. ECG and EEG signals were followed during surgery to confirm the proper installation of electrodes. The transmitters were remotely activated for measurement of body temperature, locomotor activity, ECG and EEG. After 30 min baseline recording, pharmacological treatments were performed in all rats. Pharmacological treatment order was the following: nicotine (1.25 and 2.5 mg/kg), haloperidol (0.5 and 1 mg/kg), amphetamine (1 and 2.5 mg/kg), risperidone (0.01 and 0.05 mg/kg) and pregabalin (10 and 30 mg/kg). All compounds were given intraperitoneally and n=3 for a each dose. Recordings were performed over a period of 5 h after each pharmacological treatment. Washout period was 2-3 days between treatments. The telemetric results provide key reference physiological data for five compounds commonly used in CNS research and provide further validation of the use of telemetry to assess the effects of drug treatments.

Title: Selective entorhinal cortex lesions influence visual attentional set-shifting performance in rats

Authors: *K. BOUAYAD-GERVAIS, Y. CHUDASAMA;
Dept. of Psychology, McGill Univ., Montréal, QC, Canada

Abstract: The entorhinal cortex provides highly processed visuospatial information from the perirhinal and postrhinal areas in the temporal lobe to the hippocampus. Whereas dorsolateral efferent connections of the entorhinal cortex synapse in the dorsal hippocampus, medioventral efferent connections of the entorhinal cortex target the ventral hippocampus. (Dolorfo and Amaral, J. Comp Neurol, 1998, 398-48; Prasad and Chudasama 2013, 33:8494-8503). This suggests that the dorsolateral and medioventral bands of the entorhinal cortex process different types of information in parallel. Consistent with this idea, behavioural studies have shown that the dorsolateral entorhinal cortex (dEC) mediates visuospatial input to the dorsal hippocampus, whereas the medioventral entorhinal cortex (vEC) relays emotional information directly to the ventral hippocampus (Steffenach et al., Neuron, 2005, 45:301-313). The entorhinal cortex has also been shown to enable attentional processing. For example, it has been shown that while control rats readily discriminate relevant stimulus dimensions at a faster rate than irrelevant stimulus dimensions, rats with entorhinal cortex lesions discriminate both relevant and irrelevant stimulus dimension at the same rate (Oswald et al., 2001, Behav Neurosci, 115:841-849). Thus, when entorhinal cortex is damaged, the animal cannot ignore incoming visual information that is irrelevant. In this study, we sought to determine the distinct contribution of the dEC and vEC in a visual attention set-shifting task using a touchscreen operant platform, a task analogous to the human and non-human primate version (Roberts et al, 1988, Quart J Exp Psycho, 40B:321-341). Rats were presented with complex visual stimuli of black lines superimposed onto white geometric shapes set on a light gray background. In the first stages, only the shape was relevant and the lines were to be ignored. Before the lesion, all rats successfully discriminated the shapes, and focused their attention to novel exemplars of shape as the relevant perceptual dimension whilst ignoring the lines (i.e. intradimensional shift). After the lesion, animals showed good retention of the same stimuli. However, when presented with novel shapes and line exemplars, both lesioned groups had difficulty in shifting attention to the new shapes and therefore committed many errors. However, when required for the first time to shift their attention from shapes to lines (i.e. extradimensional shift), only those animals with dEC lesions were highly attentive making fewer errors. These preliminary data implicate the entorhinal cortex in shifting attentional resources between different stimuli.

Title: Superior colliculus activity is necessary for both selectively attending and actively ignoring visual stimuli

Authors: *L. P. LOVEJOY[1], R. J. KRAUZLIS[2];
[1]Dept. of Psychiatry, Columbia Univ. / New York State Psychiatric Inst., New York, NY; [2]Lab. of Sensorimotor Res., Natl. Eye Inst. - NIH, Bethesda, MD

Abstract: Animal behavior depends on the ability to selectively attend to some sensory inputs while actively ignoring others. These two functions involve a network of cortical and subcortical structures; recent studies have shown that inactivation of neurons in the Superior Colliculus (SC) impairs selection of cued stimuli in the presence of foils. Nevertheless, there is scant evidence that any particular brain region is necessary for classic measures of selective attention such as changing sensitivity to sensory inputs based on their behavioral relevance. Here we show that activity in the primate SC is necessary for both these functions. We trained rhesus macaques to perform a motion discrimination task in which peripheral spatial cues indicated the location at which the relevant motion stimulus might appear; subjects were rewarded for indicating the direction of motion with a saccade. On some trials, the motion stimulus appeared in the absence of distractors, in which case performance and sensitivity were the highest. In the presence of distractors, sensitivity and performance decreased. Spatial cues led to recovery of performance and sensitivity when relevant stimuli appeared at the cued location, and also decreases in sensitivity and enhanced ability to ignore irrelevant stimuli at uncued locations. Reversible inactivation of the superior colliculus eliminated the ability of monkeys to use spatial cues to improve performance for stimuli placed in the affected visual field and also impaired their ability to suppress inappropriate responses based on irrelevant stimuli placed outside of the

affected visual field. This result indicates that both selectively attending and actively ignoring each depend on neural activity in the superior colliculus. In addition, we demonstrated that the combination of these two separable processes, characterized independently in these new experiments, could also accurately predict performance from published work when cued stimuli directly competed with foils. Specifically, superposition of the processes of attending and ignoring as represented by linear combination of sensitivity accurately predicted the impact of SC inactivation on selective attention as previously reported in Lovejoy and Krauzlis (2010). Thus, activity in the superior colliculus is necessary for both selectively attending and actively ignoring visual stimuli, and these simultaneous and separable processes can explain selective attention in the case of competition between cued stimuli and foils via a simple linear model.

Title: On the magnitude of signal correlations versus noise correlations

Authors: *C. M. LEWIS[1], A. LAZAR[2], B. LIMA[3], M. VINCK[4], S. NEUENSCHWANDER[5], W. SINGER[2], P. FRIES[1];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci. In Cooperation With Max Planck, Frankfurt Am Main, Germany; [2]Max Planck Inst. for Brain Res., Frankfurt am Main, Germany; [3]Columbia Univ., New York, NY; [4]Princeton Univ., Princeton, NJ; [5]Inst. do Cérebro, Natal, Brazil

Abstract: Cortical responses to repeated trials of identical sensory stimulation exhibit a large degree of variability, despite the physical constancy of the stimulus. This variability is thought to arise from activity intrinsic to the cortex itself. This intrinsically arising variability is often correlated across neurons, and these correlations may affect the fidelity of sensory responses and the effective coding capacity of neural populations. A classical approach to perceptual processing attempts to decompose sensory responses into two distinct components: an extrinsic component, arising from the physical characteristics of a stimulus, and an intrinsic component, arising from uncontrolled internal brain activity or measurement noise. The extrinsic component is most often estimated by computing the mean response across identical trials, representing the most reliable portion of the stimulus-related activity. The correlation between different neurons of their mean response to different stimuli is termed the 'signal correlation' and is a measure of the similarity in selectivity or tuning of the neurons under consideration. The intrinsic component is the residual response after removing the mean activity, and the correlation of this residual

between two neurons is termed the 'noise correlation'. Although noise correlations in a wide range (r = 0.005-0.35) have been published, recent work has stressed the small magnitude of noise correlations when spike isolation and behavioral state are properly controlled. At the same time, signal correlations are often found to be considerably larger than noise correlations (r = ~0.6), suggesting that sensory responses are dominated by extrinsic factors. Here, we point out that differences in the manner in which signal and noise correlations are computed lead naturally to different magnitudes. The fact that the values in question are averages leads to smaller variances in the samples used to compute signal correlation, as opposed to noise correlations. We present a modified measure of the signal correlation that accounts for the reproducible portion of the sensory stimulus, but avoids exaggerated values. We demonstrate that the magnitudes of the signal correlations computed in this manner are on the order of the noise correlations in a population of cells recorded from multiple electrodes in v1 of three awake, behaving macaques. This fact suggests that extrinsic and intrinsic factors contribute equally to neuronal spiking activity. We relate the relative magnitude of the extrinsic and intrinsic response components to synaptic connectivity strengths in a recurrent neural network.

Abstract: Changes in motivational state can affect the relevance of sensory stimuli and modulate neural responses to these stimuli. Our lab has developed a mouse model for understanding how different motivational states affect cortical processing. We train head-fixed, food-restricted mice in a go/no-go task to test how motivational state selectively biases behavioral and neural responses to food-associated cues. Using two-photon calcium imaging in a behaving animal, we can record from hundreds of neurons simultaneously across many days, and thus across motivational states. In this study, we imaged populations of neurons in both primary visual cortex (V1) and postrhinal cortex (POR), a higher order visual area thought to be important for object recognition. Postrhinal neurons are reciprocally connected with the hippocampus, entorhinal cortex, and amygdala - structures important for learning, memory, and encoding of motivational salience. Preliminary results suggest that POR neurons show modulation of responses to food-associated visual stimuli in hungry vs. sated states, an effect that was less common in area V1. These data suggest that POR may be part of a brain network for selective processing of motivationally-relevant sensory cues.

Title: The dependence of inter-areal functional connectivity through rhythmic synchronization on anatomical connection strength

Authors: *J. VEZOLI[1], A. M. BASTOS[1,2], C. LEWIS[1], C. A. BOSMAN[3,4], H. KENNEDY[5], P. FRIES[1,3];
[1]Ernst Strüngmann Inst. (ESI), Frankfurt, Germany; [2]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [3]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [4]Swammerdam Inst. for Life Sciences, Ctr. for Neuroscience, Fac. of Science, Univ. of Amsterdam, Amsterdam, Netherlands; [5]Inserm U846, Stem Cell and Brain Res. Inst., Bron, France

Abstract: The relationship between the strength of rhythmic neuronal synchronization and sensory stimulation, attention, or other cognitive factors is well established. We understand less well how rhythmic synchronization depends on anatomical connectivity. Synchronization has been shown to decline with distance (Leopold et al., Cereb.Cortex, 2003). Also, in primary visual cortex, synchronization between monocular neurons in strabismic animals, which largely lack lateral connections (Löwel and Singer, Science, 1992), is strongly reduced (König et al., Eur.J.Neurosci., 1993). Yet, the degree to which neuronal synchronization between brain areas depends on the strength of their anatomical connectivity has not been studied systematically. We obtained quantitative measures of anatomical connection strength for many pairs of cortical areas in the macaque (www.core-nets.org). In two macaque monkeys, we recorded with 252 channel electrocorticographic grids from the left hemisphere, while animals performed a visual attention task. We determined frequency-resolved coherence, Granger causality and power-power correlations for a large number of area pairs. This shows that across pairs of cortical areas, inter-areal functional connectivity is correlated with inter-areal anatomical connection strength. This correlation holds when it is partialized for distance, either physical distance, distance along the dural surface (relevant for potential volume conduction) or distance through the white matter. The functional-anatomical correlation was highly significant for theta, beta and gamma bands, which were prominent in this dataset. When the beta and gamma networks were investigated separately, this revealed distinct topographical differences. Consistent with the recent insight that gamma predominates in feedforward and beta in feedback signaling, we found the gamma network to be strongest among visual areas, and the beta network to be strongest among fronto-parietal areas. This is likely related to laminar differences in the origin of the respective anatomical projections. In summary, while inter-areal rhythmic neuronal synchronization can be strongly modulated by stimuli and task parameters, we have shown that it nevertheless relies on an anatomical backbone.

Title: Inter-areal synchronization in visual cortex during a divided attention task

Authors: *M. L. SCHOLVINCK[1], J. R. DOWDALL[1], E. FIEDLER[2], T. STIEGLITZ[2], P. FRIES[1];
[1]Ernst Strungmann Inst. (ESI) for Neurosci., Frankfurt Am Main, Germany; [2]IMTEK, Univ. of Freiburg, Freiburg, Germany

Abstract: When processing a visual stimulus, neuronal ensembles in different brain areas along the visual hierarchy interact with each other. Attention is known to influence these interactions; attending to a visual stimulus increases the coherence between neuronal populations in V1 and V4 representing that stimulus (Bosman et al., Neuron 2011). It is unknown how dividing one's attention over several visual stimuli impacts these interactions. Behavioral evidence in humans suggest attention might switch rhythmically between the stimuli (Landau & Fries, Current Biology 2012), but attention could also be truly divided between the stimuli. We recorded local field potential (LFP) from areas V1 and V4 in one monkey (Macaca mulatta) while the monkey was engaged in a divided attention task. Two elliptical, colored drifting gratings were presented, both of which had an equal probability of transiently changing their drift orientation slightly, after which the monkey was required to make an eye movement to this particular grating to obtain a fluid reward. LFP was recorded with a 252-contact electrocorticography (ECoG) grid covering the superficial parts of V1 and V4 that correspond to the central 8 degrees of visual angle. The two gratings were placed such that they activated separate neuronal populations in V1, but fell within the same receptive field of a chosen V4 site. Therefore, the coherence between these separate V1 sites and the V4 site could be studied as both stimuli were attended to. The V1 sites that were selectively activated by one or the other grating showed stimulus induced enhancements in power in the gamma-frequency range, peaking at around 62 Hz (mean gamma-power increase of 9300 %). When the stimuli were shown separately, a large proportion of these sites also showed coherence to the V4 site exclusively for one or the other stimulus. Peaks in the coherence spectrum were around 58 Hz (mean coherence value of 0.09). When both stimuli were shown simultaneously, peak coherence values dropped to about half of what they were during single stimulus presentations. More detailed analyses into this divided attention condition focused on the relationship between the coherence between V1 and V4 just before the orientation change and the reaction time of the monkey towards that orientation change. Together, the analyses will shed more light on the neural implementation of divided attention.

Title: The role of theta oscillations during spatial attention in monkey visual cortex

Authors: *G. SPYROPOULOS[1], C. BOSMAN[2], P. FRIES[1];
[1]Ernst Struengmann Inst., Frankfurt Am Main, Germany; [2]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The presence of theta oscillations in the primate visual cortex has been mostly linked to the successful maintenance of tokens in working memory. Their relation to attention remains, however, unknown. To investigate that relation, we used dense subdural electrocorticography grids (ECoG) in two awake rhesus macaques. In particular, we recorded local field potentials from early (V1) and intermediate (V4) visual areas of the subjects' left hemisphere while they were performing a cued spatial visual attention task. Attention away from the stimulus activating the ECoG recording sites was accompanied by a theta (3-5 Hz) peak in the power spectrum. This low-theta rhythm exhibited a similar topography as stimulus induced gamma band activity and was therefore restricted to the cortical population activated by the stimulus. Moreover, both within and between areas V1 and V4, sites exhibited phase locking in the low theta range, that was stronger in the attend-away condition. Further analysis revealed that the phase of the theta oscillation modulated the amplitude of local narrow-band gamma oscillations. This cross-frequency interaction was stronger in the attend-away condition. These findings were independent of the rate of microsaccades in the two attentional conditions. Our results are consistent with the view that attentional allocation is subserved by the transition of the underlying cortical circuit, from a low-frequency dominated to a higher-frequency dominated state, mimicking increased arousal. Theta oscillations, in the part of cortex representing the ignored stimulus, shape the temporal structure of local gamma oscillations. This would result in the rhythmic breaking of local processing and inter areal communication, which may mechanistically support the filtering-out of the distracter stimulus.

Title: Cholinergic contributions to PASA and functional compensation in rats

Authors: *B. YEGLA, J. A. FRANCESCONI, J. C. FORDE, V. PARIKH;
Psychology and Neurosci. Program, Temple Univ., Philadelphia, PA

Abstract: Neuroimaging studies have indicated increased recruitment of prefrontal regions coupled to reduced activation of posterior regions in task-performing older adults. This shift of activity in cortical networks is described as posterior-anterior shift in aging (PASA). What cellular mechanisms contribute to PASA and how it provides functional compensation for age-related decline in cognitive capacities remains unknown? Cortically-projecting forebrain cholinergic neurons modulate cortical networks and facilitate attentional processes. Here we examined whether cortical cholinergic inputs contribute to PASA expression and maintenance of attentional capacities in aging. Young (3 months) and aged (24 months) Wistar rats were trained in a sustained attention task (SAT) that requires them to distinguish between signal and non-signal events. After attaining criterion performance (≥70% correct responses for 3 consecutive sessions), rats received bilateral infusions of cholinoselective immunotoxin 192-IgG SAP either into the prefrontal cortex (PFC) or posterior parietal cortex (PPC) to produce partial cholinergic deafferentation. Control animals were infused with saline. Following behavioral testing 4 weeks post-surgery, animals were perfused 45-min after the last session to examine changes in neuronal activity in the PFC and PPC using c-fos immunohistochemistry. Partial prefrontal cholinergic deafferentation in aged rats produced robust deficits in response accuracy on signal trials as compared to aged sham ($p=0.04$) and young lesion ($p=0.03$) rats. In general, c-fos expressing neurons were higher in the PFC of aged rats as compared to young rats. Although prefrontal neuronal activity did not differ between the aged sham and PFC lesion group, there was a trend for a higher neuronal activity in the PPC of the latter. Surprisingly, attentional performance displayed a negative correlation with the prefrontal activity. Neuronal activity in the PPC did not correlate with performance. PPC-infused aged rats displayed no lesion effect on SAT and performed better than aged rats infused with 192 IgG-SAP into the PFC ($p=0.04$). Moreover, partial loss of cholinergic inputs into the PPC reduced PFC recruitment as compared to PFC lesioned aged rats. Collectively, these data suggest that reduced cortical activity in young rats compared to aged rats may represent better neural capacity, or the efficient utilization of normal brain regions, for task performance. Moreover, PASA is not triggered by prefrontal cholinergic inputs, but these inputs may regulate the reciprocal interactions between the PFC and PPC networks to maintain optimal performance in aging.

Title: Neural correlates of rhythmic selective attention

Authors: *I. C. FIEBELKORN, M. A. PINSK, S. KASTNER;
Princeton Univ., Princeton, NJ

Abstract: Classic attention theories characterize spatial selection as a sustained, indivisible spotlight that continuously scans the visual scene, pausing to illuminate particularly relevant stimuli. But recent evidence necessitates that we update this metaphor. For example, the attentional spotlight, rather than being sustained, flashes rhythmically, sampling the visual environment at frequencies in the theta band (4 to 8 Hz). We recently used human behavioral data to demonstrate such attention-related rhythmic sampling both (1) within a cued object and (2) alternating between a cued object and a second, less relevant (uncued) object. These data thus demonstrate an important consequence of rhythmic sampling: there are interdigitated windows when events at less relevant locations have a relatively increased likelihood of being selected for further processing. These windows persist under conditions of sustained spatial selection at a cued location. After replicating the behavioral findings in two monkeys, we used neurophysiological recordings to investigate neural correlates of rhythmic selective attention. We simultaneously recorded both SUA and LFP data from visual cortex and three hubs of the attention network (i.e., FEF, LIP, and the dorsomedial pulvinar). Our results link oscillatory patterns in neural data at both local and network levels to behavioral outcomes (i.e., hit rates). We characterize neural responses in these ROIs under three condition of selective attention: when receptive fields and response fields overlapped with either a cued location (i.e. under conditions of space-based selection), an uncued location within the same object as the cued location (i.e., under conditions of object-based selection), or an uncued location on a second object (i.e., in the absence of space- and object-based selection).

Title: Distinct roles of mouse visual and parietal cortex during perceptual decisions

Authors: *G. N. PHO, M. J. GOARD, B. CRAWFORD, M. SUR;
MIT, Cambridge, MA

Abstract: The posterior parietal cortex (PPC) has been implicated in perceptual decisions, but its specific role at the interface between sensation and action remains unresolved. Here, we provide evidence that mouse PPC, in functional analogy to primate parietal cortex, is neither a pure sensory area, nor directly involved in control of motor output, but rather is important for the mapping of sensory inputs to motor commands. Mice were trained on a visual discrimination task with distinct stimulus and motor epochs. We first tested the necessity of PPC and the primary visual cortex (V1) during the different task epochs using VGAT-ChR2 transgenic mice, which express ChR2 in inhibitory neurons. Optogenetic inactivation revealed that both V1 and PPC were necessary during the stimulus period, but not for execution of the motor response. We then used two-photon calcium imaging to measure population activity in V1 and PPC during engagement in the task and during passive viewing of the same stimuli. Whereas V1 responses were driven by visual stimuli alone and only weakly modulated by task engagement, PPC responses were strongly gated by engagement and signaled the impending response. PPC responses exhibited signatures of classical decision neurons: they reflected both the animal's choice on error trials, as well as the degree of sensory evidence, which was manipulated using stimuli of varying contrasts. Lastly, to test whether PPC primarily encoded information about the stimulus or the choice, we re-trained mice with a reversed stimulus-reward contingency, and imaged the same neurons before and after the switch. We found that stimulus selectivity in PPC, but not V1, was dramatically reversed after retraining on the new contingency. Our results are consistent with a role of the mouse posterior parietal cortex in transforming sensory information to motor commands during perceptual decisions.

Title: Multiple, temporally-ordered gain mechanisms of attention in macaque area V4

Authors: *I. SANI[1], M. C. MORRONE[2], L. CHELAZZI[3], E. SANTANDREA[3];
[1]Rockefeller Univ., New York, NY; [2]Dept of Physiological Sci., Univ. of Pisa, Pisa, Italy; [3]Dept of Neurolog. and Movement Sci., Univ. of Verona, Verona, Italy

Abstract: Visual attention and perceptual saliency govern selection of relevant input and the ensuing behavioral output. Yet, we still lack a universally accepted account of the interplay in visual cortex between attention and luminance contrast - a classical dimension of saliency. Neither single-neuron recordings nor fMRI and psychophysical data have so far allowed to converge on a single model to account for the attentional modulation of Contrast Response Functions (CRF). We measured the effect exerted by top-down spatial attention on V4 neurons CRFs, and applied a new approach which emphasized the temporal dynamics of cell responses, while taking in proper consideration the heterogeneity of contrast coding in are V4. Subjects (two Macaca mulatta) performed an orientation discrimination task on stimuli of varying contrast and attention was cued to different spatial positions (either inside or outside the cell receptive field) in different blocks of trials. We found that attention modulates CRFs via the temporally-ordered engagement of distinct gain mechanisms: an early contrast-gain - strongly dependent on pre-stimulus activity changes (baseline shift), a time-limited stimulus-dependent multiplicative modulation, and a late resurgence of contrast-gain modulation of CRFs. Attention produced comparable time-dependent attentional gain modulations on cells heterogeneously coding contrast, i.e. those displaying traditional sigmoidal as well as those displaying selective CRFs (Sani et al., J. Neuroscience, 2013). However, for a considerable fraction of the total cells, attention was capable of inducing radical transformations in CRF shape: from sigmoidal (monotonic) to tuned, or vice versa. These findings help clarify divergent results in the literature and offer important insights regarding the mechanisms which underlie coding of contrast and attention in the primate visual cortex.

Nijmegen, Nijmegen, Netherlands

Abstract: Effective neuronal connectivity along a given anatomical projection is likely modulated by rhythmic synchronization among the connected neuronal groups. The Communication-Through-Coherence (CTC) hypothesis posits that rhythmic neuronal synchronization within the receiving group modulates the response gain of synaptic inputs, a proposal that has so far received equivocal support. Here we test whether local gamma-band synchronization in extrastriate visual cortex modulates the response to visually evoked synaptic inputs. In a first experiment, we recorded multi-unit activity (MUA) and local field potential (LFP) in awake monkey area V4 (N=2 subjects), while neuronal gamma-band synchronization was induced for several seconds by a moving grating stimulus. A sudden color change in the grating evoked a MUA response. We found this response to be modulated by the phase of ongoing gamma-band oscillations before the stimulus change. The response modulation was not an addition of rhythmic activity onto the average response but a rhythmic modulation of multiplicative response gain. The gain modulation might occur at the input to V4, or alternatively at the output of earlier areas sending input to V4 and oscillating coherently with V4, like V1 (see e.g. Bosman et al., Neuron, 2012). While both effects are consistent with CTC, we aimed at specifically demonstrating an effect emerging at the input to a higher area. Therefore, in a second experiment, we used optogenetics to induce a local, "isolated" gamma rhythm in an extrastriate area, and subsequently probed responses to visual stimulus onsets. These experiments were performed in anesthetized cats (N=2 subjects) injected with recombinant adeno-associated viral vectors (AAV9-CamKIIa-hChR2-eYFP) into area 21a, the cat homologue of monkey V4. Four to six weeks after injection, MUA and LFP were recorded both in extrastriate area 21a and primary visual area 17. Illumination of area 21a with 1.25 s constant LASER light (473 nm, 5-10 mW) induced gamma-band synchronization with peak frequencies between 40 and 80 Hz. While this optogenetically induced gamma rhythm was strong in area 21a, it could not be detected in area 17. A visual stimulus, presented from 1-1.25 s after LASER onset evoked a visual response, which showed a multiplicative modulation by the phase of the preceding gamma rhythm. As area 17 showed no gamma, the isolated gamma in area 21a likely resulted in a rhythmic modulation

of input gain. These results show that a gamma rhythm in a receiving neuronal group modulates input gain. Effective connectivity is therefore maximal between sending and receiving neurons oscillating coherently, in line with the CTC hypothesis.

Title: Rodent model of sensory prioritization: behavioral performance and neural correlates

Authors: *C. LEE[1], M. E. DIAMOND[2], E. ARABZADEH[1];
[1]John Curtin Sch. of Med. Research, ANU, Canberra, Australia; [2]Cognitive Neurosci. Sector, Intl. Sch. for Advanced Studies, Trieste, Italy

Abstract: In a natural environment, animals need to assess when to initiate actions based on uncertain sensory evidence. This is evident when dealing with weak sensory inputs, such as small changes in luminance, sounds or vibrations induced by predators. In such scenario, animals benefit from prioritizing sensitivity in the modality that is more likely to provide the key information. To investigate the neuronal and behavioral correlates of sensory prioritization, we trained rats in two detection paradigms: a go/no-go detection (GNG) (n=4) and a two-alternative-forced-choice (2AFC) (n=4) where they detected the stimulus position (left/ right). In GNG, either a vibration (3-8μm; 40Hz) was applied to whiskers or a visual flicker (4-12% luminance change) was presented on each trial. In 2AFC, either a vibration (100μm; 40Hz) or a series of auditory pulses (50dB; 40Hz) was presented. Stimuli were adjusted in difficulty for each rat to exhibit 20% miss rate. We manipulated attention by controlling the likelihood with which the stimulus was presented in each modality. In a *whisker session*, 80% of trials were whisker vibration and the remaining 20% were visual flicker (GNG) or auditory pulse (2AFC). Likelihoods were reversed in a *visual session* (GNG) and *auditory session* (2AFC). As rats performed the task, we recorded single-cell activity from primary somatosensory cortex (n = 31) along with local field potential (LFP). Across rats, the earliest behavioral manifestation of detection (when *d'* deviated from chance) was remarkably fast in GNG task (vibration:

M=47.5ms; flicker: M=56ms) compared to 2AFC task (vibration: M = 141ms; auditory: M= 193ms). High-likelihood trials (e.g. vibration during *whisker session*) resulted in lower miss rates (vibration: 18% in high-likelihood vs. 34% in low-likelihood, $p<0.01$; flicker: 19% vs. 32%, $p<0.01$), higher performance (vibration: 66 % vs. 35%, $p<0.01$; auditory: 71% vs. 46 %, $p<0.01$), and faster decisions (vibration $_{\text{low-high likelihood}}$: 187.5ms, $p<0.01$ [GNG]; vibration $_{\text{low-high likelihood}}$: 153ms, $p<0.01$ [2AFC]; flicker $_{\text{low-high likelihood}}$: 131.3ms, $p<0.01$; auditory $_{\text{low-high likelihood}}$: 68ms, $p<0.01$) than on low-likelihood trials (e.g. flicker during *whisker session*). During entrance and exit from the stimulus presentation port, increases in single-unit activity and modulations of LFP activity reflected changes in whisking behavior. Spectral analysis of low frequency LFP (<14Hz) and changes in LFP voltage variability during nose-poke was predictive of the modality rats prioritized and was also predictive of performance. Our study provides both behavioral and neuronal evidence for sensory prioritization in rodents.

Title: Principal component model of neural activities in macaque area MT

Authors: M. SARAF[1], K. MABOUDI[1], M. ESGHAEI[1], *M. DALIRI[2,1];
[1]Sch. of Cognitive Sci. (SCS), Inst. for Res. in Fundamental Sci. (IPM), Tehran, Iran, Islamic Republic of; [2]Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of

Abstract: The modulation of neuronal activities underlying spatial attention has been shown in many areas of human and primate cortex including area MT. In this study, we have investigated the common neuronal mechanism underlying attention and direction of motion processing at the level of neuronal population. Therefore we examined the responses of 254 isolated direction-selective neurons in area MT of a male macaque monkey while the animal was performing a spatial attention task. First, the strength of the attentional modulation across the neuronal population was estimated by fitting a line with a free slope and base using the method of non-linear least squares. The estimated attention modulation is 17.1% and significant in the neuronal population (P-Value<0.001; Mann-Whiteney U test). In addition, the transformed divergence of

separability index is 0.2234 (Confidence Interval (CI): 0.2174 - 0.2295) for encoding attentional state, and 9.4307×〖10〗^(-4) (CI: 8.0×〖10〗^(-4) - 1.0×〖10〗^(-3)) for encoding motion directions. Second, the significance of information existing in the space of dissimilarities across neuronal subpopulations was elucidated using Principle Component Analysis (PCA) method applied to dissimilarity maps. Consequently, the neural distances were estimated based on the dissimilarity measurements utilizing correlation operation applied to the patterns of neuronal activities. The transformed divergence separability index is 5.0981×〖10〗^(-4) (CI: 4.697×〖10〗^(-4) - 5.5×〖10〗^(-4)) for encoding of the attentional state and it is 1.0251 (CI: 0.9904 - 1.0597) for encoding the stimulus motion direction. Moreover, in the space of neural activity, the strengths of separability between the motion directions is 3.1616×〖10〗^(-5). Our results suggest that the neural mechanism of visual attention and visual motion processing belong to different mathematical spaces. The motion directions were encoded in the space of neural distances, which did not contain any significant information about the attentional state. Reciprocally, attentional states were significantly separable in the space of neural activities, contrary to the non-severable clusters of motion directions.

Title: Attention operates uniformly throughout the Classical Receptive Field and the Surround

Authors: ***B. E. VERHOEF**, J. H. R. MAUNSELL;
Neurobio., The Univ. of Chicago, Chicago, IL

Abstract: Our eyes are constantly bombarded by a multitude of visual stimuli, yet not all stimuli can be processed thoroughly. Spatial attention sifts through the plethora of stimuli, enhancing perception at behaviorally-relevant locations, but the underlying neural principles of this process are not fully understood. During natural vision, large regions of the classical receptive field and the surround of visual-cortical neurons are stimulated. Feedforward-, feedback- and intracortical circuitries are thought to contribute differentially to the suppressive and excitatory inputs associated with stimuli in either the classical receptive field or the surround. Furthermore, the

classical receptive field and the surround presumably serve different functional roles, and the role of the surround in spatial attention is still unclear. Hence, how attention operates within the classical receptive field compared to the surround remains a fundamental open question. We trained two rhesus monkeys to perform a visual-detection task in which spatial attention was controlled and measured. Using chronically implanted microelectrode arrays we probed how attention affects neuronal responses to various stimulus configurations both inside and outside the classical receptive field of V4 neurons. We find that stimulus selectivity alone, or stimulus-related suppression (normalization or surround suppression) alone, cannot explain response modulations by attention. Instead, attention-related modulations rely on a non-additive combination of stimulus selectivity and stimulus-related suppression. A spatially-tuned normalization model, in which suppression varies across receptive-field locations, captured these non-additive relationships in all stimulus configurations. This model relates stimulus selectivity, normalization, surround suppression and attention-related modulation to each other, and unifies spatial summation and attention-related modulation across different regions of the receptive field.

Title: Prone to addiction as well as to falls: Poor attention in sign-tracking rats extends to complex movement control and is associated with regression of choline transporter capacity

Authors: ***A. J. KUCINSKI**[1], A. KOSHY CHERIAN[1], P. VALUSKOVA[2], B. YEGLA[3], V. PARIKH[3], T. ROBINSON[1], M. SARTER[1];
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Inst. of Physiol., First Fac. of Medicine, Charles Univ., Prague, Czech Republic; [3]Psychology and Neurosci., Temple Univ., Philadelphia, PA

Abstract: Some animals (sign-trackers; STs) are especially prone to attribute incentive motivational value ("incentive salience") to reward cues, relative to others (goal-trackers; GTs),

and this, along with other factors, may influence the propensity to relapse in addiction (e.g., Robinson et al., 2014). One other such factor concerns poor attentional control in the presence of drug cues. Indeed, STs exhibit low and unstable levels of attentional performance and these impairments are associated with relatively low levels of cortical cholinergic neuromodulatory activity (Paolone et al., 2013). Here we asked whether the relatively poor attentional control of STs extends to their ability to deploy attentional resources for supporting complex movement, which can contribute to falls in aged and Parkinsonian subjects, and has been associated with declining cholinergic function. STs and GTs were tested on the Michigan Complex Motor Control Task (MCMCT) that assesses gait, posture control and complex movement control by measuring the ability to traverse dynamic surfaces (Kucinski et al., 2013). Compared to GTs, STs committed more slips and fell more frequently while traversing rotating rods, particularly when the rotating direction was changed to a less familiar (reversed) direction. Furthermore, the presentation of a distractor caused more falls in STs. Secondly, we asked whether the relatively low cholinergic activity in STs performing attention-demanding tasks is associated with attenuated choline transporter (CHT) function, as CHT function is a main determinant of cholinergic activity. Brains were harvested immediately following the animals' last MCMCT trial. Interestingly, frontal cortical CHT-mediated choline uptake in STs not only failed to be mobilized by MCMCT performance but regressed below levels obtained from non-performing STs. To validate this finding, we determined the effects of basal forebrain electrical stimulation (Parikh et al., 2013). Once again, rather than exhibiting enhanced choline uptake, in STs, stimulation resulted in uptake levels below those seen in nonstimulated controls. In GTs, performance on the MCMCT did not alter choline uptake, however uptake in GTs was significantly increased with stimulation. Immunoblotting experiments indicated that performance increased surface expression of CHTs in both STs and GTs and thus changes in CHT densities do not account for the functional CHT regression in STs. Together, these results indicate that the attentional vulnerabilities of STs extend to complex movement control and they are associated with regulatory silencing of CHT regulation.

Title: Locus coeruleus firing modes differentially regulate neural processing of salience in somatosensory cortex

Authors: *E. M. VAZEY[1], D. E. MOORMAN[2], G. ASTON-JONES[3];
[1]Dept. of Biol., [2]Psychology and Brain Sci., Univ. of Massachusetts, Amherst, MA; [3]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: The noradrenergic nucleus locus coeruleus (LC) projects broadly throughout the central nervous system and is the near exclusive source of norepinephrine (NE) to cortex. Among its targets, LC sends strong projections to primary sensory regions and has long been posited to have an important role in modulating sensory processing. LC neurons fire in two distinct modes, tonically, as characterized by irregular baseline activity (1-6Hz, physiological range) and phasically during short bursts of stimulus evoked activity (10-15Hz). Under normal conditions tonic LC activity changes with arousal and/or stress whereas phasic LC activity is evoked after salient sensory stimuli that engage behavioral responses. To causally probe LC influence on cortical sensory processing, we selectively expressed ChR2 in LC-NE neurons and drove LC activity during non-salient somatosensory stimulation. This paradigm allowed us to dissociate cortical representations of somatosensation from those that have been modulated through sensory evoked LC activity. We show that selective optogenetic stimulation of LC-NE in association with non-salient sensory signals changes the population dynamics within sensory cortex and differentially alters the sensory response (n= 135 single units). Both tonic and phasic LC activation modulated basal activity of sensory neurons and repeated LC stimulation sensitized short-latency somatosensory responses. In addition, phasic LC activation recruited a distinct subset of gated somatosensory neurons that generated an additional long-latency sensory response. This long-latency signal from gated neurons evoked by sensory locked phasic LC activity was also driven by increases in stimulus intensity/saliency. Collectively these results indicate a major role of LC activity on somatosensory cortical neurons is to regulate sensory processing by providing discrete saliency signals to enhance processing in cortical targets.

Title: Methylphenidate enhances early sensory signal processing in the rat visual thalamus through noradrenergic signaling

Authors: *R. L. NAVARRA[1], A. T. GARGIULO[2], B. D. CLARK[2], B. D. WATERHOUSE[2]; [1]Pharmacol. and Physiol., [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Abnormal processing of sensory information is a core feature of many neuropsychiatric disorders, including attention deficit hyperactivity disorder (ADHD). The psychostimulant, methylphenidate (MPH), is used clinically to treat ADHD as well as off-label as a performance enhancing drug (PED) by healthy individuals. MPH enhances catecholamine transmission via blockade of norepinephrine (NE) and dopamine (DA) reuptake transporters, (NET and DAT, respectively). However, it is not clear how blockade of catecholamine reuptake impacts neural circuits responsible for sensory signal processing. We reported previously that MPH increases both speed and strength of responses to visual stimuli within the dorsal lateral geniculate nucleus (dLGN) of the anesthetized rat, suggesting that enhanced sensory signal transmission may be a significant component of the action of PEDs. To investigate the relevance of these findings to the waking state, we extended these studies to behaving animals performing a signal detection task. During a 1.5-sec nose-poke response, a light positioned above the head may or may not flash. Rats must indicate by lever response if a stimulus was detected. Consistent with findings in the anesthetized rat, latencies of multi-unit light evoked responses in the dLGN were decreased following systemic administration of MPH. Furthermore, in animals highly trained in this task, MPH administration did not improve accuracy of signal detection but did improve the speed of responding. Given the locus coeruleus (LC)-NE system's long established role in the regulation of behavioral state and state-dependent modulation of sensory processing, we propose the sensory facilitating properties of MPH depend on enhanced NE transmission within sensory circuits. Although the LC sends dense projections to the rat dLGN, it has been reported that dopaminergic innervation is sparse or non-existent. To further demonstrate that MPH-induced modulation of light-evoked activity within the dLGN is dependent on NE signaling, we immunostained sections through the dLGN for tyrosine hydroxylase (TH) and dopamine β-hydroxylase (DBH), enzymes responsible for synthesis of DA and NE, respectively. The results showed that all TH-positive axons within the dLGN were also DBH-positive, indicating they were noradrenergic and not dopaminergic fibers. This work suggests that MPH, acting via noradrenergic mechanisms, can substantially impact early stage sensory signal processing, an effect that could positively influence responses to salient stimuli in ADHD patients and healthy individuals seeking performance enhancement.

Title: Communication between the pulvinar and the layers of Area V4 during selective visual attention

Authors: *R. LY, S. KASTNER;
Princeton Univ., Princeton, NJ

Abstract: A fundamental question in neuroscience is how large-scale networks of neurons interact to give rise to cognitive function. A recent study (Saalmann et al., 2012) suggests that the pulvinar nucleus of the thalamus influences cortical visual areas during selective visual attention in the alpha (8-15 Hz) frequency band. The laminar profile of this influence could inform network-level models of visual processing and attention, but is as yet unknown. We simultaneously recorded laminar activity in area V4 using a linear multielectrode array, and spiking activity and local field potentials in the pulvinar using single-unit microelectrodes in a macaque monkey while the animal performed a spatial attention task. Receptive fields (RF) overlapped across V4 layers and the pulvinar, suggesting that we recorded from an interconnected network. We computed oscillatory power within area/layer, coherence within area/layer and across areas, and the Granger-causal influences between the pulvinar and laminar currents in V4, at gamma and alpha/beta frequencies. We compared these measures when the animal attended to the shared RF versus when the animal attended away. These effects are discussed in the context of recent evidence demonstrating alpha/beta coherence across areas as a marker of top-down processing.

Title: Musically trained mice selectively attend to their own music

Authors: *U. LIVNEH, A. ZADOR;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Although it is clear that sensory feedback is required for guiding movement, it is unknown how and to what extent such feedback is integrated into the control mechanisms of movement. Here we present a sensorimotor learning task in head-fixed mice that enables the study of feedback control. Mice were trained to play a computer-controlled musical instrument operated by a horizontally moveable rod. To obtain a reward, mice were required to produce a specific auditory stimulus by pulling the rod to a particular location. Importantly, the target location of the rod was varied frequently, to encourage the use of the auditory feedback as opposed to proprioceptive memory to solve the task. Corruption of the auditory feedback signal impaired performance, suggesting that trained mice indeed used the auditory feedback to guide their movement. To further establish the utility of the self-produced auditory feedback, we simultaneously presented the mice with distracting auditory stimuli that were not coupled to their movement. Performance on the task was not affected by the presence of the uncoupled feedback, suggesting that mice selectively attend the feedback coupled to their movements. A wide range of behaviors requires a tight sensorimotor control mechanism to enable proficient integration of information across different brain systems. Our task provides an experimental framework that is tailored for the study of this controlling mechanism in head-fixed mice, and is well-suited to electrophysiology, imaging and optogenetic investigations.

Title: A behavioral paradigm for visuospatial selection in freely-behaving mice

Authors: *W.-K. YOU, S. P. MYSORE;
Psychology and Brain Sci., The Johns Hopkins Univ., Baltimore, MD

Abstract: Attention, the ability to select and preferentially process the most important stimulus in the environment at any instant, is a hallmark of adaptive behavior. Nevertheless, the neural mechanisms underlying attention control are poorly understood. A genetically tractable model system can offer powerful advantages for investigating the underlying mechanisms. Here, we develop a behavioral paradigm for spatial attention in the freely-behaving mouse using a touchscreen-based operant platform and visual stimuli. Mice are trained to selectively respond to

the higher priority target stimulus while ignoring a simultaneously presented, task-relevant distracter. We explore the effects of systematically titrating the relative contrasts of the competing stimuli on behavioral performance.

Title: An animal model of "shift work": the interaction of sex, scheduled food, and sustained attention on daily activity rhythms

Authors: *M. M. MAHONEY[1], R. BALACHANDRAN[2], P. EUBIG[2];
[1]Vet Biosci., Univ. Illinois, Urbana, IL; [2]Comparative Biosci., Univ. of Illinois at Urbana Champaign, Urbana, IL

Abstract: Circadian rhythms are critical for homeostasis and health as they regulate numerous biological processes. These endogenously generated rhythms are regulated by daily signals; the most salient are the light:dark cycle and timed meals. Disruptions to biological rhythms as occurs with shift work results in significant health consequences including an increased risk for cardiovascular, metabolic and reproductive dysfunction. Relatively few studies however have determined the impact of "shift-work" on attention processes. Furthermore, almost no research has examined the impact of disrupted rhythms on males compared to females. Here, we tested male and female rats on a well-established behavioral measure of attention, the 5-choice serial reaction time task (5CSRTT, n= 6-8/group). Task difficulty was modified by altering cue light duration (0.1, 0.5 and 1 sec) and the delay between cues (0, 2, 4 sec). Animals were food restricted so they were motivated to complete the task to receive sucrose pellets. Experimental rats (EXP) were tested during the light or dark (4 hrs after lights-on or off, respectively). Controls (CON) were moved to the testing room and only received sucrose rewards. We analyzed activity patterns and task performance. Within all "day" rats we observed two phenotypes; a predominantly nocturnal rat that was also active at the time of the task/food pellets, and 2) a predominantly diurnal rat that began daily activity at lights-on and remained active until lights-off. As expected, in CON rats, scheduled food rewards resulted in animals becoming diurnal (42% of females and 71% of males). When animals had food rewards coupled with the attention task (EXP), there was an increase in the number of diurnal rats (66% of females and 83% of males) thus suggesting attention tasks can also alter daily activity rhythms.

Furthermore, entraining cues may alter activity rhythmicity in a sex specific manner. Within day-tested EXP rats we found diurnal rats made significantly less incorrect choices than those that remained nocturnal, indicating that cognitive function is improved if the animals align their rhythms to the time of the attention task. This performance difference, however, was only detected at the easiest task condition of 1 sec cue duration and 0 sec cue delay. Finally, regardless of activity phenotype, day-tested females made fewer incorrect responses than day-tested males indicating there a sex difference in the impact of time of day on attention. These data are among the first to use a 5CSRTT as a model for shift work and will enable us to identify the mechanisms by which vigilance can modulate biological rhythms.

Title: Cellular correlates of state dependent and methylphenidate-induced changes in prefrontal cortical activity during a sustained attention task

Authors: *B. D. CLARK[1], K. L. AGSTER[2], B. D. WATERHOUSE[2];
[1]Drexel Univ. Coll Med., Philadelphia, PA; [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The prefrontal cortex (PFC) is responsible for multiple executive functions including the ability to attend to salient events. Catecholamine projections to the PFC play a prominent role in maintaining or shifting attention as dictated by changing behavioral contingencies. The psychostimulant drug methylphenidate (MPH-Ritalin®) blocks reuptake of catecholamines and is used to treat attention disorders as well as to enhance attention and cognitive function in otherwise healthy individuals. Prior work from this laboratory has shown that MPH improves rodent performance in a sustained attention task. The goal of the present study was to identify the cellular correlates of drug-induced and state dependent changes in sustained attention. Fixed or drivable bundles of microwires were used to record the spike train activity of individual medial PFC neurons in rats performing a modified version of the McGaughy & Sarter (1995) sustained attention task. 104 single units from 11 rats were identified, displaying a bimodal distribution of spike widths. 27 (26%) were classified as putative interneurons (trough-peak duration < 250 μsec), 71 (68%) with widths > 400 μsec were classified as putative pyramidal neurons, and 6 were unclassified. 41 % of putative interneurons and 58 % of putative pyramidal neurons

exhibited brief increases or decreases in firing rate associated with either sensory or motor events in the task. Changes that were initially excitatory were more commonly observed in the anterior cingulate and prelimbic cortex, while initially inhibitory responses were more common in the infralimbic cortex. Neurons that displayed sensory responses (to signal light or lever extension) showed generally stronger responses in correct trials than in incorrect trials or omissions, consistent with the hypothesis that performance in this task is affected by the strength of representation of sensory information in the PFC. Average neuronal firing rates during task performance were not systematically altered by MPH. In contrast, MPH did have a consistent effect on sensory-responsive cells, causing a shift to shorter latencies and longer-duration responses, without having a marked effect on peak response magnitudes. The results of this study suggest that sustained attention task performance engages a subset of neurons distributed across the medial PFC, and that MPH effects on attention in the PFC are mediated not via generalized excitability changes across the region, but rather by altered activity in cells showing task-related activity.

Title: Inhibition and stimulus competition within a GABAergic nucleus in the midbrain attention network

Authors: ***M. STRAKA**, S. MYSORE;
Johns Hopkins Univ., Baltimore, MD

Abstract: In complex environments containing numerous stimuli that are all competing for attention, the brain selects the most important stimulus and processes it preferentially to guide behavior. Recent work has revealed that the superior colliculus (called optic tectum, or OT, in avians) is essential for the flexible, competitive selection of a target among distracters. Furthermore, our past work has shown that competitive interactions within the OT are mediated by an inhibitory nucleus in the midbrain tegmentum, called the Imc. Here, we explore the mechanisms by which the Imc contributes to stimulus competition. Our experiments involve extracellular recordings and focal, iontophoretic blockade of GABA receptors in the midbrain of head-fixed barn owls. We show that inhibition within the Imc plays a critical role in generating the representations of competing stimuli in the Imc and the OT: specifically, that information

regarding competing stimuli is communicated almost entirely by inhibitory inputs to the Imc (rather than by weakened excitatory inputs from the OT). These results shed new light on the neural implementation of stimulus selection for attention.

Title: Atypical encoding of sensory space by an inhibitory nucleus in the midbrain attention network

Authors: *N. R. MAHAJAN, S. P. MYSORE;
Johns Hopkins Univ., Baltimore, MD

Abstract: Selecting the most important stimulus among multiple stimuli in a complex environment is critical for the control of attention and for adaptive behavior. Previous studies have shown a key role for a midbrain network in competitive stimulus selection. This network includes the optic tectum (OT; avian analog of the superior colliculus), and a GABAergic tegmental nucleus, the isthmi pars magnocellularis (Imc). The Imc is known to receive focal excitatory input from the topographically organized OT and to send back widespread inhibition, thereby suppressing OT responses to competing stimuli and aiding selection. Here, we investigate a fundamental functional property of the Imc: how it encodes sensory space. With extracellular recordings in head fixed barn owls, we demonstrate that spatial receptive fields of Imc neurons contain multiple, discrete excitatory hotspots. With computational modeling, we explore how groups of Imc neurons might work together to generate spatially-specific competitive suppression in the OT. This work provides new insights into midbrain mechanisms of stimulus competition and selection.

Title: Methylphenidate-induced modulation of visual evoked potentials and oscillatory states in the rat visual thalamus

Authors: *L. R. MITCHELL, R. L. NAVARRA, B. D. CLARK, B. D. WATERHOUSE; Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Low dose psychostimulants have been used for decades to treat patients with attention deficits and have more recently gained popularity as performance enhancers in otherwise healthy individuals, yet the neural circuits underlying psychostimulant-induced performance enhancement have not been elucidated. Recent studies from our laboratory have investigated the effects of the psychostimulant, methylphenidate (MPH) on early sensory-signal processing. In the rat visual thalamus, low dose MPH decreases the latency and increases the magnitude of single unit responses to light stimuli by increasing noradrenergic transmission. However, the effect of MPH on stimulus-evoked local potentials and oscillatory states in the visual thalamus has not been studied. In the present study, single unit activity and local field potentials (LFPs) were recorded from the dorsal lateral geniculate nucleus of isoflurane-anesthetized Sprague-Dawley rats using eight-electrode arrays. Light flash stimuli of varying intensities were presented unilaterally before and following MPH (2 mg/kg, IP) or saline administration. Analysis of LFPs revealed a decrease in both response latency and peak-to-peak amplitude of light-evoked potentials at 15 min post-MPH administration. As shown in previous studies, MPH administration caused a decrease in mean latency of single-unit light-evoked responses. Furthermore, cross correlations between multiple LFP channels within individual animals showed an increase in the strength of correlation following MPH administration. This increase in the correlation between locally summed potentials from multiple electrodes may be consistent with an increase in local synchrony of neural discharges. Lastly, segmented auto power spectral density analyses computed for progressive 5-minute intervals following injection of MPH revealed a shift from the prevalence of low frequency oscillations of 0-4 Hz to the clear emergence of two dominant bands at 4-6 Hz and 10-14 Hz. Between the decrease in light-evoked potential response latency and the indicated facilitation of local synchrony in the 4-6 Hz and 10-14 Hz ranges, these results suggest a combination of single unit and circuit mechanisms through which MPH can increase the efficacy of sub-cortical visual processing. Such effects likely contribute to the performance-enhancing effects of MPH.

Title: A physiological role for locus coeruleus dopamine

Authors: *A. SONNEBORN[1], C. HAMILTON[2], R. W. GREENE[1];
[1]Neurosci., [2]Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: For many years the locus coeruleus (LC) has been considered the major source of cortical, cerebellar and hippocampal norepinephrine (NE) in the mammalian brain. Recently it was suggested that LC neurons can also release significant amounts of dopamine (DA), the biosynthetic precursor of NE, from their projections. These projections are known to innervate many brain regions, including area CA1 of the hippocampus. It was previously supposed that the main source of CA1 DA was the ventral tegmental area (VTA), but pharmacological studies using amphetamine (AMPH) and selective knockdown of tyrosine hydroxylase have established that the majority of CA1 DA actually originates from LC fibers. However, whether or not LC DA serves a neuromodulatory function under more physiologically relevant conditions remains unclear. In the following experiments, we use an optogenetic approach to study the co-release and electrophysiological effects of LC DA on CA1 function. We provide chemical evidence of the co-release of DA from LC terminals, and show that optogenetically evoked LC DA release is sufficient to modulate synaptic strength at hippocampal Schaffer Collateral synapses by acting on CA1 pyramidal neuron D1/D5 receptors (D1/5R). D1/5R activation can convert transient LTP into long lasting LTP, a potentially necessary step for consolidation of learning. The LC is thought to be involved in selective attention and arousal and CA1 is known to be important for the storage, retrieval, and comparison of episodic or associative memories with current sensory information. Therefore, these and future experiments provide new insight into the effects of attention and arousal states on learning and memory.

Title: Medial prefrontal cortex provides psychological stress signals to the dorsomedial hypothalamus to drive brown adipose tissue thermogenesis and hyperthermia

Authors: N. KATAOKA[1], *K. NAKAMURA[1,2];
[1]Dept. of Physiol. 2, Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [2]PRESTO, JST, Kawaguchi, Japan

Abstract: Psychological stress induces hyperthermia in many mammals including humans. Recently, we have reported that stress activates a direct neural pathway from the dorsomedial hypothalamus (DMH) to the rostral medullary raphe (rMR) to drive sympathetic heat production (thermogenesis) in brown adipose tissue (BAT), hyperthermia and tachycardia (Kataoka *et al. Cell Metabolism*, 2014). To activate this hypothalamo-medullary neural pathway, DMH neurons must receive stress signals. However, the upper brain sites that provide the DMH with psychological stress signals to drive the sympathetic responses have not been determined. To identify such upper sites, we injected cholera toxin b-subunit (CTb), a retrograde neural tracer, into rat DMH. Many CTb-labeled neuronal cell bodies were distributed in the medial prefrontal cortex (mPFC) and the lateral septal nucleus (LS). Our *in vivo* physiological experiments using anesthetized rats showed that stimulation of neurons in either mPFC or LS with a nanoinjection of bicuculline, a $GABA_A$ receptor antagonist, increased BAT sympathetic nerve activity, BAT temperature and heart rate. These bicuculline-evoked sympathetic responses were all diminished by inactivation of bilateral DMH neurons with muscimol nanoinjections. Free-moving rats exposed to social defeat stress, a sociopsychological stress model, exhibited immediate increases in BAT and abdominal temperatures, as detected with a telemetry system. These stress responses were significantly reduced by inhibition of neurons in the ventral part of the mPFC (vmPFC) with bilateral nanoinjections of muscimol. In contrast, inhibition of neurons in the infralimbic cortex, a dorsal part of the mPFC, or in the LS only weakly inhibited these stress responses. Supporting the functional contribution of the vmPFC-DMH monosynaptic pathway to driving the stress-induced BAT thermogenesis, *in vivo* optogenetic stimulation of the vmPFC-derived nerve endings in the DMH increased BAT sympathetic nerve activity. These results indicate that the vmPFC-DMH monosynaptic pathway provides the DMH with stress signals to activate the DMH-rMR sympathoexcitatory pathway driving BAT thermogenesis for the development of stress-induced hyperthermia.

Title: Changes in D2R binding potential within the striatum and PFC are modulated by psychosocial stress exposure and E2 treatment in female rhesus monkeys

Authors: ***M. PEREZ DIAZ**[1], V. MICHOPOULOS[1,2], L. L. HOWELL[1,2], M. WILSON[1,2]; [1]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [2]Dept. of Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA

Abstract: Chronic exposure to psychosocial stress produces a myriad of negative, often long-lasting, neurochemical and behavioral changes. Emotional feeding of calorically dense foods can result from chronic exposure to psychosocial stressors and likely contributes to excess food intake. This change is exacerbated in women, who consistently report more stress-induced eating and higher rates of obesity, suggesting that estrogen plays a modulatory role in the behavioral consequences of chronic stress exposure. Moreover, chronic exposure to psychosocial stress also leads to dysregulation of the reward pathway, which may increase susceptibility to addiction. Previous studies demonstrate that exposure to chronic stress reduces the availability of DA 2 receptors (D2R) in the brain, which results in a hypodopaminergic state characterized by reduced DA signaling. Although estrogen has been shown to affect behaviors associated with stress exposure, no one has evaluated its effect on the downregulation of D2R that results from this exposure. We employed a non-human primate model of female social subordination stress to test the hypotheses that 1) chronic psychosocial stress decreases D2R binding potential (BP) in the striatum and prefrontal cortex (PFC) and 2) estradiol (E2) treatment exacerbates this. Twenty-four socially housed adult female rhesus monkeys were studied during the species typical non-breeding season when endogenous estradiol levels are suppressed. Females received PET scans using [18F]-fallypride under the control condition (no E2 treatment) and after 1 week of E2 treatment (surgically implanted capsule) to mimic mid-follicular phase levels (~100 pg/ml). We found a significant effect ($p < .05$) of both social status and E2 treatment within the caudate and putamen, with dominant females and females under E2 treatment having higher D2R BP than subordinates and females under control conditions, respectively. Moreover, D2R BP in the medial PFC was also higher in females under the E2 treatment condition. Finally, we found a

significant interaction between E2 treatment and social status, with subordinate females having higher BP than dominants under the control condition and dominants having higher BP than subordinates under the E2 treatment condition. Overall, our results suggest that estradiol indeed modulates the effects of chronic stress exposure on D2R BP within the reward pathway, which may represent one of the mechanisms by which estrogen exacerbates the behavioral consequences of stress exposure in women. Title: Fkbp5 in the infralimbic cortex modulates fear conditioning and extinction

Authors: ***M. CRIADO MARRERO**[1], R. MORALES-SILVA[2], B. VELAZQUEZ[1], J. PORTER[1];
[1]Dept of Physiol. and Pharmacol., Ponce Hlth. Sci. Univ., Ponce, PR; [2]Univ. of Puerto Rico in Ponce, Ponce, PR

Abstract: Patients with PTSD have difficulty learning to extinguish fear memories. Current studies associate FK binding protein 5 (Fkbp5) variants with PTSD. Since Fkbp5 decreases the activity of the glucocorticoid receptor (GR), excessive Fkbp5 expression could reduce GR activity and impair extinction memory. In this study, we hypothesized that Fkbp5 regulates fear extinction by modulating GR activity in the infralimbic cortex (IL) a key structure of the fear extinction circuitry. To test this, adult male rats were exposed to fear conditioning and extinction and Fkbp5 mRNA and protein levels were determined in IL tissue punches. Both Fkbp5 mRNA and protein expression increased after fear conditioning and decreased after extinction. Interestingly, similar changes were not observed in the adjacent prelimbic cortex (PL). To determine whether changes in IL Fkbp5 affect fear conditioning or extinction, we reduced Fkbp5 expression in IL by infusing Fkbp5-shRNA plasmids into IL prior to fear conditioning and extinction. Unexpectedly, rats infused with Fkbp5-shRNA showed less fear during conditioning than rats infused with scramble-shRNA. Both groups showed similar levels of fear during

conditioning recall and at the end of extinction, however, the Fkbp5-shRNA group showed reduced fear during extinction recall. Conversely, infusion of Fkbp5-shRNA into PL did not affect fear conditioning or extinction. Our findings suggest that people with higher expression of Fkbp5 in the ventral medial prefrontal cortex may be predisposed to facilitated fear learning and impaired extinction.

Title: Prolonged elevations in corticosterone induces regressive dendritic spine alterations in the medial prefrontal cortex

Authors: *R. M. ANDERSON, S. JOHNSON, M. MILLER, R. GLANZ, S. ROMIG-MARTIN, J. J. RADLEY;
Psychology Dept, Program in Neurosci., Univ. of Iowa, Iowa City, IA

Abstract: The stress-responsive HPA axis plays a central role in promoting adaptations acutely, whereas adverse effects on physiology and behavior following chronic challenges may result from over-activity of this system. Elevations in adrenocortical hormones, the end-products of HPA activation, play roles in adaptive and maladaptive processes by targeting neuronal cognate receptors throughout limbic cortical cell groups to alter synaptic functioning. Work from our laboratory and others have shown that chronic stress leads to functionally-relevant regressive alterations in dendritic spine shape and number in pyramidal neurons in the medial prefrontal cortex (mPFC) following chronic stress exposure. Nevertheless, information regarding the effects of prolonged glucocorticoid exposure on dendritic spine plasticity in these cell types has not been carefully investigated. Here we examined dendritic spine alterations in the prelimbic region (PL) of mPFC in rats that were adrenalectomized (ADX) and replaced with corticosterone (B) to plasma levels that approximate the circadian mean (75 ng/ml; B75 group) or peak PM (150 ng/ml; B150 group) concentrations over a 14-day period, relative to sham-ADX controls. On day 15, animals were perfused and pyramidal neurons throughout all layers of PL were selected for intracellular fluorescent dye-filling, followed by high-resolution 3D imaging and analysis of dendritic arborization and spine morphometry. B150 animals showed decreases in apical dendritic length and spine density (by 13% for each; $p < 0.05$ for each), and these

decrements were exaggerated at distal aspects (by 16%; $p < 0.01$). Thin spine subtypes showed the greatest degree of attrition throughout apical dendrites and more distally (by 12% and 17% respectively, $p < 0.05$ for each), whereas mushroom and stubby subtypes were largely preserved. Follow-up population analyses of spine characteristics in B150 rats revealed increases in spine volume across subtypes, which is consistent with the idea that smaller volume spines are more vulnerable to pruning following higher levels of B exposure. By contrast, analyses in B75 animals failed to display any reliable decrements in dendritic morphology, spine, or subtype densities, however, population analyses carried out in these animals revealed a robust decrement in spine volume relative to B150 and sham groups. These results suggest that prolonged alterations in adrenocortical activity may be sufficient to differentially induce regressive structural changes in excitatory synaptic morphology in mPFC neurons.

Title: Baboon fetal frontal cortex response to moderate maternal nutrition reduction (MNR) in late gestation

Authors: S. YANG[1], T. NURMAMAT[2], P. W. NATHANIELSZ[1], *C. LI[1];
[1]Animal Sci., Univ. Wyoming, Laramie, WY; [2]Genet., Texas Biomed. Res. Inst., San Antonio, TX

Abstract: Introduction: Moderate maternal nutrient restriction (MNR) during pregnancy is common in both developing and developed countries. Our group previously reported that MNR induced subtle cerebral developmental changes in frontal cortex (FC) at mid gestation (0.5 G) [1]; however, the impact of MNR at late gestation (0.9 G) has not been determined. The FC of the brain plays an important role in memory, learning and complex cognition, and proper fetal FC development is critical for adult cognitive function. We hypothesized that MNR programs frontal cortex by increasing cellular proliferation at the cost of decreased neuronal cell maturation in late gestation. Methods: Morphometrically homogeneous adult female baboons were randomly selected for ad libitum feed control (CTR; n = 25) or 70% CTR global diet (MNR, n = 16) from 0.16 G through 0.9 G. Fetal FC samples were collected at Cesarean section. Gene arrays were performed for whole genome profiling of the fetal FC. Ingenuity pathway

analysis (IPA) software was used for genomic analysis. Immunohistochemistry (IHC) was conducted for determining the protein expression of B-cell lymphoma 2 (BCL-2), transforming growth factor beta (TGF-ß) and glucocorticoid receptor (GR). Image J was used for quantification of stained fraction, and Student's t-test was performed for data analysis and the significance was set at $P < 0.05$. Results: Gene array results showed that gene expression of 666 genes were altered in CTR vs. MNR fetal FC. Among those differentially expressed genes, 569 genes were up regulated and 97 genes were down regulated in MNR fetuses. IPA analysis revealed that signaling pathway involved in neuronal cell proliferation and differentiation were upregulated, while signaling pathways that are important in maturation and apoptosis signaling were down regulated in MNR group. Gene expression of BCL-2, TGF-ß and GR were all up regulated ($P < 0.05$). In keeping with gene expression, % area stained for BCL-2 and GR proteins were increased ($P < 0.05$) in gray matter of MNR fetal FC, and the protein expression of TGF-ß tended to increase ($P < 0.1$), but did not reach the significance level. Increase in BCL-2 and TGF-ß expression may mediate increased cell proliferation, while increased GR expression can reduce neuronal maturation. Conclusions: Moderate MNR leads to significant changes in fetal frontal cortex gene expression in late gestation. We also found some evidence for catch up growth in the FC in late gestation due to MNR, which may predispose the offspring to deficits in cognitive function in later life. 1. Title: Selective control of fear expression by manipulation of infralimbic cortex during extinction retrieval

Authors: H.-S. KIM[1,2], H.-Y. CHO[1], G. J. AUGUSTINE[2,3,4], *J.-H. HAN[1];
[1]KAIST, Daejeon, Korea, Republic of; [2]KIST, Seoul, Korea, Republic of; [3]Nanyang Technological Univ., Singapore, Singapore; [4]Inst. of Mol. and Cell Biol., Singapore, Singapore

Abstract: Evidence from rodent and human studies has implicated the ventromedial prefrontal cortex (vmPFC), specifically the infralimbic cortex (IL), as a critical brain structure in the extinction of conditioned fear. However, lesions or pharmacological inhibition of vmPFC before extinction reportedly has no effect on extinction or even facilitates extinction. Thus, the role of the IL activity in expression of extinction memory remains unclear. To address this issue, we used an optogenetic approach in mice. By precisely manipulating the activity of defined cells, we examined the real-time contribution of IL activity to expression of auditory conditioned fear extinction. Our results reveal that inactivation of infralimbic, but not prelimbic, cortex impaired extinction retrieval. Conversely, activation of infralimbic excitatory neurons enhanced expression of fear extinction but had no significant effect on expression of unextinguished conditioned fear. Furthermore, inhibition of fear expression by IL photoactivation was specific to the conditioned stimulus (CS), such that IL photoactivation had no effect on fear expression to the context after the auditory fear extinction. Thus, artificial IL activation produced no significant effect on expression of non-extinguished conditioned fear. Therefore, our data provide convincing evidence supporting that IL activity is critical for expression of fear extinction and establish a causal role for IL activity in controlling fear expression in a CS-specific manner after extinction.

Title: Posterior insular cortex is required for acquiring a conditioned fear inhibitor and supports fear recall

Authors: *A. R. FOILB, J. P. CHRISTIANSON;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Veridical detection of safe versus dangerous cues is critical to survival. We reported that the posterior, but not anterior or medial, insular cortex (IC) is critical for the stress-mitigating effect of safety signals on later anxiety behavior. Here, rats received “A+/B-“ fear discrimination training in a standard fear-conditioning box over 5 days. 24 h after training rats were given a summation test in the training context in which freezing, an index of fear, was

assessed during exposure to the context alone, A, A and B in compound (summation) and B alone. We then show that NMDA-receptor antagonist D-AP-5 (6μg/side) in posterior IC (Bregma -1.8) before training completely prevented conditioned inhibition learning, while intra-D-AP-5 to anterior (+2.7 Bregma) and medial (+0.5 Bregma) IC targets before training had no effect on later conditioned inhibition. Ongoing work in the lab is using optogenetic techniques to establish temporal specificity. To determine the role of IC in recall, intra-posterior IC injections of the GABAA agonist muscimol (1μg/side) were made before a summation test. Muscimol significantly reduced conditioned freezing to all cues. These data implicate a role of posterior IC in the recall of fear. This new finding may be a key to understanding why the posterior IC is a site of plasticity that leads to conditioned inhibition.

Title: Chronic unpredictable stress dysregulates glutamate transmission in the rat medial prefrontal cortex: a potential role for noradrenergic modulation

Authors: *J. D. JETT, L. EVANS, M. PATTON, D. MORILAK;
Pharmacol, Univ. Texas Hlth. Sci. Ctr, SA, San Antonio, TX

Abstract: Deficits in cognitive flexibility are associated with the onset and maintenance of stress-related psychiatric illnesses, such as depression. Cognitive flexibility, the ability to modify behavior in response to changes in the environment, depends on medial prefrontal cortical (mPFC) function. We previously showed that rats exposed to chronic unpredictable stress (CUS) exhibit deficits in mPFC-mediated cognitive flexibility, as measured by the extradimentional set-shifting task (ED) on the attentional set-shifting test. Further, acute enhancement of norepinephrine (NE) transmission in the mPFC facilitated cognitive flexibility. However, local blockade of NE receptors during CUS prevented stress-induced deficits. This evidence suggested that NE facilitation may compromise mPFC function when repeatedly evoked by CUS. We subsequently found that CUS-induced cognitive deficits are associated with attenuated *fos* induction in the mPFC following stimulation of the mediodorsal thalamus, a glutamatergic (GLU) afferent to the mPFC. NE modulates GLU in the mPFC, thus repeated NE activity during CUS may compromise cognitive function by dysregulating GLU transmission. To test this

hypothesis, we first assessed the effect of blocking NE activity during CUS on markers of plasticity associated with glutamatergic signaling and long-term potentiation, namely phosphorylation of the AMPA receptor GluR1 subunit at the S845 and 831 sites. Male Sprague-Dawley rats received injections of vehicle (40% DMSO, 2ml/kg, i.p.) or an α_1- / $\beta_{1/2}$-adrenergic antagonist cocktail (prazosin, 1.25mg/kg; propranolol, 10mg/kg) 30 min prior to each CUS or control session. Rats were then tested on AST drug free, and the mPFC collected 30 min after ED. Antagonist treatment attenuated CUS-induced cognitive deficits on ED. Further, drug treatment during CUS significantly enhanced phosphorylation of GluR1(S831) ($p<0.03$), but not S845 ($p=0.2$). S831-phosphorylation is associated with AMPA receptor translocation to the synapse. Thus, antagonist treatment may facilitate cognitive flexibility in CUS rats by enhancing GLU synaptic transmission in mPFC. For the second experiment, rats were implanted with a microdialysis cannula targeting the mPFC. After 2 weeks of control or CUS treatment, rats underwent GLU microdialysis. Following baseline sampling, rats were exposed to a novel acute immobilization stress (20 min). CUS attenuated the acute stress-evoked GLU response in mPFC compared to non-stress controls ($p<0.001$). Studies are ongoing to assess if antagonist treatment prevents CUS from compromising stress-evoked GLU response in mPFC. Funding: NIH grants MH053851 and MH072672

Abstract: Persistent anxiety following a psychological trauma is a hallmark of many anxiety disorders. However, the neural circuits mediating the extinction of fear remain incompletely understood. Here we tested for alterations in fear extinction following pathway-specific manipulation of glutamatergic projections from the ventromedial prefrontal cortex (vmPFC) to the amygdala. Selective, *in vivo* optogenetic stimulation of vmPFC-amygdala pathway facilitated extinction memory formation, but not retrieval. Conversely, silencing the vmPFC-amygdala pathway impaired extinction formation and suppressed amygdala neuronal activity. Collectively, our results provide compelling evidence that this discrete neural circuit is both necessary and sufficient for the formation of an extinction memory. Our data are consistent with a model in which vmPFC inputs instructs plastic changes in the amygdala necessary for extinction by either decreasing excitatory input or increasing inhibitory input in amygdala. To further delineate the functional contribution of vmPFC-amygdala pathway to fear extinction we test the role of amygdala local circuits in optogenetically-induced facilitation of extinction memory. One line of evidence suggests that extinction training results in increased endocannabinoids levels in the amygdala. At a cellular level, endocannabinoids cause a long-term depression of GABAergic synaptic transmission via activation of cannabinoid type 1 (CB1) receptor . Anandamide levels in the amygdala were increased by stimulation of vmPFC inputs extinction training. Since, CB1 is particularly enriched in axon terminals of cholecystokinin-positive GABAergic interneurons; we tested if these interneurons population is driven by vmPFC projection to amygdala. Our findings suggest that selectively elevating amygdala anandamide may underlie plastic changes induced by activation of vmPFC-amygdala pathway extinction memory. Taken together, these findings could help advance our understanding of the neural circuits mediating fear extinction, with possible implications for elucidating the neuropathology of impaired extinction in anxiety disorders.

Title: Perirhinal cortex involvement in fear extinction using a discontinuous light stimulus

Authors: *C. A. CALUB, N. M. POTTER, A. G. BECKNER, A. C. SARDO, S. C. FURTAK; California State University, Sacramento, Sacramento, CA

Abstract: The perirhinal cortex (PER) is known to have a mnemonic as well as a perceptual role in the processing of high level sensory information. One hypothesis is that PER functions to unitize stimuli across time or across sensory modalities (Kent & Brown, 2012; Graham et al., 2006). While many findings have supported the role of PER in fear acquisition to multi-feature and multi-modal stimuli (Bucci, Phillips, & Burwell, 2000; Bucci, Saddoris, & Burwell, 2002; Corodimas & LeDoux, 1995; Kholodar-Smith, Allen, & Brown, 2008; Kholodar-Smith, Boguszewski, & Brown, 2008), to date no study has evaluated PER involvement in processing such stimuli during fear extinction. To evaluate this, Sprague-Dawley derived Albino male rats were infused with muscimol, a GABA agonist, to temporarily inactivate the PER during extinction training. All subjects were surgically implanted with cannulae targeting PER bilaterally. Following recovery, all subjects were trained on a three-day fear extinction paradigm. All phases of the paradigm were conducted in the same context in order to avoid contextually dependent characteristics of extinction. On Day 1, animals received fear conditioning, which consisted of 5 presentations of a discontinuous visual light stimulus (conditioned stimulus; CS) paired with the unconditioned stimulus (US), a foot shock. On Day 2, subjects received bilateral PER infusions of either muscimol or saline 40 mins prior to extinction training, and subsequently received 20 trials of the CS alone. On Day 3, extinction recall was assessed by presenting an additional 15 trials of the CS without the US. Freezing behavior, defined as no movement except that necessary for breathing, was recorded throughout the experiment and later analyzed by an automated computer program. Results showed that bilateral muscimol infusions into the PER during extinction training impaired extinction recall to a discontinuous light CS, as indicated by significantly higher levels of freezing in muscimol infused animals than saline control animals during extinction recall. The results suggest that particular cues may engage brain regions outside what is typically considered the fear extinction neural circuit. Here, for the first time, results support a role for PER involvement in fear extinction, perhaps due to the discontinuous nature of the CS.

Title: Changes in limbic system responsiveness predict the behavioral emergence of conditioned freezing in developing rats

Authors: *M. A. BURMAN[1], A. D. DEAL[2], K. E. ERICKSON[2], J. DIONNE[2];
[1]Psychology, [2]Univ. of New England, Biddeford, ME

Abstract: Anxiety disorders have a lifetime prevalence of about 25%. Many begin during childhood or early adolescence. Despite the clear developmental link and the progress made in uncovering the neural substrates of fear and anxiety in adult organisms, our understanding of the development of these circuits lags relatively behind. One popular preparation for studying fear and anxiety in rodents is classical fear conditioning. In this task, which has a great face validity as a model of PTSD or specific phobias, rodents develop an association between a previously neutral cue and an aversive event, such that the previously neutral cue consequently elicits a conditioned fear response. Part of the difficultly in understanding the development of this task is that there are many potential areas for developmental dissociations. In addition to sensory and motor aspects, these likely include the acquisition of fear to different types of cues, the expression of fear, and the extinction of the fear response. The current work focuses on the acquisition and expression of fear acquired to both a specific auditory cue and the concomitant fear that develops to the background environment in infant (postnatal day; PD 17) and post-weanling (PD 23-24) rats. Our behavioral data show that conditioned freezing to both the context and a pure tone develops during this time. The data presented here extend this work by assessing immediate early gene (IEG) expression in various limbic system structures using 2 methodologies: immunohistochemistry and qPCR. First, examining c-FOS protein expression following fear acquisition we see three distinct patterns. First, we note that activation of basolateral amygdalar nuclei closely predicts the expression of fear, in that only older fear conditioned subjects demonstrate robust expression. Second, in the perirhinal cortex and hypothalamus, exposure to the aversive stimulus, but not eventual freezing levels, appear to predict expression. Finally, we do not see robust expression in dorsal CA1 of the hippocampus. Examining c-FOS and EGR-1 mRNA expression, activation appears to closely match levels of freezing only in the amygdala and perirhinal cortex when assessing EGR-1 expression during the auditory fear test. Activation of the hypothalamus appears to be related to aversive stimulus exposure and not levels of freezing. We also see age-related changes in in the amygdala, hypothalamus and perirhinal cortex. Overall, changes in amygdala and cortical circuitry could account for the ontogeny of fear conditioning in peri-weaning rats.

Title: Response of the tail of the ventral tegmental area to aversive stimuli

Authors: *M. BARROT[1], M. SÁNCHEZ-CATALÁN[2], M.-A. MULLER[3], M. MAJCHRZAK[3], I. YALCIN[2];
[1]INCI - CNRS UPR3212, Strasbourg, France; [2]INCI, CNRS, Strasbourg, France; [3]LNCA, UMR 7364, Univ. de Strasbourg, CNRS, Strasbourg, France

Abstract: The GABAergic tail of the ventral tegmental area (tVTA), also named the rostromedial tegmental nucleus (RMTg), is a mesopontine structure that exerts an inhibitory electrophysiological control over dopamine cells of the VTA and substantia nigra pars compacta (SNc). The tVTA has been implicated in motor functions, responses to drugs of abuse, reward prediction error and avoidance behavior. Stimulation of lateral habenula (LHb) inputs to the tVTA, or of the tVTA itself, induces avoidance behaviors, which suggested a role for the tVTA in processing avrsive information. In rats, psychostimulant drugs share the property to induce Fos proteins in the tVTA. The aim of the present study was to test whether various aversive stimuli might similarly recruit the tVTA. We studied Fos expression in the tVTA of Sprague-Dawley rats in response to: lithium chloride, β-carboline, naloxone, lipopolysaccharide, footshocks, restraint stress, forced swimming test, fox odor, cat odor, inflammatory pain, neuropathic pain, and opioid withdrawal. Moreover, we also assessed the effect of the bilateral excitotoxic lesion of the tVTA on the LPS and LiCl-induced conditioned taste aversion. Our results confirm that foot-shocks elicit Fos induction in the tVTA, but such induction was not present with most of the other aversive stimuli. Moreover, the tVTA lesion did not impact on conditioned taste aversion. While a stimulation of the tVTA favors avoidance behaviors, the present finding suggest that the recruitment of the tVTA may not be a general outcome of exposure to aversive stimuli and that the tVTA may not be a key brain region for some avoidance behaviors.

Title: The role of norepinephrine in the expression of Pavlovian defensive reactions

Authors: *Y. GU[1], R. M. SEARS[1,2], E. M. VAZEY[3], G. S. ASTON-JONES[3], J. E. LEDOUX[1,2]; [1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Emotional Brain Inst., Nathan Kline Inst., Orangeburg, NY; [3]Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: The modulatory role of norepinephrine (NE) in the amygdala, specifically the lateral nucleus of the amygdala (LA), has been studied in great detail using aversive Pavlovian paradigms. However, the central nucleus of the amygdala (CeA) also receives dense noradrenergic innervation, the function of which is not well understood. The CeA is the major output nucleus of the amygdala and is responsible for defensive responses to aversive stimuli. We therefore hypothesized that NE acting in CeA modules the expression of defensive reactions. Here, we used a combination of intracranial drug infusions and Designer Receptors Activated by Designer Drugs (DREADDs) to uncover the role of NE modulation of CeA functions in a Pavlovian threat conditioning paradigm. Decreased and increased expression of defensive responses were observed following direct CeA infusions of the β-receptor antagonist propranolol or the β-receptor agonist isoproterenol, respectively. Next we used viral vectors expressing DREADDs and engineered to specifically target norepinephrine-expressing neurons to study the role of the locus coeruleus (LC), a major source of norepinephrine release in the brain, in CeA-mediated defensive responses. Axon terminals in CeA were directly activated or inhibited using intra-CeA Clozapine-N-oxide (CNO) infusions before memory expression tests. Consistent with our pharmacology studies, we found that hM3Dq-mediated activation and hM4Di-mediated inhibition of LC terminals in CeA increased and decreased freezing behaviors, respectively. Taken together, these studies suggest that norepinephrine from LC activates β-receptors in CeA to positively modulate defensive responses to threatening stimuli.

Title: Vagus nerve simulation enhances extinction of conditioned fear in a rat model of PTSD

Authors: *L. J. NOBLE, I. J. GONZALEZ, K. R. RAMANATHAN, B. D. BELFORT, C. K. MCINTYRE;
Univ. of Texas At Dallas, Dallas, TX

Abstract: Trauma-related disorders, such as posttraumatic stress disorder (PTSD) are typically treated with cognitive behavioral therapy. Exposure therapy is a form of cognitive behavior therapy where patients are repeatedly exposed to the cues that elicit maladaptive conditioned responses. After repeated exposures to conditioned cues in the absence of reinforcement, conditioned responses are extinguished. Because successful extinction requires new learning, studies have examined the effects of memory enhancing drugs as adjuncts to exposure therapy. However, in humans with PTSD these results have been inconsistent. One possible explanation for this discrepancy is, when the conditioned response is not fully extinguished, memory-enhancing drugs could reinforce the association between the cue and the inappropriate fear response. Optimal treatments should reduce the anxiety produced by the conditioned cues while enhancing consolidation of extinction learning. Unfortunately, most anxiety-reducing drugs impair memory consolidation and thus interfere with progress in exposure therapy. Vagus nerve stimulation (VNS) is an FDA-approved treatment for the prevention of seizures. Recent research indicates that VNS enhances memory consolidation in rats and in humans. We recently found that pairing VNS with unreinforced exposure to conditioned cues enhanced fear extinction in rats. Additionally, we found that administration of VNS prior to testing in an elevated plus maze significantly reduced anxiety and levels of plasma corticosterone in rats. Together, these findings indicate that VNS offers a rare combination of memory-enhancing and anxiety-reducing properties and thus might provide optimal benefits as an adjunct to exposure therapy for the treatment of disorders like PTSD. Impaired ability to extinguish conditioned fear is a hallmark of PTSD. The single prolonged stressor (SPS) model is an animal model of PTSD that exhibits extinction impairments. The present study was designed to determine whether VNS could enhance extinction of conditioned fear in SPS-treated animals. Following auditory fear conditioning, extinction training was paired with VNS or sham stimulation. Animals that underwent SPS showed impaired extinction of conditioned fear and VNS administration significantly enhanced extinction of the conditioned fear ($F(3,30) = 6.85$, $p = .001$ vs. sham control). Importantly, conditioned fear responding in SPS-treated rats given VNS during extinction was not significantly different from that of non-SPS control animals ($p = 0.426$).

These findings suggest that VNS may be an effective adjunct to exposure therapy in the treatment of PTSD.

Title: Biallelic expression mapping of the imprinted Grb10 locus reveals novel fear-suppressive neurons in the periaqueductal gray

Authors: *E. SZELENYI[1,2], R. PALANISWAMY[1], H. SCHIFF[1], J. TUCCIARONE[1,2], J. HUANG[1], B. LI[1], P. OSTEN[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Program in Neuroscience, Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Neural ensembles participating in a behavioral circuit span both overlapping and mixed sets of cell types across several brain regions. Routine cell type-based dissections of circuits are therefore limited to deductive conclusions, being inherently unable to define and manipulate a circuit with great behavioral specificity. As an alternative to a cell type-based circuit approach, we have turned to the study of genomic imprinting the phenomenon of monoallelic expression based on parent-of-origin to explore whether the spatial profile and choice of allelic expression (e.g. paternal, maternal, biallelic) amongst an imprinted gene defines the nodes of a behavioral neural circuit. For this purpose, we have generated novel non-gene disruptive allelic-reporter/Cre mouse lines to map, trace, and manipulate the activity of neurons expressing the behaviorally relevant Grb10 imprinted locus. Single-cell, allele-specific expression was visualized in the progeny of reporter line crosses, in which nuclear-targeted fluorescent proteins with/without Cre recombinase (H2B-Venus and H2B-tdTomato-iCre) were assigned to either allele based on parent-of-origin. Dichromatic expression mapping revealed predominant and diffuse monoallelic paternal Grb10 (patGrb10) expression in subcortical neurons and monoallelic maternal (matGrb10) expression within non-neuronal cells of the vasculature. Biallelic neuronal populations, indicated by strong matGrb10 expression, were interestingly found in several subcortical nodes. Cre-dependent tracing of matGrb10+ neurons within the ventrolateral subdivision of the periaqueductal grey (vlPAG), the densest neuronal matGrb10+ node, revealed distinctive connectivity within a previously described fear circuit. Specifically, long-range ascending projections were observed most notably in midline thalamic, amygdalar, and extra-amygdalar structures, whereas inputs originated mainly from local tectal

sources including the superior colliculus and dorsolateral PAG. We therefore asked if these cells play a role in fear behavior using Pavlovian fear conditioning. Compared to Cre- animals, apoptotic ablation prior to fear conditioning unexpectedly enhanced the rate of fear memory acquisition and the level of its expression, thus suggesting a fear suppressive role for these cells. Our study therefore establishes the utility of imprinted gene expression mapping as a unique guide accommodating behavioral circuit discovery represented by our identification of novel matGrb10+ vlPAG neurons that gate fear responses.

Title: Topographic stress-induced sensitivity of the dorsal raphe following antidepressant treatment in a rat model of depression

Authors: ***J. A. BABB**[1,2], S. E. LINNROS[1,3], K. G. COMMONS[1,2];
[1]Anesthesiology, Perioperative, and Pain Med., Boston Children's Hosp., Boston, MA;

Abstract: The neurotransmitter serotonin (5-hydroxytryptamine; 5-HT) is strongly implicated in mood disorders such as depression. Serotonergic neurons originating in the dorsal and median raphe nuclei (DR and MR) are highly organized and provide widespread innervation to the forebrain. Yet it is poorly understood how these neurons dysfunction in depression, or if depression-related changes are topographically organized within these nuclei. Furthermore, while the effects of selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine are well studied in normal animals, it is unclear if and how they might selectively act to ameliorate dysfunction of 5-HT neurons in the depressed brain. Therefore, the goal of this study was to identify whether 5-HT neurons in the DR and MR are differentially altered in an animal model of depression, and to identify to what degree this dysfunction is reversed by antidepressant treatment. Early life stress in the form of transient maternal separation is used as a model of depression in rodents that generates many behavioral changes in adulthood. This model exhibits some construct validity for depression in humans, as it is well known that stress, particularly occurring in early life, can increase ones vulnerability to psychiatric illnesses such as depression

later in life. In this study, rat pups were subjected to 3hr of maternal separation daily from postnatal day (PND) 2 to PND 15, or were left undisturbed. After weaning, all animals were housed in same-sex groups of littermates. Then in adulthood, half of each of these groups received daily s.c. injections of the SSRI fluoxetine (10mg/kg/2ml in 0.9% saline and 1% DMSO) for 14 consecutive days while the other half of animals received daily vehicle injections. One day following the last injection, activation of 5-HT neurons in the raphe of all rats in response to an acute stress (15 min forced swim) was quantified by labeling Fos and tryptophan hydroxylase proteins using immunofluorescence. Preliminary analyses reveal that antidepressant treatment greatly attenuated activation of 5-HT neurons throughout the DR and MR, while the effects of maternal separation stress were more regionally specific. Furthermore, the capacity of fluoxetine to dampen activation of Fos in 5-HT neurons appeared larger in maternally separated rats. Taken together, these results suggest a selective dysfunction of 5-HT neurons in the DR and MR of rats in the depression model that is coupled with a more profound response to fluoxetine. Ongoing analyses are investigating the role of 5-HT1A-dependent feedback inhibition in generating these effects.

Title: Locus coeruleus-ventral tegmental area neural circuit mediates resilience to social defeat stress

Authors: *H. ZHANG[1,2], D. CHAUDHURY[1], B. JUAREZ[1], A. K. FRIEDMAN[1], S. M. KU[1], E. S. CALIPARI[1], A. R. NECTOW[3], M. CRUMILLER[3], J. CHENG[1], H. SUN[1], S. SALTON[1], J. M. FRIEDMAN[3], J.-L. CAO[2], M.-H. HAN[1];

Abstract: The hyperactivity of ventral tegmental area (VTA) dopamine (DA) neurons plays a key role in determining behavioral susceptibility versus resilience to stress in the chronic social defeat paradigm, a well-established model of depression that offers unique opportunities to perform beneficial comparison of these two behavioral phenotypes. It is known that the activity of VTA DA neurons can be regulated by intrinsic ionic mechanisms and extrinsic synaptic inputs from other neural substrates. Locus coeruleus (LC) neurons send heavy projections to the VTA, and has been implicated in the pathophysiology of depression. Here, utilizing multiple circuit-dissecting techniques, we first investigated the firing activities of LC neurons specifically projecting to the VTA (LC-VTA) in the *in vitro* brain slice preparation of stress-naïve control, susceptible and resilient mice. Unexpectedly, we found that LC-VTA neurons fired significantly higher in the resilient subgroup as compared to stress-naïve control, while LC-VTA neurons of susceptible mice had a normal firing activity comparable to that of control mice. Consistently, *in vivo* recordings from anesthetized intact mice further confirmed that LC neurons of resilient mice exhibited higher firing rates and significantly increased phasic firing events as compared to control or susceptible mice. Next, we employed *in vivo* optogenetic techniques to selectively activate LC-VTA neurons with channelrhodopsin, and found that repeated (20 min/day × 10 days), but not acute (5 min during social interaction test), optogenetic activation of LC-VTA neurons in previous susceptible mice completely reversed social avoidance behavior. Interestingly, in previously susceptible mice, repeated optogenetic activation of LC-VTA neurons also induced homeostatic plasticity of VTA DA neurons projecting to nucleus accumbens (NAc), a featured self-tuning adaptive balance between excitatory I_h and inhibitory K^+ channel currents previously identified as an important active mechanism of natural resilience. Furthermore, with a circuit- and cell type-specific molecular profiling technique (*Cell*, 2014), we found that VTA-NAc DA neurons expressed significantly more α1b and β3 adrenoceptors than overall VTA DA neurons. Repeated activation of these adrenoceptors with an agonist cocktail of α1 and β3 adrenoeceptors consistently reversed social avoidance behavior in susceptible mice. These studies unravel a novel neural circuit mechanism underlying natural resilience, and provide a highly useful circuit target to promote resilience and achieve depression treatment, such as for deep brain stimulation therapy.

Title: The effects of isolation stress on UCN1 and TH immunoreactivity in the midbrain of prairie voles

Authors: A. T. WALCOTT, C. M. HOSTETLER, *A. E. RYABININ;
Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Prairie voles (Microtus ochrogaster) are an excellent model to study mechanisms of social stress. This is because they, unlike laboratory rats and mice, are socially monogamous and form long lasting social bonds with specific animals. The corticotropin releasing factor (CRF) peptide system is important for regulation of stress responses. However, the complexity of this peptide system is only beginning to be appreciated. Although the role of CRF in stress has been extensively studied, much the functions of CRF-related peptides urocortin(UCN)1, UCN2 and UCN3 are much less understood. It has previously been shown that various acute stressors in male rats can lead to increased UCN1 expression in the centrally-projecting Edinger-Westphal nucleus (EWcp). Here we studied if male prairie voles that experience a short-term social stress would have different levels of UCN1. At the same time we also examined levels of tyrosine hydroxylase (TH) within EWcp, as a population of dopaminergic neurons are known to intermingle with UCN1 neurons in this brain region. Adult male prairie were either isolated from their cage mates for four days or kept with their same-sex cage mates during this period. We found that social isolation did not lead to significant differences in the number of UCN1- (t_9=0.33, p=0.75) or TH-positive cells (t_9=0.88, p=0.40) in the EWcp. Future studies will be completed using a longer isolation period to cause chronic social stress to understand whether the length of the social stress changes the expression of the UCN1 and TH in the EW.

Title: Critical role of the locus coeruleus-norepinephrine system in social stress-induced cytokine release

Authors: *J. E. FINNELL, C. M. LOMBARD, J. R. FADEL, C. S. WOOD, S. K. WOOD; Pharmacology, Physiology, and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Social stress precipitates psychiatric disorders, however only a subset of the population is susceptible. Coping strategy is known to impact one's resistance to stress; through the use of a resident-intruder paradigm in rats, we previously identified two distinct phenotypic responses to stress characterized by active or passive coping behaviors. Active rats spent more time resisting defeat in upright postures in the presence of a dominant resident rat than did passive rats. In addition, passive rats developed behavioral and neuroendocrine endpoints comparable to a depressive-like state and exaggerated neuroinflammation, while active rats did not. The locus coeruleus (LC), a major source of norepinephrine (NE) in the brain, is implicated in the pathogenesis of depression; however the mechanism by which LC-NE dysregulation may promote depressive disorders has yet to be determined. A growing body of evidence suggests that increased inflammation may play a role in the development of depression. Importantly, NE stimulates microglia activation and proinflammatory cytokine release (ie. IL-1β) in the brain and periphery, suggesting that exaggerated LC-NE activity is capable of increasing proinflammatory cytokines. The present study investigated the role of central NE in stress-induced cytokine release within passive rats susceptible to a depressive-like phenotype. Male Sprague Dawley rats were treated with vehicle or DSP-4 (400 μg/rat icv), a selective noradrenergic neurotoxin that lesions LC-NE projections, one week prior to social defeat or control exposure (30 mins/day, 5 days). 5 days after defeat/control manipulations all rats were exposed to a single social defeat episode (30 min) and brain and plasma were collected immediately following defeat. Cytokine analysis (BioRad Bioplex) showed that animals with a history of social defeat exposure had an exaggerated stress-induced inflammatory response, as evidenced by elevated IL-1β, IL-2 and TNF-α levels compared to rats previously exposed to control ($p<0.05$). Treatment with DSP-4 blocked the social stress-induced increase in inflammation in rats with both prior control and repeated defeat exposure ($p<0.05$). Together these data suggest that a history of social stress sensitizes the inflammatory response following a subsequent re-exposure to the same stressor. Furthermore, these data indicate that the LC plays a critical role in social stress-induced cytokine release. As such, the impact of the LC-NE system on pro-inflammatory cytokines may represent a putative mechanism by which stress can precipitate depressive-disorders. Title: Ventral tegmental area dopamine neurons trigger fear extinction learning

Authors: *R. LUO[1], Y. TAO[1,2], L. PRESTON[3,4], J. KOIVUMAA[3], J. JOHANSEN[3]; [1]RIKEN Brain Sci. Inst. - Wako, Wako-Shi, Saitama, Japan; [2]Joint Inst. for Advanced Biomed. Sci., Waseda Univ., Tokyo, Japan; [3]RIKEN BSI, Wako-shi, Japan; [4]Biol. Sci., Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: Although learning to fear and predict danger is critical to survival, reversing or extinguishing fear memories is important when threats are no longer present. The neural signals which detect when fear responses should be disengaged are not known. During fear conditioning, animals learn that an auditory stimulus (conditioned stimulus CS) predicts the occurrence of an aversive shock (unconditioned stimulus US) and learn to freeze to the CS alone. If the CS is presented over many trials in the absence of shock, animals learn to reduce their freezing behavior, a process termed fear extinction. Prior work has shown that midbrain dopamine neurons in the ventral tegmental area (VTA) are activated by better than expected outcomes including rewards and the omission of expected aversive events. This suggests dopamine neurons may provide a signal to initiate extinction learning when aversive outcomes are no longer present. To investigate whether activity in VTA dopamine neurons during the omission of expected shock is necessary for extinction learning, we expressed the inhibitory halorhodopsin in TH+ VTA neurons of TH-cre rats. After animals underwent fear conditioning, the activity of this cell population was optically inhibited during the period when the expected aversive US is omitted during fear extinction. Inhibition of VTA dopamine cells specifically during the omitted shock period resulted in an inability to extinguish fear memories, as seen in elevated CS-evoked freezing during the course of extinction training as well as 24 hours after extinction. Pairings of an auditory CS with inhibition of dopamine neurons alone without shock did not produce fear learning, indicating that optical inhibition by itself did not lead to freezing behavior. To see whether activity in VTA dopamine neurons during shock omission regulates a distributed extinction learning circuit, we examined the effect of optogenetic manipulation of this cell population on MAP kinase phosphorylation (pMAPK) in the amygdala and medial prefrontal cortex (mPFC). Because pMAPK is required for, and upregulated after extinction in both mPFC and amygdala, we assayed pMAPK levels one hour after extinction learning with or without optogenetic inhibition of TH+ VTA neurons during the shock omission period. We found that extinction learning increased pMAPK levels in both amygdala and IL and that this increase was abolished when VTA dopamine cells were inhibited. Together these results suggest that

activation of VTA dopamine cells by the unexpected omission of an aversive outcome is required to initiate fear extinction learning by regulating neural plasticity across a distributed extinction learning circuit.

Abstract: Introduction. Prior work has demonstrated stress reactivity is associated with decreased activation in the vmPFC (Pruessner et al., 2008), and altered functional connectivity within the PFC-amygdala network (Kim et al., 2011). However, the changes in functional connectivity associated with stress and the relationship between structural connectivity and cortisol release have received limited attention. Therefore, the present study investigated the relationship between functional and structural indices of brain connectivity and cortisol release in response to a stressful task. Methods. Functional magnetic resonance images (fMRI), diffusion tensor images (DTI), and stress response (indexed via cortisol, heart rate (HR), and skin conductance response (SCR)) were collected from 100 participants completing the Montreal Imaging Stress Task (MIST) (Dedovic et al., 2005). The MIST is a psychosocial stress task which contains a non-stressful 'Control' condition as well as a 'Stress' condition. Effective connectivity (EC) during the MIST was assessed using Granger causality and served as an index of functional connectivity. Cortisol data was collected pre- and post-MIST. Whole brain DTI was acquired in 60 directions following the MIST and fractional anisotropy (FA) was used as an index of structural white matter connectivity. Results. HR, SCR, and stress ratings were significantly greater during the Stress condition compared to the Control condition, confirming that the experimental manipulation was successful. Functional MRI data demonstrated differential activation of dmPFC, vmPFC, and amygdala under Stress versus Control conditions during the MIST. EC values were computed using the timecourse from these regions. EC results

demonstrated greater connectivity within the dmPFC-vmPFC-amygdala network during the Control condition compared to the Stress condition. Cortisol reactivity (i.e. increase in cortisol from pre- to post-MIST) was associated with greater FA within the bilateral uncinate fasciculus (white matter tract connecting vmPFC to amygdala). Conclusions. Structural and functional indices of neural connectivity were associated with the stress response. Lower EC during the Stress compared to the Control condition suggests functional connectivity is disrupted during Stress. In addition, participants with the greatest cortisol reactivity showed the greatest FA in the uncinate fasciculus. This finding suggests the uncinate plays an important role in mediating cortisol reactivity to psychosocial stress. Current findings provide novel insights into neural mechanisms that may mediate susceptibility to psychosocial stress.

Title: Obese rats have enhanced panic-like sensitivity to brief hypercarbic air (CO2) exposure

Authors: *A. R. ABREU[1,3], A. I. MOLOSH[3,4], L. LI[4,5], I. F. CALIMAN[8,3], C. S. BERNABE[5,6], P. L. JOHNSON[6], R. C. A. DE MENEZES[2], A. SHEKHAR[3,4,7];

Sch. of Med., Indianapolis, IN; [8]Dept. of Physiological Sci., Federal Univ. of Espirito Santo, Vitoria, Vitoria, Brazil

Abstract: Brief inspiration of hypercarbic air (air containing >10% concentrations of carbon dioxide, CO2) mobilizes respiratory, sympathetic and hypothalamic-pituitary-adrenal axis responses and increases anxiety-like behavior in normal rats and humans, whereas, such levels of hypercarbia induces panic attacks in the majority of panic disorder patients. Likewise, previous experiments from our group demonstrated that obesity, induced by a high fat diet (HFD), potentiates the cardiovascular response produced by air jet stress in rats, probably due to a reduced GABA-mediated inhibition within the dorsomedial hypothalamus (DMH). Moreover, it is known that chronic reduction of GABA function in the DMH leads to the development of panic-like disorder. Therefore the aim of this study was to evaluate the influence of obesity,

induced by HFD, on the behavior responses induced by acute CO2 gas exposure. Male Wistar (100±10g) rats were fed a control diet or a HFD (45% w/w fat, both from Harlan Laboratories) for 9 weeks. Next, conscious adult rats were placed in air-flow controlled cages and exposed to either atmospheric air (ATM) or increasing environmental CO2 concentrations (from baseline concentrations up to 20%) during a 5 min period. After this period the rats were submitted to the open-field arena. During exposure, obese rats exposed to CO2 (n=6), compared to ATM (n=5) had more fecal pellets in the chamber (0.8±0.6 vs. 3.5±0.6; p=0.0090; all results by unpaired t-test). In the open field post CO(2), obese rats demonstrated increased number of freezing episodes (65.8±2.0 vs. 81.33±3.0; p=0.0028), time freezing (71.1±7.6 vs. 115.9±5.9; p=0.0011), as well as decreased total distance (0.4±0 vs. 0.2±0; p=0.0005), line crossings (312.2±16.5 vs. 204.5±12.9; p=0.0005), entries (35.6±3.7 vs. 21.8±3.1; p=0.0186) and distance in corner (0.05±0.01 vs. 0.02±0.04; p=0.0035), distance in periphery (0.2±0 vs. 0.1±0; p=0.0075) and distance in middle (0.09±0.01 vs. 0.06±0.01; p=0.0262). In contrast, no changes were observed when control rats were exposed to CO2 (n=6) compared to ATM (n=6). Additionally, CO2 increased time freezing (95.7±6.2 vs. 115.9± 5.9; p=0.0411) and the number of fecal pellets (1.4±0.7 vs. 3.5±0.6; p=0.0428) in obese (n=6) compared with control (n=6) rats. These results suggest that high fat diet-induced obesity leads to panic vulnerability following brief CO2 gas exposure in rats.

Title: Further evidence of a role for the lateral hypothalamic area juxtadorsomedial region (LHAjd) in the expression of social context-related defensive behaviors

Authors: J. D. HAHN[1], M. J. RANGEL[2], *N. S. CANTERAS[3];
[1]Dept. of Biol. Sci., USC, Los Angeles, CA; [2]Dept. of Anat., [3]Inst. Biomed Sci., Sao Paulo 05508, Brazil

Abstract: Following a revised lateral hypothalamic area (LHA) parcellation (Swanson, L. W. 2004), several studies in recent years have reevaluated the extrinsic connections of the LHA. A major finding of these studies is indicated connectional relations between different LHA regions and different types of innate behavior: Ingestive, agonistic, and reproductive. The focus of the present research is the LHA juxtadorsomedial region (LHAjd). A recent comprehensive analysis of LHAjd connections indicated a high level of connectivity with several regions implicated in defensive behavioral responses (Hahn, J. D. & Swanson, L. W. 2012). In support of this putative role, a recent study reported increased LHAjd expression of immediate early gene product c-Fos after exposure to a social-defeat related context in a resident-intruder paradigm (Faturi, C. B., Rangel, M. J. et al., 2013). To explore this further, the present study used the same paradigm to test the hypothesis that the LHAjd is necessary for the expression of social-defeat related contextual defensive behaviors. Male Wistar rats (n = 20) received stereotaxic bilateral LHAjd NMDA injections. After a recovery period, the rats were habituated to a resident-intruder testing apparatus prior to a brief encounter with a resident male conspecific. During the encounter testing the habituated "intruder" was free to interact with the resident in the latter's home compartment. The next day the intruders were tested for behavioral responses to the encounter context in the absence of the resident. Encounter and context testing was video recorded. Intact and sham-lesion control groups were similarly tested. Behavioral scoring from the video recordings was done for stereotyped behavioral responses recorded during encounter and context testing, these included (for encounter): Passive and active defense, locomotion, grooming, and social investigation; (for context): Risk assessment, exploration, rearing, grooming, and flight. Statistical analysis revealed a significant effect on contextual behaviors: A significant decrease in risk assessment and a significant increase in exploration behaviors in LHAjd-lesioned intruders compared to LHAjd sham-lesioned and intact rats. Behavioral scores also revealed a marked encounter-associated increase in active defense and social investigation, and a marked decrease in passive defense, but these did not quite reach significance. These findings provide further evidence for LHAjd involvement in the expression of defensive behaviors, and add to the growing body of research indicating different involvement of differentiable LHA regions in the control of fundamental behaviors.

Title: Prolonged corticosterone exposure decreases neuronal activity and dampens glutamatergic drive to CRH neurons in the paraventricular nucleus of the hypothalamus

Authors: *N. RASIAH, J. BAINS;
Hotchkiss Brain Inst. - Univ. of Calgary, Calgary, AB, Canada

Abstract: Corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus of the hypothalamus (PVN) guide the endocrine output of the hypothalamic-adrenocorticotropic axes (HPA). Activation of the HPA culminates in release of corticosterone (CORT), which feeds back to modify neural circuitry. We have previously shown that acute CORT acts a metaplastic signal at glutamate and GABA synapses in the PVN, but the consequences of chronic CORT on intrinsic excitability and synaptic drive to CRH neurons are unresolved. Here, using a mouse line in which CRH neurons can be identified based on the expression of a TdTomato fluorescent marker, we obtained on-cell recordings to examine intrinsic neuronal activity. Then, from the same cells, we obtained whole-cell recordings to examine spontaneous excitatory post-synaptic currents (sEPSCs). In naïve animals, CRH neurons have a mean firing rate of 2.83 ± 0.35 Hz (n=21), a mean sEPSCs frequency of 3.27 ± 0.46 Hz (n=21), and mean sEPSC amplitude of 22.79 ± 1.43 pA (n=21). In CORT treated animals (25μg/mL CORT in drinking water for 1 week), neuronal activity was significantly reduced (0.11 ± 0.05 Hz, n=20, $P < 0.0001$ versus controls), sEPSC frequency was unchanged (3.64 ± 0.65 Hz, n=20). We did note a significant decrease in sEPSC amplitude following chronic CORT exposure (16.06 ± 0.6 pA, n=20, $P < 0.0001$ versus controls). In addition to these changes, there was a rightward shift in the F-I plot following chronic CORT, which is consistent with decreased intrinsic excitability. These results are in line with previous work showing changes to excitatory synapses following chronic CORT exposure in the PFC and hippocampus. Because CRH neurons in the PVN are key mediators of the HPA response to stress, studying the effect chronic CORT on these cells will facilitate understanding of how chronic stress leads to HPA dysfunction and ultimately, the development of various psychiatric disorders. This study was funded by C.I.H.R.

Title: Use of FDG positron emission tomography to visualize brain activation in a model of stress relief by "comfort" food

Authors: *A. E. EGAN[1,2], J. C. ELIASSEN[1], M. NORRIS[1], L. C. LEMEN[4], K. LASANCE[3], Y. M. ULRICH-LAI[1];
[1]Psychiatry and Behavioral Neurosci., [2]Neurosci. Grad. Program, [3]Vontz Res. Ctr. for Mol. Studies, Univ. of Cincinnati, Cincinnati, OH; [4]Radiology, Univ. of Cincinati, Cincinnati, OH

Abstract: A history of limited sucrose intake reduces hypothalamic-pituitary-adrenocortical (HPA) axis, sympathetic, and behavioral stress responses to stress, similar to stress relief by "comfort" foods. Prior neurotoxic lesion studies indicate that the basolateral amygdala (BLA) and medial prefrontal cortex (mPFC) are both necessary for this sucrose stress relief. In addition, the known anatomical projections of the BLA and mPFC suggest they are unlikely to work alone. However, it is not known what other brain regions work with the BLA and mPFC to produce stress relief by palatable foods. In order to address this question, brain activation was studied with [18]F-FDG positron emission tomography (PET) scans. Adult, male Long-Evans rats with ad libitum access to chow and water were given additional brief (up to 30 min), limited (up to 4 ml per session) access to 30% sucrose drink (or water as a control) twice-daily for 14 days. On day 15, rats were fasted overnight, and half of each drink group was given a 20-minute restraint stress, with the other half remaining unstressed. Immediately following the restraint stress (or equivalent unstressed time), rats underwent a 30-minute PET scan to visualize FDG uptake in the brain. Preliminary results showed that unstressed rats have higher global brain activation regardless of drink type. Further analysis will use a combination of voxel-wise comparisons and region of interest (ROI) analyses to determine specific brain regions that are differentially activated based on stress history or drink type.

Title: Aged garlic extract increases neuropeptide y, superoxide dismutase 2, catalase and glutathione peroxidase mRNA levels in hypothalamus of diabetic rats

Authors: M. BARRAGAN-BONILLA[1], P. AGUILERA[2], *M. ESPINOZA[3];
[1]Lab. Biología Mol. y Genómica, Ciencias Químico Biológicas, Univ. Autonoma de Guerrero, Chilpancingo, Guerrero, Mexico; [2]Lab. Patología Vascular cerebral, Inst. Nacional de Neurología y Neurocirugía, Distrito Federal, Mexico, Mexico; [3]Monica Espinoza Rojo, Chilpancingo, Gro., Mexico

Abstract: The hypothalamus is a brain region that regulates feeding behavior, and recent studies have shown that it has a role in glucose homeostasis. Neuropeptide Y (NPY) is an important hypothalamic orexigenic neuropeptide, related with regulation of feeding and promotion hyperphagia. Moreover, hypothalamic reactive species oxygen (ROS) production are key to the central regulation of satiety. However, during diabetes mellitus (DM), has been reported that exist hyperphagia and oxidative stress. The oxidative stress is characterized by excessive production of ROS which is involved in diabetic complications, and reduction of antioxidant defense mechanisms. It has been shown that substances with antioxidant capacity, regulate the excessive production of ROS, glucose levels and improve several complications found in the DM, but still not known molecular mechanism by which they exert this effect. Therefore, the aim of this study was to determinate whether an antioxidant as aged garlic extract (AGE) has effect on gene expression of NPY and antioxidant enzymes [superoxide dismutase (SOD), catalase (CAT) and glutathione peroxidase (GPX)] in normal and diabetic rats. For this purpose, male Wistar rats (280-350g) were used. AGE (200mg/kg bw) was administered daily oral or intraperitoneally (i.p.) for 4 weeks to control and diabetic rats. Diabetes was induced by treatment with streptozotocin (60mg/kg bw) i.p. 24 hours after last treatment, blood was collected for estimation of glucose, and the animals were killed by cervical decapitation. Hypothalamic region was separated from brain tissue to determinate NPY, SOD, CAT and GPx mRNA levels by performing RNA extraction, reverse transcription and real-time PCR. In our study model, diabetic rats showed increase of blood glucose (p0.05). I.p. and oral administration of AGE to diabetic rats attenuated their increment in blood sugar level. These findings suggest that the daily administration of 200 mg/kg bw AGE have anti-hyperglycemic activity. However, gene expression of NPY, SOD-2, CAT and GPX was increased significantly in hypothalamus of control and diabetic rats treated with AGE only via i.p. ($p<0.05$), probably by their ability to activate the transcription factor as Nrf2, which is activated by S-allylcisteine (SAC), an abundant component of AGE. Finally, whether the increased expression of NPY is associated with hyperphagia or not is yet to be determined.

[1]Max Planck Inst. of Psychiatry, Munich, Germany; [2]Lead Discovery Ctr., Dortmund, Germany

Abstract: Anxiety-related psychiatric disorders represent one of the largest health burdens worldwide. Single nucleotide polymorphisms of the FK506 binding protein 51 (FKBP51) gene have been repeatedly associated with anxiety-related disorders and stress sensitivity. Given the intimate relationship of stress and anxiety, we hypothesized that amygdala FKBP51 may mediate anxiety-related behaviors. Mimicking the stress effect by specifically overexpressing FKBP51 in the basolateral amygdala (BLA) or central amygdala (CeA) resulted in increased anxiety-related behavior, respectively. In contrast, application of a highly selective FKBP51 point mutant antagonist, following FKBP51mut BLA-overexpression, reduced the anxiogenic phenotype. We subsequently used a novel FKBP51 antagonist, SAFit2, in wild-type mice via BLA micro-injections, which reduced anxiety-related behavior. Remarkably, the same effect was observed following peripheral administration of SAFit2. To our knowledge, this is the first in-vivo study using a specific FKBP51 antagonist, thereby unraveling the role of FKBP51 and its potential as a novel drug target for the improved treatment of anxiety-related disorders.

Title: Prostaglandin E2 inhibits GABAergic synaptic transmission onto parvocellular neuroendocrine cells in the paraventricular nucleus of the hypothalamus

Authors: *W. INOUE;
Univ. of Western Ontario, London, ON, Canada

Abstract: Immune-induced activation of the hypothalamic-pituitary-adrenal (HPA) axis and ensuing release of anti-inflammatory glucocorticoids are critical for the fine tuning of the inflammatory response. Although prostaglandin E2 (PGE2) has a well defined role in the immune-induced activation of parvocellular neuroendocrine cells (PNCs) in the hypothalamic

paraventricular nucleus (PVN), it remains unclear if and how PGE2 modulates synaptic inputs onto PNCs. Using whole-cell patch clamp recordings obtained from PNCs in an *ex vivo* hypothalamic slice (P21-35 male Sprague-Dawley rats), I evaluated the effect of PGE2 on GABAergic-mediated inhibitory synaptic transmission. Bath application of PGE2 (0.01−100 μM) dose dependently decreased the amplitude of evoked inhibitory postsynaptic currents (eIPSCs) with maximal effect at 10 μM (48.9 ± 7.9 % of baseline). The PGE2-mediated (10 μM) depression of eIPSCs had a rapid onset (significant inhibition by 3 min), was long-lasting (55.2 ± 10.1 % inhibition at 25 min after wash out) and accompanied by an increase in paired pulse ratio (149.5 ± 14 % of baseline). In addition, PGE2 decreased the frequency (41.1 ± 6.1 % of baseline) but not the amplitude (101.0 ± 11.0 % of baseline) of spontaneous IPSCs, suggesting that PGE2 acted at a presynaptic locus to decrease the probability of GABA release. Inclusion of BAPTA (10 mM) in the pipette solution to prevent a rise in postsynaptic Ca2+ failed to affect the PGE2-mediated inhibition of eIPSCs, thereby ruling out a role for the Ca2+-dependent release of a retrograde messenger. I demonstrate that PGE2 causes a long-lasting depression of GABA release onto PNCs, providing a plausible mechanism for the disinhibition of HPA output during inflammation.

Title: The lateral septum and anterior hypothalamus work in tandem to regulate defensive burying

Authors: *S. J. LAMONTAGNE, M. C. OLMSTEAD, J. L. MENARD;
Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: The lateral septum (LS) and anterior hypothalamus (AHA) are heavily inter-connected and independently implicated in behavioural defense regulation. The current study examined whether these two structures work in tandem to regulate rats' defensive responses toward a potential threat (as modeled in the elevated plus-maze) and a present, localizable threat (as modeled in the shock-probe burying test). A pharmacological disconnection technique was used: rats (n = 8) in the experimental condition received co-infusions of muscimol into one side of the lateral septum and contralateral anterior hypothalamus, and rats in the three control conditions received either contralateral infusions of saline (n = 9) into both structures or unilateral infusions

of muscimol into one structure (LS, n = 8; AHA n = 6), combined with saline in the contralateral side of the other structure. Five minutes after their infusions, rats were tested in the plus-maze. One week later, they received a second infusion and were tested in the burying test. Co-infusions of muscimol into one side of the LS and the contralateral AHA significantly suppressed rats' shock-probe burying without altering their open-arm avoidance in the plus-maze. No behavioural effects were observed following unilateral infusions of muscimol into either structure alone. Together, these findings suggest that the LS and AHA work in a serial fashion to regulate rats' innate defensive behaviours toward threats that are present and localizable in their immediate environment but not toward potential threats that might or might not be present.

Title: The minor spliceosome snRNA's U4atac and U6atac are down regulated in starvation induced stress response

Authors: *N. STURROCK[1], J. SIKKA[2], M. BAUMGARTNER[2], C. LEMOINE[2], R. KANADIA[2];
[1]Physiol. and Neurobio. U3165 Kanadia, [2]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: The drive to eat versus satiation is mediated through the oppositional firing behavior of orexigenic neurons expressing AgRP and NPY along with anorexigenic neurons expressing POMC. This balance in neuronal activity relies on signaling from a variety of stress response pathways, which if disrupted can cause eating disorders like anorexia or hyperphagia. The consequence of hyperphagia is often obesity, a growing global epidemic. Significant effort has been placed on understanding the neurophysiological and metabolic regulation of these neurons. However, not much is known about the role of splicing in regulating the production of proteins required to execute the neuronal activity necessary for the proper functioning of these neurons. The minor spliceosome, responsible for splicing just 1% of genes, is implicated in regulating calcium homeostasis, which when disrupted can cause increased reactive oxygen species (ROS). Eating behaviors reliance on ROS levels means that changes in calcium homeostasis may affect its regulation, which suggests that the minor spliceosome might play a vital role in regulating

eating behavior. The minor spliceosome, as the name suggests is splicing machinery that parallels the ubiquitous major spliceosome. The minor spliceosome has four essential small nuclear RNAs (snRNA's) including U11, U12, U4atac, U6atac and shares U5 snRNA from the major spliceosome. Recently it was shown that U6atac levels are rate-limiting to the efficiency of minor spliceosome and is upregulated under stress to increase efficiency of minor intron splicing thereby increasing protein production. Here we explored the expression of minor spliceosome snRNA's in the ventral medial hypothalamus and the arcuate of 48-hour fasted animals. Section *in situ* hybridization and qPCR showed that the minor spliceosomes snRNAs U6atac and U4atac were downregulated in the ventral medial hypothalamus and the arcuate of 48-hour fasted animals. Importantly, this change was not observed in the cortical neurons. These data suggests the minor spliceosome is actively downregulated as a response to fasting and exploration of its targets (ongoing) will help bring to light the role of minor spliceosome in regulation of feeding behavior.

Title: Delays in proactive inhibition are specific to adolescence

Authors: *M. CHODAKEWITZ[1], H. C. MEYER[2], D. J. BUCCI[2];
[2]Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH

Abstract: Previous research has postulated that the differential development of subcortical reward areas and top-down control systems results in a functional imbalance that affects inhibitory control during adolescence. Specifically, that development of the prefrontal cortex lags behind development of the nucleus accubmens (NAC) and that NAC is sensitized in adolescents compared to both children and adults. This model has garnered substantial support in recent years from neuroimaging and behavioral studies in humans, as well as electrophysiological studies in lab animals. However, little research has focused on the pattern of inhibitory behavior across the adolescent period in rodents. The present research aimed to model inhibition as it most often manifests in the lives of adolescents; specifically, situations in which

the meaning of a stimulus (respond or not) is ambiguous and can change on a moment to moment basis. Thus, the present research utilized a negative occasion setting paradigm (NOS), in which the inhibitory properties of a stimulus only apply to a specific circumstance. In this paradigm, a "target" stimulus presented by itself is followed immediately by delivery of a food reward. However, when a "feature" stimulus is presented just before the target, food is not delivered. Importantly, NOS involves learning the meaning of a cue in the environment and applying it to withhold a response before it is initiated. This form of proactive inhibition is distinct from forms of inhibition present in other behavioral models, such as Stop-Signal Reaction Time task and the 5-choice serial reaction time task. Our laboratory has previously demonstrated that adolescent rats (ie, starting training on PND 35) require ~18 sessions, almost twice as many as adults, to exhibit inhibition during NOS. To determine how this behavior manifests across development, separate cohorts of rats began training on PND 40 or PND 30. Consistent with our results in 35 day old rats, we observed a delay in the ability to withhold behavior when rats began training at PND 40. Indeed, these rats required 13 sessions to exhibit inhibition, three more than required for adult rats. Importantly, this suggests that the ability to withhold behavior improves across adolescence. Conversely, rats that began training at PND 30 only required 10 sessions to exhibit inhibition. These data are consistent with evidence suggesting that although the ability to control behavior is evident earlier in development, adolescents often forgo appropriate behaviors in the face of reward. Taken together, these results indicate that NOS performance is mediated by factors that are differentially activated during adolescence.

Title: Age differences in the extinction of Pavlovian excitatory responding

Authors: ***D. J. BUCCI**[1], H. C. MEYER[2];
[2]Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH

Abstract: Previous research suggests that environmental cues signaling a potential reward may drive incentive-seeking behavior to a greater extent in adolescents than in children or adults. Furthermore, adolescents are often unable to exert behavioral control in the face of environmentally salient cues. However, the majority of results demonstrating that reward-cue

processing differs during adolescence comes from human neuroimaging and behavioral studies. Indeed, rodent literature has primarily focused on behavioral differences during the implementation of an instrumental response in service of obtaining reinforcement. Conversely, less is known about how adolescent rodents process and respond to Pavlovian cues. Thus, the present experiments elucidated the age differences in Pavlovian anticipatory responding during an auditory stimulus indicating the impending delivery of a reinforcer. Separate cohorts of adolescent (beginning training on PND 35) and adult rats were trained in a simple discrimination consisting of 8 presentations of a reinforced stimulus (CS1+) immediately followed by a food reward and 8 presentations of a non-reinforced stimulus (CS2-). The primary variable of interest was anticipatory nose-pokes into the recessed magazine where food was delivered. We determined that adolescents and adults learned to discriminate between these stimuli at comparable rates and responded significantly more during CS1+ than CS2-. After 8 days of acquisition training, responding was extinguished during two daily sessions in which all rats were presented with 30 presentations of each stimulus and no reinforcer (CS1-; CS2-). We found that adolescent rats persisted in responding during the previously reinforced CS1 for longer than adult rats, although by the end of the second training session all rats displayed similar low levels of responding during all cues. In a subsequent test for retention 96-hours later, adolescents displayed higher levels of spontaneous recovery of responding to CS1 than adults. Our data suggest that although adolescents acquire Pavlovian approach to a novel cue at an equal rate, they experience difficulties learning a secondary inhibitory meaning of same cue during extinction. The acquisition of competing excitatory and inhibitory representations during extinction parallels the type of learning that occurs during negative occasion setting, in which rats must learn to respond differentially during presentations of one cue based on the presence or absence of a second cue. Thus, the present results may be useful in elucidating the behavioral patterns observed during adolescent negative occasion setting (see accompanying poster).

Title: Response inhibition after extinction: optogenetic activation of the infralimbic prefrontal cortex reduces the spontaneous recovery and reinstatement of appetitive Pavlovian conditioning

Authors: *F. LACROIX, D. SPARKS, C. SANIO, A. CHAPMAN, N. CHAUDHRI; Psychology/Center for Studies in Behavioural Neurosci., Concordia Univ., Montreal, QC, Canada

Abstract: Extinction occurs when a Pavlovian conditioned stimulus (CS) that predicts a reinforcer is subsequently experienced without that reinforcer. The infralimbic prefrontal cortex (IL) is believed to play a pivotal role in inhibiting responding to a CS after extinction has taken place. Based on this hypothesis, we predicted that activating the IL during CS trials using optogenetics would decrease spontaneous recovery (SR) and reinstatement of sucrose-seeking. To investigate this research question, male Long-Evans rats (Charles River, 220-240 g) received a unilateral microinfusion (0.5 µl) of virus coding for yellow fluorescent protein (AAV-CAMKIIa-eYFP) or channelrhodopsin-2 and eYFP (AAV-CAMKIIa-hChR2-eYFP) into the IL (AP +2.9, ML ±0.6, DV -5.1), followed by an optical fiber targeting the same region. Next, rats underwent Pavlovian conditioning sessions (9 sessions, 40 min each) in which CS trials (10 s white noise, 14 trials/session, VT-120s) were paired with 10% sucrose (10S, 0.2 ml/CS). Entries into a fluid port where 10S was delivered were measured. Extinction sessions were then conducted in which the CS was presented as before, but without 10S. In Experiment 1, rats received 1 extinction session, followed by 2 additional extinction sessions 24 h and 26 days later to test SR. Photostimulation (473 nm; 20 Hz; 5 ms pulses; 10,002 ms duration) was administered during each CS trial at test. The spontaneous recovery of port entries during the CS observed in rats expressing eYFP only (n=6) was significantly reduced on a trial-by-trial basis in the ChR2 group (n=6). In Experiment 2, Pavlovian conditioning was followed by 6 extinction sessions and two reinstatement tests. At test, a 0.2 ml prime of 10S occurred before the first CS trial, and each CS trial was paired with photostimulation. A reinstatement of port entries during the CS was observed in rats expressing eYFP only (n=12), but not in rats expressing ChR2 (n=8). Subsequently, photostimulation delivered during CS trials enhanced the reacquisition of Pavlovian conditioning in rats expressing ChR2, compared to eYFP controls. *In vitro* patch clamp recordings confirmed that IL pyramidal neurons expressing ChR2 spiked with high fidelity in response to light stimulation frequencies up to 20Hz inclusively. These findings support the hypothesis that the activity of IL neurons suppresses conditioned behavior after extinction, and suggest a novel role for the IL in promoting the re-learning of excitatory, appetitive Pavlovian associations following extinction.

Title: Differential recruitment of the medial prefrontal cortex and hippocampal formation during renewal of conditioned responses to food cues in male and female rats

Authors: *L. C. ANDERSON, G. D. PETROVICH;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Food cues can stimulate appetite in the absence of hunger and contribute to obesity. Renewal, or reinstatement, of responding to food cues after extinction may explain the inability to resist palatable foods and change maladaptive eating habits. Recently, we found sex differences in renewal of extinguished Pavlovian conditioned responses to food cues. Here, we examined recruitment (Fos induction) of telencephalic regions important for associative learning, decision-making, and contextual processing, the medial prefrontal cortex (mPFC) and hippocampal formation, during renewal in male and female rats. We used a context-dependent renewal protocol where conditioning and extinction are conducted in different contexts and the renewal of responding is induced by return to the conditioning context (ABA renewal). Control groups remain in the same context during acquisition, extinction, and test (AAA). Rats were trained to associate a tone (conditioned stimulus, CS) with food (unconditioned stimulus) in 5 acquisition sessions. Acquisition was followed by 2 extinction sessions with CS-only presentations. Rats were then tested for renewal of responding with CS-only presentations in a single session. The measure of learning was an increase in the expression of food cup behavior (conditioned response, CR) during CSs. There were no sex differences during acquisition and responding was similar in extinction. During the test males showed renewal of CRs, while females did not. There was a main effect of sex and experimental condition interaction for CRs ($p < 0.05$), and a significant difference between male groups ($p < 0.05$), but no differences between female groups ($p > 0.05$). Following testing, brain tissue was processed with immunohistochemistry for detection of Fos and total number of neurons with Fos induction was analyzed in areas of interest. Significant differences were found within the infralimbic (ILA), prelimbic (PL), ventral subiculum (SUBv), and dorsal CA1 (CA1d). Within the ILA and PL, Fos induction in males was significantly higher in experimental compared to control groups ($p < 0.05$). The pattern of Fos induction was opposite in females: it was significantly lower in the experimental compared to control groups ($p < 0.05$). Within the CA1d, there was more Fos in the experimental compared to control groups in males, while there were no differences between the female groups ($p < 0.05$ for males). In contrast, in the SUBv, both males and females had significantly higher Fos induction in experimental compared to control groups ($p < 0.05$). These results indicate a distinct mPFC and hippocampal system is recruited during context-dependent renewal in a sex specific way.

Title: Blockade of orexin/hypocretin receptor 1 signaling attenuates Pavlovian cue-food conditioning and extinction

Authors: *S. E. KEEFER, S. COLE, H. S. MAYER, G. D. PETROVICH;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Food cues can drive feeding in the absence of hunger, and orexin/hypocretin (ORX) signaling is necessary for this type of overeating. The current study examined whether ORX also mediates cue-food learning during the initial acquisition and extinction of these associations. In Experiment 1, male, Long-Evans rats underwent two sessions of Pavlovian appetitive conditioning. Conditioning sessions included 8 presentations of a 10s tone (conditioned stimulus, CS) followed by immediate delivery of 2 palatable food pellets (unconditioned stimulus, US) distinct from standard chow. Thirty minutes prior to each session, rats received an i.p. injection of either the ORX 1 receptor antagonist SB-334867 (SB) or vehicle (V) in a crossover design: V/V, V/SB, SB/V and SB/SB (n=8/group). During conditioning session 1, SB had no effect on conditioned responses, measured as percentage of food cup behavior during the CS, or on latency to approach the food cup after the CS onset. During conditioning session 2, all groups that received SB prior to either conditioning session displayed significantly less food cup behavior and had longer latencies to approach the food cup after CS onset compared to the V/V group, signifying SB attenuated learning. In Experiment 2, another group of rats underwent 5 sessions of appetitive conditioning (drug free) followed by 2 extinction sessions, each consisting of 8 CS-only presentations. Thirty minutes prior to each extinction session, rats received an i.p. injection of either SB or V resulting in 4 groups as described above. During extinction session 1, SB had no effect on food cup behavior or latency. During extinction session 2, three distinct differences were found across groups. First, the SB/V group displayed overall more food cup behavior during the CS, and had shorter latencies to the food cup throughout the session compared to the other 3 groups. Food cup behavior of this group persisted during the 10 sec after CS offset when pellets were previously delivered during conditioning, signifying an inhibition of extinction due to exposure to SB during extinction session 1. Second, The SB/SB group displayed more CS specific food cup behavior during the first half of the session compared to the other 3 groups, but significantly decreased this behavior during the session. Third, both groups that received SB prior to session 2 displayed an increase in latency time throughout extinction session 2, while the groups treated with V prior to session 2 did not show this increase. Locomotor behavior was unaffected by SB in either experiment. Together these results suggest a role for ORX signaling during Pavlovian appetitive conditioning and extinction.

Title: Disconnection of the medial prefrontal cortex and lateral hypothalamus system prevents cue-potentiated feeding in sated rats

Authors: ***S. COLE**, S. E. KEEFER, H. S. MAYER, G. D. PETROVICH;
Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: Environmental influences, particularly cues for food, can stimulate feeding in the absence of hunger and ultimately lead to maladaptive overeating behavior. In the cue-potentiated feeding paradigm, a learned food cue can drive eating in sated rats. Previous work has shown that lesions of the medial prefrontal cortex (mPFC) prevent feeding driven by a food-associated context, and that mPFC neurons projecting to the LHA are selectively activated during feeding under a food cue. These findings suggest that communication between the mPFC and LHA is a critical component of the network mediating cue-potentiated feeding. To examine this possibility, here we functionally disconnected the mPFC and LHA prior to a discriminative cue-potentiated feeding procedure. Male, Long-Evans rats received unilateral neurotoxic lesions of the mPFC and LHA in opposite hemispheres (group CONTRA; n=7), the same hemisphere (group IPSI; n=7), or vehicle infusions (group SHAM; n=6). After recovery from surgery, rats were food-deprived and trained across eight days. On each training day all rats received one session consisting of cue-food pairings (CS+), and a second session consisting of a different cue presented alone (CS-). The two cues were a 180s tone and a 180s light, which were counterbalanced across groups. At the completion of training rats were allowed ad libitum access to chow for 3 days prior to the beginning of testing. All animals were tested for consumption during presentations of the cues, CS+ and CS- separately, in a counterbalanced order across two consecutive days. On each day, consumption was first measured before presentations of the cues (baseline), and then during cue-food presentations (CS+ and CS- tests). There were no differences in baseline consumption between groups immediately prior to either CS test (p values > 0.05). During the CS tests, rats consumed significantly more food during the CS+ presentations than during CS- presentations ($p < 0.05$), confirming cue-potentiated feeding. Importantly, this difference was reduced significantly in the CONTRA group compared to the IPSI and SHAM groups ($p < 0.05$), but this difference in consumption between CS+ and CS- tests did not differ significantly between these two control groups ($p > 0.05$). These findings demonstrated that

disconnection of the mPFC and LHA system prevented cue-potentiated feeding in sated rats. Furthermore, the effect was specific to eating driven by a food cue, because the disconnection had no effect on baseline consumption. Future work will examine the specific neurotrasmitter and neuromodulator mechanisms within this mPFC-LHA system that drive this non-homeostatic eating.

Title: Individual variability in outcome devaluation and second- order conditioning predict sign-tracking behavior

Authors: *H. M. NASSER, Y.-W. CHEN, K. A. FISCELLA, A. B. KAWA, D. J. CALU; Behavioral Neurosci. Res. Br., Natl. Inst. of Drug Abuse, Baltimore, MD

Abstract: During autoshaping, where the extension of a lever precedes the delivery of reward, rats show individual differences in conditioned responding; sign-tracking (ST) rats approach/contact the lever, while goal-tracking (GT) rats approach/contact the food cup more than ST. It is hypothesized that ST behavior results from heightened incentive motivation for reward-associated cues, together with reduced goal-directed behavior driven by the current value of the reward. Rats were tested in outcome devaluation (Exp. 1) or second order conditioning (Exp 2) prior to the ST/GT assessment to determine whether ST rats show reduced goal-directed behavior and heightened incentive motivation. To assess goal-directed behavior (Exp. 1), we trained rats to associate a light conditioned stimulus (CS) with food reward. Paired rats received homecage access to the food reward, followed by injections of LiCl (0.3M, 5 ml/kg i.p.), which causes gastric malaise. Unpaired rats received homecage exposure to food reward and LiCl injections, separated by 24 h. Conditioned responding to the light CS was measured in a single probe session. The level of conditioned responding in paired rats during outcome devaluation correlated with the rats' subsequent ST/GT preference scores, with ST rats failing to suppress responding after outcome devaluation. To assess incentive motivation (Exp. 2), we trained rats to discriminate between two light CSs, one light (A) was reinforced with food reward while the other light (B) was non-reinforced. During second order conditioning, one auditory CS predicted A, where another auditory CS predicted B. Conditioned responding to the auditory CS was measured in a single probe session. Second-order conditioning was observed in all rats. ST/GT

scores were correlated with responding to B. That is, ST, but not non-ST rats, show intact auditory CS discrimination, suggesting the incentive properties of A can support second order conditioning in ST rats. The results support the view that ST rats are more sensitive to incentive properties of rewarded cues and have deficits in using information about devalued outcomes to guide goal-directed behavior. This work was supported by IRP/NIDA/NIH.

Title: Disconnection of ventral pallidum and nucleus accumbens shell with DREADDs enhances sign-tracking in rats

Authors: *S. E. CHANG, T. P. TODD, K. S. SMITH;
Dartmouth Col., Hanover, NH

Abstract: An initially neutral conditioned stimulus (CS) that signals delivery of a food unconditioned stimulus (US) can acquire rewarding properties due to the attribution of incentive salience, in which the incentive motivational value of the US is transferred to the CS. As a result, subsequent presentations of the CS may lead to behavior directed towards the CS itself (i.e., sign-tracking) rather than the site of US delivery. Recently, we have shown that disrupting activity in the ventral pallidum (VP) attenuates the acquisition of sign-tracking using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs), a technology that allows for repeated activation of engineered receptors by systemic injection of the otherwise inert ligand clozapine N-oxide (CNO). Previous studies have shown that the nucleus accumbens (NAc) and its dopaminergic inputs are critical for sign-tracking. The VP and NAc are bidirectionally connected, and their disconnection has previously been found to disrupt the ability of a CS to direct instrumental choice behavior. Here we investigated the effects of disconnecting VP and NAc shell on the acquisition of sign-tracking using DREADDs. Two groups of rats received surgery in which unilateral infusions of the inhibitory hM4Di DREADD were virally inserted into the VP and NAc shell. Half of the rats received hM4Di delivery into the VP and NAc shell

in contralateral hemispheres (Group Contra), while the other half received ipsilateral infusions (Group Ipsi). Rats underwent 12 days of training in which each session consisted of 25 CS+ and 25 CS- trials. CS+ trials consisted of insertion of one lever for 10 s that resulted in the delivery of a food US (2 grain pellets) upon retraction, while CS- trials consisted of insertion of another lever that was followed by nothing. Rats received systemic injections of CNO prior to each session. Thus when hM4Di receptors were activated, the VP-NAc shell pathway was disrupted for rats in Group Contra, while the VP-NAc shell pathway was left intact in one hemisphere of Group Ipsi. In contrast to bilateral VP disruption, disconnection of VP and NAc shell dramatically enhanced levels of sign-tracking in Group Contra relative to Group Ipsi. In addition, disconnection of VP and NAc shell reduced food cup behavior during CS presentations. These results suggest that disrupting the VP-NAc pathway can magnify the incentive value attributed to reward-paired cues. This conclusion paradoxical in the context of viewing the NAc and VP as complementing one another for motivation, and suggests that for incentive salience there may be mutual inhibition between them (which current electrophysiological efforts are examining).

Title: Inhibiting ventral pallidum disrupts adaptive salt-seeking behavior in rats

Authors: *K. J. STANSFIELD, S. E. CHANG, K. S. SMITH;
Dartmouth Col., Hanover, NH

Abstract: Much of reinforcement learning involves a process of trial-and-error in which ongoing behavior is iteratively updated when outcomes are received. However, prior experience is not always required for changes in reward seeking. Such non-incremental learning is illustrated by the “salt appetite” phenomenon: animals that have learned to associate a cue with aversively concentrated salt taste will, if deprived of sodium, immediately orient to the cue and seek out salt before the salt has ever been tasted in the sodium-deprived state. The ventral pallidum (VP) plays an important role in aspects of reward learning, motivation, and hedonics, and represents salt appetite in neural dynamics. In a homeostatic state, VP activity occurs to cues associated with pleasant sugar tastes, but not to cues for aversive salt tastes. Yet, immediately after the sodium deprivation, VP neurons become activated by salt-paired cues similarly to sugar-paired cues. The

present study investigated the causal influence of VP on adaptive salt seeking in rats using optogenetics. Half of the rats received infusions of halorhopdopsin (Group Halo) or a control virus (Group Control) into the VP. All rats received bilateral intra-VP fiber implants. Rats then underwent 8 days of place preference training in which they learned to associate one context with a pleasant flavored sucrose solution (4 days) and another context with a distinctly flavored salt solution (4 days). Rats were given a baseline test session in which they were given access to both contexts for the first time with the sucrose and salt removed to measure their baseline preference. Following 2 retraining days in each context, rats were sodium-depleted through systemic injections of furosemide. After 48 hours, rats were placed into the chamber with access to both contexts without sucrose or salt to measure their preference. All rats received yellow laser stimulation (3 s on/off pulses) throughout the entire test session. Thus, VP was inhibited for rats in Group Halo but not for rats in Group Control. We found that rats in Group Control showed a normal "salt appetite", spending more time in the salt-paired context than the sucrose-paired context following sodium depletion (a form of "unconditioned place preference"). In contrast, rats in Group Halo were indifferent and spent equal amounts of time in the contexts. VP inhibition did not affect general motor activity nor salt/sucrose consumption when the solutions were made available. Thus, inhibiting VP selectively impaired the ability of rats to use environmental cues to guide adaptive salt-seeking behavior, highlighting a critical role for this area in adaptive reward seeking.

Title: Genome-wide association study for the propensity to attribute incentive salience to reward cues in outbred rats

Authors: *A. GILETA[1], S. GOPALAKRISHNAN[1], J. GAO[1], C. J. FITZPATRICK[2], S. B. FLAGEL[2], T. E. ROBINSON[3], A. A. PALMER[1];
[1]Human Genet., Univ. of Chicago, Chicago, IL; [2]Dept. of Psychiatry, [3]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Incentive salience refers to the motivational value attributed to a reward-predicting stimulus, which causes it to become desirable and able to bias attention and elicit approach. In the case of addiction, reward-associated stimuli (conditioned stimuli) that acquire incentive

salience can trigger powerful craving and motivate drug-seeking/taking behaviors. Pavlovian Conditioned Approach (PCA) is a behavioral paradigm used to reliably quantitate the propensity of rats to approach and interact with a reward-paired cue. This conditioned response, known as sign-tracking, reflects the extent to which the cue is attributed with incentive salience. This trait has been shown to be both highly heritable and variable in Sprague-Dawley (SD) rats. Over the past 3 years, our collaborators phenotyped a cohort of ~4,000 outbred SD rats from multiple vendors for PCA. We will use this cohort to perform the first large-scale genome-wide association study (GWAS) for the attribution of incentive salience. A subset of these rats (n=80) are being whole-genome sequenced to assay the standing genetic variation and linkage structure in the component subpopulations. To obtain genotypes for the remaining rats, we utilize double digest genotype-by-sequencing (GBS), a reduced-representation sequencing approach we have optimized for this study. Due to the extensive structure observed in SD rat populations, association analyses will be performed using mixed models containing a random effect term with a genetic relatedness matrix estimated from the SNP genotype data. The marker data will also be used to precisely estimate the narrow-sense heritability of this trait.

Title: Enhanced cue-triggered motivation in obesity-prone rats; interactions between predisposition and junk-food exposure

Authors: *R. C. DERMAN[1], C. R. FERRARIO[2];
[2]Pharmacol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: While the decision to seek out food can be controlled by endogenous hunger signals, it can also be influenced by external Pavlovian cues that predict food availability. Human studies suggest that enhanced sensitivity to food-cues may promote obesity and hamper weight loss in susceptible individuals. Here, we asked whether the incentive-motivational properties of a food-cue are enhanced in obesity-prone vs. obesity-resistant rats in the absence of overt obesity. We

used a Pavlovian-to-instrumental transfer (PIT) procedure to assess the motivational strength of food-associated cues and their ability to invigorate ongoing food-seeking behavior. First, rats were trained to lever-press for food. Next, they received 8 Pavlovian training sessions where one cue (CS+) was paired with the delivery of food pellet and another cue (CS-) was presented without food delivery. During PIT testing, no food was available, rats had continual access to the levers, and each CS was presented 4 times. PIT was demonstrated by enhanced active lever responding in the presence of the CS+ relative to the CS-. During PIT testing, obesity-prone rats showed enhanced conditioned approach to the food cup during CS+ presentation and expressed strong and persistent PIT. In contrast, PIT was nearly absent in obesity-resistant rats, though they did show conditioned food-cup approach. Thus, in the absence of obesity, the ability of the CS+ to invigorate instrumental responding was stronger in obesity-prone rats. These data show that individual susceptibility to obesity is associated with pre-existing differences in the motivational significance of Pavlovian food-cues and are consistent with our recent findings in outbred rats (Robinson et al., 2015). Next, we determined the effects of exposure to a sugary, fatty, "junk-food" diet on PIT. Training and testing were identical, except that prior to initial training rats were given intermittent access to discrete amounts of "junk-food". We found that exposure to "junk-food" abolished PIT, but not conditioned approach, in obesity-resistant rats. Conversely, "junk-food" exposure in obesity-prone rats resulted in a highly focused PIT effect, with responding in the presence of the CS+ almost exclusively dedicated to lever pressing, and very little approach to the food cup. Thus, in susceptible individuals junk-food exposure further enhanced PIT. These data show that interactions between pre-disposition and consumption of fatty, sugary, foods enhance the incentive motivational properties of food-paired cues and will be discussed in light of the role of altered mesolimbic reward circuits in obesity.

Title: Differential changes in appetitive taste memory and aversive new learning induced by prolonged consumption of sugar or high fructose corn syrup

Authors: *D. BADILLO JUAREZ, M. MIRANDA;
behavioral and cognitive neurobiology, Inst. De Neurobiología UNAM, Queretaro, Mexico

Abstract: Sweet food induces taste preference that increases consumption; brain reward pathways are involved in such preference. Accordingly, it has been reported that after long term, but intermittent, sucrose intake some brain areas present neurochemical changes similar to those produced by addictive substances, suggesting the convergence of structures involved during learning and memory, and in the regulation of rewarded-related behavior. Currently, high fructose corn syrup 55 (HFCS-55) and sucrose are the sweeteners most used in America. Thus the objective of this work was to evaluate the effect of sweet withdrawal, after prolonged, permanent or intermittent intake of sucrose or HFCS-55 solution, on anxiety, taste preference, and during a new aversive learning with the same taste stimulus. Thus, Wistar male rats for the intermittent group, had access to food and sweet solution (10% sucrose or 8% HFCS-55) only for 6 hours a day, during 21 days; other rats in the permanent group, had *ad libitum* chow and sweet solution (10% sucrose or 8% HFCS-55) during 21 days; all groups had water *ad libitum*. After 21 days rats were deprived of sweet solution during 2 days. Then anxiety levels were tested in the elevated plus-maze task, and subsequently taste preference and the ability to acquire conditioned taste aversion (CTA) were also evaluated. The results demonstrated that rats after withdrawal of intermittent sucrose consumption or after withdrawal HFCS-55 showed less time on the open arm, indicating more anxiety after withdrawal of intermittent sucrose consumption; rats after withdrawal of intermittent HFCS-55 consumption showed less time on the open arm, compared with permanent HFCS-55 group. In addition, withdrawal of intermittent sucrose induced a significant taste preference compared with permanent sucrose consumption; however similar taste preference was observed after removal permanent or intermittent, HFCS-55 intake. Moreover, after intermittent sucrose consumption, rats required more CTA training sessions than rats after HFCS-55 consumption, to achieve aversive memory. These results suggest that sucrose induced stronger taste preference and higher latent inhibition of CTA compared with HFCS-55. Altogether this data indicates that withdrawal of prolonged but intermittent sucrose consumption generates anxiety, significant increase in consumption (like binge-eating) and decreases the ability to acquire new aversive memory association of the same taste. Title: Differences in cue-directed appetitive behavior and its relation to c-fos expression in the prefrontal cortex

Authors: *S. M. LEWIS[1], D. J. KRAAN[2], M. H. MONFILS[3], H. J. LEE[3];
[1]Univ. of Washington, Seattle, WA; [2]Univ. of Texas, Austint, TX; [3]Univ. of Texas, Austin, TX

Abstract: Repeated illumination of a panel light (the conditioned stimulus; CS) followed by release of food pellets (the unconditioned stimulus; US) reliably results in acquisition of a US-directed response in rats: conditioned food cup approach. However, some rats also acquire a CS-directed response: conditioned orienting. We have previously shown that rats that acquire conditioned orienting in our paradigm (Orienters) tend to make more risky and impulsive choices, be more distracted in an attentional task, and to display more 50 kHz ultrasonic vocalizations (USVs) in response to amphetamine, than those who do not acquire conditioned orienting (Non-Orienters). We were interested in which specific brain regions could be responsible for these differences in the behavioral phenotypes between the two groups. Research has already shown that the central amygdala and its connections to the nigrostriatal pathway are important in conditioned orienting. However, the role of prefrontal cortical regions in conditioned orienting is yet unknown. We hypothesized that prefrontal cortical functions might be different between Orienters and Nonorienters given that prefrontal cortex plays an important role in impulsive/risky decision-making and attentional function. Therefore, we investigated neural activity as measured by c-fos in prefrontal cortical regions of Orienters and Non-orienters. Adult Sprague-Dawley rats were conditioned using our standard light-food pairing paradigm. Rats were perfused immediately after the last training session and brain sections were immunostained for c-fos. Minimal c-fos expression in the pre- and infra- limbic cortical areas is found in either group, but significantly higher expression in the orbitofrontal cortex. Furthermore, our data suggests reduced c-fos expression in the orbitofrontal cortex of Orienters.

Title: The reinforcement omission effect on the behavioral repertoire of rats with lesions on the nucleus accumbens

Authors: *J. O. BUENO, E. F. BERNARDES;
Univ. São Paulo, Ribeirao Preto, Brazil

Abstract: The reinforcement omission procedure, in fixed-interval schedules of reinforcement, produces a reduction in post-reinforcement pause and, consequently, an increase in frequency responses in the next interval. There are different interpretations related to reinforcement omission effect (ROE), based upon motivational and/or attentional components. Preliminary studies have examined the role of activation of some amygdala nuclei to modulate these components. Recent studies suggest that the substructures of the amygdala may be involved in different processes, and connections between different amygdala nuclei and cortical/subcortical structures also seem to be involved in processes related to rewards and expectancy. Other studies suggest that the interaction between the amygdala and nucleus accumbens (NAC) is important for the modulation of motivational processes. However, there are no studies in the literature assessing whether neurotoxic lesions in different cortical and subcortical regions may interfere in ROEs. This study aimed to examine the ROEs on the behavioral repertoire of rats with lesions of the NAC, in classical conditioning procedures and non-contingent reinforcement. Thirty male Wistar rats, divided in NAC and SHAM groups, were submitted to 28 training sessions with 8 trials each one: 20 pre-lesion, two retraining sessions and six post-lesions sessions with omission of reinforcement. Each trial constituted of a 20 seconds signal (tone), followed by the release of a drop of water in the 19th second. In sessions with omission, the water was released in the half of trials. Ten categories of behaviors were analyzed. Comparison between duration rates during omission and reinforcement trials showed that NAC and SHAM groups showed the ROEs. NAC group was less sensitive to the ROEs. Regarding the behavioral categories Magazine sniffing and Near magazine sniffing, the duration rates of SHAM group during omission were higher in relation to rates of NAC group. For the categories Magazine licking, Far from magazine sniffing, Rearing, Locomotion and Grooming duration rates of SHAM group were lower than the NAC group. The results suggest that NAC can be part of circuitry involved in the modulation of ROEs and also indicate the need to consider the involvement of more complex neural network for evaluating the ROEs.

Title: Role of dopamine in learning Pavlovian cues associated with different rates of reward

Authors: K. GIRVEN, K. FONZI, I. OLIVA, *M. J. WANAT;
Neurosciences Inst., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Learning the multiple cues that predict a significant outcome is critical for an animal's survival. These neurobiological processes are thought to involve the mesolimbic dopamine system. Specifically, dopamine neurotransmission encodes the expected value of an anticipated reward in response to a reward-predictive cue. Recently we identified that reward rate is another parameter encoded by cue-evoked dopamine release. Dopamine is also critical for certain forms of learning which involve a single cue - reward relationship. However, real world situations often entail learning about multiple cue - reward relationships simultaneously; though it is not clear how dopamine is involved in these processes. Here, we examined the role of dopamine during the acquisition of a Pavlovian conditioning task incorporating multiple cue-reward relationships. In this paradigm, distinct auditory cues were associated with different reward rates. We recorded phasic dopamine release in the nucleus accumbens throughout learning with fast scan cyclic voltammetry. Preliminary results indicate that dopamine release in the nucleus accumbens core encodes reward rate early in training. In contrast, the pattern of dopamine release in the nucleus accumbens shell is dynamic throughout learning. Antagonizing dopamine receptor function during different phases of training suggests dopamine is involved solely in the expression of Pavlovian conditioned responding, and not in the learning or in the performance of the task. Collectively, these results illustrate the heterogeneity in the pattern of dopamine release throughout the nucleus accumbens in a Pavlovian conditioning task that incorporates multiple cue-reward relationships. Furthermore, our results suggest a selective role of dopamine in the expression of conditioned responding in this task.

Title: How does reward devaluation control behavior? Expectancy and S-R habits in appetitive conditioning

Authors: *M. R. PAPINI, A. C. GLUECK, S. E. CONRAD;
Dept of Psychology, Texas Christian Univ., Fort Worth, TX

Abstract: Transitions from outcome-dependent behavior to outcome-independent, habitual behavior have been described in the course of instrumental learning, spatial learning, and during the development of addictive behavior. Outcome-dependent behavior is sensitive to current

reward value, whereas habitual behavior is released by the training stimulus and is less dependent on current reward value, at least in the short term. These two modes of behavioral control are usually depicted as arising sequentially, with outcome expectancy guiding behavior early in training, whereas habit becomes typical of extensively trained responses. It is thought that this behavioral transition is mediated by a shift in control from the dorsomedial striatum to the dorsolateral striatum. To test this sequential view, rats received autoshaping training in which the presentation of a lever (L) was paired with the presentation of 12 pellets per trial (6 trials/session). Consistent with the sequential view, Experiment 1 showed that presession feeding (a reward-devaluation procedure) suppressed lever pressing early in training (after 5 sessions), but not late in training (after 20 sessions). Thus, autoshaping exhibits both outcome-dependent and outcome-independent properties as a function of amount of practice. In Experiment 2, rats received pairings of one lever presentation (L1) with 12 pellets per trial, while a second lever (L2) was paired with 2 pellets per trial (3 trials with each lever per session). In late training, when one lever was presented in a given trial (L1 or L2), there was no evidence that a 12-to-2 pellet reduction in L1 (another reward-devaluation procedure) controlled lever pressing_outcome-independent, habitual behavior. However, occasional choice trials with both L1 and L2 present simultaneously yielded evidence of reduced responding for L1 (the downshifted lever) relative to L2 (the unshifted lever)_outcome-dependent behavior. These results suggest that even after the kind of extensive training that yields evidence of habitual behavior, control of appetitive behavior by outcome expectancy can be rescued by encouraging comparisons among alternative outcome expectancies. It is hypothesized that both dorsal striatal streams coexist in late training and are differentially activated by testing conditions that either encourage (two-lever choice) or discourage (single lever) incentive comparisons.

Title: Neuronal ensemble characterisation following exposure to reward-associated cues

Authors: J. J. ZIMINSKI[1], *E. KOYA[2];
[1]Sch. of Psychology, [2]Univ. of Sussex, Brighton, United Kingdom

Abstract: Learned associations between natural rewards and the environmental cues that predict their availability are encoded by a minority of sparsely distributed, behaviorally activated neurons, called ‘neuronal ensembles’. The glutamate synapse plays an important role in many learning and memory processes. Yet, to date very little is known about the alterations at glutamate synapses specifically on these neurons that encode this type of association. The aims of our laboratory are to identify neuronal ensembles activated by environmental cues associated with sucrose in corticostriatal brain areas, and to characterise their physiology at glutamate synapses. To that end, we measured conditioned behavioural and neuronal ensemble activity (using GFP immunohistochemistry) using Fos-GFP mice that express GFP in strongly activated neurons. We trained these mice to associate an auditory cue with non-contingent sucrose delivery following multiple training sessions. Five to seven days following conditioning, sucrose cue exposure elicited conditioned approach towards the sucrose delivery site, and enhanced ensemble activity in the orbitofrontal cortex and nucleus accumbens. These data suggest that neuronal ensembles that encode sucrose memories reside in these areas. Investigations are underway into characterizing the synaptic properties in these activated neurons using Fos-GFP mice. Also, we plan to compare these synaptic properties with neurons activated by environmental cues associated with non-contingent cocaine.

Title: Contribution of lateral habenula to midbrain dopaminergic neurons in the Pavlovian appetitive conditioning

Authors: ***B.-R. CHOI**, D.-H. KIM, J.-S. HAN;
Konkuk Univ., Seoul, Korea, Republic of

Abstract: Lateral habenula (LHb) is known as major dopamine (DA) inhibition center, which is contribute to reward learning. In the previous study, DA system is activated by reward delivery and inhibited by reward emission and LHb works in an opposite manner, with DA system. However, no study has done to examine how LHb acts in Pavlovian appetitive conditioning. The present study, therefore, examined the neuronal activity of LHb in Pavlovian appetitive conditioning, with paired group and unpaired group. In a paired group, light was presented for 10 sec and immediately delivered two reward pellets, and 16 trials per one session for 64 min with 4

min variable inter-trial interval and conditioning was performed for 8 days. For rats in a unpaired control group, the same number of lights and food pellets were pseudorandomly presented using an unpaired procedure in which the CS and US were noncontingent, with the provision that the identical stimulus did not appear three consecutive times. Three control groups were included to exclude alterations of neural activity by stimuli presentation and apparatus exposure (groups that received either light or food only and naïve group). Neural activity in LHb and other brain area, substantia nigra pars compacta (SNc) and ventral tegmental area (VTA) and basolateral amygdala (BLA), central amygdala (CeA) were measured by c-fos expression. LHb neural activity was only increased in unpaired group. And SNc, VTA, BLA, and CeA neural activity were increased only in paired group. These results indicate that increased LHb activity in unpaired group contributed to inhibition of midbrain DA neurons. Additionally, using retrograde tracer fluoro gold (FG) and cholera toxin B subunit (CTb), we examined the neural activity which was projected from LHb to SNc or VTA in Pavlovian associative conditioning. We unilaterally injected FG or CTb into SNc or VTA of rats. These rats received Pavlovian appetitive conditioning for 8 days. Most LHb neurons expressing c-fos in unpaired group innervated neurons in SNc or VTA, suggesting that LHb neurons that were activated by unpaired training condition inhibit midbrain DA neurons. Title: Pontomesencephalic tegmental afferents to VTA are necessary to develop prepotent response inhibition

Authors: ***H.-J. YAU**[1], D. V. WANG[1], J.-H. TSOU[1], B. T. CHEN[1], K. DEISSEROTH[2,3], S. IKEMOTO[1], A. BONCI[1,4];

Abstract: Dopamine neurons fire phasic burst activity during presentation of reward or reward predictive cues. It is believed that DA neuron burst activity depends on afferent inputs. Several

lines of evidence lead us to study the regulatory roles of the pedunculopontine tegmental nucleus (PPTg) in VTA circuits and its role in modulating behaviors. Anatomically, PPTg provides ascending cholinergic and non-cholinergic inputs to the VTA. Further, inactivation of PPTg decreases VTA DA burst activity to conditioned stimuli. These studies suggest that PPTg may relay sensory information onto VTA to modulate firing activity of midbrain DA cells. In line with this evidence, lesion of PPTg impairs stimulus-reward learning. Nevertheless, direct evidence linking PPTg-to-VTA inputs in the acquisition of stimulus-reward association is lacking. Conventional methods of lesion or pharmacological inactivation in PPTg can neither conclusively establish a causal link between specific PPTg outputs and observed behavioral or cellular deficits, nor distinguish the relative contributions of different PPTg neuronal populations. To overcome these limitations, we employed optogenetic approach to selectively inhibit PPTg glutamatergic or cholinergic inputs to the VTA in order to examine the contribution of these inputs in Pavlovian appetitive conditioning. Furthermore, we performed *in vivo* optetrode recording in freely moving mice as they performed a Pavlovian task to examine the regulation of VTA circuits by PPTg glutamatergic or cholinergic afferents. Here we report that PPTg-to-VTA excitatory inputs play a critical role in the acquisition of stimulus-reward associations by influencing development of prepotent response inhibition. We also identify an unprecedented role of PPTg-to-VTA pathways in modulating the activity of VTA non-DA neurons.

Title: Microstructural analysis of cue evoked sucrose consumption and its dependence on dopamine

Authors: ***A. T. LIU**, B. HALBOUT, S. B. OSTLUND;
UC Irvine, Irvine, CA

Abstract: It is widely believed that cues associated with palatable foods are capable of triggering food cravings and over-eating. The current study was designed to probe if cues associated with a palatable sucrose solution potentiate feeding through Pavlovian (stimulus-reward) incentive motivation and to characterize cue-triggered changes in the microstructure of sucrose licking, focusing on measures associated with palatability (lick bout duration) and motivation (lick bout frequency). In the first experiment, food restricted rats were given Pavlovian conditioning to associate an auditory cue (CS+) with small aliquots of 20% sucrose solution located in a liquid well in one end of the behavioral chamber. A control cue (CS-) was not paired with sucrose delivery. After training, rats were shifted to a state of general satiety with ad lib access to home chow and given a pair of tests to characterize cue-triggered sucrose licking. Sucrose solution concentration varied across the two tests (2% vs. 20%, order counterbalanced). During each test, rats were given continuous access to sucrose, and the CS+ and CS- were noncontingently presented in pseudo-random order to assess their influence on sucrose licking. We found that the CS+ was effective in eliciting sucrose licking, an effect that was more prominent when 2% sucrose was available, which, consistent with a motivational interpretation, seems to be driven by an increase in the frequency of licking bouts during the CS+. To more directly assay the influence of Pavlovian incentive motivation on sucrose licking, we conducted an experiment identical to the first, except that sucrose solution was consumed from a distinctive bottle dispenser located on the opposite side of the chamber as the well used during Pavlovian conditioning. This ensured that previous stimulus-response habits were incompatible with sucrose licking at test, letting us attribute any cue-related increases in behavior to Pavlovian incentive motivation. We found that the effects of the CS+ on licking were most evident in the 2% sucrose test and were most clearly associated with increases in licking bout frequency rather than bout length. Additional testing examined the dependence of cue-triggered sucrose drinking on dopamine signaling, which is known to be critical for the expression of Pavlovian incentive motivation in other experimental settings. We found that pre-treatment with the D1 dopamine antagonist SCH-23390 abolished the sensitivity of sucrose licking to the CS+. These findings indicate that cues associated with palatable foods can trigger excessive food intake through a dopamine-dependent incentive motivational process.

Title: Modulation of cue-triggered reward seeking by cholinergic signaling in the dorsomedial striatum

Authors: *S. B. OSTLUND[1], A. T. LIU[1], B. HALBOUT[1], K. M. WASSUM[2], N. T. MAIDMENT[3];
[1]Dept. of Anesthesiol. and Perioperative Care, UCI Sch. of Med., Irvine, CA; [2]Psychology, UCLA, Los Angeles, CA; [3]Psychiatry and Biobehavioral Sci., UCLA Sch. of Med., Los Angeles, CA

Abstract: Reward-predictive cues acquire the ability to motivate and guide the selection of reward-seeking behaviors. This tendency for external cues to promote the pursuit of rewards - sometimes independently of, or even at odds with, more pressing physiological needs - is widely believed to contribute to over-eating and excessive drug and alcohol use. The influence of reward-paired cues on reward seeking can be studied in rats using the Pavlovian-to-instrumental transfer (PIT) task. Previous PIT studies have established that the dorsomedial striatum (DMS) is required for the expression of action selection based on cue-elicited reward expectations. While acetylcholine (ACh) is known to be an important modulator of local neurotransmission and cellular activity within the DMS, how this contributes to cue-evoked reward seeking is largely unknown. To investigate this issue, hungry rats were pre-trained using an outcome-specific PIT protocol known to depend on the DMS. At test, rats were allowed to freely perform two different lever-press actions, each associated with a different food reward. Cues that were separately trained with these rewards were noncontingently presented at test to assess their ability to influence reward-seeking behavior. Prior to testing, rats received bilateral intra-DMS injections of vehicle, mecamylamine (nicotinic ACh receptor antagonist), or scopolamine (muscarinic ACh receptor antagonist). We found that rats tested after vehicle treatment showed normal sensitivity to the outcome-specific influence of reward-paired cues, selectively increasing their performance of whichever action was associated with the reward they expected based on the current cue. Interestingly, nicotinic and muscarinic antagonists had distinct effects on PIT performance; whereas mecamylamine facilitated expression of PIT, scopolamine abolished this effect. These findings indicate that ACh signaling in the DMS modulates the expression of cue-triggered reward seeking, with its actions at nicotinic and muscarinic receptors playing opposing roles. Further study of the mechanisms underlying this behavior may guide efforts to treat disorders associated excessive reward seeking, like overeating and drug addiction.

Title: Temporal information is transferred in a general Pavlovian-Instrumental transfer task

Authors: R. B. DELLA VALLE, *M. S. MATELL;
Psychology, Villanova Univ., Villanova, PA

Abstract: The temporal relationship between stimuli plays an integral role in associative learning, but is not often studied using Pavlovian-Instrumental transfer designs (PIT). Previous work has shown that systematic variation of the time between a conditioned stimulus (CS) and unconditioned stimulus (US) mediates the timing of operant responses in sensory-specific PIT procedure (Delamater & Holland, 2008). The current experiments aimed to extend these results to general PIT, and then examine the involvement of the amygdala on such temporal information transfer. In two experiments, forty rats were trained on a Pavlovian delay conditioning procedure (CS-US interval 60s (Exp. 1) or 120s (Exp. 2)) using a house light and a 4 KHz tone as a CS+ and CS-, counterbalanced. Following training, temporal control was assessed using non-reinforced probe trials that lasted 3-4 times the CS-US interval. After temporal control was established, as evidenced by maximal responding around the time of the US on probe trials, subjects were trained to nosepoke on a low density reinforcement schedule. Finally, nosepoke responding was tested in extinction, and PIT was assessed by presenting the CS+ and CS- as probes. In both procedures, general PIT was seen as rats were found to increase response rates during the CS+ compared to the CS-. Importantly, maximal operant responding occurred at the CS-US interval learned in the Pavlovian phase of training. These results indicate that temporal knowledge can be transferred from a Pavlovian procedure to an instrumental procedure under general PIT conditions, thereby suggesting temporal modulation of arousal. A subsequent experiment, currently ongoing, aims to determine if the retrieval of temporal knowledge in testing is prevented by lesions of the central and basolateral amygdala, which have been previously shown to differentially mediate the general and outcome-specific forms of PIT (Corbitt and Balleine, 2005). The results of this experiment are expected to suggest whether or not temporal knowledge is mediated via the same pathway as the associative knowledge or whether it is generated via a parallel pathway.

Title: Effects of protracted withdrawal from repeated cocaine exposure on goal-directed learning

Authors: *B. HALBOUT[1,2], A. T. LIU[2], S. B. OSTLUND[2];
[1]UC Irvine, Irvine, CA; [2]Anesthesiol., Univ. of California Irvine, Irvine, CA

Abstract: Repeated exposure to drugs of abuse facilitates habitual learning processes that may contribute to compulsive drug taking and seeking. Recently, several studies have shown that exposure to pyschostimulants accelerate the onset of habitual control over food-seeking behaviors, possibly to the detriment of goal-directed control. The present study used behavioral tests that strongly implicate action-outcome learning and investigated more directly cocaine exposure effects on goal-directed actions. We tested whether prolonged withdrawal from repeated cocaine exposure alters goal-directed behaviors mediated by the representation of an outcome value associated with a particular action (outcome specific devaluation) and by the detection of a change in the causal relation between an action and its consequence (contingency degradation). Male Long Evans adult rats (n = 10 / group) received 5 or 15 days of daily cocaine (0, 15 or 30 mg/kg, i.p.). Following a 30-day withdrawal period they were trained to perform two different lever press actions for distinct food pellets (e.g., Left press - Grain & Right press - Chocolate). For the outcome specific devaluation test, rats were selectively satiated on one of the two pellets immediately before undergoing a test to assess their ability to flexibly adjust their choice between the two actions in accord with current goal values. During contingency degradation training one of the outcomes (Grain or Chocolate) was delivered non-contingently with the same probability regardless of whether the rat performed the appropriate lever-press response or not. An extinction test assessed how this contingency manipulation altered rats' choice between the two actions. Overall cocaine-treated rats did not differ from saline-treated rats in their ability to use up-to-date value assignments for expected outcomes when selecting between reward-seeking actions, suggesting preserved goal-directed control. Surprisingly, prolonged cocaine exposure facilitated the sensitivity of action selection to action-outcome contingency degradation. While further investigation should confirm the robustness of these effects, our findings indicate that withdrawal from chronic cocaine can actually promote processes that support certain flexible behavior.

Title: Effect of glycogen synthase kinase-3 inhibition on cocaine cue-conditioned activity

Authors: *J. F. ROCCA, R. J. BENINGER;
Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Exposure to contextual cues previously associated with reinforcers, such as drugs of abuse, can elicit drug craving in humans and approach and other responses in laboratory animals. Incentive learning is the process by which contextual cues gain the ability to elicit responses. Conditioned activity is a paradigm used to study incentive learning and to model drug craving in rodents. In this paradigm, rodents are given cocaine paired with a specific test environment (cocaine-paired), while control groups are given saline during testing and cocaine later in their homecage (cocaine-unpaired). When these groups are tested with saline-only in the test environment, paired animals display conditioned locomotor activity. Prior research has implicated dopamine D2-like receptors in the acquisition and expression of conditioned activity. D2-like receptor activity decreases the production of the second messenger, cyclic adenosine monophosphate, and consequently reduces protein kinase A activity. Recently, however, another cell-signaling pathway, the β-arrestin2/Akt/glycogen synthase kinase-3β (GSK-3β) pathway, has been shown to be affected by D2-like receptor activity. We investigated the potential role of GSK-3 in conditioned activity involving 3 days of cocaine (10 mg/kg)- or saline-paired exposure to the test environment followed by a test with saline for both groups. The selective GSK-3 inhibitor SB-216763 was given to Wistar rats during the conditioning phase or test day phase. Preliminary results show a trend towards a block of expression at lower doses than those needed to block acquisition of conditioned activity. Several more doses are currently being tested. Results may implicate the β-arrestin2/Akt/GSK-3β pathway more strongly in the expression than acquisition of incentive learning in some conditioning paradigms.

Title: Improvement of memory reconsolidation induced by polyaminergic agents involves calcium-dependent protein kinase in rats

Authors: *M. A. RUBIN, B. A. GIRARDI, C. SIGNOR, D. A. RIBEIRO, C. F. MELLO; Federal Univ. of Santa Maria (UFSM), Santa Maria, Brazil

Abstract: The reactivation of a memory results in its destabilization, requiring a process of memory reconsolidation to maintain it. Spermidine is an endogenous aliphatic amine with polycationic structure that modulates N-methyl-D-aspartate (NMDA) receptor activity and improves memory. Recent evidence suggests that systemic administration of spermidine improves the reconsolidation of fear memory. In the current study we determined whether the calcium-dependent protein kinase (PKC) signaling pathway is involved in the improvement of fear memory reconsolidation induced by intrahippocampal (ih) administration of spermidine in rats. Male Wistar rats were trained in a fear conditioning apparatus using a 0.4 mA footshock as unconditioned stimulus. Twenty-four hours after training, animals were re-exposed to the apparatus in the absence of shock (reactivation session). Immediately after the reactivation session, spermidine (2 - 200 ρmol/site); the PKC inhibitor, 3-[1 (dimethylaminopropyl)indol-3-yl]-4-(indol-3-yl) maleimide hydrochloride (GF 109203X, 0.3 - 30 ρg/site); the antagonist of the polyamine-binding site at the NMDA receptor, arcaine (0.2 - 200 ρmol/site) or the PKC activator, phorbol 12-myristate 13-acetate (PMA, 0.02 - 2 nmol/site) were injected intra-hipocampally. Testing was carried out in the same apparatus, twenty-four hours after reactivation. Freezing scores at testing were considered a measure of memory. While the post-reactivation administration of spermidine (20 and 200 ρmol/site) improved, GF 109203X (1, 10 and 30 ρg/site) impaired memory reconsolidation. GF 109203X (0.3 ρg/site) prevented spermidine (200 ρmol/site)-induced improvement of memory reconsolidation. The post-reactivation administration of arcaine (200 pmol/site) impaired and the PMA (2 nmol/site) improved memory reconsolidation. PMA (0.2 nmol/site) prevented arcaine (200 ρmol/site)-induced impairment of memory reconsolidation. These drugs had no effect on memory if they were administered in the absence of reactivation. These results suggest that the enhancement of memory reconsolidation induced by the administration of spermidine involves PKC activation.

Title: Sleep-scoring in mice using gamma frequency in the olfactory bulb

Authors: ***S. BAGUR**, M. LACROIX, G. LAVILLEON, K. BENCHENANE;
ESPCI, Paris, France

Abstract: The growing interest in the physiology of various behavioral states demands reliable and systematic methods of wake and sleep stage scoring. Traditional methods identify sleep by monitoring movement or muscular activity, however if sleep and wake are truly different brain states the two should be identifiable using information on neuronal activity alone. It has been shown that gamma oscillations in the olfactory bulb (OB) of the mouse are strongly reduced during sleep (Manabe et al. 2013). Here, we show that low gamma power in the 50-70Hz band recorded from the OB shows a bimodal distribution that allows to separate sleep and waking states. Moreover rapid-eye-movement (REM) and non-REM (NREM) sleep can be distinguished using theta-band power (6-10Hz) recorded in the hippocampus (HPC). We therefore present a method of constructing a two-dimensional phase space allowing to distinguish between waking, REM and NREM sleep that relies exclusively on LFP recordings from the HPC and the OB. This method can be automatically calibrated and is robust from day to day and across multiple states of vigilance including task-driven behaviour. This technique allows for identification of brief periods of arousal and dozing, it is therefore a promising tool for the fine study of sleep microstructure.

Abstract: A novel experience induces dynamic gene expression changes in the brain. The learned information through the experience is encoded as memory in the brain, and the memory becomes stable through processes called consolidation. It is well-known that memory consolidation requires the gene expression regulation. Therefore, to understand the molecular mechanism of how long-term memory is formed, it is of critical importance to map how gene expression is regulated following the learning. Although there have been extensive studies focusing on the regulation and action mechanism of individual genes during long-term memory formation, genome-wide landscape of gene expression following the learning process is still elusive. Through unbiased genomic analyses, we have identified previously undiscovered gene regulatory events and pathways in the mouse hippocampus following the contextual fear conditioning. With accompanied validation experiments, our analysis is thought to open a new window for investigating the molecular mechanism of learning and memory. N.-K. Yu and H. Kim contributed equally to this work.

Title: Chronic *in vitro* imaging in a H2B::Pa-GFP-expressing transgenic mouse model reveals experience-induced nucleus-scale remodeling of chromatin in neocortical neurons

Authors: ***S. RUMPEL**[1], D. ASCHAUER[1], F. GROESSEL[2], W. HAUBENSAK[2], M. PETER[3]; [1]Johannes Gutenberg Univ. Mainz, Mainz, Germany; [2]Res. Inst. of Mol. Pathology (IMP), Vienna, Austria; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Dynamic remodeling of gene expression patterns in response to behavioral experiences is believed to crucially contribute to the brain's ability to adapt the structure of neuronal networks in a dynamic manner and to mediate higher cognitive functions such as memory formation. A body of evidence for short- and long-lasting changes in expression patterns induced by experiences has been obtained in recent years, primarily highlighting regulatory processes at the molecular level. Furthermore, it is long known that neuronal activity can induce remodeling of neuronal chromatin also at the scale of the whole nucleus *in vivo* (1). However, most of this data stems from post-hoc analyses that cannot provide information on the

longitudinal dynamics. Here, we describe the generation and functional characterization of a novel transgenic mouse model conditionally expressing a fusion protein of H2B and a photoactivatable form GFP (PA-GFP). We take advantage of this mouse model to chronically label and image chromatin in neurons of the mouse auditory cortex *in vivo* using two-photon microscopy through a chronically implanted cranial window. We observed that photolabeled patterns on the chromatin remain stable over several hours in most neurons, while it appears dynamic in other neurons. Combining chronic imaging with classical auditory cued fear conditioning, we observe an increase in the fraction of neurons showing remodeling of chromatin, indicating an experience-dependent regulation of chromatin dynamics. We furthermore demonstrate in acute brain slices prepared from transgenic mice that pharmacological manipulation of neuronal activity impacts on the dynamics of chromatin on the time scales of few hours, similar to the observations *in vivo*. In summary, we establish a methodology to follow chromatin dynamics chronically *in vivo*. We furthermore provide a first longitudinal description of neuronal chromatin during behavioral procedures that have been previously shown to induce alterations in gene expression in the auditory cortex and the formation of sound-related memories (2). 1)Barr, M. Title: The NMDA receptor antagonist (±)-3-(2-Carboxypiperazin-4-yl) propyl-1-phosphonic acid impairs consolidation, but not acquisition, of hippocampal spatial memory in the rat

Authors: *C. MARSHALL, D. C. GIDYK, R. J. MCDONALD;
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: ***N-methyl-D-aspartate*** receptors (NMDAR) are a class of post-synaptic glutamate receptors located in the hippocampus, a brain area critical for spatial memory. A large body of evidence supports its role in the induction of synaptic plasticity and the acquisition of hippocampal memories. However, previous findings from our group have suggested that NMDARs may instead be involved in the consolidation of learned information into long term memory, as opposed to its acquisition. One caveat associated with our work was that only NMDA receptors in the dorsal hippocampus were blocked. The purpose of the current experiment was to determine whether NMDARs are involved in the acquisition or consolidation

of spatial information in the rat hippocampus when NMDA receptors are blocked across the entire septal/temporal poles of the structure. We used 16 Long Evans rats for each part of the experiment. Rats were given bilateral, dorsal and ventral hippocampal cannulations. After recovery, a 3 phase rapid acquisition version of the Morris water task was used to train and test the animals. This consisted of 4 days of spatial pre-training to a fixed hidden platform, intrahippocampal infusion of the NMDAR antagonist **(±)-3-(2-Carboxypiperazin-4-yl) propyl-1-phosphonic acid** (CPP) or saline followed by 2 hours of mass training to a new position, and a probe test. For part 1 of the experiment all procedures occurred in a single spatial context and for part 2 the mass training and probe test will occur in a different spatial context. Within the same spatial context, rats given saline before mass training learned the new platform position and showed a preference for this new position when given a probe 24 hours later. Rats given the CPP before mass training learned the new platform location but when given the probe test 24 hours later showed no preference for the quadrant it was located in. Contrary to the leading theory in the field, These results suggest that NMDARs in hippocampus are essential for consolidation of spatial information acquired in the spatial version of the water task but not acquisition.

Abstract: Reconsolidation has been defined as the process of memory stabilization after retrieval involving, among others, gene expression regulation and post-translational modifications. Many of these mechanisms are shared with memory consolidation. Here, we studied hippocampal ERK participation on memory reconsolidation of an inhibitory avoidance task in CF-1 mice. We found a retrieval-induced cytosolic ERK2 activation in the hippocampus (HIP) 15 min after memory reactivation, and an inhibition at 45 min. PD098059, a MEK1/2 (MAPK/ERK kinase) inhibitor, administered in the HIP immediately after retrieval impaired memory in a dose-dependent fashion. However, infusions of the highest dose of PD098059 performed 40 min after retrieval enhanced memory in mice trained with a weaker footshock. These results suggest for the first time that ERK2 is involved in memory reconsolidation in a biphasic fashion. Furthermore, the inhibition of ERK could either impair or enhance mice performance depending on ERK state of activation.

Title: Associative and affective contributions to context fear conditioning

Authors: L. M. TURNBULL, A. A. SCHMELING, E. J. DONZIS, B. R. SCHWARCZ, *N. C. TRONSON;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Two commonly used context and fear-associated conditioning paradigms show discrepancies in susceptibility to manipulations of memory reconsolidation, the process that maintains or updates memory after retrieval. There are several hypotheses as to why these protocols differ: differences in molecular mechanisms or brain regions activated after retrieval, or the different relative contribution of associative components and affective responses elicited at test. The goal of the current study was to directly compare the circuit and molecular pathways activated after retrieval in context fear conditioning (CFC) and inhibitory avoidance (IA), and directly manipulate the relative contributions of associative strength (ie, CS-US association) and affective load (ie. shock level) to each. We show that at low levels of shock (0.2mA), mice effectively learn to avoid a shock-paired context in inhibitory avoidance. However, in context fear conditioning, mice fail to show a robust freezing response. In contrast, at high levels of shock (0.8mA), we observed both avoidance in IA and freezing in CFC. Using immunohistochemistry for immediate early genes cFos, Arc, and Egr1 and the promiscuous

signaling kinase Erk/MAPK, we found similar patterns of activation after retrieval of either IA or CFC in dentate gyrus, CA3 and anterior cingulate cortex. In contrast, greater activation of amygdala, retrosplenial cortex, and CA1 occurred after retrieval of CFC compared with IA. Differences in brain regions and signaling pathways activated after retrieval of a high shock-intensity fear memory vs. low-intensity pairings suggest new potential targets for disrupting affective components of a memory. This may also pose novel treatments for disorders of emotion and memory, including Post-Traumatic Stress Disorder.

Title: Involvement of δCalcium/calmodulin-dependent protein kinase II in persistent forms of memory

Authors: *G. P. ZALCMAN[1], N. FEDERMAN[3], A. FISZBEIN[2], A. ROMANO[1];
[1]Lab. de Neurobiología de la Memoria, [2]Lab. de Fisiología y Biología Mol., IFIByNE-CONICET, Ciudad Autónoma de Buenos Aires, Argentina; [3]IBioBA-CONICET, Ciudad Autónoma de Buenos Aires, Argentina

Abstract: Calcium/calmodulin-dependent protein kinase II (CaMKII) is an abundant synaptic signaling molecule that is essential for both memory formation and synaptic potentiation. In mammals, CaMKII exists in multiple isoforms that are the product of four closely related genes: α, β, γ, and δ. Little information is available on the role of the δCaMKII in memory processes. In a previous study, we showed that Camk2d gene promoter is acetylated in the mouse hippocampus one hour after strong novel object recognition (NOR) training and that its mRNA levels were specifically induced 3h post-training. Strong training induces long-term-memory (LTM) formation, which can be assessed up-to 7 days after training. In the present work, we carried out experiments aimed at determining the epigenetic regulation, expression and role of CamK2d on recognition memory. In the first place, we studied the Camk2d promoter and found

there was nucleosome remodeling during NOR memory consolidation and 7 days after NOR training. Secondly, we measured δCamKII mRNA expression outside the memory consolidation window, more specifically 24 hs and 7 days after training, and we found that mRNA expression levels for animals trained with a strong protocol were significantly increased when compared to a non-trained control group at both time points. Finally, to study the requirement of δCaMKII in recognition memory we knocked down δCaMKII expression with an oligodeoxynucleotide antisense to its mRNA 3 hs after strong training and tested the memory effect 24hs and 7days afterwards. We found that NOR memory was intact 24hs after training but it was impaired when assessed on day 7, indicating that δCamKII knock-down during memory consolidation specifically affects persistent forms of recognition memories. Altogether, our results support a key role for δCaMKII isoform in persistent forms of memory and suggest that Camk2d may have a sustained expression throughout the "lifetime" of this kind of memory. Furthermore, this is the first work that provides insight information about nucleosome remodeling during memory formation and maintenance.

Title: H2B ubiquitination-dependent histone "cross-talk" is a critical regulator of synaptic plasticity and fear memory formation

Authors: *T. J. JAROME, W. M. WEBB, R. B. CREED, F. D. LUBIN;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Monoubiquitination of histones is a dynamic epigenetic controller of gene transcription changes in mammalian cells. Some evidence suggests that H2B monoubiquitination mediates "cross-talk" between histone methylation marks at gene promoters (Sun & Allis, 2002). However, while histone methylation has been shown to play critical roles in synaptic plasticity and memory formation, histone monoubiquitination has not been previously examined in this context. Here, we found that learning in a contextual fear conditioning (CFC) paradigm

transiently increased levels of H2B monoubiquitination at lysine 120 (H2BubiK120) in area CA1 of the hippocampus. Further experiments revealed accumulation of H2BubiK120 levels at gene promoters congruent with H3 lysine 4 trimethylation (H3K4me3) and H3 lysine 9 dimethylation (H3K9me2) histone methylation marks. Additionally, intra-CA1 siRNA-mediated knockdown of the ubiquitin E3 ligase for H2BubiK120, RNF20, prevented the learning-dependent increases in global and promoter-specific H2BubiK120 levels. RNF20 Knockdown also blocked H3K4me3 and H3K9me2 levels and altered mRNA expression of the H3K4me3 and H3K9me2 effector genes, c-fos and G9a respectively. This suggests that RNF20 mediated H2BubiK120 is involved in establishing histone methylation marks at gene promoters during CFC memory consolidation. Interestingly, we found that H2BubiK120 levels at the c-fos promoter was associated with increased binding of the 19S proteasomal subunit Rpt6, which has been shown to "bridge" H2B monoubiquitination to H3K4me3 marks in yeast (Ezhkova & Tansey, 2004). Intra-CA1 RNF20 knockdown impaired CFC memory and late, but not early, long-term potentiation (LTP), suggesting that H2BubiK120 was critical for activity-dependent synaptic plasticity and memory formation. Remarkably, the memory impairments resulting from RNF20 knockdown were completely rescued by simultaneous knockdown of the histone lysine-specific demethylase 1 (LSD1), which resulted in histone hypermethylation in the hippocampus. Collectively, these results provide the first evidence of histone monoubiquitination as a critical regulator of activity-dependent synaptic plasticity and memory formation, and suggest that H2B monoubiquitination dynamically regulates histone methylation cross-talk to mediate gene transcription control during long-term memory formation.

Title: Cognitive impairments caused by sleep deprivation is prevented by increasing protein synthesis in the hippocampus

Authors: ***J. C. TUDOR**[1], E. J. DAVIS[1], C. W. CHUNG[1], R. HAVEKES[1], P. PIERRE[2], T. ABEL[1];

[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Ctr. d'Immunologie de Marseille-Luminy, Marseille, France

Abstract: Sleep loss produces deficits in hippocampus-dependent memory storage, but the molecular and cellular mechanisms that underlie these effects of sleep deprivation remain unclear. Several studies have suggested that signaling pathways associated with translation are altered during sleep and after periods of sleep deprivation. Here, we demonstrate that five hours of total sleep deprivation increases phosphorylated AMP-activated protein kinase (AMPK) alpha, reduces mTOR complex 1 (mTORC1) and reduces phosphorylated eukaryotic translation initiation factor 4E binding protein 2 (4EBP2), which subsequently leads to impaired protein synthesis in the hippocampus. However it is yet to be determined whether restoring protein synthesis in the hippocampus is sufficient to prevent the cognitive deficits associated with sleep deprivation. Viral expression of 4EBP2 selectively in hippocampal excitatory neurons in mice that were sleep deprived for five hours increased phosphorylated 4EBP2 levels, which was sufficient to restore hippocampal protein synthesis to non-sleep deprivation levels. Furthermore, viral expression of 4EBP2 prevents the memory deficits associated with sleep deprivation in the object place recognition task. These findings indicate that AMPK-mTORC1-4EBP2 signaling and subsequent impaired protein synthesis is the critical component underlying the memory deficits associated with sleep deprivation in hippocampus-dependent learning tasks. Furthermore, this study defines the molecular mechanism by which loss of sleep impairs cognitive processes and highlights a vital role for protein synthesis and mTOR signaling on long-term memory formation.

Title: Dopamine in hippocampus is required for spatial novelty detection and consolidation of an updated memory

Authors: *D. AVILA AGUIRRE[1], F. BERMUDEZ RATTONI[2];
[1]Univ. Autonoma De Mexico, Mexico, Mexico; [2]Univ. Nacional Autonoma de Mexico, Mexico, Mexico

Abstract: The ability to identify objects in a particular context and differentiate the experience of a previous familiar configuration from a novel configuration depends largely on the maintenance of such spatial information of the object and the successful discrimination between actual experience and the internal representation of the environment. It has been hypothesized that this ability depend mostly on the hippocampal formation particularly on CA1 region on which occurs the match-mismatch between the previous spatial information and the current novel configuration. Also, it's known that the CA1 region receives dopamine projections, this projections seem to play a role in the novel context detection. In the present study was evaluated the dopamine role during an context memory update model for the novelty detection as for the consolidation of the new context. For this study were used 4 weeks old Balb/c mice cannulated in the dorsal hippocampus. For the memory updating it was used the Object Location Memory protocol, consisting on a two day for the acquisition of two different objects, on the third day,in which memory update occurs, one of the objects was displaced to a novel position, finally on the fourth day the updated memory was evaluated by repeating the third day configuration. The role of dopamine function was evaluated by the D1-D5 antagonist SCH 23390 administration prior the novelty context presentation or immediately after. The results indicate that dopamine activity is required for both, novelty detection and for the consolidation of the updated memory.

Title: The essential role of BAF53b in learning-related synaptic structural plasticity and long-term fear memory formation in the lateral amygdala

Authors: *M. YOO[1], K.-Y. CHOI[2], J. SHIM[3], J.-H. CHOI[3], J. KIM[1], J. OH[1], B.-K. KAANG[3], J.-H. HAN[1];
[2]Grad. Sch. of Med. Sci. and Engin., [1]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [3]Dept. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Epigenetic regulation of gene expression has been implicated in long-lasting memory formation. However, little is known about the role of chromatin remodeling mechanism in learning and memory. Recent study reports that BAF53b, a post-mitotic neuron specific subunit of Brg/Brm-associated factor (BAF) chromatin remodeling complex is involved in hippocampus-

dependent long-term memory formation. However, whether BAF53b plays a role for long-term fear memory formation in the lateral amygdala (LA), a key brain site for fear memory storage, and its underlying mechanisms remain unknown. To address these issues, we used viral vectors to manipulate the expression level of BAF53b specifically in the LA neurons during memory formation and investigated its effects on learning-related synaptic structural plasticity and long-term fear memory formation using auditory fear conditioning paradigm. First, we found that BAF53b knockdown in the LA neurons impaired long-term, but not short-term, fear memory formation, proving that BAF53b function in the LA is essential for long-term fear memory formation. Second, transient BAF53b overexpression in the LA enhanced long-term memory up to one month with no effect on short-term memory. Third, at the synapse level, confocal imaging of synaptic spines, which was visualized with GFP fluorescence or dye injection, in the LA brain sections after fear learning revealed that the density of thin-type spine was specifically increased in BAF53b-overexpressing LA neurons one hour after auditory fear conditioning compared to GFP expressing control neurons, while head volume of mushroom-type spine in BAF53b knockdown neurons was specifically smaller compared to that in control neurons 24 hours after auditory fear conditioning. In parallel to this result, our RT-PCR analysis showed that BAF53b knockdown blocked activity-dependent upregulation of miR132, which is known to be involved in regulation of activity-dependent spine enlargement. Taken together, our results demonstrate that BAF53b in the LA is essential for long-term fear memory formation of auditory fear conditioning and reveal novel underlying mechanisms of BAF53b during long-lasting memory formation.

Abstract: Long-term memory consolidation is a tightly regulated process that requires de novo gene expression and protein synthesis. Histone deacetylases (HDACs) have been well studied as negative regulators of memory consolidation, and pharmacologically relieving HDAC-mediated repression elicits robust long-term memory enhancements in multiple rodent learning paradigms. In contrast, little is known about the transcriptional repressor complexes that localize HDACs to their target genes. One co-repressor, SIN3A, is a strong candidate memory regulator that forms a complex with HDAC1 and HDAC2 and represses transcription via interactions with MECP2, REST, MEF2, and NCOR. To elucidate the role of SIN3A in memory consolidation, we generated conditional SIN3A neuronal hypomorph (Sin3aNH) mice with reduced expression of SIN3A in forebrain excitatory neurons. Here we show that Sin3aNH animals have enhanced long-term memory for contextual fear and enhanced hippocampal synaptic plasticity. We identified Homer1 as a gene target of SIN3A, and showed that Sin3aNH animals show activity-dependent upregulation of Homer1 transcripts in the hippocampus, increased localization of Homer1b/c and mGluR5 to the post-synaptic density, and expanded mGluR5 activity. These studies support a role for SIN3A as a novel memory repressor molecule that regulates synaptic plasticity and memory consolidation via Homer1/mGluR5 signaling.

Title: Hippocampal BDNF-dependent mechanisms mediate the formation of long-lasting latent memory traces during the infantile amnesia period

Authors: *A. TRAVAGLIA, R. BISAZ, C. M. ALBERINI;
New York Univ., New York, NY

Abstract: Aversive experiences in early life profoundly affect the neural systems critically involved in cognition and emotions. However, in adulthood, there is very little conscious recollection of episodic experiences that occurred during the early period of life, a phenomenon

known as infantile amnesia. This points to the paradox of how early memories can be so powerful if they cannot be remembered. We found that rats trained in inhibitory avoidance (IA) at postnatal day (PN) 17, which corresponds to early childhood in humans, acquire and express memory immediately after training, but they lose it rapidly and lack long-term memory 1 and 7 days after training, recapitulating the phenomenon of infantile amnesia. However, a later reactivation (up to a month after training) of the trace with both context exposure and footshock presented in a temporally unpaired manner, which per se does not evoke IA response, produces a significant memory reinstatement. The memory is context-specific. These data suggest that reminders occurring later in life can reinstate an early life memory trace that remained latent for a long time. The reinstatement of memory does not occur if the dorsal hippocampus is inactivated with muscimol at the time of training, whereas the same inactivation at the time of the reminders has no effect. Quantitative western blot analyses of dorsal hippocampal extracts indicated that training at PN17 leads to the activation of the BDNF/TrkB pathway and bilateral injection of blocking antibody to BDNF (anti-BDNF) into the dorsal hippocampus at the time of training prevents memory reinstatement, suggesting that dorsal hippocampal BDNF is induced and required for the formation of a latent memory trace. We conclude that BDNF-dependent mechanisms in the hippocampus are required for the formation of latent memory traces during the period of infantile amnesia. These traces are stored long-term, despite the fact that memories are not expressed; however, memories can be reinstated at later times by reminders.

Title: Sex differences in generalization and molecular mechanisms of context fear conditioning

Authors: ***A. A. SCHMELING**, E. J. DONZIS, L. M. TURNBULL, N. C. TRONSON; Univ. of Michigan, Ann Arbor, MI

Abstract: Prevalence for disorders of fear and anxiety are more than twice as common in women compared with men, possibly due to sex differences in learning about trauma-related contexts and cues. Supporting this view, studies of both human fear conditioning and animal models have demonstrated differences between males and females in models of fear conditioning. Such sex differences in fear-related memories may emerge from several distinct processes including learning about context, learning about the aversive event, the association of

context and shock, or differences in the modulatory effects of aversive stimuli on memory formation. Here we aimed to determine whether differences in context learning in males versus females contribute to sex differences in context fear conditioning. To do this, we examined generalization of fear after context fear conditioning from the training context to a similar context in male and female mice. We demonstrated that females, but not males, show generalization of fear responses in a similar context, suggesting sex differences in how - and what - information is learned during context fear conditioning (CFC). Pre-exposure to the training context 24 hours before CFC alleviated generalization of fear in females, but only under some conditions. These data demonstrate stronger context learning in males compared with females, and imply that females use an alternative strategy for learning CFC. To determine activation of brain regions mediating fear conditioning in males and females, we examined activation of immediate early genes (IEGs). We observed similar activity in the hippocampus and amygdala in males and females after context fear conditioning. However, in the pre-exposure + CFC group males showed significantly lower activation in hippocampus compared with CFC only group, whereas there was no difference in females. In contrast, females in the pre-exposure + CFC group showed significantly reduced basal amygdala IEG activity compared with the CFC only group. Overall, these data suggest that males and females differentially utilize context information in context fear conditioning memories. Broadly, these findings highlight the concept that males and females may rely on different neural mechanisms even when behavioral outcomes are similar.

Title: Characterizing sub-stages of Non REM sleep: importance for memory consolidation

Authors: ***M. M. LACROIX**[1], S. BAGUR[2], K. BENCHENANE[2];
[1]Brain Plasticity Unit, UMR8249 ESPCI CNRS, Paris, France; [2]CNRS UMR8249, Paris, France

Abstract: Non Rapid-Eye-Movement Sleep (NREM) is characterized by different patterns of oscillations that are conserved from humans to rodents (Iber et al. 2007): thalamo-cortical spindles (8-14Hz), hippocampal sharp-wave ripples (SPW-Rs, 150-200Hz) and cortical slow

oscillations including delta waves (cortical down state <1Hz) and delta rhythm (1-4Hz). Accumulation of evidence shows the importance of those patterns in memory consolidation. Indeed, SPW-Rs have been shown to support neuronal reactivations in hippocampus, replaying previous experience after spatial learning in rodents, and are necessary for memory consolidation during sleep (Girardeau, Benchenane et al. 2009; de Lavilléon, Lacroix et al. 2015). Slow oscillations and spindles are increased after declarative learning in humans and rodents, and this increase is correlated with subsequent performances at memory recall (Genzel et al. 2014). Accordingly, artificial increase of slow oscillations in humans improves memory performance and is associated with an increase in spindles occurrence (Marshall et al. 2006). This suggests that coordination between rhythms might be crucial for memory consolidation, as hypothesized by many studies characterizing the time relationship of those patterns. Yet, if a relationship between these rhythms is regularly found in various studies, the precise relationship between them fluctuates. We hypothesized that this discrepancy might be influenced by the different NREM stages that cannot be distinguished easily in rodents. Indeed, although different sleep stages are well characterized in humans, only few attempts to differentiate between several phases in rodents were reported (Bergmann et al. 1987, Gottesmann et al. 1992). Using chronic recordings of the local field potential at multiple brain sites together with tetrodes recording of neuronal spiking activity in the prefrontal cortex in mice, we were able to clearly establish three sub-stages of NREM: 1) a light sleep, characterized by low occurrence of delta waves and few spindles, 2) a sparse slow wave sleep, characterized by the presence of spindles and some delta waves, and 3) a dense slow wave sleep, characterized by presence of spindles and very high density of delta waves. SPW-Rs activity followed the profile of spindles and not delta waves'. These sub-stages were very reproducible across animals in terms of duration and patterns distribution. In accordance with previous study, this new approach will allow to further decipher the role of each oscillatory pattern in memory processes.

Title: Promoter specific effects of DREADD modulation on synaptic plasticity and hippocampal learning

Authors: *A. J. LOPEZ[1], E. KRAMAR[2], J. KWAPIS[3], A. O. WHITE[3], D. MATHEOS[3], A. VOGEL-CIERNIA[4], M. WOOD[3];
[1]Dept. of Neurobio & Behavior; Ctr. for the Neurobio. of Learning & Memory, Univ. of California, Irvine, Irvine, CA; [2]Univ. of California, Irvine, Irvine, CA, CA; [3]Univ. of California, Irvine, Irvine, CA; [4]Univ. of California, Davis, Davis, CA

Abstract: Chemogenetics can lead to a dramatic change in how neural circuits are studied and understood. Particularly, Designer Receptors Exclusively Activated by Designer Drug (DREADDs) are a novel tool with the potential to bi-directionally drive cellular, circuit, and, ultimately, behavioral changes. These receptors have no endogenous ligand and can only be activated with exposure to clozapine-n-oxide (CNO), which is otherwise an inert ligand. To examine how this technique can be used to manipulate the activity of specific cell populations, we used this chemogenetic system to test memory formation in a hippocampus-dependent task. Here, we use DREADD technology to show the explicit role of the CA1 hippocampal subfield in object location memory (OLM), but not object recognition memory (ORM) formation. Excitatory DREADD (HM3D), inhibitory DREADD (HM4D), or GFP control were expressed virally in the CA1 subfield of the hippocampus. The lab has previously shown that for both OLM and ORM tasks, a 3 minute training session is a subthreshold event for long-term memory (LTM) formation, while a 10 minute training session is sufficient for LTM formation. For activation experiments, mice were given a 3 minute training session in the OLM and ORM tasks paired with systemic CNO administration. For inactivation experiments, mice were given a 10 minute training session in the OLM and ORM tasks paired with system CNO administration. Mice were tested for LTM 24 hours following each respective training event. Compared to control animals, HM3D mice showed dramatic increase in LTM formation in the OLM task, but not ORM task. In contrast, HM4D mice showed LTM impairments in the OLM task, but showed no such impairments in LTM formation for the ORM task. However, DREADDs expressed under the hSyn promoter led to an inverse electrophysiological phenotype, compared to DREADDs expressed under the CaMKIIα promoter. Together, these experiments show a novel way of modulating LTM formation in behaving animals while further demonstrating hippocampal dependence in OLM but not ORM task LTM formation. Moreover, this provides evidence for promoter-specific effects on neural circuit function.

Title: Expression of a Noonan syndrome-associated mutant PTPN11 in excitatory neurons impairs learning

Authors: M. KANG[1], T. KIM[2], H.-H. RYU[1], A. J. SILVA[3], B.-K. KAANG[2], *Y.-S. LEE[1]; [1]Chung-Ang Univ., Seoul, Korea, Republic of; [2]Seoul Natl. Unviersity, Seoul, Korea, Republic of; [3]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Noonan syndrome (NS) is a neurodevelopmental disorder highly associated with congenital heart disease, short stature, facial abnormalities and cognitive deficits such as learning disabilities. Mutations in *Ptpn11* which encodes SHP-2, a positive regulator for Ras-Erk signaling are responsible for ~ 50% of NS cases. Previously, we showed that the mutant mouse harboring NS-associated mutant *Ptpn11* show enhanced excitatory synaptic function, suggesting that the imbalance between excitatory and inhibitory synaptic transmission could be the cellular mechanism underlying learning and memory deficits in the NS mouse models. Here, we examined the effect of cell type-specific ectopic expression of a NS-associated mutant SHP-2 on spatial learning and memory in adult mice. We infused floxed adeno-associated viral vector containing a NS-associated mutant *PTPN11* into the hippocampal CA areas of neuronal cell type-specific Cre mouse lines. We found that overexpressing SHP-2^{D61G} in the hippocampal excitatory neurons, but not in the inhibitory neurons impairs spatial learning and memory, demonstrating that deregulation of SHP-2 signaling cascade in the excitatory neuron is responsible for the learning deficits in NS mouse models. Our results also show that SHP-2 in the excitatory neuron is critically involved in hippocampus-dependent learning and memory.

Title: Temporal profile of BDNF-dependent protein synthesis requirement for rat hippocampal memory consolidation: A computational analysis

Authors: *Y. ZHANG, P. SMOLEN, D. A. BAXTER, J. H. BYRNE;
Neurobio. & Anat., Univ. Texas, Houston, TX

Abstract: Long-term memory (LTM) is labile to disruption for up to two days after acquisition, after which it is more resistant to disruption and remains intact for prolonged time periods (days to lifetimes). The dynamical properties of the mechanisms that underlie consolidation are not well understood. To gain insights into molecular underpinnings of consolidation, we developed a differential-equation based model of key regulatory elements including BDNF, CREB, and C/EBP that underlie consolidation. To the extent possible, the model was constrained by data from an empirical study (Bambah-Mukku et al., J Neurosci 34:12547, 2014). These data suggest that a positive BDNF-autoregulatory feedback loop mediates hippocampal memory consolidation following inhibitory avoidance (IA) training. Interesting features of the data are a significant delay of bdnf transcription and a relatively abrupt termination of the feedback loop at or about 48 h. To examine the role(s) of feedback, the model was driven by a stimulus analogous to IA training. Sustained increases in the levels of phosphorylated CREB and C/EBP represented consolidation of LTM. The model simulated the complete time courses of transcription and translation for BDNF and the time courses of CREB phosphorylation and C/EBP expression after training, and fit the empirical measurements at 30 min and at 6, 12, 20 and 48 h after training. Simulations showed two waves of increased BDNF activity, which were accompanied by two phases of CREB phosphorylation and C/EBP expression. These simulations suggest that the first phase of CREB phosphorylation and C/EBP expression was independent of the feedback loop. The second phase was induced by the delayed increase of bdnf transcription. To simulate this delayed increase it was necessary to hypothesize that the same transcriptional repressors implicated in the termination of the loop at 48 h (Bambah-Mukku et al., 2014) are also active initially to inhibit the loop and then are inactivated, allowing closure of the positive feedback. Therefore we predict that the delayed initiation and termination of the BDNF feedback loop are controlled by the biphasic regulation of bdnf transcription by a group of transcriptional repressors. We also predict a time window during which late CREB phosphorylation and C/EBP expression is required for developing resistance of IA memory to disruption.

Title: The Role of IL-1 signaling in behavior and neurodegeneration after soman (GD) exposure

Authors: *T. M. FERRARA-BOWENS[1], J. CHANDLER[1], J. IRWIN[1], K. LAITIPAYA[1], L. SHUMWAY[1], M. WEGNER[2], E. A. JOHNSON[1];
[1]Pharmacol., [2]Comparative Pathology, USAMRICD, Gunpowder, MD

Abstract: Chemical warfare nerve agent (CWNA) exposure can initiate status epilepticus (SE), which can lead to severe neuropathology and behavioral impairment. While treatments are available to ameliorate SE, the therapeutic window for control is relatively short, with no approved treatments available to address the neurodegenerative process. Following exposure, brain damage resulting from SE activates microglia and astrocytes to upregulate inflammatory cytokines, including the pro-inflammatory cytokine interleukin (IL)-1. This creates a positive feedback loop to exacerbate neurodegeneration and to damage potentially healthy neuronal tissue. Inhibition of neuroinflammation reduces acute neurodegeneration in various CNS injury models and may also be beneficial following CWNA exposure. A soman (GD) model was developed using wild-type and IL-1 signaling knockout (KO) mouse strains (i.e., IL-1R1 and IL-1Ra) to validate IL-1 signaling as a viable neuroprotective target. Behavioral studies were conducted with the open field, zero maze, and Barnes maze to assess mobility, anxiety, and cognitive function. Results showed that the WT and IL-1Ra KO mice were more hyperactive and anxious compared to the IL-1R1 KO mice, and that the absence of IL-1 signaling may attenuate anxious behavior. There was also progressive brain damage in the amygdala and hippocampus between 24 hours and 25 days of exposure. In addition, the IL-1 signaling inhibitor anakinra produced post-exposure neuroprotection in these brain regions. These results show that therapeutically targeting the IL-1 signaling pathway is necessary to attenuate brain damage, and therefore, research into neuroprotective strategies is important to improve brain pathology and potentially improve behavioral outcomes.

Title: Learning regulates the mRNA demethylase fto and mRNA methylation

Authors: *B. J. WALTERS, V. MERCALDO, P. W. FRANKLAND, S. A. JOSSELYN;
Neurosci. and Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Translation of mRNA into proteins is vital for memory formation, as evidenced by local, spine-specific mRNA translation occurring in response to synaptic stimulation and the inhibition of memory expression produced by the administration of translational inhibitors. Although the role of translation in memory is well accepted, the actual mechanism that underlies local control of translation is poorly understood. In this study, we explored whether mRNA methylation is involved in regulating learning-induced translational control, providing a first test of this novel mechanism in learning and memory. RNA can be heavily modified, with the most abundant modification being the methylation of adenine, but technical difficulties involved in interrogating this modification have left its function elusive for nearly 5 decades. Two recent advances brought RNA methylation back into the spotlight and have begun to elucidate the potential roles of mRNA methylation in particular. First, the identification of the first mRNA demethylase Fto and its link to human obesity and cognitive decline demonstrated diseases which can be influenced by dysregulation of RNA methylation. Second, the advent of next generation sequencing allowed the potential functions of RNA methylation to be investigated. Using these techniques, a plethora of potential functions of RNA methylation were identified, with its most promising role being the potential to control mRNA translation. Specifically, mRNA methylation dictates the incorporation of mRNA into P-bodies that store or degrade mRNA, providing a probable mechanism for translational control. The ability to locally control translation via mRNA methylation makes this modification particularly enticing for regulating synaptic activity, where local control of translation in synapses is vital for synaptic plasticity. Here, we provide the first direct exploration of the role of mRNA methylation and the mRNA demethylase Fto in cognition. Using contextual fear conditioning in mice, we demonstrate that associative learning dynamically regulates Fto expression and mRNA methylation in area CA1 of the dorsal hippocampus. This regulation appears to be specific for Fto as Alkbh5, the other identified mRNA demethylase, is unchanged. Similarly, even though every type of RNA can be methylated, it appears that only mRNA is differentially methylated after learning. These studies represent the first attempt to bridge the gap between transcriptional control and the local translational control in learning and memory, thus identifying an essential missing link and a new layer of regulation in learning and memory.

Title: NF-kappaB regulates DNA demethylation in the hippocampus via Gadd45beta during fear memory formation

Authors: *F. D. LUBIN, T. J. JAROME, A. A. BUTLER, N. L. PACHECO, J. N. NICHOLS; Dept. Neurobiol, Univ. Alabama Birmingham, Birmingham, AL

Abstract: Experience-driven learning triggers critical mechanisms for turning genes on and off in neurons across several brain regions during long-term memory formation. In addition to transcription factors, epigenetic mechanisms such as DNA methylation and ***de***methylation have emerged as critical regulators of these gene expression changes required for memory "consolidation" or formation. While several mechanisms have been identified for DNA methylation events during memory formation, very little is known about how the DNA ***de***methylation process is regulated as a function of learning. Recently, Gadd45β has been identified as a potential mechanism for regulation of active DNA ***de***methylation in the hippocampus during memory consolidation; however how *Gadd45β* activity is regulated remains equivocal. Here, we found that learning in a contextual fear conditioning (CFC) paradigm increased *Gadd45β*, but not *Gadd45α* or *Gadd45γ*, gene expression in area CA1 of the hippocampus. The Gadd45β gene contains several κB consensus sequences for the nuclear factor kappa B (NF-κB) transcription factor, a critical regulator of memory formation. Thus, we found that pharmacological inhibition of NF-κB prevented the learning-induced increases in *Gadd45β* mRNA levels and decreased DNA methylation at the learning permissive gene, *Bdnf*, suggesting that NF-κB is involved in the regulation Gadd45β expression and DNA ***de***methylation events during the memory consolidation process. Next, we determined the subunit make-up of the active NF-κB dimer complex involved in Gadd45β-mediated DNA ***de***methylation. We found that while conditional *relA/p65* mutations in pyramidal neurons impaired hippocampus-dependent memory formation in the CFC learning paradigm, we observed no alterations in Gadd45β mRNA levels in area CA1. Intriguingly, in *c-rel -/-* mice, learning failed to induce increases in Gadd45β mRNA levels in the hippocampus and prevented increases in Gadd45β protein levels at the *Bdnf* gene and subsequent *Bdnf* DNA ***de***methylation. Congruently, intra-CA1 region specific *c-rel* knockdown prevented Gadd45β expression and *Bdnf* DNA ***de***methylation following CFC learning in adult animals. Collectively, these results identify a novel role for activity-dependent NF-κB in the process of DNA ***de***methylation events in hippocampal neurons during fear memory formation and nominate Gadd45β as a target effector of NF-κB in this process. Together, these studies further increase our understanding of epigenetic DNA ***de***methylation mechanisms necessary for fear memory processing, which will have broad relevance for the treatment of phobias and anxiety.

Title: HDAC3: An epigenetic key to ameliorating synaptic plasticity and memory impairments in the aging brain

Authors: *J. L. KWAPIS, Y. ALAGHBAND, E. A. KRAMÁR, D. P. MATHEOS, D. RHEE, A. J. LOPEZ, M. A. WOOD;
Neurobio. and Behavior and Ctr. for the Neurobio. of Learning & Memory, Univ. of California, Irvine, Irvine, CA

Abstract: Aging is accompanied by cognitive impairments, including difficulty forming long-term memories. Long-term memory formation requires gene expression, a process that may be disrupted with age (Rowe et al., 2007; Berchtold et al., 2008). Epigenetic alterations (changes in gene expression that occur through alterations in chromatin structure) may therefore contribute to age-related impairments in both gene expression and long-term memory. One major epigenetic mechanism important for memory is histone acetylation, in which acetyl groups are added or removed from histone tails by acetyltransferases (HATs) or histone deacetylases (HDACs), respectively. Increasing histone acetylation by blocking HDAC activity generally enhances both gene expression and long-term memory. In particular, histone deacetylase 3 (HDAC3) appears to be a key negative regulator of long-term memory formation, as blocking HDAC3 produces persistent object location memory following subthreshold training. Here, we tested whether HDAC3 activity also contributes to age-related impairments in synaptic plasticity and long-term memory. We hypothesized that dysregulated HDAC3 activity in the aging brain contributes to an unusually repressive chromatin structure that limits synaptic plasticity and memory formation. To test this, we focally deleted HDAC3 in the dorsal hippocampi of aging (18-month-old) mice before training them in the hippocampus-dependent object location memory (OLM) task. As predicted, aging wild type mice showed severe impairments in long-term memory for OLM. Deleting HDAC3 in the hippocampus rescued this deficit; 18-month-old mice lacking hippocampal HDAC3 showed robust long-term memory. This suggests that HDAC3 negatively regulates hippocampus-dependent memory formation in the aging brain. To test whether HDAC3 also limits synaptic plasticity, we next examined long-term potentiation (LTP) in hippocampal slices from 18-month-old mice. A single train of 5 theta bursts failed to produce stable LTP in

these slices, suggesting that LTP, like memory, is impaired with age. Blocking HDAC3 activity with a dominant negative mutant (HDAC3Y298H), however, ameliorated LTP deficits, resulting in a robust and stable potentiation. Together, our results indicate that HDAC3 is a key negative regulator of both long-term memory and synaptic plasticity in aging mice. We are currently working to understand how gene expression dynamics downstream of HDAC3 change with age to result in these impairments in synaptic plasticity and long-term memory.

Title: Extension of the sensitive period for imprinting in chickens by manipulating experience-dependent translation initiation

Authors: ***G. BATISTA**[1], J. JOHNSON[2], M. COSTA-MATTIOLI[2], J. PENA[1];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Neurosci., Baylor Col. of Med., Austin, TX

Abstract: The brain can be transiently sensitive to learning during short periods of time, known as sensitive periods (SP). Extending SPs may thus permit behavioral plasticity beyond early stages in life. Experience-dependent protein synthesis underlying long-term memory formation is a potential target for SPs extension. We tested this idea using imprinting in chickens as a learning task. We trained chickens to recognize an object paired to a sound on a computer screen, to test visual and auditory imprinting. Using Western Blotting and pharmacology we investigated whether eIF2α and mTORC1, which can independently regulate translation initiation, affect imprinting. Non-phophorylated eIF2α, which enhances translation initiation, was increased in the area involved in auditory imprinting but not in the site for visual imprinting. Accordingly, manipulation of this pathway either blocked or triggered consolidation of auditory, but not visual, memory. Notably, facilitating translation initiation through eIF2α also extended the critical period for auditory imprinting. The mTORC1 pathway was activated in both visual and auditory areas. However, blocking mTORC1 with Rapamycin only disrupted the formation of visual memories. In addition, we found that thyroid hormones, which can extend the critical period for visual imprinting, induced mTORC1 activation. Together, these data strongly suggest that the formation of auditory and visual long-term memory is mediated by two independent

pathways that regulate translation initiation. Furthermore, manipulating these pathways can extend the SP for imprinting in each sensory modality.

Title: The effects of post-acquisition blockade of hippocampal NMDA receptor subunit GluN2A and/or GluN2B on spatial memory forgetting

Authors: *K. SHINOHARA[1,2], T. HATA[1];
[1]Doshisha Univ., Kyotanabe City / Kyoto Prefecture, Japan; [2]Res. Fellow of Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Many studies have demonstrated that the hippocampal N-methyl-D-aspartate type glutamate receptors (NMDARs) are involved in the acquisition of spatial memory. However, we have repeatedly shown that the antagonism of the NMDARs suppresses “forgetting,” which is defined as the deterioration of a previously acquired memory. Here, we investigate the roles of the GluN2A and GluN2B NMDAR subunits in forgetting using the Morris water maze place task. Thirty-one rats were divided into four groups: artificial cerebrospinal fluid infused (aCSF; n = 8), NVP-AAM077 (the GluN2A selective antagonist) infused (NVP; n = 8), Ro 25-6981 (the selective GluN2B antagonist) infused (Ro; n = 7), or joint NVP/Ro infused (NVP+Ro; n = 8). Following four days of training (four trials per day), each rat received a chronic infusion into the bilateral dorsal hippocampus for 5 days using Alzet osmotic pumps (0.5 μl per hour). In the first probe test, which was delivered 7 days after the end of the acquisition training, both NVP-infused groups (i.e., NVP and NVP+Ro) spent significantly more time in target quadrant than the other two groups and compared to the chance level (25%). In the second probe test, which was delivered 24 hours later, only the NVP group spent significantly more time in the target quadrant compared to chance. In summary, the post-acquisition blockade of the GluN2A subunits enhances spatial memory retention, which suggests that hippocampal GluN2A-containing NMDARs play an important role in forgetting of a previously acquired spatial reference memory. In addition, the blockade of the GluN2B subunits suppresses the facilitative effect of the GluN2A antagonist, as indicated by the results of the NVP+Ro group during the second probe test.

Title: Correlation analysis between remote memory and CREB phosphorylation in cerebral cortex using *in vitro* imaging

Authors: *T. ISHIMOTO, H. MORI;
Univ. of Toyama, Toyama 930-0194, Japan

Abstract: Cyclic adenosine monophosphate response element binding protein (CREB) is a transcription factor that is considered important for memory consolidation and recovery process of depression. Once serine 133 of CREB is phosphorylated, kinase inducible domain (KID) of CREB binds to KIX domain of CREB binding protein, and the downstream gene expression is induced. However, the spatiotemporal pattern of the phosphorylation of CREB *in vivo* has not been fully analyzed because of technical difficulty. We employed the split luciferase technique to monitor the phosphorylation of CREB in live animals. In this technique, firefly luciferase was cleaved into N-terminal and C-terminal segments. The KID and KIX domains were fused with N-terminal and C-terminal segments of luciferase, respectively. By the interaction between these two fusion proteins mediated by serine 133 phosphorylation of KID, split segments complement each other to be a functional luciferase that can emit light. After we confirmed that these probe proteins emitted light serine 133 phosphorylation-dependently using HEK293T cells, we generated a transgenic mouse line that expressed probe proteins. Contextual fear memory is first formed hippocampus-dependently (recent memory) and then becomes hippocampus-independent over time (remote memory). It is considered remote memory is encoded in cerebral cortex, but molecular basis of remote memory consolidation is unclear. We measured the light emission from cerebral cortex every week after contextual fear conditioning using our transgenic mice. Four weeks after conditioning, remote memory consolidation was tested, and we found that CREB phosphorylation in prefrontal cortex 1 week after conditioning was correlated with remote memory. This result indicates the importance of CREB-dependent gene expression in prefrontal cortex for remote memory consolidation.

Title: The role of neuron-specific nucleosome remodeling complex subunit baf53b in cocaine-associated memories

Authors: *A. O. WHITE, D. P. MATHEOS, E. A. KRAMÁR, A. J. LÓPEZ, J. DOAN, M. DAVATOLHAGH, M. WOOD;
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Cocaine exposure in a distinct environment can lead to the formation of persistent drug-associated memories. Re-exposure to that environment in the absence of cocaine can lead to robust drug-associated behaviors. Recent evidence has implicated epigenetic mechanisms in drug-associated behavior and memory formation. Hitherto, there has been little research into a possible role for one major epigenetic mechanism, nucleosome remodeling, in drug-associated behaviors and memories. We examined the role of the neuron-specific nucleosome remodeling Brg1-Associated Factor (nBAF) complex in cocaine-associated behaviors and memories. Genetic manipulations targeting the BAF53b subunit of nBAF establish a differential role for nucleosome remodeling in the acquisition/consolidation cocaine-associated memories but not cocaine sensitization behavior. The deficits in cocaine-associated memories were concomitant with aberrant gene expression in the nucleus accumbens during cocaine memory consolidation. Additionally, mutant mice displayed disrupted synaptic plasticity in the nucleus accumbens. This study provides the first evidence that a neuron-specific nucleosome remodeling has a role in drug-associated memory formation.

Title: Hippocampal synaptic NF-kappa B during inhibitory avoidance long-term memory consolidation in mice

Authors: *A. SALLES[1], M. BOCCIA[3], M. BLAKE[3], N. CORBI[4], A. ROMANO[2], R. FREUDENTHAL[2];

Abstract: NF-kappa B is a transcription factor whose nuclear activity has been proven to be necessary for consolidation of long term memory in several species ranging from crabs to mice. This transcription factor has a wide distribution in the nervous system, with a well-reported presence in dendrites and synaptic terminals. This localization of the transcription factor, plus evidence pointing to different functions, is what gave rise to two general hypotheses for synaptic NF-kappa B: (a) The transcription factor plays a role in the synapse to nucleus communication, and it is retrogradely transported from polarized localizations to regulate gene expression; (b) The transcription factor modulates the synaptic function locally. Evidence indicates that both mechanisms can operate simultaneously. Our work focuses on the mice hippocampus in an associative learning paradigm such as the inhibitory avoidance learning task. We pay special attention to the local role of the transcription factor at the synapse. We describe its activation and localization dynamics during memory consolidation in this task and also we report NF-kappa B strongly bound to synaptic membranes. Furthermore we explore the role of synaptic NF-kappa B in this associative learning paradigm and how its activation is independent of the aversive or appetitive nature of the stimulus.

Title: To extract and interpret dynamics of functional and effective connectivity

Authors: *H. WANG, P. P. QUILICHINI, C. BERNARD;
Inst. De Neurosci. Des Systemes, INSERM U1106, Aix-Marseille Univ., Marseille, France

Abstract: Many analysis methods have been proposed to extract functional connectivity (or statistical dependency) graphs from neuroimaging data; however, they cannot identify the directed coupling or effective connectivity among network nodes. We introduce MULAN - a method that uses fuzzy inference and statistical tools, to optimally integrate information from multiple analysis methods, and to infer effective connectivity. We evaluated MULAN using thousands of simulated datasets under different scenarios, such as varying the number of nodes, link densities, connectivity motifs, the presence of hidden nodes and different connection strengths. MULAN outperformed all individual analysis methods and can reliably infer effective connectivity graphs. We have shown how to cross-validate the inference, using sub-datasets with hidden nodes. Moreover, we provided a concrete example of how to apply MULAN to empirical data. After evaluation of MULAN on the analyzed network is in a steady state regime, here we determine how to compute dynamic effective connectivity graphs, when the connectivity fluctuates over time. We used functional connectivity dynamics (both the correlation and consine similarity across the time windows) to capture the major switching time of the underlying structure. We used 27 methods to build the functional connectivity dynamics matrices. Among them, methods - GGC, BTED, PTED, BCorrU- can distinguish switching time when the underlying ground-truth structure undergoes major changes but with stable periods larger than 12 seconds (the minimal time is 4 seconds). Then we proved MULAN algorithm is able to extract the underlying structures within each stable period. We applied the dynamics of connectivity analysis on local field potential recordings in the hippocampal CA1 region and in the entorhinal cortex. The dynamics of functional connectivity matrix could distinguish the slow wave from theta oscillation. We extracted and explained the dynamics of effective connectivity from MULAN algorithm.

Abstract: Numerous behavioral and physiological activities are regulated in a circadian manner, including core temperature, feeding and sleep. In the brain, the master time keeping machine is the suprachiasmatic nucleus (SCN), and the core time keeping mechanism is made of several transcriptional/translational feedback loops. As a result, 10-20% of the genes oscillate, resulting in a daily remapping of the SCN neuronal network at the protein level. Such remapping allows switching between different physiological/behavioral states to optimize function. Many neurological/psychiatric disorders show altered circadian patterns (in particular sleep), and disruption of circadian rhythms can lead to pathological states (e.g. obesity). Whether genes and proteins oscillate during the night/day cycle in the brain outside the SCN, thus changing the functioning mode of networks, and whether such circadian activity is reprogrammed in pathologies is not clearly established. Here, we demonstrate: (i) that a circadian gene/protein remapping occurs in the mouse hippocampus, thus changing its functional mode during the night/day cycle, and (ii) that there is a reprogramming of this circadian regulation in experimental temporal lobe epilepsy (TLE). More than 1200 genes are oscillating in control conditions, and 1600 in epileptic animals. Only 400 genes oscillated in both conditions; with a change of phase. Proteomics supported the gene array data. We conclude that the molecular landscape undergoes a continuous remapping during the night/day cycle in the hippocampus; and that these dynamic rules are considerably modified in epilepsy.

Title: Interictal epileptiform discharges induce pathological hippocampal-cortical coupling in temporal lobe epilepsy

Authors: *J. GELINAS[1], D. KHODAGHOLY[4], T. THESEN[2], O. DEVINSKY[2], G. BUZSAKI[4,3];
[2]Dept. of Neurology, Comprehensive Epilepsy Ctr., [3]Ctr. for Neural Sci., [1]New York Univ., New York, NY; [4]New York Univ. Langone Med. Ctr., New York, NY

Abstract: Interictal epileptiform discharges (IEDs) are consistent indicators of epileptic brain regions, but their interactions with other brain regions and known physiologic network patterns are mostly undefined. Physiological hippocampal ripples are weakly correlated with medial prefrontal cortex (mPFC) spindles, and this coupling is implicated in memory consolidation during sleep. We show that spontaneously occurring hippocampal IEDs in freely moving rats effectively induce DOWN states and timed spindle oscillations in the mPFC during NREM sleep. IEDs occurring during REM sleep and wakefulness also generate patterns resembling DOWN states and spindle oscillations in the mPFC. Closed-loop cortical electrical stimulation triggered by IEDs can modulate this cortical response. Patients with focal epilepsy exhibit similar correlation of frontotemporal IEDs with spindles over anatomically restricted cortical regions. These findings reveal that IEDs can hijack physiologic coupling mechanisms between structures critical for memory processes, suggesting a possible contribution to cognitive impairment in epilepsy and new options for therapeutic intervention.

Title: A contained closed-loop electrical stimulation system

Authors: ***Z. ZHAO**[1,2], D. KHODAGHOLY[1], J. GELINAS[1], Y. WAN[2], G. BUZSAKI[1];
[1]Neurosci., NYU Langone Med. Ctr., New York, NY; [2]Neurosci., Peking Univ., Beijing, China

Abstract: Closed-loop electrical stimulation is increasingly used as a therapy in neuropsychiatric disorders, epilepsy and other neurological diseases. Here, we introduce a novel contained closed-loop system with potential applications to a broad range of neurophysiological questions. By developing a novel analog front-end design, the number of components used in the system is greatly reduced. Our design provides a scalable solution for high speed, high channel count, simultaneous acquisition and, importantly, stimulation of neural network activity. We have used our system to record high quality neural signals from silicon probes implanted in the hippocampus of freely moving rats and stimulate the hippocampal commissure through a bipolar electrode to successfully evoke a hippocampal population response. Furthermore, our system was used to apply transcranial electrical stimulation (TES) to the rat skull and bias the firing rates of hippocampal neurons. Lastly, we have used the onboard digital signal processing unit to detect interictal epileptiform discharges (IEDs) from rats with epilepsy and control feedback stimulation. The combination of acquisition, detection, and stimulation in a contained form potentially allows for stable, long-term, wireless monitoring of physiological and pathological neural networks.

Title: Neurogrid: large-scale hippocampal-cortical interactions

Authors: ***D. KHODAGHOLY**, J. N. GELINAS, G. BUZSÁKI;
NYU Langone Med. Ctr., New York, NY

Abstract: Large-scale recording from neural networks and their interactions is critical for understanding how information is processed and transmitted in the brain. Coupling between specific limbic and cortical brain regions is implicated in aspects of memory acquisition, consolidation, and retrieval, but how these interactions are coordinated over topographically diverse functional networks during online task performance and in offline states is unclear. Here we demonstrate large-scale hippocampal and cortical interactions by simultaneous acquisition of local field potential (LFP) and spiking activity from a large part of the dorsal cortical surface and multiple locations in the hippocampus in rats. We investigate the spatiotemporal interactions of the hippocampus with diverse functional cortical regions, as well as the physiological interactions of these cortical regions with each other. Moreover, we define the neuronal volumes involved in generation of LFP oscillations with varied frequencies and determine their capacity for traveling across the cortical surface. The ability to acquire and analyze LFP simultaneously from multiple functionally distinct brain regions will enhance comprehension of neural network processes and has implications for brain disorders characterized by disordered network function such as epilepsy.

Title: Replay is supported by a sub-population of CA1 pyramidal cells

Authors: *A. D. GROSMARK[1], G. BUZSAKI[2];
[1]NYU Neurosci., Brooklyn, NY; [2]Neurosci., New York Univ., New York, NY

Abstract: Hippocampal sequence replay, the preservation from a 'Maze' epoch to a subsequent 'Post' epoch of the spike-timing relationships between groups of cells, has been hailed as a key advance of systems neuroscience in the understanding of memory and systems consolidation. However, the interpretation of the replay phenomenon has been complicated by recent findings suggesting that A) network activity patterns change due to non-learning specific (homeostatic) mechanisms B) hippocampal network patterns subsequently associated with the coding of novel

stimuli are observable before the first exposure to these stimuli (pre-play) and C) mean firing and coactivation rates vary by orders of magnitude between pyramidal neurons but are largely preserved within units across time and behavioral states. The replay phenomena, to date, has most convincingly been demonstrated by the use of 'higher-order' (ensemble-based) methods but the relationship between these measures and physiological changes occurring at the level of individual cells or synapses has not been addressed. Here we use a higher-order (Bayesian) replay analysis to re-examine previous reports of replay and pre-play. We developed a novel analytic method for estimating the relative contribution of individual cells to the higher-order pre/replay signal. Using this method we find that replay (after correction by the 'pre-play' signal) of a novel experience is supported by a minority of hippocampal CA1 cells. We find that these 'replay cells' tend to be deep (dorsal) in the CA1 layer and bursty. Furthermore, we find that while 'replay cells' display increased ripple modulation (firing rate gain) from the pre to the post epoch, these cells already display elevated levels of ripple modulation in the pre-epoch. These findings support the view of learning-induced plasticity as underlying subtle and circumscribed changes within the context of a predominantly rigid hippocampal network organization.

Title: Modulation of neurons and assemblies by sleep

Authors: *B. O. WATSON[1,2], J. P. GREENE[3], G. BUZSAKI[1];
[1]New York Univ., New York, NY; [2]Dept. of Psychiatry and Feil Family Brain and Mind Res. Inst. Weill Cornell Med. Col., Weill Cornell Med. Col., New York, NY; [3]Univ. of Chicago, Chicago, IL

Abstract: The mammalian brain is a complex dynamical system with two major functional states: waking and sleep. During waking experience the brain accomplish a variety of tasks, many of which involve plastic changes moving the system state away from homeostatic baseline. Sleep may serve the purpose of re-balancing the brain to both ensure it does not become dis-

equilibrated and prepare it for future work and learning. We have pursued a technique of monitoring multiple neurons as well as local electrical potentials simultaneously in frontal neocortex in order to study the major changes accomplished by sleep. First we re-capitulate prior findings that overall cortical neuronal spike rates decrease over the course of sleep and extend this observation by demonstrating that this drop in spike rate is exponential in nature. Second, we look at 1-4ms timescale interactions between pairs of neurons which may be indicative of synapses and find that these functional synaptic-timescale interactions also weaken over sleep. We then observe how a major functional unit of the neocortex, the assembly, is altered over sleep. Assemblies naturally defined by the slow waves of slow wave sleep have been shown to replay waking activity and we show that they become less coherent as sleep progresses. Finally we examine assemblies defined during the wake state and find that they are differentially activated over the many sleep oscillations including slow waves, sleep spindles and Rapid Eye Movement sleep. Furthermore, different assemblies are differentially modulated across these brain states. This heterogeneous modulation of waking assemblies, when set on a background of largely homeostatic decreases in various forms of activity over sleep opens the door for future experiments aimed at understanding how sleep differentially effects learning-related versus learning-unrelated neuronal, synaptic and assembly activity.

Title: Physiological properties of the hippocampus-amygdala networks during sleep and wakefulness

Authors: *G. GIRARDEAU, I. INEMA, G. BUZSÁKI;
NYU Med. Ctr. Neurosci. Inst., New York, NY

Abstract: Amygdala network dynamics during the acquisition and retrieval of classical and contextual fear conditioning have been extensively studied in rodents. However, little is known about the basal physiological properties of the amygdala and its interactions with the hippocampus during wakefulness, slow-wave-sleep (SWS) and REM-sleep. Here we designed a new task combining extensive spatial sampling of a linear track with a location-specific fearful element (airpuff), to investigate neuronal dynamics in the hippocampo-amygdala networks. Large neuronal ensembles were recorded in the amygdala and dorsal hippocampus in rats, during experimental sessions including extensive sleep periods before and after training on the task. We first characterized oscillatory activity in the basolateral amygdala (BLA) : we showed strong 20Hz (beta) and 50Hz(gamma) frequency bands that decrease in power during active running. Theta is strongest in REM-sleep, while there is a broad increase in low frequencies (1-12Hz) during slow-wave sleep. Subpopulations of cells in BLA and neighbouring nuclei are differentially modulated by these specific frequencies. Interestingly, the firing rate of BLA pyramidal cells (but not interneurons) specifically increases during REM-sleep compared to SWS and wakefulness. Finally, while the proportion of BLA cells modulated by hippocampal theta is low (12%), we were able to identify two populations of BLA cells that respond to hippocampal SWS ripples by increasing their firing rate during ripples (15%) or decreasing it (19%), suggesting amygdalo-hippocampal communication during SWS. Further analysis will examine the link between different subpopulations and task-related activity (response to reward/airpuff).

Title: Local circuit dynamics and spatial information coding in the hippocampal dentate gyrus

Authors: *Y. SENZAI[1], L. ROUX[1], E. STARK[1,2], G. BUZSÁKI[1];
[1]New York Univ., New York, NY; [2]Tel Aviv Univ., Tel Aviv, Israel

Abstract: The dentate gyrus (DG) is a 'gate' to the trisynaptic DG-CA3-CA1 pathway of the hippocampus. Local field potentials (LFP) in DG show different dynamic patterns during different brain states. However, it is not clear how the local circuit of DG supports those dynamics as well as computation in DG. To address these questions, we performed large-scale recordings of LFP and unit firing from DG of freely moving mice, combined with optogenetic and physiologic identification of different cell types. For optogenetic identification, we used promoter-specific Cre lines to express channelrhodopsin or archaerhodopsin in specific cell types. For physiologic identification, we used parameters such as the trough-to-peak latency of the averaged waveform, the burst index based on the autocorrelogram, and the amplitude versus depth profile of the dentate spikes types 2 (DS2) observed during slow wave sleep (SWS). The anatomical location of each recorded unit was estimated based on amplitude depth distribution. Based on these measures, we classified recorded units into six subgroups: somatostatin (SST) positive cells, narrow-waveform cells, wide-waveform cells, putative molecular layer perforant pathway associated (MOPP) cells, putative granule cells, and hilar bursty cells. We then analyzed how those classified DG units were recruited to local circuit dynamics such as DS1 and DS2 during SWS, as well as theta and gamma oscillations during the awake state. We found that, compared to all other cell types except wide-waveform cells, SST cells (1) were less recruited to DS1 and DS2, and that (2) tended to fire in later phase in both theta and gamma LFP oscillations. Moreover, we analyzed the spatial correlates of identified DG neurons while mice were running on a linear track for water rewards. We observed that (1) only a few putative granule cells had place fields while almost all hilar bursty cells had place fields, and that (2) several interneurons also had stable spatial firing modulation. We will also investigate how each cell type in DG contributes to behavior by examining their behavioral correlates in different environments.

Title: Functional labeling of restricted populations of head direction neurons in the postsubiculum

Authors: *D. F. ENGLISH, A. PEYRACHE, S. KILJAN, G. BUZSAKI;
Neurosci., The Neurosci. Institute, New York University, Sch. of Med., New York, NY

Abstract: The rodent navigation system includes three types of neurons whose activity codes for spatial information: place cells, grid cells and head direction (HD) cells. HD cells are components of a neural compass whose population activity encodes the directional heading of the animal in the yaw axis irrespective of other behavioral variables. This signal is generated by vestibular information and stabilized by visual landmarks. The postsubiculum (PoS; previously referred to as the dorsal presubiculum) is the first cortical area to receive the HD signal from the vestibular system via the anterodorsal nucleus of the thalamus, and where the vestibular and visual systems converge to produce a precise and stable representation of the animal's current heading. While the behaviorally related firing patterns of HD neurons in the PoS and other areas have been thoroughly investigated, there is a paucity of knowledge about the fine structural organization of the circuits which support the HD signal. To facilitate interrogation of this circuitry we aimed to express fluorescent proteins and opsins in restricted populations of HD cells with overlapping tuning fields to enable the visualization and control of a cohesive section of the neural compass. FosCreEr transgenic mice (Guenthner et al. 2013) express tamoxifen-dependent Cre recombinase under control of the Fos promoter, allowing for Cre dependent transgenes to be selectively expressed in cells active during temporally restricted tamoxifen exposure. FosCreEr mice were injected intracranially with AAV encoding either DIO-mCherry or DIO-ChR2-EYFP and subsequently injected with 4-hydroxytamoxifen during unidirectional head fixation in a familiar environment, yielding transgene expression in a subpopulation of PoS neurons. The accuracy of the restriction of transgene expression to HD cells with overlapping tuning fields will be tested using diode probes (Stark et al. 2012), which enable optical tagging of ChR2 expressing single units in freely moving mice. Title: Transformation of a head-direction signal into a spatial code

Authors: *A. PEYRACHE[1], N. SCHIEFERSTEIN[2], G. BUZSAKI[2];
[1]Neurosci. Inst., New York Univ. Langone Med. Ctr., New York, NY; [2]Neurosci. Inst., New York Univ. Langone Med. Ctr., New York, NY

Abstract: The brain's cognitive map is represented by neurons firing in specific regions of the environment explored by the animals. The head-direction (HD) signal is critical for the establishment of this representation of space and for navigation capabilities. However, how this signal is transformed into higher spatial representation remains unknown. The HD signal is relayed to the parahippocampal areas by the antero-dorsal nucleus (ADn) of the thalamus, primarily to the post-subiculum (PoS). Head-directions cells, tuned for a specific orientation of the animal's head in the horizontal plane, are present in the two brain areas. Here, we show that the amount of HD and spatial information conveyed by HD cells in both structures is correlated, suggesting that HD cells convey an actual spatial signal. However, for each ADn cell, the spatial information conveyed by a generic cell spiking only in function of animal’s heading and the same HD tuning curve as the original neuron is quantitatively identical. This reveals that the spatial information conveyed by thalamic HD cells results from the animal's head direction behavior, which is non-uniform and therefore informative due to environmental constraints such as boundaries. This was not the case for a subpopulation of PoS cells which conveyed a conjunction of HD and spatial information. Thus, this thalamo-cortical circuit may transform a pure HD signal into a spatial code under geometric constraints from the environment.

Title: A re-examination of the relationship between rodent dCA1 and behavior

Authors: *J. D. LONG II, G. BUZSAKI;
Neurosci. Inst., New York Univ., New York, NY

Abstract: Research into the function of the hippocampus over the past several decades has resulted in a paradoxical description of the hippocampus as necessary for both declarative memory formation and spatial navigation. A conceptual tension uniting these interpretations is the implicit assumption of a homunculus that retrieves memories and reads maps. The central hypothesis of this work is that the hippocampus serves both these apparent functions by forming associations between complex stimuli, composed of many elements, and sequences of behavior, composed of many movements. This hypothesis predicts that neural correlates of specific behaviors exist within rodent dCA1 hippocampus above and beyond spatial location and head direction. Several conditions must be met prior to testing this hypothesis in the rodent dCA1 hippocampus. Firstly, the subjects must not be placed in highly constrained environments which induce strong correlations between their trajectories and behaviors e.g. linear/circular tracks, T-mazes, radial arm mazes. In this study, we utilize a cheeseboard maze, allowing the subjects (n = 4) to form stereotyped, idiosyncratic behavioral plans while foraging for water reward. Next, the time-series of the subjects' behavioral output must be accurately quantified. We use a custom-made markerless motion capture system to generate accurate 3D kinematic tracking data of our subjects at 50 frames per second (to be open source released). Lastly, the behavioral states of the subjects must be quantified to calculate correlations between these and the time-series of neural data (all subjects were implanted with 6-8 shank silicon probes bilaterally in dCA1). We define behaviors as stereotyped dynamics in the kinematic data and leverage recently developed techniques in machine learning to identify behaviors in an unsupervised manner (van der Maaten and Hinton 2008). This allows for both generalization across subjects as well as the discovery of novel behaviors (Berman et al. 2014). With this framework in place, we apply standard analysis methods in systems neuroscience to search for neural correlates of behavior in the rodent dCA1 hippocampus. At the single unit level, reverse correlation is used to determine whether the firing of individual neurons map onto specific behaviors. At the population level, ensemble decoding techniques are used to determine whether information about the moment to moment variations in the subjects' behaviors are available within the population activity. This ongoing research offers a unified interpretation of the function of the hippocampus.

Title: Segmentation of space by theta sequences recorded across the longitudinal axis of the hippocampus

Authors: *S. A. MCKENZIE[1], J. PATEL[1], A. CHADWICK[2], G. BUZSÁKI[1]; [1]NYUMC, New York, NY; [2]Inst. for Adaptive and Neural Computation, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: For hippocampal principal cells, movement through space is associated with spiking at earlier phases of the theta rhythm,a phenomenon known as theta phase precession. Relatedly, cells with adjacent place fields are sequentially active within each theta period. Recent evidence suggests that these theta sequences reflect more than a fixed amount of space around the subject and could code for meaningful segments of the environment. Variations in place field size and the systematic shift in theta phase across the longitudinal axis complicate these models of temporal coding. We recorded ensembles across the septotemporal axis of CA1 to test how cells coordinate in time to represent space. Consistent with prior reports that slowly evolving neural patterns show about a ten times compression into theta sequences, the cross-correlograms between cell pairs revealed a correlation between the timing of the peak lag observed on theta time scales and that observed on behavioral time scales. This correlation was observed for cell pairs recorded from tetrodes separated by up to 5mm in which the theta phase offset of the LFP exceeds 90º. Next, we computed the translation in space at every time bin that best predicted spiking given a cell's trial-averaged place field. The mean translational offset was calculated for binned phases of local theta or for a global, dorsal reference. Remarkably, cells across the longitudinal axis showed temporally coherent retrospective and prospective coding with reference to the dorsal theta rhythm. Next, we performed Bayesian decoding of the rat's position using ensembles of spikes binned according to dorsal theta or ensembles in which the instantaneous spike counts were time-shifted to globally align theta phases. We found better decoding accuracy for the observed, non-shifted ensembles. Finally, Bayesian decoding of cell sequences bounded by peaks in dorsal theta revealed long sweeps of decoded positions that

began at a route's start location and finished at the route's end. Combined these results suggest interlaminar coordination across the septotemporal axis. The complex phase by position relationships of the more temporal cells may explain the deviations of the current results from predictions of simple models that generate theta sequences from linear phase precession over Gaussian place fields and a traveling theta wave. We propose that ensemble activity during theta is embedded within the temporal context of a past and future bounded by representations of salient events.

Title: Monolithicalyl integrated micro-LED probe for high-precision optogenetics

Authors: ***F. WU**[1], E. STARK[2,3], K. KIM[1], G. BUZSAKI[2], E. YOON[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]New York Univ., New York City, NY; [3]Dept. of Physiol. and Pharmacol., Tel Aviv Univ., Tel Aviv, Israel

Abstract: Recently, optogenetics has opened up a new way to analyze neural circuits by introducing photo-sensitive proteins (opsins) into specific cell types. In principle, this type of cell-specific targeting allows precise manipulation of neural activity, testing spike timing during specific neural computations and behaviors at a temporal resolution of a few milliseconds, in the intact brain. Despite the rapid advancement of optogenetics in recent years, supporting technology to reliably deliver light to and record electrical signals from deep brain structures in freely-moving animals has been lagging. Early work involving *in vivo* optogenetics relied on manual assembly of commercially available recording components such as metal electrodes or passive high-density probes with optical fibers, which may suffer from misalignment errors and cause tissue damage. Moreover, the spatial resolution of fiber-based optogenetic devices is limited by the bulk of the implanted fibers. This work describes an innovative solution to enhance the spatial resolution and scalability of optogenetic stimulation and recording probes. We monolithically integrated 12 InGaN μLEDs (10 μm x 15 μm) and 32 recording electrodes (11 μm x 13 μm) on a 4-shank silicon probe. Combined with the measured electroluminescence characteristics of the fabricated μLEDs, thermal modeling using COMSOL Multiphysics provided a reference to drive the μLEDs to produce sufficient light intensity without overheating the tissue (< 1°C). To understand the interference between stimulation and recording channels, an equivalent circuit model of the μLED probes was built using COMSOL and SPICE,.and validated in comparison with the *in vivo* data; the analysis suggested specific fabrication steps to

further minimize interference. We implanted the μLED probes into the hippocampal CA1 pyramidal layer of 6 mice for chronic studies. We observed optically induced activity in all CaMKII::ChR2 animals (n=4) but not in wild type animals (n=2). Specifically, spikes were robustly induced by as low as 60 nW light power, and fast population oscillations were induced at the microwatt range. To demonstrate the spatiotemporal precision of parallel stimulation and recording, we achieved independent control of distinct cells ~50 μm apart and of different somato-dendritic compartments of single neurons. The scalability and spatiotemporal resolution of this novel monolithic optogenetic tool are unprecedented, providing versatility and precision for cellular level circuit analysis in deep structures of intact freely-moving animals.

Title: Mechanisms of theta sequence formation during exploration of a novel environment

Authors: C. DRIEU[1], R. TODOROVA[1], *M. B. ZUGARO[2];
[1]CIRB, CNRS - Collège de France, Paris, France; [2]CIRB, CNRS - Col. De France, Paris, France

Abstract: The hippocampal formation plays a critical role in spatial and episodic memories. In freely behaving rats, hippocampal 'place' cells selectively discharge in specific locations of the environment ('firing fields'). When a rat crosses successive overlapping firing fields, the spike trains of the corresponding place cells overlap in time. Strikingly, at a fast time scale of ~100 ms corresponding to one cycle of the theta rhythm (7-10 Hz), these cells fire in a stereotyped order, forming sequences that reflect the ongoing trajectory. These 'theta' sequences could be related to episodic-like memory. Although the underlying mechanisms remain unknown, two theoretical frameworks have been proposed. The first posits that sequences result from asymmetric connectivity between cell assemblies. Each active cell assembly drives subsequent activation of the next assembly to generate a sequence. In the alternative model, external inputs determine when each assembly starts firing, and sequences result from independent advancement of each assembly relative to theta as the animal moves ahead (phase precession). Asymmetric

connectivity then results from, rather than causes, theta sequences. We have designed an experimental protocol that perturbs the precise spiking dynamics of hippocampal assemblies in a novel environment. Animals were transported on a miniature treadmill mounted on a model train. We have previously shown that when the treadmill is turned on (ACTIVE), place cells phase precess and form theta sequences, but when the treadmill is turned off (PASSIVE), few cells phase precess. We asked whether theta sequences would be disrupted in the passive condition. The rats underwent three successive sessions: PASSIVE-1, ACTIVE, PASSIVE-2. Spatial specificity and theta modulation of place cell activity decreased during both passive sessions compared to the active session. Fields formed during PASSIVE-1 often shifted during ACTIVE, but remained stable between ACTIVE and PASSIVE-2. In addition, the proportion of significant theta sequences across theta cycles increased two-fold during ACTIVE compared to PASSIVE-1. This would argue against pre-established connectivity between cell assemblies underlying theta sequences. Interestingly, we found the same difference between ACTIVE and PASSIVE-2, indicating that sequences formed during the active session were not preserved during the subsequent passive session. This in turn would be inconsistent with the theta sequences yielding stable connections between assemblies. Our preliminary results appear partly at odds with both families of theoretical models of theta sequences.

Title: Cross-frequency coupling and network dynamics in entorhinal-hippocampal circuits

Authors: *A. FERNÁNDEZ RUIZ[1,2,3], A. OLIVA[1], G. BUZSÁKI[3], A. BERÉNYI[1,3];

Abstract: In the entorhino-hippocampal circuits theta rhythm organizes the activity of interconnected cellular populations during behavior and REM sleep. Sequential activation of cell assemblies mediates information flow and processing in the different nodes of the circuit and is reflected as gamma oscillations in the local field potentials (LFPs). We employed large-scale silicon probes (up to 512 channels) to record LFPs and single-unit activity simultaneously in all hippocampal subfields and layers of the entorhinal cortex in rats during various navigational tasks and sleep. Using advanced analytical techniques we characterized the spatial distribution and spectro-temporal properties of the identified sources of hippocampal gamma oscillations to elucidate if they arise as a result of local circuit computations or reflect rhythmic inputs to the target region. We found that distinct gamma patterns mediated by the different entorhinal and intrahippocampal inputs are precisely organized within the theta cycle and are coupled preferentially to characteristic frequency bands. Moreover, changes in phase preference of gamma bursts and their cross-frequency coupling with theta oscillations display topographic changes associated to behavioral states. Hippocampal and entorhinal units display variable phase-locking with the different gamma inputs according to memory demands and environmental novelty. We found that slow gamma patterns are transmitted more reliably along the whole network than faster ones, however high-frequency oscillations originated locally as a result of excitation-inhibition loops are more efficient to synchronize spiking. Different inputs can cooperate or compete to entrain local networks allowing a fast switching between different computational modes. Beyond the traditional scheme of information flow in the entorhino-hippocampal circuit we reported the coexistence and dynamic interactions of multiple channels of bidirectional communication carrying multiplexed frequency codes. Hippocampal and entorhinal spiking appear to be coordinated in a wide range of gamma frequencies and theta phases, enabling a large computational flexibility that can support different behaviors. Our results argue in favor of theta-gamma coupling as a functional mechanism to dynamically adjust the information processing to support the broad repertoire of animal behavior.

Title: Targeted transcranial electrical stimulation protocols: spatially restricted intracerebral effects via improved stimulation and recording techniques

Authors: *M. VOROSLAKOS[1], A. OLIVA[1], K. BRINYICZKI[2], T. ZOMBORI[2], B. IVÁNYI[2], G. BUZSÁKI[3], A. BERÉNYI[1,3];
[1]Univ. of Szeged, Szeged, Hungary; [2]Dept. of Pathology, University of Szeged, Hungary; [3]Sch. of Med., Neurosci. Inst., New York University, NY

Abstract: Neural activity can be induced or modulated by an exogenous electric field, which can be generated non-invasively by transcranial electrical stimulation (TES). The physiological effects of TES are determined by the spatial distribution and temporal pattern of the induced intracerebral currents. In most cases in human patients there is no direct data accessible about the local neuronal entrainment by TES, but still the a priori knowledge on the expectable local intracerebral effects of given stimulation parameters may allow to design targeted treatment plans. In principle, TES can be also spatially selective (similarly to deep brain stimulation) by modulating the distribution of the electric fields. In our experiments, we set out to measure the TES generated electric fields in human brains and to test the viability of a spatially focused TES protocol. Our assumption is that the effect of repetitively delivered high frequency (>1 kHz) Gaussian pulses on multiple bilateral electrode pairs may be temporally integrated by the neuronal membranes, leading to a stronger neuronal entrainment around the overlapping region of the diagonal fields than at the periphery. We recorded TES-generated field potentials in human cadavers and anesthetized rats. Stimulation was applied by placing Ag/AgCl EEG electrodes over the external surface of the skull. We used independently isolated stimulation pairs to deliver sinusoidally modulated TES with various parameters and repetitive high-frequency Gaussian stimulus trains in various arrangements. Custom made multiple-site electrodes (>200 contact points) and 32-channel silicon probes were used to thoroughly sample the field potentials in the brain. We also measured the shunting effect of the skin during transcutaneous stimulation. In addition to our earlier results, we found that the skin dramatically reduced the generated intracranial electric fields, and alters its geometry. We recorded the unit activity during the high-frequency pulsed TES, and estimated its effects on neuronal activity. We found that the high-frequency stimulation generates a relatively small diameter axial voltage gradient in the geometrical axis of the stimulator electrodes (<50% gradient strength off-axis vs in-axis). The multiple crossing stimulation pairs protocol resulted in a spatially focal effect after

temporal integration (>30% larger electric field magnitude at the crosspoint than at the periphery). We also suggest a protocol to selectively and unilaterally stimulate the frontal cortex via TES.

Title: Place cells properties in CA1 depend on different inputs

Authors: *A. OLIVA GONZÁLEZ[1], A. FERNÁNDEZ-RUIZ[1,2,3], G. BUZSÁKI[3], A. BERÉNYI[1,3];
[1]Szeged Univ., Szeged, Hungary; [2]Sch. of Physics, Complutense Univ., Madrid, Spain; [3]Neurosci. Inst., New York Univ., New York, NY

Abstract: The specific spatial related firing of the various entorhinal and hippocampal cells and the computational processing schemes of these structures entail the circuit as the navigational system of the brain. However, the physiological mechanisms connecting single cell physiology with the emerging functional properties of these networks still remain unclear, thus preventing to establish a solid framework to deduct the particular role of each cell type during the navigation process. To address these questions we used large-scale high-density silicon probes to record population activity (LFP) and single unit activity simultaneously along the subiculofimbrial (transversal) axis of the hippocampus and entorhinal cortex (EC) in behaving rats. First, we found that spatial coding properties differed between the proximal and distal poles of the hippocampal axis. Proximal cells show single place fields and carry more spatial information

while distal ones have sparser place fields and are less spatially informative. Secondly, investigating the theta modulation of these neurons we found that cells located at different poles fire preferentially at different phases. Proximal cells tend to fire later in the theta cycle, closer to the preferred phase of CA3 input, and distal cells earlier, closer to the phase of the EC input. The gamma frequency modulation of spiking showed stronger slow gamma (30-50 Hz) phase-locking in the proximal site, which has been associated to the CA3 input, while distal cells showed stronger phase-locking with mid-gamma (80-100 Hz), associated with EC input. The distribution of probability of functional monosynaptic connections of CA3 or EC cells to CA1 cells along the hippocampal transversal axis support the previous findings by showing a gradually shifting balance in the contribution of EC and CA3 inputs to the CA1 local populations. Together these results suggest that the different cortical and intrahippocampal inputs have distinct contribution to control the activity of cells along the hippocampal transversal axis, and may explain the variable place coding efficacy of CA1 neurons along the transversal axis also reported in other works. Taking into account the specificity of the projections from different portions of the EC cortex and CA3 to the CA1, we propose a new scheme of CA1 functional specialization based on the role of the different inputs during navigational behaviors.

Title: I(h) attenuation impairs learning and underlying entorhinal-hippocampal network oscillations

Authors: ***A. MERSEBURG**[1], K. MEIER[2], S. MARGUET[1], F. MORELLINI[2], D. ISBRANDT[1];
[1]Exptl. Neurophysiol., DZNE Res. Team, Koeln, Germany; [2]Ctr. for Mol. Neurobio., Hamburg, Germany

Abstract: The entorhinal cortex (EC)-hippocampus (HC) circuitry plays a pivotal role in memory consolidation and retrieval. We wanted to determine how network activities within and between the EC-HC circuit regulate memory formation, and how these are influenced by intrinsic resonance properties of specific neuronal populations. The hyperpolarization-activated

cyclic nucleotide-gated cation (HCN)/h channels mediating I(h) are an important determinant of the biophysical properties of neurons, regulating the RMP, resonance frequency and dendritic integration. We hypothesize that changes in the intrinsic properties of specific neuronal populations affect local network activity and hence, communication within and between the EC-hippocampal circuit. We developed transgenic mice with attenuated HCN/h channel activity in adulthood using the Tet-Off system to conditionally express a dominant-negative HCN/h channel subunit (HCN-DN) in specific neuronal populations. Network oscillations within the EC-HC circuitry were investigated by using mice with CaMKII-alpha promoter-mediated, forebrain projection neuron-restricted I(h) deficiency. To assess the coordination of activity between the two regions we also studied mice with EC-specific attenuated HCN/h channel activity in principal neurons, which was achieved by expressing the HCN-DN under control of the neuropsin promoter. Phenotypes were characterized in a battery of behavioral tests that we later additionally combined with electrophysiology. Local field potentials were recorded in freely moving mice implanted with 16-site linear silicon probes along the hippocampal CA1-dentate gyrus axis. Both transgenic mouse lines show impaired learning in a hippocampus-dependent single-trial spatial learning task. EC-specific I(h) attenuation caused additional impaired learning in the fear conditioning test. Both groups differ from controls in local hippocampal and EC-HC network patterns during sleep. CaMKII-alpha-mediated I(h) attenuation led to larger amplitude sharp waves but ripples of lower spectral frequency, as well as power changes in stratum lacunosum theta and gamma, a region that receives EC-input. In contrast, EC-specific ablation of I(h) decreased modulation of gamma by theta and reduced gamma coherence between stratum lacunosum moleculare and radiatum during REM-like sleep. Thus, changing the intrinsic properties of specific neuronal populations within the EC-HC network differentially affects the underlying network oscillations.

Title: Development of hippocampal network activity patterns in mice during the first two weeks of life

Authors: *R. HINSCH[1], S. MARGUET[1], A. SIROTA[2], W. FAZELI[3], D. ISBRANDT[1]; [1]DZNE, Cologne, Germany; [2]BCCN, Munich, Germany; [3]Univ. children's hospital, Cologne, Germany

Abstract: An open challenge in neuroscience is to map the structural and functional network changes that accompany early brain development. Early network oscillations, which qualitatively and quantitatively differ from adult patterns, are thought to contribute to the functional and structural maturation of different brain regions. Most studies on neonatal hippocampal activity are based on in-vitro, or anesthetized in-vivo preparations. Characterizing hippocampal activity during the transition from immaturity to adulthood in unanesthetized mice is a major step towards understanding brain maturation. During adult slow-wave sleep, hippocampal activity in mouse CA1 is dominated by sharp-wave (SPW)-ripple complexes, whereas paradoxical sleep primarily consists of theta/gamma oscillations. To characterize the development of oscillatory network activities in unanesthetized neonatal mice, we adapted acute head-fixed recording techniques with multichannel silicon microelectrodes in awake, locally anesthetized mice aged between postnatal day two (P2) and P15. The qualitative and quantitative characterization of spontaneous local field potentials (LFPs) along the CA1-dentate gyrus axis revealed oscillations in CA1 apical dendritic layers in the beta frequency range (10 to 30 Hz) that lasted 2-30 s. Their mean duration increased with age, reaching a maximum between P9 and P14. Hippocampal SPWs were detected as early as at P2. At P9, SPWs occurred simultaneously with fast oscillations (~100-150 Hz) resembling SPW-ripple complexes in adult mice. Also at P9, current source density analysis of the LFP revealed an additional current sink occurring between the sink-source pair already present in the first week of life; this may indicate early functional input from entorhinal cortex (EC) to CA1, and maturation of the CA3 input via Schaffer collaterals (SC) only around P9. This finding contrasts the current hypothesis of hippocampal SPWs generation at P1-P7, which is that early hippocampal sharp waves are correlates of CA3 population activity. To further investigate developmental changes in CA1 inputs, we electrically stimulated either the perforant path (PP) (EC input) or CA3 (SC input). Preliminary data indicate that both inputs are functional at P9. Additional recordings at earlier time points from both hippocampus and EC are needed to further characterize the maturation of SC and PP functional inputs onto CA1. Together with the data described above, these will provide a basis for the characterization of functional connectivity development in the hippocampus of awake neonatal mice.

Title: Burst generation and propagation during hippocampal sharp waves in a lognormal recurrent network model

Authors: *T. FUKAI[1,2], Y. OMURA[3], M. M. CARVALHO[4], K. INOKUCHI[3,2];
[1]RIKEN BSI, Wako, Japan; [2]CREST JST, Kawaguchi, Japan; [3]Dept. of Biochem., Univ. of Toyama, Toyama, Japan; [4]São Carlos Inst. of Physics, Univ. São Paulo, São Paulo, Brazil

Abstract: The strength of cortical synapses was suggested to distribute lognormally, with a long tail of strong synapses. Here, we model a recurrent neural network of the hippocampal CA3 with the weights of recurrent excitatory connections distributed lognormally. Using multi-timescale adaptive threshold neurons, we construct a low-frequency spontaneous firing state of bursty neurons, which well replicates the observed statistical properties of population synchrony in hippocampal pyramidal cells. Furthermore, we show that various properties of neuronal activity, such as the average firing rates of neurons, the rate and magnitude of spike bursts, the magnitude of population synchrony, and the correlations between pre- and postsynaptic spikes, also obey lognormal-like skewed distributions, as recently shown in the hippocampal CA1 and CA3 areas. Our model demonstrates that bursts spread over the lognormal network much more effectively than single spikes, implying an advantage of spike bursts in information transfer. This efficiency in burst propagation is not found in neural network models with Gaussian weighted recurrent synapses. Our model proposes a potential network mechanism to generate sharp waves in CA3 and associated ripples in CA1 because bursts occur in CA3 pyramidal neurons most frequently during sharp waves.

Title: Theta phase precession in spatial non-grid cells in the medial entorhinal cortex

Authors: *G. W. DIEHL[1], O. J. HON[1], C. C. CANNOVA[1], M. P. BRANDON[1], S. LEUTGEB[1,2], J. K. LEUTGEB[1];

Abstract: The precisely timed activation of hippocampal and medial entorhinal cortex (MEC) cell populations is thought to support memory for sequences of events. As an animal travels through the spatial firing fields of cells in these brain regions, each cell fires at progressively earlier phases of subsequent theta cycles. At the network level, this phase precession results in the sequential firing of co-active neurons within a single theta cycle, and thus within a time frame that allows for spike-time-dependent plasticity processes. Theta phase precession has been observed in all hippocampal subregions and in grid cells located in layer II of the MEC, upstream of the hippocampus. Phase precession could either emerge independently in each of these cell populations, or it could propagate through the circuitry by inheritance from one phase-precessing cell population to another. In contrast to models that exclusively rely on local mechanisms, hippocampal phase precession has been shown to be disrupted by MEC lesions (Schlesiger et al, SfN Abstract #578.29, 2013). This finding is consistent with the notion that grid cells are necessary for hippocampal phase precession. To examine this possibility, we asked whether the selective disruption of MEC grid cells by inactivation of the medial septal area (Koenig et al, Science, 2011; Brandon et al, Science, 2011) would result in diminished hippocampal phase precession. Surprisingly, analysis of hippocampal firing patterns during septal inactivation revealed preserved phase precession. These results raise the possibility that inputs to the hippocampus from non-grid cells within the MEC may be sufficient to support hippocampal phase precession. We find that approximately 20 % of spatial non-grid cells recorded from the superficial layers of MEC in 5 rats (n = 15 of 75) exhibit significant phase precession ($P < 0.05$, circular-linear correlation) during random foraging in an open field environment. These cells precessed on average through 1/3 of the theta cycle (32 ± 6 % of a theta cycle). Furthermore, following septal inactivation we did not find substantial disruption of phase precession in entorhinal non-grid cells, while MEC grid cells lost both spatial periodicity and theta phase precession. Even though the MEC is necessary for hippocampal phase precession, it

appears that grid firing patterns are not essential for this network computation. Instead, our data demonstrate that spatial non-grid cells in the MEC exhibit phase precession, and we identify a new candidate MEC population for supporting theta phase precession in the hippocampus.

Title: The role of recurrent networks in the medial entorhinal cortex layer II and parasubiculum for grid cell generation

Authors: *I. ZUTSHI[1], V. LILASCHAROEN[1], M. P. BRANDON[1], J. K. LEUTGEB[1], B. K. LIM[1], S. LEUTGEB[1,2];
[1]Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC-San Diego, La Jolla, CA; [2]Kavli Inst. for Brain and Mind, San Diego, CA

Abstract: Spatial memory and navigation are thought to depend on location-selective firing of various spatially modulated cell types, including grid cells. Grid cells have periodic, hexagonally-arranged firing fields and are most abundant in layer II of the medial entorhinal cortex (MEC). To understand the functional role of grid cells, it is essential to determine how grid firing patterns are generated. Grid cell spatial tuning is disrupted by inactivating the medial septal area (MSA), or by systemic injections of scopolamine, a muscarinic antagonist. Cholinergic projections to the MEC layer II originate in the MSA and selectively terminate on patches of calbindin-positive (Cb+) pyramidal cells. Previous studies have indicated that grid cells in layer II could be either Cb+ or Cb-. Irrespective of the cell identity of Cb+ cells, we hypothesize that the effect of MSA inactivation on grid cells could be mediated by Cb+ cells and their recurrent connectivity within the MEC. A transgenic mouse line expressing cre recombinant protein under the wolfram syndrome 1 (wfs1) promoter has been described to express cre in cells that exclusively overlap with the layer II Cb+ pyramidal patches. We demonstrate that wfs1+ cells are also present in the parasubiculum, but not in other subicular areas or layers of the MEC. Retrograde viral tracing has established that the wfs1+ cells receive

inputs from the ipsilateral and contralateral MEC, pre- and para-subiculum, the anterior thalamic nucleus, and cholinergic cells within the MSA. Anterograde tracing with viral tracers that selectively label synaptic terminals reveals that wfs1+ cells exclusively project to cells in layer II of the MEC and to cells at the border between the stratum radiatum and the stratum lacunosum moleculare in the dorsal CA1. In addition, wfs1+ cells send dense axon bundles through the fimbria-fornix to the contralateral Cb+ patches and the contralateral parasubiculum. By optogenetically manipulating wfs1+ cells while performing *in vivo* multi single-unit recordings in freely moving mice, we are determining the functional role of these cells and their contribution to spatial firing patterns in the MEC. Preliminary data indicates that the wfs1+ cells are functionally coupled to most cells within layer II MEC. The results from selectively manipulating subpopulations of entorhinal cells can provide experimental data on the role of intra-entorhinal recurrent networks for generating grid cell firing. These manipulations will advance our understanding of how the brain generates and uses location-selective firing patterns to facilitate spatial memory.

Title: Hippocampal and medial entorhinal cortex lesions result in only a transient impairment in delayed spatial alternation: Physiological evaluation of the functional recovery

Authors: *M. SABARIEGO[1], B. L. BOUBLIL[1], G. DE GUIA[1], J. K. LEUTGEB[1], R. E. CLARK[3,2], S. LEUTGEB[1,4];
[1]Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., [2]Dept. of Psychiatry, Sch. of Medicine., UC-San Diego, La Jolla, CA; [3]Veterans Affairs San Diego Healthcare Syst., San Diego, 92161, CA; [4]Kavli Inst. for Brain and Mind, San Diego, CA

Abstract: Medial entorhinal cortex (MEC) cells project directly to the hippocampus and are thought to be the key source of spatial and temporal information to hippocampal place cells. Accordingly, MEC lesions result in impaired spatial precision and stability of place cells and in substantially reduced phase precession in the hippocampus. However, it remains unclear to what extent the spatial and temporal firing patterns in MEC are necessary for the performance of

memory tasks. We hypothesize that a primary function of MEC is to generate the temporal organization of hippocampal firing such that the population code can bridge gaps between discontinuous events during memory performance. To test this hypothesis, rats with either a hippocampal lesion, an MEC lesion, or a sham lesion were trained to perform a continuous spatial alternation task in which the animals alternated between left and right sides of a figure-8-maze on a trial-by-trial basis to receive food reward. After animals reached criterion (90% correct for 3 days), blocks of trials were introduced with 2-second and 10-second delays. All groups performed similarly during the trials without delay, but when a delay was inserted, the hippocampus and MEC lesion groups made significantly more errors with the 2-second as well as the 10-second delay ($p<0.001$). After the initial behavioral testing, electrode arrays were implanted into the hippocampus to record hippocampal single units and local field potential. When behavioral testing resumed after electrode implantation, MEC-lesions rats reached control level performance in the delayed spatial alternation task. This suggests that neuronal computations in a circuit with only lateral entorhinal cortex projections to the hippocampal circuit were sufficient to support the spatial memory. By recording from the hippocampus while MEC-lesion rats perform the spatial alternation task, we are able to examine which spatial and temporal firing patterns in the hippocampus are preserved to support behavioral performance after permanent MEC damage. By identifying which neuronal firing patterns are spared and how the remaining circuits compensate for reduced phase precession after MEC lesions, our results can lead to therapeutic approaches that either strengthen remaining physiological functions or that restore function in diseases with damage to the medial temporal lobe.

Title: Theta oscillations shape the precise temporal response of a network of stellate cells

Authors: A. NERU, *C. G. ASSISI;
Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: Sequential activity of groups of neurons is known to coordinate complex movements, encode our perception of the world and form new memories. A number of experiments have demonstrated that sequences of spikes in neuronal populations in the hippocampal formation encode spatial and temporal information. Competitive interactions between stellate cells, the predominant cells in the entorhinal cortex, via inhibitory interneurons, form a prominent motif in the medial entorhinal cortex. Using a model network of stellate cells we show that these interactions mediated via inhibition from fast spiking interneurons are sufficient to generate sequential activity in groups of neurons. However, sequences thus generated are not reliable in the presence of noisy variations in background synaptic activity. We show that heterogeneity in the topology of the network introduced due to variability in the strengths of inhibition combined with prominent theta oscillations that drive the network can serve to stabilize these spatiotemporal sequences. The biophysical properties of stellate cells dictate the preferred range of theta frequencies that ensure reliable spike sequences and constrain the duration of these sequences.

Title: Direct evidences for the involvement of orexin-1 receptor in the mesolimbic reward-related behaviors in conditioned place preference paradigm

Authors: *A. HAGHPARAST[1], Z. FATAHI[1], Z. TASLIMI[2], M. MORADI[1];
[1]Neurosci. Res. Center, Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of;
[2]Dept. of Physiol. and Neurophysiol. Res. Ctr., Hamadan Univ. of Med. Sci., Hamadan, Iran, Islamic Republic of

Abstract: Orexin neurons located in the lateral hypothalamus (LH) are primarily involved in reward processing. This effect might be mediated by the LH projections to the ventral tegmental area (VTA), nucleus accumbens (NAc) dorsal hippocampus (CA1 region) and which form circuit that could be particularly important in reward processing. Our laboratory tries to clear the new aspect of orexin, for that reason we have done three project s. Male albino Wistar rats were used in these projects as a three groups. In first group cannula were implanted into the LH and VTA, second group into the LH and NAc and third into the LH and CA1. The conditioned place preference (CPP) paradigm was done; conditioning score and locomotor activity were recorded by Ethovision software. In all groups LH orexinergic projection stimulated with effective dose of carbachol (250 nM/0.5 µl saline) as a cholinergic agonist lonely or 5 min after administration of

different doses of SB334867 (1, 3, 10 and 30nM/0.5µl DMSO) as a orexin-1 receptor (OX1r) antagonist into the VTA in the first, in the NAc as a second and in the CA1 in third group during 3-day conditioning phase separately. Data showed that LH stimulation could induce CPP. On the other hand, inhibition of orexin-1 receptors in the VTA, NAc and CA1 before LH stimulation could decrease the acquisition (development) of LH stimulation-induced CPP in the rats. In conclusion, our research highlights the effect of LH orexinergic projection to the important target of the reward circuit and shows that this kind of receptor (OX1r) in these areas has an important role in inducing reward-related behaviors in CPP paradigm.

Title: Development of the objective method for evaluating nest building behaviors in mice using a 3-D depth camera

Authors: *A. TOYODA, T. GOTO, T. OKAYAMA;
Ibaraki Univ., Inashiki Ibaraki, Japan

Abstract: Animal behaviors have been widely studied by various fields of researchers. Especially, experimental animals such as rodents have been used for analyzing both innate and learned behaviors. Behavior analyses are mainly based on the observation by human eyes or 2-D video camera, therefore the objective analysis is very difficult for 3-D behaviors of animals. Recently, we developed a novel objective method for mouse behaviors using an inexpensive 3-D depth camera. In this study, we focused on the nest-building behavior, one of the representative innate behaviors in mice. Using 3-D information from the depth camera, the objective features for assessing nest-building behavior were obtained including “volume,” “radius,” and “mean height”. The “volume” represents the change in volume of the nesting material, a pressed cotton square that a mouse shreds and untangles in order to build its nest. During the nest-building process, the total volume of the nesting material was increased. The “radius” refers to the radius of the circle enclosing the fragments of cotton, and it shows the extent of nesting material dispersion. The average “radius” was approximately 60 mm when a nest was completely finished. The “mean height” represents the change in the mean height of objects. If the nest walls were high, the “mean height” was also high. These features provided us with useful information for assessment of nest-building behavior, similar to conventional methods for the assessment of

nest building. Fortunately, we found that JF1 mice built nests with higher walls than B6 mice, and B6 mice built nests faster than JF1 mice using our novel method. Thus, it can evaluate the differences in nest-building behavior that cannot be detected or quantified by conventional methods.

Title: Exposure to different macronutrients during post-weaning and its effects on the consumption of standard and obesogenic diets in adulthood

Authors: *J. A. MATA-LUÉVANOS[1], J. JUAREZ[2];
[1]Lab. de Farmacología y Conducta, Inst. De Neurociencias, Univ. De Guadala, Guadalajara, Mexico; [2]Lab. de Farmacología y Conducta, Inst. De Neurociencias, Univ. De Guadalajara, Guadalajara, Mexico

Abstract: Overweight and obesity are now conceived as an epidemical issue. Currently, it is more important the palatability that an adequate nutrimental balance in food, which may produce, besides mal-nourishment, inadequate alimentary patterns and eating disorders. The food palatability is generally associated with high content of carbohydrates (carbs) and fats and it is well known that this macronutrient content of food affects eating behavior. There is evidence that infancy may be a critical period for the exposure to food with high content of carbohydrates and fat, which in turn may have an important impact in the selectivity of food and eating patterns on later life. However there are very few works that have explored the relation between these factors. On this basis, the aim of this work was to study the exposure to different macronutrients during infancy and its repercussion on the consumption of an obesogenic food in adulthood. For this purpose, male Wistar rats were used. Six groups (n=10) were exposed to a different diet in infancy during 18 days, starting at 23 postnatal day (PND); as adults, five out of the six groups received the same diet during 28 days starting at 75 PND. Food intake and body weight were registered during the study. Groups (name and diet): a)Control/Obesogenic (Ob): standard food (SF) in childhood, obesogenic diet (OD) as adult. b)Carbs/Ob: SF and carbs as child, OD as adult. c)Fat/Ob: SF and fats as child, OD as adult. d)Carbs+Fat/Ob: SF, carbs, and fats as child, OD as adult. e)MIX/Ob: SF and a mixture of carbs and fats as child, OD as adult. f)Control/Control: SF as child and as adult. Results showed that there were not significant differences between groups in caloric intake during infancy, but the Carbs group showed a tendency of consuming more calories than the other groups, this could be due to appetite is not

only mediated by the palatability of the food but beside for its post-oral actions. Changes on body weight were not observed in infancy, which agrees with the regulation of caloric intake at this period. In adulthood, results showed that MIX group significantly consumed more calories and gain more body weight than other groups; on the other hand, Carbs+Fat group consumed significant fewer calories than Control/Control and MIX, and have a tendency to gain less body weight than the other groups. These findings indicate that a free-choice between carbohydrates and fat vs. the availability of a mixture of these two macronutrients in infancy could play a critical role on the later election for food. These results gain relevance if it is considered that most of highly palatable food available to human being is an enriched mixture of these two macronutrients

Title: Emotional modulation on action control in a stop-signal task

Authors: *H.-J. LEE, W.-J. KUO;
Inst. of Neurosci., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Emotion plays an important role in action control. In this study, we investigated interaction between emotion and action control by using the stop-signal paradigm, where emotions were elicited by monetary gains (positive feedback condition), losses (negative feedback condition) and neutral feedbacks. Behavior data indicated that the time for processing stop signals was shorter when participants receiving a feedback of monetary gains than when receiving a neutral feedback, suggesting that it was easier to inhibit an ongoing action when participants felt rewarded. In the fMRI results, there were several interesting findings. First, activation in the dorsal striatum showed descending pattern across conditions. While the dorsal striatum had strongest activity in the positive feedback condition, it showed the lowest activation level in the negative feedback condition. The pattern is consistent with the previous findings. Second, comparing to the neutral feedback condition, both positive and negative feedback conditions showed higher activity in the bilateral ventro-lateral PFC, dorso-lateral PFC, pre-SMA and superior parietal regions. The results suggested that the networks related to attention and high-level action control were sensitive to the emotion perturbation.

Title: Basolateral amygdala mu opioid receptor activation and connections to the orbitofrontal cortex mediate outcome-specific Pavlovian-instrumental transfer

Authors: *N. T. LICHTENBERG, V. Y. GREENFIELD, A. S. WANG, K. M. WASSUM; Psychology, UCLA, Los Angeles, CA

Abstract: Environmental reward-predictive stimuli provide a major influence over reward-seeking behavior. The basolateral amygdala (BLA) is involved in this, and is particularly critical for situations in which such cues provide reward-specific information that allows them to selectively invigorate and bias selective actions. But how the BLA functions within a larger circuit to carry out this complex function is largely unknown. The BLA shares dense and reciprocal excitatory connections with several cortical areas, including the orbitofrontal cortex (OFC), which is itself implicated in the ability of environmental cues to convey information about anticipated rewards. Here using the outcome-specific Pavlovian-instrumental transfer (PIT) task we evaluated the role of OFC-BLA circuitry in the selective invigorating and action selection biasing effects of reward-predictive cues over reward seeking. Pharmacological disconnection of these structures by contralateral transient inactivation impaired the ability of reward-predictive cues to, in a choice test, selectively invigorate the performance of actions that earned the same specific reward associated with the stimulus. Unilateral inactivation of either structure and ipsilateral OFC-BLA inactivation were without effect. Interestingly, OFC-BLA disconnection appeared to spare the action-selection biasing effect of the cues; rats were able to choose actions on the basis of the specific reward predicted by the cue, but the performance of this action was not invigorated above baseline response levels. To explore the specific mechanisms of this within the BLA we examined the role of BLA opioid receptors in PIT. While selective blockade of the delta opioid receptor was without effect, blockade of BLA mu opioid receptor activity abolished both the selective excitatory and response-biasing effect of reward-predictive cues over reward-seeking actions. These data suggest that connections between the OFC and BLA are vital for representing specific rewards, in this case provided by Pavlovian conditioned stimuli, and using this information to guide reward seeking, with mu opioid receptor activation in the BLA potentially working to modulate this excitatory circuit.

Title: Comparison of rapid dopamine signaling dynamics in the nucleus accumbens core and shell during a magnitude-based decision making task

Authors: *D. A. SACKETT[1], M. P. SADDORIS[2], X. WANG[1], R. M. CARELLI[1]; [1]Psychology Dept., UNC Chapel Hill, Chapel Hill, NC; [2]Univ. of Colorado, Boulder, Boulder, CO

Abstract: To maximize resources, organisms must choose actions that result in the most valuable outcome available and maintain that information to guide future behaviors. Integral to this decision making process is the mesolimbic dopamine system, including the nucleus accumbens (NAc) and its dopaminergic input from the VTA. In the rat, the NAc is divided into two discrete subregions, the core and the shell, believed to process information about reward learning, reward value, and decision making related to goal-directed actions. However, the precise role of those subregions in processing information about magnitude-based decisions remains unclear. Here, dopamine (DA) release was first measured in the NAc shell using fast-scan cyclic voltammetry (FSCV) during a magnitude-based decision making task. Male Sprague-Dawley rats (n= 7) were trained to lever press following distinct visual cues that predicted the magnitude of future rewards. On Forced Choice Low Magnitude trials, a cue light predicted the opportunity to press a lever for a small reward (one 45mg sucrose pellet). On Forced Choice High Magnitude trials, another distinct cue light predicted the opportunity to press a different lever for a large reward (two 45 mg sucrose pellets). Lastly, on Free Choice trials, both cue lights and levers were presented and rats were able to choose between both magnitude options. All rats accurately discriminated between cue types on Forced Choice trials and developed preferences for the high magnitude option on Free Choice trials. Electrochemical recordings from electrodes in the NAc shell show increases in rapid DA release following presentation of Forced Choice cues, with peak DA concentrations being significantly greater during the high forced cue. However, results on the Free Choice trials indicate that peak DA during the choice cue was the same regardless of whether the animal subsequently chose the large or small magnitude option. In an ongoing second study, rapid dopamine release is being monitored in the NAc core in another set of rats during the same task. Preliminary results (n= 2) suggest a similar trend in dopamine release dynamics in the NAc core to Forced and Free Choice cues. The current findings implicate the NAc shell in encoding comparative reward value during reward

magnitude-based decision making, and ongoing studies will confirm if the NAc core plays a similar role in this process. Supported by NIH DA034021 to RMC.

Title: Examination of a history of cocaine self-administration on rapid dopamine signaling during a delay discounting task

Authors: *T. M. MOSCHAK, D. R. TERRY, R. M. CARELLI;
Psychology, Univ. of North Carolina, Chapel Hill, NC

Abstract: Cocaine use has been associated with heightened impulsivity in both humans and rodents. However, the precise neuronal mechanisms through which these two behaviors are related remains unclear. Several brain regions integral to impulsive control are altered by cocaine use, including the nucleus accumbens (NAc) and its dopaminergic input. Indeed, prior work from this lab has shown that rapid dopamine (DA) signaling in the NAc core tracks reward value during delay discounting, an impulsive decision making task. To examine the relationship between cocaine history, impulsive behavior and rapid DA release dynamics, we trained animals (n= 24) in a delay discounting task where they learned that distinct cues signaled the opportunity to choose between a small reward available immediately after a response versus a large reward that was available after either no delay (0 sec), a short delay (10 sec), or long delay (20 sec). Next, rats were trained to self-administer either intravenous cocaine (n=12) or water (n=12) during 2 hr daily sessions for two weeks. Animals were tested on the delay discounting task immediately after completion of the two weeks of self-administration and following an additional 3 week abstinence period (rats put in home cage, no drug). In a subset of rats (cocaine: n = 4; water: n = 3), rapid DA release was measured in the NAc core using fast-scan cyclic voltammetry during delay discounting. All rats exhibited typical delay discounting behavior, shifting preference from the large reward to the small reward as the delay to the large reward increased. Contrary to other findings, however, a history of cocaine self-administration did not significantly alter delay discounting behavior compared to water controls when tested either immediately after completion of the two weeks of self-administration or after an additional 3 week abstinence period. Nonetheless, consistent with prior work in our lab (Saddoris et al., Biol Psyc, 2014), cues predictive of available choices evoked DA release that scaled with the rat's

preferred choices and dynamically shifted as delay to reinforcement for the large reward increased. Interestingly, although a history of cocaine did not alter delay discounting behavior, cocaine-experienced rats released significantly less DA to the cues signaling available choices in the task than did water rats. These preliminary data suggest that while a history of cocaine self-administration did not make rats more impulsive, it did dampen DA processing of cues that signaled the availability of small immediate versus large delayed rewards. Title: Nucleus accumbens subregions (core vs shell) differentially encode reward-associated cues following reinforcer devaluation

Authors: *E. A. WEST, E. L. THOMAS, R. M. CARELLI;
Psychology Dept., Univ. of North Carolina, Chapel Hill, NC

Abstract: Nucleus accumbens (NAc) neurons encode features of stimulus learning and action selection associated with rewards. Additionally, the NAc is necessary for using information about expected outcome values to guide behavior as measured by reinforcer devaluation tasks. Further, evidence suggests that the distinct subregions of the NAc (core and shell) may play unique roles in guiding motivated behavior. Here, we recorded neural activity in the NAc core and shell during training (after cue-outcome associations were established) and performance of a reinforcer devaluation task. Specifically, male Long-Evans rats (n=25) were trained to press a lever following an illuminated cue light that predicted a specific reinforcer (e.g., raspberry flavored pellet). Rats received an alternative reinforcer in their home cages following training (e.g., peanut butter food pellets). Once rats achieved 90% accuracy during training, they were probed in a devaluation test under extinction conditions. Specifically, each rat was allowed ad libitum access to one of the two foods (selective satiation). On a separate day, the other food was devalued (counterbalanced). Rats lever pressed significantly less when the same reinforcer received during training was devalued (66.9 +/- 8.6) compared to devaluation of the alternative reinforcer (nondevalued, 86.8 +/- 9.3; $p<.05$) showing successful outcome specific devaluation. We recorded NAc neural activity on the last day of training, as well as the two test days

(devalued vs nondevalued). We found that in the NAc core (but not shell) there was a significant correlation between the percentage of neurons that encoded the cue on the last day of training and subsequent behavioral performance following outcome devaluation (i.e., the ability of rats to stop responding when the outcome had been devalued). Further, in the NAc shell (but not core), we observed a significant decrease in the percentage of NAc neurons that showed phasic responsiveness (i.e., cells that either increased or decreased firing) to the reward-associated cue when the same reinforcer received during training was devalued (5 out of 79, 6%) compared to the satiation of the alternative reinforcer (nondevalued, 21 out of 86, 24%). These data suggest that NAc core and shell neurons differentially encode information about reward-associated cues following outcome devaluation. Specifically, NAc core neural encoding during training predicts behavioral performance on subsequent test days. In contrast, the NAc shell dynamically encodes information about the cue with respect to the current value of the outcome.

Title: Dopamine decreases during extinction and increases during signaled food reward in core, but not shell region of NAc

Authors: *J. P. HUSTON[1], C. BIESDORF[2], A.-L. WANG[1], B. TOPIC[1], D. PETRI[1], H. MILANI[2], M. A. DE SOUZA SILVA[1];
[1]Univ. of Dusseldorf, Dusseldorf, Germany; [2]Dept. of Pharmacol. and Therapeut., State Univ. of Maringá, Maringá, Brazil

Abstract: Microdialysis studies in rat have generally shown that appetitive stimuli release dopamine (DA) in the nucleus accumbens (NAc) shell and core. Here we examined the release of DA in the NAc during delivery of reward (food) and during extinction of food reward in the freely moving animal by use of *in vivo* microdialysis and HPLC. Fifty-two male Wistar rats were

trained to receive food reward associated with appearance of cue-lights in a Skinner-box during *in vivo* microdialysis. Different behavioral protocols were used to assess the effects of extinction on DA and its metabolites. Results Exp.1: (a) During a 20-min period of cued reward delivery, DA increased significantly in the NAc core, but not shell subregion; (b) For the next 60 min period half of the rats underwent immediate extinction (with the CS light presented during non-reward) and the other half did not undergo extinction to the cue lights (CS was not presented during non-reward). DA remained significantly increased in both groups, providing no evidence for a decrease in DA during extinction in either NAc core or shell regions. (c). In half of the animals of the group that was not subjected to extinction, the cue lights were turned on for 30 minutes, thus, initiating extinction to cue CS at a 1h delay from the period of reward. In this group DA in the NAc core, but not shell, significantly decreased. Behavioral analysis showed that while grooming is an indicator of extinction-induced behavior, glances toward the cue-lights (sign tracking) are an index of resistance to extinction. Results Exp. 2: (a) As in Exp. 1, during a 30-min period of cued reward delivery, DA levels again increased significantly in the NAc core but not in the NAc shell. (b) When extinction (the absence of reward with the cue lights presented) was administered 24 hrs after the last reward session, DA again significantly decreased in the NAc core, but not in the NAc shell. Conclusions: a) These results confirm the importance of DA release in the NAc for reward-related states, with DA increasing in the core, but not shell subregion. b) They provide first evidence that during the withholding of expected reward, DA decreases in the NAc core, but not shell region. c) This decrease in DA appears only after a delay between delivery of reward and extinction likely due to it being masked by persisting post-reward DA release. We hypothesize the decrease in extinction-induced release of DA in the NAc core to be a marker for the despair/depression that is known to accompany the loss of expected rewards/reinforcers.

Title: Assessing macronutrient diet preference in rats selectively bred to run long vs short distances

Authors: *J. R. LEE, J. MUCKERMAN, B. WAHLE, A. WRIGHT, F. BOOTH, M. WILL; Univ. of Missouri, Columbia, MO

Abstract: The current study used two novel Wistar rat phenotypes, developed by selectively breeding for either high- or low-levels of voluntary running (HVR and LVR). As of the 10th generation, HVRs ran approximately 10-fold greater distances compared to the LVRs, providing a unique model to examine influence of inactivity on diet preference and feeding behavior. Previous animal studies suggest an interaction between voluntary exercise and diet preference. Recent experiments from our lab found that in an acute diet preference test, HVRs demonstrate a slight preference for a high-fat diet, while the LVR rats strongly preferred a high-carbohydrate diet. However, six weeks of voluntary running or sedentary home cage environment had no effect on this trend. The current study extends these findings by examining home cage diet preference in both male and female HVR, LVR, and outbred rats provided ad lib access to high-fat (60%), high-sucrose (33%), and a high-corn starch (50%) diet for four weeks. Animals were housed with either access to a running wheel, starting one week prior to the diet testing, or sedentary conditions throughout the study. At the conclusion of four weeks, animals were analyzed for various biomarkers associated with chronic consumption of the diets. Microbiome samples were collected for analysis before the introduction of diets and after the four-week diet preference. Present data reveal a heterogeneous pattern of diet preference across outbred population. The outbreds demonstrate a preference for the high-fat diets, but also consume both types of high-carbohydrate diets. Like the outbred rats, LVRs also prefer the high-fat diet but consume the other two diets as well. However, there is less variation of consumption patterns within the LVR phenotype. Unlike the outbred or LVR rats, HVRs have only consumed the high-fat diet, avoiding both types of high-carbohydrate diets. Analysis of the influence of voluntary exercise versus sedentary conditions are ongoing.

Abstract: Food choice is driven to a large extent by anticipated effects of food [1]. Previous research found that the vmPFC and striatum tracks caloric density of foods, using a wide range of low- and high-caloric food pictures [2]. Here, we investigate neural representations of food reward anticipation based on subjective food valuations and caloric density, relying purely on taste and using foods from a single category. The current study revealed distinct roles for the globus pallidus and the ventral striatum in these respective processes. Outside the MR scanner, participants (N=35; normal to overweight; 18 men) learned picture cue-taste mappings through a forced-choice memory training. Cues were coupled to the following food products: three commercially available ketchups that differed in caloric content, a control ketchup (mashed tomatoes), and chocolate mousse. Participants were only informed that they would be tasting different ketchups and a chocolate mousse. Next, we obtained participants' valuation of the food items through a willingness to pay measure [3]. In the fMRI session, a motivation task was used in which participants worked to obtain food rewards, while hungry. In each trial, one of the trained cues indicated which food could be earned with fast and accurate responses. In the case of a hit, they would earn one gram of toasted bread with the ketchup distributed on it. At the behavioral level, we observed a significant positive correlation between willingness to pay and calories of the food products. On the neural level, we compared responses to the taste cues of the four different ketchup tastes and related this to the subjective valuation (willingness to pay) and caloric content of the foods, within the same model. A region in the right globus pallidus was linearly activated with monetary bids for the foods. BOLD signal in the ventral striatum/subgenual cingulate, on the other hand, was positively correlated to the caloric content of the ketchups that the cues represented. These findings are reminiscent of proposed distinct roles of these brain regions, where the ventral pallidum plays a role in ‘liking’ for rewards, and the ventral striatum in ‘wanting’ food rewards [4]. Our results suggest different neural representations of subjective and objective properties of food products, based purely on taste and in the absence of top-down marketing influences. Title: MK212 disrupts maternal response through suppressing maternal motivation in rats

Authors: *R. WU, M. LI;
Dept. of psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Abstract Our previous study has shown that activation of 5-HT_{2A} or 5-HT_{2C} receptors disrupts maternal behavior in rats. However, whether this disruptive effect was conducted through suppressing maternal motivation remains unclear. It has been shown that pup-separation treatment can significantly increase the maternal motivation. Here, we examined how activation of 5-HT_{2A} or 5-HT_{2C} receptors may influence the expression of maternal behavior under pup-separation condition. As a comparison, activation of both receptors was also examined in a food-holding test (a nonmaternal motivated task). On postpartum days (PPD) 4 and 6, Sprague-Dawley mother rats were injected with vehicle (0.9% saline), 5-HT_{2A} agonist TCB-2 (5.0 mg/kg), or 5-HT_{2C} agonist MK212 (2.0 mg/kg), and their maternal behaviors were tested under either pup-separation (pups were removed from their mothers for 4 h) or non-pup-separation condition, at 30 min before and 30 min, 2 h and 4 h after injection. On PPD 8 and 10, these rats were injected with vehicle, TCB-2, or MK212 and their food pellet retrieval behavior was tested under either food-deprivation (6 h) or non-food-deprivation condition. Injection of TCB-2 and MK212 time-dependently disrupted maternal behavior (e.g. pup retrieval). However, MK212-induced disruptions, but not those induced by TCB-2 were significantly attenuated by pup separation. On the other hand, both TCB-2 and MK212 significantly increased latency of food pellet approach and decreased the number of food pellets retrieved, independent of the food deprivation condition. These findings suggest that activation of 5-HT_{2C} impairs maternal behavior partially inhibiting maternal motivation. **Keywords** 5-Hydroxytryptamine 2A receptor, 5-Hydroxytryptamine 2C receptor, Maternal behavior, TCB-2, MK212, pup separation. Title: Positive reinforcement learning is impaired in rats bred for helplessness and not reversible by monoamine oxidase (MAO)-B inhibitor deprenyl

Authors: *D. SCHULZ[1], D. PETRI[2], J. P. HUSTON[2], F. A. HENN[3];
[1]Dept. of Psychology, Yeditepe Univ., Istanbul, Turkey; [2]Ctr. for Behavioral Neurosci., Univ. of Duesseldorf, Duesseldorf, Germany; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Principles of negative reinforcement learning may play a critical role in the etiology and treatment of depression. For example, the removal of an escape platform in the water maze induces not only extinction of a negatively reinforced response, but also depression-like behavior. Conversely, rats selectively bred for helplessness, a congenital animal model of depression, are severely impaired in the acquisition of a negatively reinforced lever press response. In the present study, we examined the integrity of positive reinforcement processes in cLH rats using a random ratio (RR) schedule and a devaluation-extinction procedure. Furthermore, we tested whether the monoamine oxidase (MAO)-B inhibitor deprenyl which reversed the deficits of cLH rats in negative reinforcement learning, would also reverse any deficits in positive reinforcement learning. We found that cLH rats (n = 9) were impaired in the acquisition of even simple operant contingencies, such as a Fixed Interval (FI) 20 schedule. cLH rats exhibited no apparent deficits in reward valuation or 'hedonia'. For example, they reacted to the devaluation of food in a manner consistent with a dose-response relationship. Reinforcer motivation as assessed by the number of lever presses across sessions with decreasing reward probabilities was highest in congenital non-helpless (cNLH, n = 10) rats as long as the reward probabilities remained relatively high. cNLH compared to wild type (WT, n = 10) rats were also more resistant to extinction across sessions. Compared to saline (n = 5), deprenyl (n = 5) reduced the duration of immobility of cLH rats in the forced swimming test, indicative of antidepressant effects, but it did not restore any deficits in the acquisition of a FI 20 schedule. We conclude that positive reinforcement learning was impaired in rats bred for helplessness due to anergia or a learning deficit, but not anhedonia. Deprenyl which exerted antidepressant effects in cLH rats did not reverse the deficits in positive reinforcement learning.

Title: Opposing roles for dopamine D1 and D2 receptor expressing accumbens medium spiny neurons in cocaine induced neuroplasticity and reinstated cocaine seeking

Authors: *J. A. HEINSBROEK[1], Y. M. KUPCHIK[2], W. C. GRIFFIN III[1], P. W. KALIVAS[1]; [1]Med. Univ. of South Carolina, Charleston, SC; [2]Dept. of Med. Neurobio., Inst. for Med. Res. Israel-Canada, The Hebrew Univ., Jerusalem, Israel

Abstract: Medium spiny neurons (MSN) in the nucleus accumbens link internal motivational states and environmental information to motor action within the addiction circuit. Classically, dopamine D1-receptor expressing MSNs in this region are thought to drive motivated behavior through their projections to the ventral mesencephalon. In contrast D2-expressing MSN are canonically thought to inhibit and refine motivational drive through a circuit comprising the ventral pallidum (VP) and subthalamic nucleus. Recent data from our lab demonstrates, however, that both D1- and D2-expressing neurons project to the VP and that their projection from nucleus accumbens to ventral pallidum, but not to ventral mesencephalon is critical for reinstatement of cocaine seeking behavior (Stefanik *et al.*, 2013). In addition, we recently demonstrated that after withdrawal from cocaine self-administration GABA-mediated LTD is lost in accumbens to ventral pallidum synapses due to an elevated enkephalin tone onto presynaptic μ-opiod receptors (Kupchik *et al.*, 2014). These observations demonstrate that the circuitry driving cocaine related behavior is more nuanced than previously thought. To assess whether cocaine self-administration diminishes LTD in D1- or D2-MSN projections to the VP, we expressed channelrhodopsin 2 in the nucleus accumbens of D1-Cre or D2-Cre driver mouse lines. Following ten days of cocaine self- administration and subsequent extinction acute brain slices were taken and a LTD protocol was run while recording from VP neurons. In cocaine-extinguished mice, μ-opioid driven LTD was abolished in the D2-to-VP projection while the D1-to-VP projection was unaffected, suggesting that cocaine selectively alters D2-driven plasticity in the VP. To test the hypothesis that altered D2-MSN function plays a role in the motivation to seek cocaine, we selectively expressed designer receptors exclusively activated by designer drugs (DREADDs, activated by clozapine-N-oxide) in D1-Cre or D2-Cre mice to modulate the activity of D1- or D2-MSN at the level of the nucleus accumbens. Inhibiting D2-MSN using the inhibitory Gi-coupled DREADD hM4D strongly potentiated cue induced reinstatement of cocaine seeking while inhibiting D1-MSN did not have a profound effect. Conversely, preliminary data suggests that activation of D1-MSN using the excitatory Gs-coupled rM3D DREADD drives reinstated behavior. Future studies will be aimed at the dissection of D1-to-VP and D2-to-VP contributions to cue induced cocaine seeking at the level of the ventral pallidum.

Title: Junk food consumption induces abnormal food-seeking responses to environmental stimuli in rats

Authors: A. R. KOSHELEFF[1,2], K. QUIZON[2], J. ZHOU[2], J. HSUEH[2], A. LE[2], S. B. OSTLUND[3], N. T. MAIDMENT[2], *N. P. MURPHY[2];
[1]Psychology, [2]Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; [3]Anesthesiol. and Perioperative Care, Univ. of California, Irvine, CA

Abstract: The pervasiveness of highly palatable, energy-dense foods in modern diets is considered a leading cause of obesity, which has become a significant public health concern. While the legitimacy of "food addiction" is currently under debate, overeating shares many characteristics with drug addiction, such as compulsive pursuit despite potentially dire health consequences. Cues associated with palatable foods (e.g., auditory cues such as commercial jingles, etc.) can trigger food-seeking, even when sated, which could lead to decreased inhibitory control over food intake. Here, we explored whether a junk food diet dysregulates rats' ability to respond appropriately to food-paired cues in a Pavlovian-to-instrumental transfer test. Rats were first trained to lever press for a food reward. Subsequently they learned to associate free delivery of the reward with an auditory cue. Rats were then exposed to either normal chow (Control rats) or chow and a junk food diet for either 2 hrs (Binge rats) or 24 hrs (All-Day rats) per day, for up to 6 weeks. At test, rats were sated for 1 hour on chow, and presented with food-paired (CS+) and neutral (CSo) cues, and lever presses and food-cup entries recorded. Control rats increased lever pressing and food-cup entries at the onset of the CS+, but not the CSo, as expected. Binge rats increased lever pressing to both the CS+ and the CSo, though food-cup entries increased only during the CS+. All-Day rats showed markedly reduced lever pressing and food-cup entries to both cues. These results suggest that chronic junk food consumption induces atypical responding to environmental stimuli predictive of food rewards, and that different dietary access produces unique behavioral abnormalities in response to environmental stimuli. Specifically, Binge rats appear to generalize the excitatory properties of reward-paired cues to other, neutral cues, inappropriately triggering food-seeking, while All-Day rats appear insensitive to the motivational properties of the CS+. These data emphasize that junk food diets induce aberrant food-seeking in response to environmental cues, and this action may contribute to maladaptive feeding behavior leading to obesity.

Title: Differential effects of ghrelin on alcohol intake in C57BL/6J mice and Sprague Dawley rats

Authors: E. T. BROCKWAY[1], J. A. SELVA[1], L. J. ZALLAR[1], E. E. GARLING[1], H. M. BAUMGARTNER[1], M. B. SHESKIER[1], I. MORALES[1], R. PASTOR[1,2], *P. J. CURRIE[1]; [1]Dept. Psychology, Reed Col., Portland, OR; [2]Area de Psicobiología, Univ. Jaume I, Castellón, Spain

Abstract: Recent research in rats indicates that ghrelin receptor (GHS-R1A) antagonism decreases voluntary alcohol (ethyl alcohol; EtOH) consumption and EtOH operant self-administration. The same pharmacological agent used in rats, the GHS-R1A antagonist JMV2959, reduced EtOH intake in mice, and a similar suppression of EtOH drinking was found in ghrelin knockout (KO) mice. Ghrelin KO mice also showed reduced EtOH-induced conditioned place preference and locomotor stimulation. Blockade of central ghrelin signaling using mice lacking GHS-R1A was, additionally, found to decrease EtOH intake. Overall, these data represent a growing body of literature indicating that ghrelin mediates key aspects of EtOH reward via the GHS-R1A. Some previous results in mice, however, showed that systemic injections of ghrelin (10 or 30 mg/kg; ip) did not alter EtOH intake when measured using alcohol-preferring C57BL/6J (B6) mice and a binge-like limited access drinking test. This study, nevertheless, did show an increase in food intake induced by ghrelin (indicating that those doses of ghrelin were physiologically relevant) and a trend towards increased EtOH drinking. In the present study we used male and female B6 mice to investigate whether a slightly higher dose of systemic ghrelin (35 mg/kg), and a shorter drinking test (2 vs 4 h) would help identifying an effect of ghrelin on EtOH intake. Consistent with the previous study, our results indicated that systemic ghrelin did not alter EtOH intake in B6 mice. We then investigated the potential stimulatory effect of ghrelin on EtOH intake in male Sprague Dawley rats. The peptide was administered systemically or directly into the ventral tegmental area (VTA), the nucleus accumbens, or the hypothalamic arcuate nucleus at the onset of the nocturnal period. In this study we found that both systemic and VTA treatment increased EtOH intake at 2 and 6 h postinjection. Other brain areas appeared less responsive to ghrelin's action. Overall our work

demonstrates possible differential effects of ghrelin on alcohol reward in mice and rats with rats exhibiting robust responding to the stimulatory action of ghrelin on alcohol intake.

Title: A role for the accumbens shell - lateral hypothalamus pathway in the inhibition of alcohol seeking

Authors: ***G. GIBSON**, G. P. MCNALLY;
UNSW Australia, Sydney, Australia

Abstract: The nucleus accumbens (Acb) plays a critical role in the expression of both reinstatement (i.e., relapse) and extinction (i.e., abstinence) of drug seeking. These roles have been observed across a variety of drug reinforcers. The accumbens shell sub-region (AcbSh) is implicated in these roles and past tracing experiments have implicated AcbSh interactions with the lateral hypothalamus (LH). Here we studied the role of the AcbSh-LH pathway in extinction and reinstatement of alcohol seeking. We applied AAV encoding eYFP or ChR2(H134R) to AcbSh and implanted bilateral fibre optic cannulae above LH. Rats were trained to self-administer 4% (v/v) alcoholic beer and then extinguished. Rats were tested for reacquisition of alcohol seeking and then later for locomotor activity and food intake. Photoactivation of the AcbSh-LH pathway had no effect on expression of extinction but significantly attenuated reacquisition, and not acquisition, of alcohol seeking. This reduction in relapse was observed on measures of alcohol seeking and alcohol con¬sumption. There was no effect of ChR2 stimulation of the AcbSh-LH pathway on locomotor activity or on food intake in hungry or sated rats. Thus, these results show that stimulation of the AcbSh-LH pathway protects against relapse. Subsequent experiments characterised the effects of this stimulation on well established, but never extinguished, alcohol seeking to determine if the protective effects of ChR2 stimulation required extinction training.

Title: Affective temperament and smoking history predict a response to anticipated reward in the ventral striatum

Authors: *Y. OGURA[1,2], Y. WAKATSUKI[1], T. MIYAMOTO[1], Y. TSUCHIDA[1,3], Y. NAKAI[1,2], A. TOYOMAKI[1], N. HASHIMOTO[1,4], T. INOUE[1,5], I. KUSUMI[1];

Abstract: Major Depressive Disorder (MDD) can be associated to reduced response to reward in the striatum. Functional magnetic resonance imaging (fMRI) studies showed suppressed reward-related striatal response in MDD patients (Pizzagalli et al. 2009, Stoy et al. 2012; but see Knutson et al. 2008). Clinically, however, applying fMRI for all MDD patients is unrealistic. fMRI is unsuitable for the diagnosis due to large inter-individual variance in BOLD signals. On the other hand, questionnaires are easy to conduct and useful for the diagnosis in clinical practice. For example, the patient health questionnaire (PHQ)-9 is a reliable and valid measure of depression severity (Kroenke et al. 2001). Our previous study revealed that affective temperaments, which were measured by Temperament Evaluation of Memphis, Pisa, Paris and San Diego-autoquestionnaire version (TEMPS-A; Akiskal et al. 2005), directly and indirectly predict PHQ-9 score in the general population (Nakai et al. 2014). Affective temperaments could be a good predictor of the biological phenotype of depression. However, few studies have investigated the relationship between questionnaire scores associated with MDD and brain response measured by fMRI. We hypothesized that questionnaire scores, especially affective temperaments, predict the striatal response to reward. We administered fMRI and questionnaires to general adults (n = 63; M = 48, F = 15). In the fMRI study, we adopted a modified version of "monetary incentive delay task" (Knutson et al. 2000). The subjects were instructed to watch a number which corresponds to monetary reward he/she would receive if they succeeded in subsequent button press. We focused just on anticipatory phase and subtracted beta value of "¥500" minus "¥0" contrast in the ventral striatum. In the questionnaire study, we asked the subjects to complete 9 sets of questionnaires. We also questioned demographic data to subjects. We constructed linear model to estimate the effects of explanatory variables on the beta value, and conducted a stepwise model selection by AIC. The model with minimum AIC contained 6

explanatory variables; smoking history, TEMPS_anxiety, TEMPS_ cyclothymic, TEMPS_hyperthymic, Life Experiences Survey (LES; Sarason et al.1978)_negative events, and the total score of Child Abuse and Trauma Scale (CATS; Sanders and Becker-Lausen 1995). However, coefficients of TEMPS_hyperthymic, LES_negative events and CATS were not reliable. Therefore, (1) no smoking history, (2) higher TEMPS_anxiety, and (3) lower TEMPS_cyclothymic predict higher beta values in "¥500" minus "¥0" contrast. TEMPS-A might be related to the striatal function in general adult population.

Title: A novel hypocretin receptor 1 antagonist, RTIOX-276, regulates cocaine self-administration and dopamine signaling in the nucleus accumbens core

Authors: *K. A. LEVY[1], J. K. SHAW[1], D. A. PERREY[3], Y. ZHANG[3], R. A. ESPAÑA[2]; [2]Neurobio. and Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA; [3]Res. Triangle Inst., Research Triangle Park, NC

Abstract: Accumulating evidence indicates that the hypocretins / orexins (HCRT) influence cocaine reinforcement via actions on the mesolimbic dopamine (DA) system. We previously demonstrated that blockade of the hypocretin receptor 1 with SB-334867 attenuates cocaine self-administration and reduces cocaine-induced enhancement of dopamine signaling in the nucleus accumbens core. The current study sought to access the utility of a novel hypocretin receptor 1 antagonist, RTIOX-276, which has a higher affinity and greater specificity for the hypocretin receptor 1 than SB-334867. We examined the effects of RTIOX-276 on self-administration of cocaine under a progressive ratio schedule of reinforcement. We also accessed whether RTIOX-276 decreases the effects of cocaine on dopamine signaling in the nucleus accumbens core using *in vivo* fast scan cyclic voltammetry. Results suggest that RTIOX-276 attenuates the motivation to self-administer cocaine and decreases cocaine-induced enhancement of dopamine signaling. Together with previous work using SB-334867, the current findings provide further evidence for hypocretin receptor 1 involvement in the regulation of reward and reinforcement processes, particularly as it relates to cocaine. Therefore, the hypocretin receptor 1 may be a viable target for development of pharmacotherapies for the treatment of cocaine addiction.

Title: A new tool to exam molecular alterations in synapses of neuronal ensembles

Authors: *F. C. CRUZ[1], R. M. LEAO[2], P. C. BIANCHI[2], P. CARNEIRO-DE-OLIVEIRA[2], V. P. SELVAN[3], G. M. A. LIMA[1], F. C. COSTA[1], C. S. PLANETA[2], B. T. HOPE[3]; [1]Univ. of Sao Paulo, USP, Sao Carlos, Brazil; [2]PANT, Sch. of Pharmaceut. Sci., Lab. of Pharmacol., Universidade Estadual Paulista - UNESP, Araraquara, Brazil; [3]Behavioral Neurosci. Br., NIH, NIDA/IRP/NIH/DHHS, Baltimore, MD

Abstract: Learned associations between drug effects and stimuli in the drug environment (context) play an important role in drug addiction and are thought to be encoded by sparsely distributed patterns of neurons called neuronal ensembles that are selected by the drug-related stimuli. We are now developing methods for assessing unique alterations within pre- and post-synaptic components of synapses onto these activated neuronal ensembles. To selectively label post-synaptic components on only activated post-synaptic neuronal ensembles, we injected AAV1 virus with the transgene CMV::DIO-PSD95_Myc into nucleus accumbens of c-fos-tetop::iCre transgenic rats and injected the rats with 30 mg/kg cocaine four weeks later. The neural activity-dependent c-fos promoter in the rat transgene induces Cre recombinase protein expression that activates the DIO-PSD95-Myc viral gene in only strongly activated accumbens neurons. The fusion protein PSD95-myc is translocated to post-synaptic dendritic spines. Immunohistochemical labeling of Myc peptide indicated high levels of expression of PSD95_Myc in post-synaptic dendrites of activated neurons one week after the cocaine injection. To selectively label vmPFC presynaptic terminals in accumbens, we injected AAV1 virus with the transgene EF1α::Synaptophysin_Flag into vmPFC into wild-type rats. The fusion protein synaptophysin_Flag is translocated to presynaptic terminals. Immunohistochemical labeling of Flag peptide indicated high levels of expression of synaptophysin in vmPFC terminals in accumbens four weeks after the virus injection. Expression of both fusion proteins was confirmed using Western blotting and flow cytometry. For flow cytometry, synaptoneurosomes containing pre- and post-synaptic components were obtained from nucleus accumbens of virus-injected rats and immunolabeled for PSD95-Myc and Synaptophysin-Flag. Flow cytometry indicated expression of both fusion proteins in the nucleus accumbens as well as double-labeling of synaptoneurosomes with PSD95-Myc and Synaptophysin-Flag. Identification of synapses on activated neurons will allow us to assess unique synaptic alterations on activated neuronal ensembles that mediate context-induced reinstatement of ethanol-seeking.

Title: The temporal dynamics of fear learning: A single-trial fMRI study

Authors: *S. YIN[1], M. DING[1], A. KEIL[2], Y. LIU[3];
[1]Biomed. Engin., [2]Dept. of Psychology and Ctr. for the Study of Emotion & Attention, Univ. of Florida, Gainesville, FL; [3]Ctr. for Mind and Brain, Univ. of California, Davis, Davis, CA

Abstract: Research in rodent models has firmly established the amygdaloid complex as playing a central role in mediating defensive responses to conditioned threat cues. In human imaging studies, however, activation of the amygdala by conditioned stimuli is not always observed. Temporal habituation has been proposed as a possible explanation. In this study we sought to gain further insights into the problem by examining the detailed time course of neural responses during fear learning. Functional MRI was recorded from 18 subjects performing a classical differential fear conditioning task. The experiment consisted of three trial blocks: habituation, acquisition, and extinction. During the habituation block two Gabor patches (45° and 135°) were presented in random order; no response was required from the subject. During the acquisition block, one Gabor patch, denoted as CS+, was occasionally paired with an aversive human scream (US; 25% reinforcement rate), whereas the other Gabor patch (CS-) was never paired with the US. The extinction block followed the acquisition block. CS+ and CS- were presented without US pairing. Comparing BOLD activity evoked by the unpaired CS+ against the CS- during acquisition, ACC and insula, but not the amygdala, were found to be activated by CS+. To examine the temporal dynamics of the amygdala, ACC, and insula, the beta series method was employed to estimate the BOLD response to each cue presentation. We found that amygdala activity was significantly reduced over the second half of the acquisition block. Importantly, similar decrease was also found in dmPFC and insula. No such decrease was found in any structures in either habituation or extinction blocks. These results support the hypothesis that amygdala habituated over time during fear acquisition and demonstrated for the first time that such temporal habituation also occurred in dmPFC and insula.

Title: Light-induced anxiety-like behavior in the unpredictable chronic mild stress model in mice: a time-dependent trajectory based approach

Authors: K. MISQUITTA[1,2], M. BANASR[3], *E. SIBILLE[4,1];
[1]Campbell Family Mental Hlth. Res. Inst. of CAMH, Toronto, ON, Canada; [2]Pharmacol. and

Toxicology, Univ. of Toronto, Toronto, ON, Canada; [3]Psychiatry, Yale Univ., New Haven, CT; [4]CAMH - Univ. of Toronto, Toronto, ON, Canada

Abstract: Unpredictable chronic mild stress (UCMS) induces anxiety-like and depressive-like behaviors in rodents, and is a well-documented model used to investigate biological mechanisms related to depression. Classical behavioral tests designed to measure these deficits can be invasive and are rarely used repetitively. Our research analyzed the effects of UCMS on regular animal behavior and the data obtained provided information on the time-dependent trajectory of symptom development. Behavior was assessed weekly for 12 hours during the dark cycle, using Noldus Phenotyper apparatus in UCMS-exposed and control BALB/c (8-12 week-old, n=12/group) male mice. An anxiogenic white spotlight was applied for the duration of 1 hour over the food zone 4 hours into the dark cycle. Time spent within the designated zones (food, drinking and shelter) over the 12 hours was measured using EthoVision tracking software. After 5 weeks of UCMS, animals were tested in the elevated plus maze, open field, novelty suppressed feeding, coat state assessment, forced swim, sucrose consumption and cookie tests. Using the phenotypers, under baseline conditions UCMS-exposed mice exhibited a progressive and significant increase in time spent in the shelter zone [$F(1,22) = 17.223$; $p<0.001$] in disfavor of the two other zones. A 1 hour white spotlight challenge under the food zone induced reduced time spent in that zone in control mice compared to the hour before and after the white light application. Across weeks UCMS-exposed mice showed a progressive and significantly greater decrease in time spent in the food zone [$F(1,22) = 10.333$; $p<0.01$] compared to non-stressed mice. This newly designed light-induced anxiety test, demonstrates that UCMS induces a progressive effect, prominent during the 4th and 5th weeks of stress exposure. Upon completion of the chronic stress paradigm we confirmed heightened anxiety in the UCMS induced mice from the elevated plus maze [$F(1,19) = 11.603$; $p<0.05$] and novelty suppressed feeding [$F(1,19) = 5.733$; $p<0.05$]. Further studies will examine the effects of strain, sex and potential antidepressant therapeutic treatment to validate this new paradigm. Classical behavioral testing involves invasive, one-time readout for assessing the effects of UCMS. Regular behavioral monitoring allows for a simple approach to measure the progressive effects of UCMS-induced anxiety-like behavior over the course of stress exposure.

Title: Hippocampal neuronal activation and neurogenesis in a pharmacological model of anxiety

Authors: *A. R. COSTA[1,2], B. R. LEVONE[3], C. LINO-DE-OLIVEIRA[4], T. G. DINAN[2], O. F. O'LEARY[2], T. C. M. DE LIMA[4], J. F. CRYAN[2];

Abstract: Understanding the neural basis of anxiety is important to develop novel therapeutic strategies. It is well known that the cholinergic system plays an important role in mediating emotional states related to anxiety, acting on limbic structures such as the hippocampus, amygdala and prefrontal cortex.It has recently been shown that the administration of a single systemic subconvulsant dose of the cholinergic agonist pilocarpine induce a long-term state of anxiety in rats lasting from 24 h to 3 months post-administration. This positions this paradigm to be a novel animal model of anxiety. The neural basis of these effects on anxiety are unclear. Increased neuronal activation and alterations in neurogenesis have both been implicated in anxiety. Thus, we investigated if such changes could subserve the behavioural alterations in the model. To this end, pilocarpine (150 mg/kg, i.p.) and vehicle-treated male Wistar rats (90 days of age) were exposed to the open arms of the elevated plus maze test as a stressor to induce neuronal activation patterns. Subsequently, c-Fos and NeuN/BrdU stainings were performed and used as an index for neuronal activation and neurogenesis respectively. Our data shows that the number of stress-induced c-Fos positive cells in the dorsal dentate gyrus was higher in pilocarpine treated compared with control animals. These results suggest that the increased stress responsivity of pilocarpine-treated rats could be due to an overactive dorsal hippocampus. In addition, the single treatment of pilocarpine increased the survival of newly-born neurons. This increase is observed in SGZ and hilus, but not in the granular zone, suggesting the occurrence of an ectopic neurogenesis which could alter hippocampal synaptic connections. These findings can help us understand how altered cholinergic signaling can lead to maladaptive responses to stress and induce anxiety and fear responses.

Title: PFC-VTA neuronal substrates for anxiety-related alteration of motivated behavior

Authors: *J. PARK[1], A. DEL ARCO[1], B. YU[2], B. MOGHADDAM[1];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Electrical & Computer Engin. and Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In a variety of circumstances, motivated behavior leading to reward is associated with anxiety of unpredictable aversive outcomes; for instance, losing money in gambling or encountering a predator during foraging. Such risk of an aversive outcome must be appropriately represented and used for flexible adjustment of behavior given that either excessive risk aversion or risk taking may lead to maladaptive behavior. We investigated the neuronal representation of the anxiety-related changes in motivated behavior in two brain regions critically involved in encoding of action-outcome relationship: the prefrontal cortex (PFC) and the ventral tegmental area (VTA). The activity of PFC and VTA neurons was simultaneously recorded while rats performed a task consisting of three blocks in which an instrumental action (a nose poke) was rewarded with a sugar pellet continuously, but was intermittently punished with a mild electrical shock at varying risks (0, 6 or 10 %). A significant increase in action latency and portion of immobile time was observed in blocks with higher risk of punishment. In both regions, substantial proportions of single neurons, responding to critical task events, differentiated their firing rates as a function of the risk. The proportion of risk-encoding PFC neurons was greater than VTA neurons. To quantify the trial-to-trial discriminability of the punishment risk at the population level, we tested how accurately the risk could be decoded by considering the activity of neural population jointly in each region, using a Poisson naïve Bayes classifier. Decoding of PFC population yielded a higher accuracy than VTA population. These suggested that different neural population trajectories might underlie the risk-based behavioral alteration. Importantly, sizable trial-to-trial variability in action latency was observed, which may be associated with the trial-to-trial variability of the neural population trajectory. To test these, we extracted single-trial neural population trajectories of the simultaneously recorded PFC and VTA populations, using dimensionality reduction. When compared, the PFC population trajectories were associated with a more pronounced discriminability based on the risk, than that of the VTA population. Taken together, these findings indicate that both PFC and VTA neurons are involved in the anxiety-based control of motivated behavior, but that the PFC may better represent risk-based control of behavior.

Title: The habenulo-raphe circuit is not sensitive to the dimension of behavioral control and mediates the anxiety-like response produced by tailshock

Authors: ***S. D. DOLZANI**[1], M. V. BARATTA[2], L. R. WATKINS[2], S. F. MAIER[2];
[1]Inst. For Behavioral Genetics, Univ. of Colorado, Boulder, CO; [2]Psychology/Neuroscience, Univ. of Colorado, Boulder, CO

Abstract: Exposure to uncontrollable stress or acute trauma is a critical etiological factor in the onset of anxiety-like behavioral states in humans and rats. Serotonergic (5-HT) neurons in the dorsal raphe nucleus (DRN) are activated during uncontrollable (inescapable) tail shock (IS), but not during controllable (escapable) tail shock (ES). This activation leads to sensitization of the DRN, resulting in acute anxiety-like behavior in rats. Moreover, activation of the DRN is both necessary and sufficient for the behavioral and neurochemical consequences of IS. The lateral habenula (LHb) provides the primary glutamatergic input to the DRN and dysregulation of the LHb and DRN is implicated in stress-related psychiatric disorders. In the present study, the role of the LHb in regulating the behavioral response to acute stress was examined. First, it was necessary to determine whether stress-induced activation of the LHb is modulated by the controllability of the stressor. ES and IS resulted in an equivalent increase in Fos protein in the LHb, as compared to home cage controls (HC). Next, Fos expression restricted to the LHb-DRN pathway was measured. The retrograde tracer Fluorogold (FG) was injected into the DRN and Fos protein was quantified in FG-positive cells in the LHb following ES, IS or HC. ES and IS yielded a similar increase in activation of the LHb-DRN pathway, with no effect of controllability of the stressor. Finally, an optogenetic strategy was implemented to determine whether silencing the LHb during IS would protect against the behavioral consequences of IS. Halorhodopsin silencing of the LHb during IS produced resistance to the anxiety-like behavioral outcome of IS, as measured in a juvenile social investigation test. These data suggest that the LHb modulates DRN activity during stress, and that silencing this pathway during uncontrollable stress may protect against stress-related psychiatric disorders.

Title: Effects of neonatal dopamine depletion on anxiety-related behaviors and c-Fos expression in the dorsal raphe nucleus in adult rats

Authors: ***M. OGATA**, K. NODA, H. AKITA, H. ISHIBASHI;
Dept of Physiol, Kitasato Univ, Sch. Allied Hlth. Sci., Sagamihara, Japan

Abstract: Dopamine neurons originating in the substantia nigra and ventral tegmental area of the midbrain is involved in several brain functions, including motor control, attention and emotion. Rats with dopamine depletion during adulthood and neonatal period exhibited akinetic motor activity and spontaneous motor hyperactivity, respectively, indicating that behavioral effects of dopamine depletion depend on the period of lesion development. Ameliorative effects of amphetamine or methamphetamine treatment on the motor hyperactivity induced by neonatal dopamine depletion have been reported. Although several reports have shown that dopamine depletion during the adulthood results in a significant increase in anxiety-related behavior, effects of neonatal dopamine depletion on anxiety-related behavior in the adulthood are poorly understood. In the present study, we investigated responses to anxiogenic stimuli in the adult rats with neonatal dopamine depletion using the behavioral tests (i.e., open field test, light/dark box test and elevated plus maze test) and immunohistochemical analysis of c-Fos expression in the dorsal raphe nucleus. The adult rats that received intra-ventricular injection of 6-hydroxydopamine 4 days after birth showed significant increases in distance traveled and time spent in the center area in the open field test. Intraperitoneal treatment of methamphetamine (4 mg/kg) 40 min prior to the open field test ameliorated the increased distance traveled, but not the increased time spent in the center area of open field. Increased time spent in the open arm of elevated plus maze was also observed in the adult rats with neonatal dopamine depletion. There is no significant effect of neonatal dopamine depletion on the anxiety-related behavior in the light/dark box test. In the histological analysis, a significant increase in the number of c-Fos immunoreactive-positive neurons in the dorsal raphe nucleus was observed at 2 h after the elevated plus maze test in the adult rats with neonatal dopamine depletion. These data indicate that neonatal dopamine depletion results in a spontaneous motor hyperactivity and decrease in anxiety-related behavior during adulthood, and suggest that the mechanism of abnormal anxiety-

related behavior differs from that of spontaneous motor hyperactivity and that the neuronal hyperactivity in the dorsal raphe nucleus is implicated in the abnormal anxiety-related behavior induced by neonatal dopamine depletion.

Title: Deep brain stimulation in Internal Capsule and ventral Striatum: Effects on spontaneous grooming and anxiety in Sapap3 mutant mice

Authors: C. PINHAL[1,2], F. SANTANA[1,2], L. FELLINGER[1,2], I. EHMER[1,2], R. HAMELINK[1,2], G. FENG[3], M. FEENSTRA[1,2], *I. WILLUHN[1,2], D. DENYS[1,2];
[1]Netherlands Inst. For Neurosci., Amsterdam, Netherlands; [2]Dept. of Psychiatry, Academic Med. Ctr., Amsterdam, Netherlands; [3]Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Background: Obsessive-compulsive disorder (OCD) is a psychiatric condition characterized by unwanted thoughts (obsessions), anxiety, and repetitive behaviors (compulsions). Recently, deep-brain stimulation (DBS) has been identified as a promising therapy for patients who are otherwise therapy-refractory. Clinical studies with DBS in the anterior limb of the Internal Capsule (ALIC) and ventral Striatum (vS) have shown to be effective. However, it often takes months to determine optimal stimulation parameters and some patients do not respond at all, indicating the need for a better understanding of DBS in OCD. The *Sapap3*$^{-/-}$ mutant mice are an animal model for OCD as they exhibit compulsion-like behavior (excessive grooming), increased anxiety, and abnormal cortico-striatal neurotransmission (Welch et al, 2007). In the present study, we investigated the effects of DBS in ALIC and vS on compulsion-like grooming and anxiety. **Methods:** *Sapap3*$^{-/-}$ mice were phenotyped and only mice grooming more than 13% of time were selected for further experiments. Mice were implanted with DBS electrodes (bilateral) in the ALIC or vS (Rodriguez-Romaguera et al, 2012). After recovery, mice were placed in an open field and stimulated for 60min (300µA, 80µs, 120Hz), while grooming was scored. Then, anxiety was assessed on an elevated plus maze. In this test, mice were stimulated for 20min in their home cages and then placed in the maze and stimulated for additional 10min. A few days later, mice were stimulated for 20min and perfused 90min thereafter. Brains were sectioned, and c-Fos expression was assessed using immunohistochemistry. **Results:** We demonstrate that DBS of the ALIC effectively reduces excessive self-grooming in *Sapap3*$^{-/-}$ mice, with stimulated animals showing a maximum decrease in levels of grooming to 7% of Sham-stimulated mice ($p<0.001$). In contrast, open-arm

exploration on the plus maze, a measure of anxiety, was not affected by DBS. Preliminary results suggest that DBS of the vS has no effect on grooming or plus-maze behavior. **Conclusion:** Our findings suggest that DBS in the ALIC reduces compulsivity in the *Sapap3*$^{-/-}$ mouse model of OCD, but does not affect unconditioned anxiety. Only "pathologically" increased levels of grooming were responsive to DBS, as no effect was seen in animals grooming less than 13% of the time. Together with our previous results showing that ALIC stimulation reduces conditioned anxiety in normal rats (van Dijk et al, 2013), the ALIC seems to be a good target for reducing OCD symptoms in rodents. An important future step is to clarify the network involved in the decrease of compulsivity via ALIC-stimulation to unravel the neurobiology of OCD.

Title: Evidence for psychosocial stress-induced inflammation, altered dopamine status and impaired reward-directed behaviour in mice

Authors: *G. BERGAMINI[1], H. SIGRIST[1], S. AUER[1], J. MECHTERSHEIMER[1], T. SUTER[2], B. FERGER[4], E. SEIFRITZ[3], C. PRYCE[1];

Abstract: Understanding the aetio-pathophysiology of depression is the route to identification of efficacious anti-depressant strategies. A major theory is that stress-induced inflammation is aetiological in depression and that one of its effects is to alter dopamine signaling leading to symptoms of maladaptive response to punishment and hyposensitivity to reward. In rodents and humans, stimulation of the immune system results in a number of behavioural changes which overlap both with those exhibited during infection/sickness and those that constitute symptoms of depression. They are mediated by circuitry to which the basal ganglia and dopamine (DA) function are central, suggesting that changes in the latter underlie the behavioural pathologies. Inflammatory cytokines can act in the brain to affect the monoamine neurotransmitter systems and dopamine signalling in the basal ganglia may be a primary target. The kynurenine-pathway is known to be activated by inflammatory signals as well as chronic stress and it has been

implicated in the pathophysiology of depression. It is hypothesized here that psychosocial stress in mice can induce a) peripheral and CNS inflammatory response, b) activation of the kynurenine pathway, c) attenuation of mesolimbic DA signaling and d) changes in reward-directed behaviour. Mice exposed to chronic social defeat (CSD) exhibited peripheral inflammatory responses including splenomegaly accompanied by increased splenic granulocytes, inflammatory monocytes and T helper 17 cells. CSD-induced peripheral activation of the kynurenine pathway was found in the liver. Immunohistochemical analysis in mesolimbic regions revealed microglia activation in the ventral tegmental area (VTA) in CSD mice. Regarding the effects of CSD on DA signaling, CSD mice showed decreased dopamine turnover (DOPAC/DA) in the nucleus accumbens (NAcc) and a reduced hyper-locomotor activity in response to a DA transporter inhibitor (GBR 12909). The operant behaviour tests, progressive ratio schedule (PRS) and learned non-reward (LNR), were used to assess CSD effects on reward-directed behaviour under demanding conditions. CSD mice obtained less rewards in the PRS test and more errors in the LNR test, compared to controls. Dopamine depletion in the NAcc - achieved using the neurotoxin 6-hydroxydopamine - also induced these operant effects, implicating mesolimbic DA dysfunction in CSD mice. These data support the stress-inflammation-dopamine hypothesis for depression and the model will be utilised to identify novel targets for restoring DA function as an antidepressant treatment. Funded by the Swiss National Science Foundation 31003A-141137.

Title: The development of a novel animal model of depression to study the implication of inflammation, stress and hippocampal neurogenesis

Authors: *K. MUSAELYAN[1], M. T. EGELAND[2], C. M. PARIANTE[2], C. FERNANDES[3], S. THURET[1];
[1]Basic and Clin. Neurosci., [2]Psychological Med., [3]MRC Social, Genet. & Developmental Psychiatry Ctr., Inst. of Psychiatry, KCL, London, United Kingdom

Abstract: A growing body of evidence supports the involvement of the immune system in depression neurobiology; however its role in the causality of depression and in the mechanisms of antidepressant response is not yet clear. To study the role of inflammation in depression and in the mechanisms of antidepressant action a valid animal model is required. To develop such a model, we combined exposure to an inflammatory stimulus modelled by peripheral lipopolysaccharide (LPS) injection with an environmental stress-based model of depression - unpredictable chronic mild stress (UCMS) to achieve a depression-like phenotype incorporating behavioural, immune and neurogenic changes seen in depression. In a pilot experiment we exposed adult male BALB/c mice to UCMS for 6 weeks. A behavioural test battery was applied at the end of UCMS. In a separate experiment mice were administered LPS (0.1 mg/kg, 0.33-0.83 mg/kg and 0.83 mg/kg treatment groups) or saline once weekly for 6 weeks via intraperitoneal injections. At the end of both experiments blood and brain tissues were collected for cytokine analysis, gene expression and immunohistochemistry (IHC) respectively. To access hippocampal neurogenesis IHC with Ki67 as a proliferation marker and doublecortin (DCX) as a neuroblasts marker were used. To detect microglial cells ionized calcium-binding adapter molecule 1 (Iba1) marker was used. UCMS exposed mice displayed significant coat state deterioration and locomotor hyperactivity in a novel arena, but did not display anxiety-like avoidance behaviour in an anxiogenic environment or behavioural despair in the forced swim test. Additionally, mice displayed altered food reward behaviour in sucrose preference, cookie and novelty suppressed feeding tests. LPS exposed mice displayed signs of sickness behaviour, such as reduced food intake and weight loss 24 hrs after injection, with the 0.33-0.83 mg/kg group showing persistent phenotypes throughout 6 weeks of treatment, as well as elevation of peripheral cytokines interleukin 6, tumour necrosis factor α and interleukin 2. These results showed that hyperlocomotion was the dominating phenotype induced by UCMS and this observed hyperactivity may have masked potential anxiety and behavioural despair responses. LPS treatment resulted in a sickness behavioural response and cytokine elevation, which persisted in the 0.33-83 mg/kg treatment group. Analysis of adult hippocampal neurogenesis, microglial activation and gene expression in the brain will further reveal the endophenotypes induced by this model and their relevance for depression.

Title: Modulation of glutamatergic transmission by amphetamine in cognition related circuits of hippocampus and prefrontal cortex

Authors: *S. A. NEALE[1,2], P. H. HUTSON[3], T. E. SALT[2];
[1]Neurexpert, London, United Kingdom; [2]Visual Neurosci., UCL Inst. of Ophthalmology, London, United Kingdom; [3]Shire Pharmaceut., Wayne, PA

Abstract: An emerging body of evidence suggests the psychostimulant amphetamine (AMPH) may affect neuronal function by mechanisms additional to modulation of monoamine levels, such as modulation of glutamatergic neurotransmission1. Understanding these effects of AMPH may be of value when considering the potential therapeutic benefits of AMPH for treatment of psychiatric disorders1. The current study investigates actions of AMPH on neuronal activity in acute *in vitro* slice preparations of adult rat hippocampus and prefrontal cortex (PFC). In the hippocampus, field excitatory postsynaptic potentials (fEPSPs) were evoked by Schaffer collateral/commissural pathway stimulation and recorded from the CA1 region. In the PFC, fEPSPs were evoked by stimulation in the forceps minor and recorded in layer V/VI. In both regions the fEPSPs appeared to be predominantly AMPA receptor-mediated. In the CA1 region, AMPH (10 μM) did not significantly alter the mean fEPSP amplitude, although slice-to-slice variability suggested a heterogenous effect. AMPH (100 μM) increased the fEPSP amplitude. This effect increased during a 15 min washout period to 122 ± 2% of control (n=8; mean ± SEM; $P < 0.001$). Associated with the increase in amplitude there were significant effects on fEPSP slope and the time to peak. The effects of AMPH on the fEPSP amplitude, slope and time to peak were all significantly less in slices pre-incubated with the NMDA receptor antagonist D-AP5 (50 μM), suggesting these actions of AMPH involve, at least partially, NMDA receptor activation. In the PFC, AMPH (100 μM) produced a depression, rather than an increase, of the evoked fEPSP: following 15 minutes of AMPH application the fEPSP amplitude was reduced to 73 ± 7% of control amplitude (n = 7; mean ± SEM; $P < 0.05$). On washout of AMPH there was a small recovery in the amplitude to 80 ± 4% of baseline levels (n = 7; mean ± SEM; $P < 0.05$). FFT analysis of activity in the PFC revealed changes across biologically-relevant aspects of the power spectrum, including statistically significant increases in power in the gamma-frequency range. By contrast overall there was no significant effect of AMPH on the power spectrum in the CA1 region. In conclusion, these results show that AMPH can differentially affect glutamatergic transmission in different cortical circuits and that some of these actions appear to be via interactions with NMDA-receptor-mediated response components. Furthermore, the changes seen in the power spectrum suggest that the actions of AMPH affect neuronal circuit behaviour,

and such selective effects may be important in the effects of AMPH on cognition and attention. Hutson et al. Pharmacology & Therapeutics 143 (2014) 253-264

Title: Infralimbic BDNF regulates extinction of active avoidance

Authors: ***L. E. ROSAS-VIDAL**, W. A. RAMOS-GUASP, G. J. QUIRK;
Psychiatry and Anat. & Neurobio., Univ. of Puerto Rico, San Juan, PR

Abstract: The infralimbic prefrontal cortex (IL) is necessary for fear extinction (Do-Monte et al., 2015) as well as the extinction of platform-mediated avoidance (Bravo-Rivera et al., 2014). Brain-derived neurotrophic factor (BDNF) is necessary for synaptic plasticity underlying learning and memory processes. We recently reported that blocking extracellular BDNF in IL during fear extinction training impairs its acquisition and recall (Rosas-Vidal et al., 2014). Here we show that blocking extracellular BDNF in IL during avoidance extinction training had no effect on the acquisition of extinction (Sal, n= 12; anti-BDNF, n= 13; p= 0.609), but impaired the recall of avoidance extinction the next day ($p< 0.001$). Using immunohistochemistry to measure neuronal BDNF, we found that avoidance extinction did not increase BDNF in IL neurons (p=0.61; No-Ext., n= 5; Ext., n= 8), suggesting that BDNF in IL may be released by inputs from the ventral hippocampus (vHPC) and/or the basal amygdala (BA), both of which show increased neuronal BDNF after fear extinction (Chhatwal et al., 2006; Rosas-Vidal et al., 2014). Accordingly, avoidance extinction increased neuronal BDNF in vHPC (p= 0.004) and

mediodorsal thalamus (MD; p=0.049), but not BA (p=0.99). Our findings suggest that avoidance extinction may depend on BDNFergic inputs to IL from the vHPC and MD, rather than from BA.

Title: Optogenetic silencing of prelimbic cortex in active avoidance

Authors: ***M. M. DIEHL**, J. RODRÍGUEZ-ROMAGUERA, P. A. PAGÁN-RIVERA, G. J. QUIRK;
Psychiatry, Univ. of Puerto Rico, Sch. of Med., San Juan, PR

Abstract: We previously showed that pharmacological inactivation of prelimbic prefrontal cortex (PL) with muscimol impairs the expression of platform-mediated avoidance in response to a conditioned tone (Bravo-Rivera, et al., 2014). Here, we used an optogenetic approach to silence PL glutamatergic neurons only during the tone period, in rats trained in our avoidance task. Silencing PL somata with archaerhodopsin (CaMKIIα-eArchT3.0) during the entire 30 sec tone did not block avoidance, as most rats had moved to the platform by the final 2 sec (n=9/9 eYFP controls, n=12/15 Arch, p=0.27). However, PL silencing decreased the amount of time rats spent on the platform (eYFP=90%, Arch=49%, p=0.002), suggesting that silencing PL delayed platform mounting. In agreement with this, Arch increased the latency to mount the platform (eYFP=4.8s, Arch=11.6s, p=0.03). This delay in mounting was not due to a decrease in fear, as freezing (p=0.96) and bar press suppression (p=0.22) were unaffected. This suggests that PL glutamatergic activity accelerates, but may not be necessary for, avoidance responses. We next wanted to assess whether silencing PL during specific time periods within the tone presentation would also affect platform mounting. We have previously reported that PL neurons exhibit responses to both tone onset and platform mounting in this task (Bravo-Rivera, et al., 2014 SFN abstract). We therefore assessed if silencing PL during platform mounting (typically 3 to 20 sec after tone onset) would also delay mounting. Our preliminary data (Arch n=7, eYFP n=3) show that silencing 3-20 sec during the tone did not delay platform mounting (eYFP=83%, Arch=79%,

p=0.45), suggesting that the initial tone response (0-3 sec) may be important for accelerating avoidance, a hypothesis we are currently testing.

Title: Inducible pharmacogenetic inhibition of protein synthesis in lateral amygdala

Authors: *P. SHRESTHA[1], P. AYATA[2], N. HEINTZ[2], E. KLANN[1];
[1]NYU, New York, NY; [2]Rockefeller Univ., New York, NY

Abstract: Auditory fear conditioning is a widely used behavioral paradigm for studying the neural and molecular mechanisms underlying learning and memory. The first clues that de novoprotein synthesis may be necessary for long term memory formation came about in the 1960s (Flexner, 1963) when broad protein synthesis inhibitors (PSI) blocked long-term memory (LTM) leaving the short-term memory intact. Similar pharmacological methods have been applied over the years to demonstrate that protein synthesis in lateral amygdala is required for consolidation of long-term fear memory. However, methodological concerns and off target effects of broad PSIs such as anisomycin and cycloheximide have made it necessary to seek out alternative approaches to investigate the role of protein synthesis in memory processes. It was recently shown that eukaryotic initiation factor 2α (eIF2α) phosphorylation, the rate limiting step in translation, bidirectionally regulates the switch from short- to long-term synaptic plasticity and short- to long-term memory. Here we present a novel drug inducible pharmocogenetic strategy to modulate eIF2α phosphorylation in a cell type specific manner. We show that our approach is able to reversibly block protein synthesis both *in vitro* and in the lateral amygdala *in vivo*. We currently are determining the requirement for proper eIF2α phosphorylation and de novo protein synthesis in specific cell types in the lateral amygdala for the consolidation of long-term memory following auditory fear conditioning.

Title: Adiponectin regulates anxiety behaviors and DA neuron firing in the VTA

Authors: F. SUN, S.-Y. CHENG, *X. FANG, J. LIU, D. LODGE, X.-Y. LU;
Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Adiponectin is a protein hormone secreted from adipocytes. Our previous studies have shown that adiponectin regulates depressive behaviors. In this study, we examined the effects of adiponectin on anxiety behaviors. We found that intracerebroventricular infusion of adiponectin produces anxiolytic effects in the elevated plus-maze and light/dark tests, whereas adiponectin haploinsufficiency causes anxiogenic-like behaviors. *In vivo* extracellular electrophysiological recordings revealed that infusion of adipoRon, a novel potent and selective adiponectin receptor agonist, into the ventral tegmental area (VTA) inhibits DA neuron firing. Furthermore, acute restraint stress increased anxiety and DA neuron firing in the VTA. The effect of acute stress on DA neuron firing was reversed by intra-VTA infusion of AdipoRon. Taken together, these results suggest that adiponectin is involved in regulating anxiety behaviors and modulating VTA DA neuron activity.

Title: Antidepressant effects of ketamine in male and female rats

Authors: *A. SARKAR[1], F. JOHNSON[2], M. KABBAJ[1];
[1]Biomed. Sci., [2]Psychology, Florida State Univ., Tallahassee, FL

Abstract: Depression, one of the most common mood disorders in the world, is twice as prevalent amongst women as in men. Several studies have linked gender to the occurrence of depression and the efficacy of antidepressant treatments. Studies from our lab have shown female rats to be more sensitive to the antidepressant ketamine, an NMDA receptor antagonist, as compared to males. A single injection of 2.5 mg/kg dose of ketamine has antidepressant-like effect in females but not in males, that respond to doses of 5 mg/kg and above. We hypothesize a role for gonadal hormones in the treatment efficacy of ketamine at lower doses in females. Social isolation stress (IS) is known to evoke depression and anhedonia-like behaviour in rats. In this study we investigated the effect of ketamine on IS induced a) anhedonia and depression-like behaviour, b) changes in spine density in the mPFC, using HSV-GFP infusion and confocal microscopy and c) molecular changes at the synaptoneurosomes in the mPFC, in male rats and in female rats that received ketamine either during the diestrus or the proestrus phase of their estrus cycles. Our results showed that 8 weeks of IS gives rise to anhedonia and depression-like behaviour in the sucrose preference test and Porsolt's forced swim test in males, concomitant with a decline in spine density in the pre-limbic region of the mPFC. Analysis of spine morphology revealed a decline in the number of mushroom spines and thin spines in the proximal segment of the apical tuft of dendrites of layer V of the PL. IS also evoked a decline in the levels of pre-synaptic protein Synapsin1 and post-synaptic proteins GluR1 and PSD95 implicated in synaptic maturation, in synaptoneurosomal preparations. A single dose of ketamine (5 mg/kg) administered to animals after 8 weeks of IS completely removed the behavioural, spine density and molecular deficits in males, while the 2.5mg/kg dose rescued only a subset of these deficits partially. Additionally, we observed an interesting growth in thin spine population concomitant with a decline in stubby spine numbers, post 3 hours of ketamine treatment. Studies are currently underway to investigate the efficacy of the same doses of ketamine administered during different phases of the estrus cycle in female rats, on behaviour, spine density and synaptosomal protein levels. Upon completion, our study will provide a novel understanding of the influence of gonadal hormones on susceptibility to stress and the efficacy of antidepressant treatments in male and female animals.

Title: Neuro circuitry changes in response to unconditioned fear exposure

Authors: *A. MITCHELL[1], A. F. MOHED[1], R. E. JACOBS[2], E. L. BEARER[1];
[1]Pathology, Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM; [2]Biol., Beckman Institute, California Inst. of Technol., Pasadena, CA

Abstract: In post-traumatic stress disorder (PTSD) the response to fear is damaged or changed. People with PTSD may feel fear even when they are not in danger. We hypothesize that the biological basis for this is an alteration in neurocircuitry, particularly in the mesocortical limbic system. In this study we investigate the effects of unconditioned fear, focusing on a validated PTSD model, the serotonin transporter knock-out (SERT-KO) mouse. Our hypothesis is that the experience of unconditioned fear (UF) affects the structure and functional circuitry of the brain even in wildtype mice. We theorize that these changes will resemble those found in the SERT-KO in the absence of fear exposure. By looking at UF circuitry dynamics with magnetic resonance imaging (MRI), we are analyzing mouse brain circuity in an entirely new way. Each genotype, SERT KO and WT littermates, received manganese intraperitoneal injections and then were imaged by MRI at five time points in an 11.7T Bruker magnet. Manganese is a contrast agent for MRI that detects electrical activity in the brain, as Mn^{2+} enters active neurons through voltage-gated Ca^{2+} channels and gives a hyperintense signal in T_1-weighted MRI. We used a naturally occurring UF provocateur, predator odor. We followed behavior before and after predator odor in the light-dark box. We used our automated “skullstripping” pipeline to remove the non-brain image and then aligned them. Statistical parametric mapping with SPM8 identified statistically relevant voxel-wise intensity changes. ANOVA comparisons between SERT KO and WT mice reveled statistical differences across and between genotypes and time. Lastly we conducted region of interest analyses (ROIs) on the images to pin point the degree of intensity changes in particular brain areas, and to determine overall manganese levels over time. Normalization of intensities across time points will allow more sensitivity in finding significant differences produced by UF, and to determine their persistence or resolution over time. Preliminary results show significant differences in brain activity in immediate response to unconditioned fear between SERT KO and WT littermates, and persistence of the effect in the SERT.

Title: Differential medial prefrontal cortex Egr-1 expression in variants of standard contextual fear conditioning

Authors: *T. CHAKRABORTY, A. ASOK, W. SCHREIBER, M. E. STANTON, J. B. ROSEN;
Psychology, Univ. of Delaware, Newark, DE

Abstract: Contextual fear conditioning variants, such as standard contextual fear conditioning (sCFC) and the context preexposure facilitation effect (CPFE), allow the study of different aspects of fear learning. Single trial SCFC gives insight into context acquisition and context-shock association (context-US) in one trial. The CPFE temporally dissociates incidental context and context-US learning so each phase can be studied individually. Using the early immediate gene, *Egr-1*, we demonstrate different *Egr-1* expression profiles in the prefrontal cortex (PFC) for the two CFC variants in adult rats. Male Long Evans rats were trained in the CPFE or sCFC. During sCFC, rats were preexposed, then shocked in a single trial. 24h later retention of fear conditioned freezing was tested. Controls included a no shock and an immediate shock group. In the CPFE, animals were preexposed to either the training (PRE) or an alternate (ALT) context on Day 1. On Day 2, rats were given an immediate shock in the PRE context. Context conditioned freezing was tested on Day 3. *In situ* hybridization in the PFC for *Egr-1* expression was performed after sCFC training, CPFE preexposure, and CPFE training. Homecage controls were used as a baseline measure *of Egr-1* activity. Rats exposed to sCFC froze significantly more than control rats during the retention test. sCFC rats expressed higher levels of *Egr-1* in the anterior cingulate and orbitofrontal cortices compared to all controls. *Egr-1* in prelimbic and infralimbic cortices was elevated above homecage rats in sCFC, no- and immediate- shock rats, which did not differ from each other In the CPFE, PRE rats froze more than ALT rats during retrieval. PRE and ALT *Egr-1* levels in all PFC regions were elevated above HC both after preexposure and training. After training PRE rats expressed more *Egr-1* activity in the anterior cingulate, orbitofrontal, infralimbic and prelimbic cortices compared to ALT rats. These results suggest that *Egr-1* in the adult PFC exhibits different expression profiles after sCFC and CPFE, and replicate *Egr-1* patterns previously found in juvenile animals. The findings suggest the role of various prefrontal cortex regions are involved in different aspects of contextual fear conditioning at an early age that persists into adulthood.

Title: The Lateral Hypothalamic Parvafox-nucleus projects to emotional circuits

Authors: *A. BILELLA[1], G. ALVAREZ-BOLADO[2], M. R. CELIO[1];
[1]Med., Univ. of Fribourg, Fribourg, Switzerland; [2]Dept. of Neuroanatomy, Univ. of Heidelberg, Heidelberg, Germany

Abstract: The neural circuits underlying emotional valence and motivated behaviors involve several brain areas. Two of the most studied and discussed of them are the prefrontal cortex (PFC) and the periaqueductal gray (PAG). Moreover, several studies describe an involvement of the hypothalamus in the regulation of the emotions. Here we describe the efferent connections of a novel hypothalamic nucleus projecting to the PAG and PFC. This particular group of cells, recently discovered, is the Parvafox-nucleus. It is a cord-like structure comprised of intermingled parvalbumin-positive neurons and Foxb1-expressing neurons, and lodged within the ventrolateral hypothalamus. By using Cre-dependent viral constructs stereotactically injected in the Parvafox nucleus of *Foxb1-Cre* and *parvalbumin/Foxb1-Cre* mice we have mapped its efferent connections. These experiments have revealed a strong caudal projection to the PAG and the hindbrain and a minor rostral projection to the PFC. The caudal projection divides into two different bundles and reaches the dorsolateral and ventrolateral portions of the PAG. Labeled terminals are found also in the supraoculomotor nucleus (Su3), the cuneiform nucleus (CnF), the dorsomedial tegmental area (DMTg) and the locus coeruleus (LC). A small group of axons terminates in the gigantocellular formation (Gi) of the midbrain. These tracing results pave the way for further functional investigation of the Parvafox-nucleus. On this preliminary basis, we are tempted to speculate that the Parvafox nucleus participates in the regulation of emotional expression.

Title: Differential contributions of FoxP2 isoforms to vocal learning and variability

Authors: *Z. D. BURKETT[1], J. A. MORALES[2], S. A. WHITE[1];
[1]Integrative Biol. & Physiol., [2]Ecology and Evolutionary Biol., UCLA, Los Angeles, CA

Abstract: The transcription factor FoxP2 is essential for the proper development of learned vocalizations such as speech and birdsong. In humans, FOXP2 mutations that affect its ability to interact with DNA cause a severe speech and language disorder characterized by an inability to execute fine orofacial movements necessary for speech as well as difficulty in language processing. Multiple endogenous splice isoforms of FoxP2 exist in humans and the zebra finch species of songbird. The full-length isoform contains a poly-Q repeat, a zinc finger and leucine zipper domain to mediate dimerization, a forkhead box necessary for nuclear localization and DNA binding, and an acidic C-terminus domain. A second isoform, referred to as FoxP2.10+, lacks both the forkhead box and acidic C-terminus but retains the zinc finger and leucine zipper domain and is therefore capable of dimerizing with other FoxP molecules but deficient in entering the nucleus or influencing transcription on its own. Previous work indicates that knockdown or over-expression of the full-length isoform in zebra finch basal ganglia song nucleus Area X during sensorimotor learning result in similarly poor learning and elevated vocal variability. The similar deficits of these opposing interventions suggest that behaviorally regulated cycling of FoxP2 is a key component of proper vocal development. Here, we use constructs to over-express the full-length or 10+ FoxP2 isoforms in Area X of juvenile zebra finches and observe differential behavioral results for each isoform. The results replicate our previous finding that over-expression of the full-length isoform results in poor tutor song copying and blocks practice-induced changes in vocal variability. Surprisingly, over-expression of the 10+ isoform has no observable effect on tutor song copying. However, birds over-expressing the 10+ isoform show pronounced alterations in practice-induced vocal variability. Unlike birds with full-length or GFP over-expression, those over-expressing the 10+ isoform sing increasingly stable songs with practice. These novel results indicate a potentially unique function for multiple endogenous isoforms of FoxP2 in vocal learning and the acute regulation of variability.

Title: Beyond sensorimotor learning: Striatal FoxP2 affects maintenance of learned vocalizations in adult zebra finches

Authors: *N. F. DAY, C. Y. KIM, S. A. WHITE;
Integrative Biol. & Physiol., UCLA, Los Angeles, CA

Abstract: Human mutations in the FOXP2 transcription factor result in language disorders and altered basal ganglia structure. The neural underpinnings of speech learning can be investigated in songbirds because, like speech, birdsong is learned through social interactions, relies on auditory feedback and cortico-basal ganglia circuitry, and compensates for experimentally-induced errors. In the songbird brain, most FoxP2-enriched areas (e.g. cortex, thalamus) show a static expression level, whereas Area X (a song-dedicated basal ganglia nucleus), shows dynamic regulation: FoxP2 mRNA and protein decrease when juvenile and adult males sing, after which songs are more variable. In contrast, when adult male zebra finches engage in courtship (directed) song or refrain from singing, FoxP2 is high. Song stereotypy is greater when FoxP2 is high in non-singing juvenile birds. This 'on-line' regulation during singing is critical for song learning, but the role of FoxP2 in the active maintenance of a learned vocal motor skill is poorly understood. What is known includes that auditory feedback is crucial for the learning and the maintenance of song and speech, because deafness in adulthood causes both to deteriorate. In songbirds, hearing and FoxP2 are linked: The more a bird hears itself practice, the lower its Area X FoxP2 levels; no such correlation is observed in deaf birds. We hypothesize that cycles of behavior-driven FoxP2 regulation in adult songbirds enable song maintenance. Thus, we used an adeno-associated virus (AAV) to constitutively augment levels of FoxP2 in Area X of adult zebra finches to test whether singing behavior in the mature organism is altered. Birds were injected with either GFP- or FoxP2-overexpressing AAV constructs; a subset of each group were then deafened. FoxP2-mediated song stereotypy and deafening-induced song de-crystallization were quantified. We observe that FoxP2 overexpression in deafened birds hastens deterioration of phonological and syntactical song elements. We also examined social context-associated syllable variability and investigated synaptic interactions between cortical auditory afferents and FoxP2-expressing neurons in Area X. Our findings suggest that behavior-driven regulation of FoxP2 in adult animals is important for song maintenance, indicating that it influences song beyond the sensorimotor phase of vocal learning. Post-organizational effects of FoxP2 in adult birds suggest that human cases of FoxP2 mutations involve post-developmental deficits in addition to developmental ones.

Title: Neural representation of learned vocal behavior in motor cortex of juvenile songbirds

Authors: *R. C. YUAN, S. W. BOTTJER;
USC, Los Angeles, CA

Abstract: Similar to speech acquisition in humans, vocal learning in zebra finches entails a process of sensorimotor integration in which auditory feedback of juvenile birds' vocalizations guides refinement of variable immature vocal sounds into stereotyped adult vocal patterns. In zebra finches, the output of this sensorimotor processing is conveyed to RA, a region of motor cortex that drives vocal output. Neurons in RA of adult zebra finches demonstrate greater response strength to playback of the bird's own song than to playback of conspecific songs. However, little is known about the selectivity of RA neurons during the learning period: do neurons in RA of juvenile birds demonstrate selective tuning for their own immature song over other vocal stimuli? We investigated this question by making extracellular recordings in RA of anesthetized juvenile zebra finches (40-48 dph) and testing the neural response to playback of each bird's own song (OWN) against playback of two additional juvenile songs (mirror reverse of each bird's own song and age-matched conspecific song) and two adult songs (adult tutor song and adult conspecific song). All multi-unit sites demonstrated significant excitatory responses to playback of OWN and at least one other stimulus (n = 23/23), displaying an increase in mean firing rate during song playback. Across all sites, response strength to playback of each juvenile stimulus was significantly greater than the response to either adult song stimulus. Within responses to juvenile song stimuli, there was no significant difference in response strength between playback of OWN and age-matched conspecific song (n = 6). This pattern of results suggests that neurons in RA of juveniles engaged in sensorimotor learning prefer acoustic features inherent to juvenile vocalizations over adult vocal patterns, but do not prefer the bird's own song over other immature vocal sounds. Surprisingly, preliminary single-unit analysis revealed a minority of units that demonstrated an excitatory response to song playback (n = 5/46); a large number of units showed response suppression (n = 23/46), and many units did not change their baseline firing rate in response to song (n = 18/46). Qualitative inspection suggested that single RA neurons in juveniles (as in singing adult birds) shift from tonic firing during baseline to phasic bursting separated by periods of suppression during song playback, such that units excited by song show no significant change in mean firing rate during playback compared to baseline. Further analysis will test this observation, which predicts an increase in mean burst fraction and peak instantaneous firing rate of single units during song playback.

Title: Timing vs. sequencing in song learning

Authors: *J. HYLAND BRUNO, O. TCHERNICHOVSKI;
Psychology, Hunter Col., New York, NY

Abstract: What sort of central pattern generator gives rise to birdsong? Male zebra finch song is a complex learned vocal sequence, but it is also highly rhythmic: how is the learning of phonology, syntax, and rhythm orchestrated during song development? One possibility is that song units are learned and then chained together by some sequence generator. Alternatively, if the CPG is a rhythm generator, then song changes (such as adding a syllable) must comply with a metronomic framework. To test this question, we trained juvenile zebra finches to change their songs by incorporating a new syllable which either fit or violated the prior song rhythm. Preliminary results indicate that birds were more likely to accomplish this task when the rhythmic framework was preserved. In contrast, when the duration of the new syllable was not a small integer multiplier of the prior song meter, pupils' endpoint songs remained unstable and off-target, both in terms of temporal regularity and syntactical stereotypy. These findings provide motivation for investigating where and how rhythm may be generated in the songbird brain.

Title: Sequentially tutored zebra finches exhibit mirror patterns of lateralized neuronal activation in the avian auditory cortex

Authors: E. M. OLSON, R. K. MAEDA, *S. M. H. GOBES;
Neurosci., Wellesley Col., Wellesley, MA

Abstract: In monolingual humans, language-related brain activation shows a distinct lateralized pattern, in which the left hemisphere is often dominant. Studies are not as conclusive regarding the localization of the underlying neural substrate for language in bilinguals. Lateralization of the neural substrate for first and second language appears to depend on a number of factors including proficiency and early experience with each language. Similar to humans learning speech, songbirds learn their vocalizations from a conspecific tutor early in development. In the wild, zebra finches (*Taeniopygia guttata)* are exposed to several adult conspecific tutors at the same time and tutoring by two adult conspecifics is also possible in the laboratory (Yasaki-Sugiyama, et al. 2004). Here, we used a similar dual tutor paradigm to investigate memory-related neuronal activation (measured as the expression of the immediate early gene *ZENK*) in sequentially tutored male zebra finches. We measured the number of Zenk positive neurons and calculated lateralization ratios in response to exposure to the first tutor song, learned early in development (before 33dph), and to the second tutor song, learned later in development (61dph-90dph), in the caudomedial nidopallium (NCM) and in the caudomedial mesopallium (CMM). There were no differences in the absolute number of Zenk positive neurons between sequentially tutored birds exposed to songs from their first or their second tutor. However, when comparing the lateralization ratios in the NCM, we found mirror patterns of lateralization in the two song exposure groups. The more the birds had retained from their first tutor (% similarity), the more right-lateralized they were when exposed to that song (Pearson's $r = -0.91$, $p = 0.001$); however, the more birds had learned from their second tutor, the more left-lateralized they were when exposed to that song (Pearson's $r = 0.89$, $p = 0.003$). Our results suggest that in sequentially tutored songbirds, memory of song learned later in development is encoded predominantly in left-hemispheric circuits. In humans, perceptual traces of memories from the first language remain in the left hemisphere even when a second language subsequently replaces the first (Pierce, et al. 2014). Whether learning from a second tutor in songbirds results in overwriting of the original memory engram or generates parallel traces of two tutor song memories remains to be elucidated, but if song learning resembles language learning, traces of the first memory may remain in the left hemisphere.

Title: mTOR cascade signaling in the songbird auditory cortex is required for developmental song learning

Authors: *S. AHMADIANTEHRANI[1], S. E. LONDON[2];
[2]Psychology, [1]Univ. of Chicago, Chicago, IL

Abstract: The mechanistic Target of Rapamycin (mTOR) cascade regulates both transcription and translation, processes required for learning and memory. Young male zebra finches (*Taeniopygia gutatta*) learn to sing by memorizing a song from an adult "tutor" bird during a sensitive period (days 30-65 post-hatch; P30-65). We set out to determine if the mTOR cascade is activated in the auditory cortex, a region necessary for tutor song memorization, and contributes to tutor song memorization. First, we confirmed the presence of this cascade in the juvenile auditory cortex using Western blot analysis for mTOR and two of its downstream targets. We next tested if the mTOR cascade is activated in young males and females after hearing song playbacks. We used immunohistochemistry to quantify mTOR activation in the higher order auditory areas, the caudomedial nidopallium (NCM) and the caudomedial mesopallium (CMM). To ascertain if playback-induced mTOR activation coincides with the age of onset for tutor song memorization, we tested P23 and P30 birds. In P23 birds, song playbacks did not result in mTOR cascade activation in either the NCM or CMM. In contrast, song playbacks led to the activation of mTOR signaling in the NCM and CMM of P30 males, but not P30 females. Because we observed playback-mediated mTOR activation in P30 males, we hypothesized that this cascade is necessary for tutor song memorization. To test this possibility, we used a controlled tutoring procedure with intra-auditory cortex infusions of either rapamycin, which specifically inhibits mTOR activation, or SC79, which constitutively activates mTOR signaling. When we quantitatively compared the pupils' songs to the tutor's song, we found that birds who received rapamycin or SC79 copied significantly less of the tutor song compared with birds in the control vehicle group. This demonstrates that finely tuned mTOR signaling in the auditory cortex during tutoring experiences is required for song copying. Our behavioral data are consistent with a growing body of molecular evidence that suggests that both inhibition and excessive activation of mTOR signaling are equally detrimental. In *ex vivo* and *in vivo* models, mTOR acts as a molecular hub, integrating incoming synaptic signals and directing multiple outputs to form an appropriate neuronal response. Thus, our results provide a foundation for the use of developmental song learning in the zebra finch as a powerful *in vivo* model of how precisely modulated experience-dependent activation of mTOR during a specific developmental stage encodes meaningful information to shape behavior.

Title: Epigenetic histone modifications correlate with learning potential in the auditory forebrain of juvenile songbirds

Authors: *S. E. LONDON[1], T. K. KELLY[2];
[1]Dept of Psychology, Univ. of Chicago, Chicago, IL; [2]Active Motif, San Diego, CA

Abstract: Sensitive periods are phases in life when experience has maximal influence on brain organization. One hallmark of a sensitive period is that experience itself is the dominant signal ending the phase. Juvenile male zebra finches have a sensitive period for learning a complex natural behavior, song. The sensitive period is likely primarily represented in the sensory component of developmental song learning; preventing a young male from hearing song extends his ability to copy song from another bird but does not upset the normal onset or progression of vocal motor production. Notably, the experience required to close the sensitive period for sensory song learning (tutor song memorization) is song - other auditory stimuli such as calls is not sufficient. This suggests that identifying the mechanisms by which song experience is encoded during the sensitive period for tutor song memorization can provide novel insight into sensitive periods for cognition. Epigenetics is a powerful mediator of brain function, as modifications to DNA and histone proteins can be added and removed based on experience and can coordinate downstream molecular and cellular processes by regulating transcription of sets of genes. Here, we assessed if histone modifications are regulated by tutor experience in a neural locus essential for tutor song memorization, the auditory forebrain. We compared Posthatch day 65 (P65) males exposed to tutor song (low learning potential) to those prevented from hearing song during the normal learning phase (high learning potential) to examine epigenomic differences of age-matched birds in different learning potential states. We performed genome-wide DNA sequencing after chromatin immunoprecipitation (ChIP-seq) for histone modifications (H3K9me3, H3K27me3, H3K4me3) associated with silent, repressed, and active chromatin respectively, as well as for RNA Polymerase II (PolII), a direct measure of transcription. Results indicated that tutor experience globally reduces transcription in the auditory forebrain. Further, functional enrichment analysis suggested that genes involved in cellular differentiation, stabilizing neural circuits, and learning and memory are regulated by tutor experience-dependent histone modifications. Thus, tutor experience is encoded in the epigenome, with clear potential to regulate molecular and cellular processes that may underlie neural circuit learning potential. As tutor song memorization is a tractable model for sensitive periods for learning, this line of inquiry has implications to define cognitive sensitive periods for normal and disordered neural development.

Title: miR-9 regulates vocal learning and performance in the zebra finch

Authors: *Z. SHI, A. WEBER, X. LI;
Neurosci. Center, Louisiana State Univ. He, New Orleans, LA

Abstract: Mutations in the FOXP2 gene cause speech and language impairments in humans. Dysregulation of FoxP2 expression in Area X of the zebra finch, a basal ganglia nucleus required for vocal learning, leads to impairments of vocal communication behavior. Thus proper function and precise regulation of the FOXP2 is critically required for vocal communication. We recently identified microRNA miR-9 as a potential regulator of the FOXP2 gene by *in vitro* experiment. We also showed that miR-9 is abundantly expressed in Area X, and miR-9 expression is regulated during development, suggesting its roles in vocal development and learning. To understand the *in vivo* functions of miR-9, we used a lentiviral system to manipulate miR-9 expression in Area X in male juvenile zebra finches, and examined vocal learning of the virally injected animals. We found that comparing to non-injected animals and animals injected with a control virus, miR-9 overexpression in Area X in juvenile zebra finches resulted in abnormal songs when these juveniles reach adulthood. Their songs are less similar to their tutor's song at both the syllable and motif levels. Following the developmental trajectory of vocal learning in these animals, we found that impairments in vocal learning are already apparent at post hatching day 60 and persist through adulthood. Moreover, the acoustic features of the songs of these animals are more variable comparing to controls, suggesting that vocal performance is also impaired in these animals. In addition to FOXP2, miR-9 is known to regulate the expression of FOXP1, a paralog gene of the FOXP2. FOXP1 is thought to function as a transcription factors by forming a heterodimer with FOXP2, and dysfunctions of FOXP1 have been implicated in neurodevelopmental disorders such as autisms. Here we show that overexpression of miR-9 in Area X downregulates the expression of both FoxP1 and FoxP2 *in vivo*; and several FOXP2 downstream genes, which have important functions in neural development and plasticity, are also regulated. Taken together, our results provide evidence to support the roles of miR-9 in vocal development and learning via regulating complex gene expression network, which includes the FoxP1 and FoxP2 and their respective downstream genes.

Title: Familial genetic bias in vocal babbling pattern at early song development

Authors: D. SATO[1], *K. WADA[2];
[1]Grad. Sch. of Life Sci., [2]Hokkaido Univ., Sapporo, Hokkaido, Japan

Abstract: Learned vocalization is used as one of the crucial acoustic biosignals representing individual traits for mating and territorial defense. Songbirds learn song patterns by listening to a tutor song and performing self-motivated vocal practice during the sensitive developmental period. However, when and how individual differences in song patterns develop during learning remains unelucidated. Here we provide evidence indicating that an individual difference exists in the vocal output even at the earliest stage of song learning. Zebra finch male juveniles start singing a subsong, which is not merely disordered a vocalization but is regulated with biased variability at the temporal regulation of syllables. Epigenetic developmental factors, parental care before fledging and song tutoring, do not affect the generation of differences in subsong patterns among juveniles. In contrast, parental pair combination produces a familial bias of the distribution of syllable duration in the subsongs of their juveniles. These results indicate a potential genetic mechanism for generating individual differences in vocal outputs at the starting point of vocal development, suggesting an inherited trait of learning bias for the acquisition of vocal patterns.

Title: Genetic constraints on the learning of a complex song phenotype

Authors: *D. G. METS, M. S. BRAINARD;
UCSF/HHMI, San Francisco, CA

Abstract: Learning reflects the influence of experience on genetically determined circuitry. Both the ways in which experience shapes behavior during learning and the ways in which genetics shape non-learned phenotypes have been widely studied. However, little is known about how experience and genetics interact to determine complex learned phenotypes. Vocal learning in songbirds provides a rich system for investigating experiential and genetic contributions to learning; the output of learning (song) is quantifiable and we can manipulate both the experiential contributions (through computer tutoring) and genetic contributions (through breeding). Here we examine the relationship between experiential and genetic contributions to learning of an ethologically relevant phenotype, the tempo of song production (quantified in syllables produced per second). Distinct genetic lines of the Bengalese finch (Lonchura striata domesitca) were bred from parents with different song tempos. When juvenile birds of a given line were tutored with synthetic songs that varied only in tempo, they developed adult songs with tempos that varied with the tutor song. Hence, as expected, the structure of song was shaped by experience. However, when the tempo of the tutor song was held constant, juveniles from different genetic lines developed song tempos that strongly correlated with those of their fathers, even though these juveniles had never heard their fathers sing. Thus, under controlled tutoring conditions, we found an unexpectedly strong genetic contribution to the mean song tempo. We further investigated the interaction between genetics and experience by tutoring several genetic lines (that expressed slow, medium and fast songs) on a set of synthetic songs that differed only in tempo. We again found that, across all lines, tutoring experience influenced song tempo. However, each line learned different amounts of the stimulus tempo, revealing a significant gene by environment interaction (GXE; a non-linear interaction between genetic and experiential contributions to song tempo). Taken together, these findings demonstrate a strong genetic contribution both to the mean tempo of song and to the degree to which tempo is influenced by experience. Our results provide a striking demonstration of how genetics can both shape and constrain the influence of experience on a complex learned phenotype.

Title: Rapid learning of auditory discrimination via observation and its limited generalization

Authors: *G. NARULA, R. H. R. HAHNLOSER;
Inst. of Neuroinformatics, Univ. of Zurich - ETH Zurich, Zurich, Switzerland

Abstract: Learning to imitate members of your own species in order to survive, prosper, or procreate has been identified in social animals such as humans, non-human primates, and several avian species. Typically, successful imitation is reported when observing animals selectively mimic complex motor behaviors performed by expert demonstrators. For example, songbirds such as the Zebra Finch (Taeniopygia guttata) have the capability of vocal learning by imitating the songs of a tutor experienced early in life. However, little is known about the ability of zebra finches, a highly social species, to learn simple stimulus-response mappings from demonstrating conspecifics. Here, we investigate whether adult zebra finches have the capacity for observational learning of a difficult auditory discrimination task. Briefly, pairs of adult zebra finches were placed in adjacent cages in sound isolation chambers, with one bird acting as a 'Demonstrator' for the other, the 'Observer'. In the first phase of the experiment, the Demonstrator is trained to discriminate between short and long renditions of a typical zebra finch song syllable. We use a Go/No-Go operant conditioning protocol (Tokarev & Tchernichovski 2014, Canopoli et al 2014), where the reinforcing agent associated with one of the two stimulus classes is a strong puff of air applied one second after stimulus offset. A special perch is used by the Demonstrator to trigger stimuli and/or air-puffs, as well as to interact with the Observer. Demonstrators eventually learn to stay or leave the perch before the onset of the air-puff, providing the Observer with a behavioral response to the stimulus. After reaching a given performance criterion, we replace the Demonstrator with the Observer and subject it to the same task. We show that Observers are significantly faster than Demonstrators at achieving the performance criterion. A control group that was exposed to several stimulus and reward cue (sound of air-puff) pairings prior to the actual training period did not show a similar increase in learning rate, allowing us to reject perceptual learning as the mechanism of accelerated learning in observers. We also show that prior knowledge of stimulus value does not provide observers the ability to rapidly learn stimulus-reward associations, allowing us to reject observational conditioning as well. Furthermore, we show that observers are slower than demonstrators at generalizing their learned behavior to new instances of the same stimulus. Finally, we present preliminary findings which suggest that vocal communication between the birds plays an important role in producing the benefits of observation.

Title: What information can zebra finches extract from video clips?

Authors: *I. LJUBICIC[1,2], J. GORDON[1], O. TCHERNICHOVSKI[1];
[1]Psychology Dept., Hunter College, CUNY, New York, NY; [2]Biol., Grad. Center, CUNY, New York, NY

Abstract: Video playbacks can be a powerful research tool to study avian visual communication, species recognition, mate choice, and song learning. We are developing a system for studying how controlled sensory and social scenarios may affect song imitation in zebra finches. A serious challenge is that the color output of a video monitor does not match the color vision of zebra finches. To test if this would hinder identification of birds in a video, we automatically segmented the colorful beak and cheeks of a singing male and varied the context they were presented in. We can also rotate the color space in the videos to more closely match the reflectance spectra of the birds' feathers and stimulate the correct photoreceptors in zebra finches. Even without such manipulations, preliminary results show that video colors have a positive effect in attracting the birds compared to B&W videos. Furthermore, presenting a moving, colored beak and cheeks (without the bird) makes the video less attractive. The birds perceive the colors in the context of the singing male. Surprisingly, rotating the video image by 180 degrees to show the male upside-down, did not reduce preference for the video. This suggests that, in contrast to many mammals, zebra finches can perceive rotated images with relative ease. Our results indicate that zebra finches are attending broadly to the information in the videos, and are not just responding to the patterns of colors and lights. We can now design a "zebra finch TV" that will allow us to test which social contexts are important for tutor choice and song learning.

Title: The brain in flux: transient changes in hemispheric lateralization accompany prolonged exposure to a novel auditory environment

Authors: *L. YANG, D. S. VICARIO;
Rutgers Univ., New Brunswick, NJ

Abstract: Over the course of a lifetime, an individual is exposed to a wide and varying range of acoustic stimuli. While developmental auditory exposure may establish the groundwork for perceptual processing, exposure to novel acoustic stimuli can modify perceptual filters in the mature individual, e.g., during acquisition of a second language. Songbirds provide a model for studying adult plasticity in auditory cortex as a function of recent auditory experience, due to many similarities with the human auditory system, e.g. a critical period for vocal learning, and hemispheric lateralization for complex acoustic stimuli. Lateralization of auditory processing has been shown in electrophysiological and IEG studies of the songbird caudo-medial nidopallium (NCM), a higher auditory area. Zebra finches passively exposed to heterospecific (HET) aviary sounds for 4 or 9d showed a narrowing of tuning width and a reversal in the normal pattern of lateralization compared to controls that heard playback of a conspecific (CON) aviary. In the present study we continued these playbacks to later time points to assess changes in lateralization after prolonged exposure to a novel HET environment. Adult male zebra finches were exposed to either CON or HET auditory environments via playbacks for a period of 14 or 30d. Then, multi-unit activity was recorded using electrodes placed bilaterally in NCM of awake restrained zebra finches during presentation of novel zebra finch and canary songs. Hemispheric differences in absolute response magnitude (ARMs) and stimulus-specific adaptation (SSA) were measured. Subjects in the 14 and 30d groups showed the normal pattern of right side higher ARMs and right side faster SSA, regardless of recent auditory experience (CON or HET). Thus, the pattern of lateralization in the 14 and 30d HET groups was reversed from the reversed pattern seen at 4 and 9d groups (Yang & Vicario, 2014), but was similar to the baseline pattern of lateralization (Phan & Vicario, 2010). These data suggest that exposure to a novel acoustic environment initially challenges the system to modify its perceptual filters, accompanied by a reversal of lateralization after 4 and 9d. However, after prolonged exposure, the HET environment becomes familiar and no longer poses a challenge, leading to a reversion back to the normal pattern of lateralization. We will also test whether patterns of lateralization at various time points correspond to an enhancement in behavioral discrimination. In conclusion, hemispheric lateralization changes transiently during auditory perceptual learning, perhaps as part of an underlying process by which perceptual filters are modified to process new sounds.

Title: Differential effects of experience on immediate early gene response in black-capped chickadees

Authors: *A. H. HAHN, L. M. GUILLETTE, D. LEE, N. MCMILLAN, J. HOANG, C. B. STURDY;
Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Black-capped chickadees produce a chick-a-dee call containing four note types (A, B, C, and D). D notes are a biologically important component of the call that is used to identify flock, species, food availability, and predator threat level. In a recent study, using adult wild-caught black-capped chickadees we found that the immediate early gene (IEG) response in the caudomedial mesopallium (CMM) and caudomedial nidopallium (NCM) was similar following presentation of heterospecific vocalizations with acoustic structure similar to D notes. In the current study, we examined how rearing environment affects IEG response to conspecific D notes. Black-capped chickadees were reared with adult conspecifics, with adult heterospecific mountain chickadees, or without adults. All hand-reared birds and a group of field-reared black-capped chickadees were presented with conspecific D notes and we quantified IEG expression in CMM and NCM. We found that chickadees reared with conspecifics had an IEG response similar to field-reared birds, while birds reared without adults had significantly less IEG expression. Birds reared with heterospecifics had an IEG response that was intermediate between the other two hand-reared groups. We also examined the vocalizations produced by all of the hand-reared birds, and we found that birds reared with heterospecifics and birds reared without adults were not producing species-typical D notes. Taken together, these results suggest that having prior experience with conspecific D notes was not the only factor driving the IEG response. But, our results suggest that experience with adults or adult vocalizations (i.e., conspecifics or closely-related heterospecifics) also influences the IEG response in chickadees.

Title: Rhythm does not influence ZENK expression in NCM of zebra finches up to day 45

Authors: *J. A. LAMPEN[1], K. JONES[2], J. MCAULEY[2], S.-E. CHANG[3], J. WADE[2]; [1]Neurosci., [2]Psychology, Michigan State Univ., East Lansing, MI; [3]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Rhythm is important in language processing and learning. Many human disorders involve deficits in rhythm perception and production, including stuttering, autism, and Parkinson's disease. Zebra finches present a strong model for investigating the neural responses to rhythm because they are a vocal learning species with a naturally rhythmic song. Adult zebra finches exhibit increased expression of the immediate early gene ZENK following exposure to arrhythmic compared to rhythmic song in the caudomedial nidopallium (NCM), caudomedial mesopallium (CMM), and nucleus taeniae (Tn). NCM and CMM are homologous to auditory association cortex in humans and Tn is the avian homolog of the amygdala. To understand development of rhythm discrimination, we exposed male and female juvenile zebra finches at three stages to sets of natural zebra finch songs (rhythmic) or songs in which the duration of the silences between notes was modified to disrupt the natural timing (arrhythmic). We hypothesized that rhythm discrimination develops following template formation, which is complete by day 45. Juveniles were exposed to one of the stimulus types at day 15 post hatching, prior to song template memorization, day 25, during template formation but prior to sensorimotor integration, or at day 45, during sensorimotor integration in males. We expected a greater ZENK response to arrhythmic vs. rhythmic songs in birds at day 45. Immunohistochemistry for ZENK revealed a significant effect of age in NCM ($F=10.7$, $p<0.001$), with 15-day-old birds having greater density of ZENK expressing cells than birds at both days 25 and 45 (Tukey HSD $p<0.05$). Effects of sex and rhythmicity were not detected. These results are consistent with findings of high levels of constitutive ZENK expression within NCM at day 20, and that ZENK expression is not inducible by song exposure until later ages (Stripling et al., 2001). The lack of sex differences in this brain region parallels the pattern found in adults. The lack of an effect of rhythm condition at any juvenile age, in contrast with our findings in adults, suggests that NCM function related to song quality discrimination might occur in both sexes later in development than we anticipated. The data also suggest that early sensorimotor integration in males is not sufficient to allow rhythm discrimination within this brain region. In NCM, the ability to compare the song with a template or to detect temporal regularity through another mechanism seems to develop closer to adulthood. Additional brain regions relevant to auditory-motor integration for song learning are under investigation.

Title: State-dependent auditory selectivity for familiar songs in the auditory association cortex of juvenile songbirds

Authors: ***S. YANAGIHARA**, Y. YAZAKI-SUGIYAMA;
Okinawa Inst. of Sci. and Technol., Onna-Son, Japan

Abstract: Sensory information processing can be modulated depending on behavioral states of animals, such as asleep, awake, or attentive. The latter states regulate higher cognitive function, like learning. As in human speech acquisition, songbirds learn to sing through social interaction with adult birds. Juvenile zebra finches scarcely copy recorded songs just by passive hearing. However, when a recorded song is presented during operant conditioning (key peck triggers song playback), juveniles successfully learn from it (Tchernichovski et al. 2001). This raises the possibility that bird's behavioral state modulates auditory information processing, which regulates song learning. Recently, we found that subsets of neurons in the zebra finch auditory association cortex, the caudomedial nidopallium (NCM), exhibit highly selective responses to tutor song (TUT) or the juvenile bird's own developing song (BOS) following tutor song experience (Yanagihara & Yazaki-Sugiyama 2014 SFN abstract). These neurons are thought to encode memories of songs that the birds have experienced. Here, we examined whether experience-dependent auditory activity in NCM is modulated by behavioral states or social context. Previous studies show that neurons in the song system nuclei robustly respond to BOS during sleep, while they do not during wakefulness (Dave et al. 1998, Schmidt & Konish 1998, Nick & Konishi 2001, Rauske et al. 2003, Cardin & Schmidt 2003, 2004). Unlike song system nuclei, we found that song-selective neurons in NCM of juvenile zebra finches, greatly decreased selectivity to familiar songs while birds were asleep. Furthermore, we found that social context markedly modulates auditory responses of song-selective neurons. Presence of a tutor enhanced auditory responses in those neurons to both TUT and BOS, but not to other songs. In preliminary experiments, we also found that infusion of noradrenaline, a neuromodulator involved in arousal/attention, similarly enhanced auditory responses only to TUT and BOS, but not to other

songs. Taken together, auditory response selectivity is modulated by both behavioral state (awake or asleep) and social context (presence of a tutor) in NCM. Presumably these state-dependent modulations of auditory response selectivity are partially mediated by the noradrenergic system. These elements are suggested to underlie behavioral state-dependent memory formation of tutor song.

Title: Courtship song preferences in female zebra finches arise independently of early auditory experience

Authors: *Y. CHEN[1], O. CLARK[2], V. NG[2], S. C. WOOLLEY[2];
[2]Biol., [1]McGill Univ., Montreal, QC, Canada

Abstract: Early social and sensory experiences are critical in shaping perception and social behavior; consequently, such developmental experiences can also profoundly influence adult preferences for particular stimuli. Female songbirds use song to identify male conspecifics and choose preferred mates. However, we know little about how early social and sensory experience affect female song preferences and the neural circuits underlying female preferences. We have previously found that female zebra finches prefer a male's courtship ('directed') song over his non-courtship ('undirected') song, regardless of the familiarity of the male. To test whether this preference is dependent on a female's early auditory experience, we compared song preferences and neural response to song between female zebra finches raised without exposure to adult male song ('isolate females') and normally reared females. Using a callback assay, we quantified adult female responses to directed and undirected songs from multiple different males and found that isolate females preferred the courtship songs to non-courtship songs. In particular, they significantly increased their calling in response to the courtship songs and decreased calling in response to non-courtship songs when compared to baseline calling. Moreover, their responses were indistinguishable from normally reared females, suggesting preferences for courtship song are not significantly affected by developmental exposure to song. In a separate group of birds, we investigated the degree to which developmental song exposure affected auditory responses. Our preliminary analysis of immediate early gene (EGR-1) expression indicates that auditory

responses in higher-level auditory areas, including the caudomedial mesopallium (CMM) and caudomedial nidopallium (NCM), are not significantly different between normally and isolate reared birds. These data indicate that the strong preference for female-directed courtship song is not dependent on early auditory exposure to song but may instead reflect an inherent bias in the auditory system.

Title: Experimental manipulations in the developing songbird affect both vocal imitation and auditory memories

Authors: ***D. S. VICARIO**[1], B. BELL[1], M. L. PHAN[1], K. L. BUCHANAN[2];
[1]Rutgers Univ., Piscataway, NJ; [2]Sch. of Life and Envrn. Sci., Deakin Univ., Geelong, Australia

Abstract: Songbirds provide a translational model for two forms of learning that occur during a critical period in development: 1) sensory-motor learning that subserves vocal imitation; and 2) the formation of long term sensory memories. Normal vocal development requires auditory and social experience with an adult tutor and extensive vocal practice, guided by a memory of the tutor song. In the songbird, the outcome of this imitation process can be quantified as the similarity of the bird's song to the tutor model. We have previously documented a neuronal memory for the tutor song, formed in the juvenile period, that can be measured in the adult caudomedial nidopallidum (NCM); the strength of this memory is correlated with imitation quality. In addition to storage of the tutor's song, NCM contributes to discrimination and memory for species-specific vocalizations heard in adulthood. However, this system for vocal learning and memory is sensitive to perturbations. Various studies have shown that pharmacological inhibition of NCM produces decrements in song learning and that bilateral NCM lesions impair song discrimination. Dosing with oral atorvastatin, beginning in the critical period for song learning, degrades song copying, reduces memory for the tutor song, and impairs the formation of memories for novel auditory stimuli in NCM in adulthood. The present study tested for the effects of environmental stressors (e.g. handling and an impoverished diet) on vocal learning and memory. We reduced the quality of food available to parents (who regurgitate food to their young) and handled the birds daily to weigh them during a limited early portion of the critical period for vocal learning (days 5-30phd). After an initial lag in weight gain, birds

achieved normal weight by 30phd, at which times all subjects received a normal diet ad libitum and handling was minimized. In adulthood (110phd), song imitation fidelity and electrophysiological responses to conspecific songs were assessed. The data suggest that mild environmental stress during the early critical period of development (n=10; 4 females; 6 males) can result in deficits in the quality of song imitation and in the neuronal memory for conspecific songs. Taken together, these results show that the quality of sensorimotor learning can be affected not only by direct experimental insults like pharmacological lesions, but also by side effects from commonly prescribed medicines and enhanced stress during the early stages of development.

Title: Longitudinal *in vitro* diffusion tensor imaging study maps structural plasticity in the brain of juvenile male zebra finches throughout the critical period for vocal learning

Authors: J. HAMAIDE, G. DE GROOF, *A.-M. VAN DER LINDEN;
Univ. of Antwerp, Antwerp, Belgium

Abstract: Structural development of the zebra finch (ZF) brain has been investigated mainly by invasive methods such as histology. These *ex vivo* imaging techniques are highly sensitive and specific to particular biological phenomena but do not allow repeated measures or correlations with behavioral changes. Here we present a longitudinal Diffusion Tensor Imaging (DTI) study aimed at mapping structural development of the male ZF brain related to the process of vocal learning. DTI has proven to be a non-invasive Magnetic Resonance Imaging (MRI) tool sensitive to changing myelin contents and microstructural reorganization of the brain[1]. Juvenile male ZFs (Taeniopygia guttata; n=16) underwent repeated imaging sessions at seven time points throughout the sensory and sensorimotor phase of vocal learning and after song crystallization. A whole-brain voxel-based analysis (repeated-measures ANOVA) was performed on the DTI parameter maps i.e. fractional anisotropy (FA), mean diffusion (MD) and the eigenvalues. Most significant microstructural rearrangements take place in two waves situated within the sensory

and sensorimotor phase i.e. between resp. 20 - 30 days post hatching (dph) and 40 - 65 dph. From the early sensory phase (20 dph) until song crystallization (90-120 dph), MD and FA gradually decrease and increase resp. and this happens in a caudal-to-rostral wave mostly involving pallial and subpallial brain areas. Interestingly, from 40 dph onwards, the rostral border of Field L appears to delineate the caudal border of the area that still displays a change in MD values compared to adulthood. These observations are in line with studies investigating human brain development using DTI, where it has been shown that sensorimotor cortices mature prior to higher-order associative brain areas[2]. When zooming in on the main effect of age for FA, a DTI parameter sensitive to fiber- or myelin- containing structures, specific subparts of the lamina mesopallialis, the lamina frontalis superior and the tractus occipitomesencephalicus can be identified and, interestingly, their establishment can be situated in time. Songs recorded during the sensorimotor phase and after song crystallization will be analyzed and correlated to the DTI data of the same individual. Voxel-wise correlation of DTI findings to song output and to the outcome of a parallel auditory fMRI study targeting the neural substrate of tutor song selectivity in ontogeny performed at the lab will shed further light onto structural and functional neuronal changes during the critical period of vocal learning. Title: Sensory expectation in male HVC for call communication in zebra finches

Authors: ***S. MA**[1,2], A. TER MAAT[1], M. GAHR[1,2];
[1]Max-Planck-Institute For Ornithology, Seewiesen, Germany; [2]Grad. Sch. of Systemic Neurosciences (GSN), Planegg-Martinsried, Germany

Abstract: Zebra finches are social animals that communicate with each other using calls and songs. While only the males are singing, female and male share a similar repertoire of calls to communicate within their social group and in particular with their mates. To facilitate these social interactions, it requires brain mechanisms for call communication. Forebrain nucleus HVC is a cortex-like sensorimotor area essential for song production and learning. In order to study the role of the HVC in call communication, we used a wireless telemetric system for simultaneous measurement of neural activity and vocalizations in animals that freely interacted with each other. HVC displayed stereotypic activity patterns for call production and processing of those female calls that were uttered in bouts of male-female vocal exchange. The premotor activity in

HVC did not necessarily produce a call but fictive motions to compare between sensory states of self and external cues to predict upcoming female calls. The prediction with fictive motions could not be done independently without sensory cues. The male HVC also displayed a neural activity to sensory inputs of incoming female calls, which may be responsible for evaluating the precision of call production with incoming sensory inputs of female calls. Such HVC based response to female calls depends on a fictive premotor activity that equals sensory expectation of female calling.

Title: Vocal sequence predictability modulates traveling wave activity in songbird auditory forebrain

Authors: ***G. J. BECKERS**[1], J. A. BROEKHUIZEN[1], N. C. RATTENBORG[2], J. J. BOLHUIS[1];
[1]Utrecht Univ., Utrecht, Netherlands; [2]Max Planck Inst. for Ornithology, Seewiesen, Germany

Abstract: Bird songs arguably have the most complex structure among all animal vocalizations, except human speech, as they may consist of long and variable sequences of different vocal element types. How such sequences are perceived remains poorly understood. Of particular interest is whether their recognition depends mainly on memory of (generalized) recurring sound objects consisting of element chunks, or, perhaps additionally, involves analysis of regularities in the sequence per se (sequence rule learning). Previously we have shown that secondary regions in the auditory forebrain of anesthetized zebra finches, Taeniopygia guttata, are sensitive to short-term stimulus history statistics, as they exhibit synchronized activity of action potential firing preferably in response to calls that are deviant within a series of calls that are standard (i.e. statistically expected). Such activity could reflect a stimulus-specific form of short-term auditory memory, but it may also reflect a violation of predicted auditory input. We recorded action and local field potentials at 64 sites in parallel in the auditory forebrain of isoflurane anesthetized zebra finches, and played sequences of song elements in random order, interspersed with episodes where elements followed a simple sequence rule (repetitions, bigrams). In addition to temporally and spatially stereotypic responses that are confined to the primary thalamorecipient

area L2, we found slow-oscillations that travel in complex temporospatial patterns across secondary auditory areas. These propagating waves appear to be similar to those that have been described earlier in other zebra finch brain regions and that have been linked to NREM sleep. We found that in the auditory forebrain such traveling slow oscillation activity is stronger during episodes with random sequences than it is during episodes where vocal elements are repeated. Further, random vocal elements that immediately followed a regular sequence elicited stronger slow-wave activity than the same elements situated in a random context. Taken together, these data suggest that traveling slow-wave activity in the songbird auditory forebrain is modulated by short-term predictability of elements in a vocal sequence.

Title: Inhibition systematically silences an instructive signal during motor learning

Authors: *D. VALLENTIN[1], G. KOSCHE[1], D. LIPKIND[2], M. A. LONG[1];
[1]NYU Sch. of Medicine, Dept. of Physiol. and Neurosci., New York, NY; [2]Dept. of Psychology, Lab. of Vocal Learning, Hunter Col., New York City, NY

Abstract: Zebra finches learn their songs by listening to and imitating a tutor. During development, sensory input is necessary in order to effectively imitate the tutor's song. Recent experiments have demonstrated that disrupting neuronal activity in the premotor nucleus HVC during tutor song exposure can significantly block song imitation (Roberts et al. 2012), suggesting that the passive engagement of the motor pathway may be necessary to establish proper singing behavior. Here, we directly measure the impact of the tutor song on HVC neurons during and after learning. We recorded intracellularly from premotor cells and found that the tutor song has the potential to drive precise spiking responses in the awake juvenile zebra finch, but not in the adult bird. What is the mechanism that can affect a developmental decrease in the premotor neuron's response to tutor song input during song learning? To measure developmental changes in the strength of auditory representation, we performed voltage clamp recordings of

HVC premotor neurons in awake zebra finches. We found that the amplitude, frequency and precision of identified excitatory events evoked by the tutor song did not decrease during learning. However, the firing of local inhibitory interneurons as well as inhibitory synaptic events onto premotor neurons in HVC became significantly more precisely timed to the tutor song motif depending on the learning stage of the bird. To investigate whether the emergence of precise inhibition during learning is sufficient to prevent premotor neurons from spiking in the adult zebra finch, we pharmacologically minimized the impact of inhibition. Local application of a low concentration of the GABAA antagonist gabazine led to a reemergence of tutor song-driven spiking responses in premotor neurons. We then asked whether the precise inhibition can accurately target the portions of the song that have been learned. We trained zebra finches with a simple tutor song consisting of four identical syllables (AAAA). After the birds gained proficiency in the performance of syllable A, we extended the tutor song by adding syllable B (ABAB) (Lipkind & Tchernichovski 2011). We recorded interneuron activity and inhibitory currents onto premotor neurons in zebra finches that copied A well and copied B poorly, and found that inhibition was selectively stronger during syllable A versus syllable B. Taken together, these data suggest that inhibition within HVC progressively blocks an instructive signal in an accurate manner during motor learning, potentially to 'write protect' that motor skill.

Title: High order interactions between synapses affect the average dynamics of the synaptic efficacy in recurrent neural networks

Authors: *N. RAVID[1], Y. BURAK[2,3];
[1]ELSC, Hebrew Univ., Jerusalem, Israel; [2]Edmond and Lily Safra Ctr. for Brain Sci., [3]Racah Inst. of Physics, Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The structure and plasticity of synaptic connectivity underlies much of our ability to process and store information. In the past two decades, spike timing dependent plasticity (STDP) has become one of the main foundations of theoretical research on plasticity and learning. Previous works that explored theoretically the change in the synaptic efficacy according to STDP mainly focused on local approximated terms that depend on the firing rate of the pre- and the

post-synaptic neurons and the synaptic efficacies between them (for example: Babadi and Abbott 2013). We recently developed an analytical framework in which the average change in the synaptic efficacy, due to STDP, can be evaluated precisely in recurrent networks of Poisson neurons with arbitrary connectivity. In this framework, the local learning plasticity rule of Babadi and Abbott arises in a systematic manner as the first order term of an expansion in the strength of synaptic efficacies. We show that higher order terms lead to an effective interaction between synapses of different neurons that can significantly alter the dynamics, and affect the global structure of the neural network in steady state. As an example, we consider the spontaneous formation of wide synfire chains, in which distinct groups of neurons share similar connectivity, and sequentially project to each other. It has been hypothesized that this architecture underlies the synchronous neural activity observed in the premotor nucleus of songbirds HVC (Hahnloser et al. 2002 , Long et al. 2010). We show that the high order terms in our theory can promote the formation of wide synfire chains without the need to introduce structural constraints or correlated external input.

Title: Sequence processing in a songbird secondary auditory area

Authors: ***N. GIRET**, A. CAZALA, C. DEL NEGRO;
Neurosci. Paris Saclay Institute, UMR CNRS 9197, Orsay, France

Abstract: The complexity of the human language is thought to be unique in the animal kingdom, given several human specific features such as the recursive aspects of syntax, which consists in embedding phrases within phrases. However, songbirds can be trained to behaviorally distinguish sequences of syllables according to their recursive structure. As humans, songbirds are able to learn and produce vocalizations containing sequences of syllables with specific transition probabilities. How sequences are processed into the songbird brain remains to be characterized. Songbirds offer a great opportunity to address this issue: they have a set of interconnected telencephalic auditory brain areas including an analog of the mammalian secondary order auditory cortex, the nidopallium caudo-medial (NCM). In this area, repeated exposure to a conspecific vocalization induces a decrement of the elicited spiking response or

gene expression. In order to investigate whether the NCM is involved in syntax processing, we played back sequences of syllables to anaesthetized birds while recording the neuronal activity of NCM neurons. The sequences contained one introductory note followed by sequences with (AnBn) or without ((AB)n, (CD)n, ABCD or CDEF) a recursive structure (where A, B, C, D, E, F are song syllables and n the number of repetition). During an exposure, we broadcasted a given sequence 50 times and then either the same sequence or a different one (thus differing either in syllable identity or order) 10 times. Preliminary results show habituation of the spiking responses to the repeated exposure of a sequence. Changing the syllable identity but not the syllable order induces an increase of the spiking response, thus suggesting a sensitivity of NCM neurons to acoustic features of the syllables but not to the sequence structure.

Title: Neuritin (CPG-15) may contribute to synaptic plasticity in brain areas for sensory song learning during development

Authors: *B. BORDEN[1], S. E. LONDON[2];
[1]Inst. For Mind and Biol., Chicago, IL; [2]Dept of Psychology, Inst. for Mind and Biology, Committee on Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Young male zebra finches learn to sing by memorizing the structure of a "tutor's" song. Tutor song memorization normally occurs during one sensitive period from posthatch day 30-65 (P30-65). Birds constantly experience song in their social environment, thus the limited learning window suggests that there are neural properties that permit tutor song memorization, and that these characteristics change across the sensitive period. Balancing synapse plasticity and stabilization is an essential processes in neural development and learning and memory. Neuritin (also called CPG-15) promotes synapse stabilization and is developmentally regulated, activity dependent, and implicated in cognitive function in other systems. We therefore assessed neuritin expression in the zebra finch to determine its potential role in developmental song learning. We focused on P25, P45, and P65 males and females who were either raised normally (i.e. in a social environment and exposed to song) or with one adult female (in a social environment, but isolated from song) to assess the effect of age, sex, and song experience on neuritin expression just prior to, during, and at the close of, the sensitive period for tutor song memorization. *In situ* hybridization revealed that all three ages, neuritin is present in the secondary processing regions of the auditory forebrain, CMM and NCM, and in HVC. We did not detect neuritin mRNA in

RA, LMAN, or Area X, suggesting a greater role for neuritin in auditory processing than in motor production. Preliminary results also suggest that the levels of neuritin mRNA are higher in male HVC than female HVC. Surprisingly, song playbacks in adults does not seem to induce neuritin expression in the auditory forebrain, likely because acoustic isolation for up to two weeks does not lower baseline mRNA levels. It may be therefore that neuronal activity regulates neuritin in the songbird differently than in rodents, and/or neuritin is regulated differently in secondary sensory cortex than other regions. As neuritin contributes to synaptic plasticity during development, after neural activity, and in adult cognitive disorders, these data provide a foundation for future studies to tie neuritin with the neural processes that underlie normal and disordered cognitive function during development.

Title: Rapid molecular profiling of genetically defined cell types using viral TRAP

Authors: *E. F. SCHMIDT[1], A. R. NECTOW[2], M. I. EKSTRAND[2], A. MOUSA[1], K. L. MCGUIRE[1], C. E. SFERRAZZA[1], B. C. FIELD[2], Y. LIANG[3], G. S. RABINOWITZ[4], K. SAWICKA[4], N. HEINTZ[1,5];

Abstract: Recent advances in translational profiling methods have enabled the systematic characterization of the molecular properties of specific cell types in complex tissues. These methods have proven particularly useful for studies of the mammalian central nervous system, where hundreds of heterogeneous cell types are intermixed, making neuronal subtype isolation exceptionally difficult. The translating ribosome affinity purification (TRAP) technique is a direct, rapid method for isolating polysomal RNA from genetically defined cell populations *in*

vivo. It requires the targeted expression of EGFP-tagged ribosomal subunit L10a (EGFPL10a) in identified cell populations. Traditionally, this has been achieved through the generation of novel BAC transgenic mouse lines that label cell types of interest (bacTRAP), or crossing Cre recombinase expressing lines to Cre-dependent EGFPL10a reporter mice, thus requiring the expression of two independent alleles. Here, we report the development of a viral strategy for the rapid profiling of CNS cell types that can be used in combination with any existing Cre driver line. This strategy allows for TRAP profiling of genetically and anatomically defined cell types within a few weeks of virus injection and circumvents the need to create new transgenic strains or undergo lengthy breeding strategies. We engineered an adeno-associated viral (AAV) vector to express EGFPL10a in a Cre-dependent manner (AAV-FLEX-EGFPL10a). We demonstrate the incorporation of the EGFPL10a transgene into functional polysomes *in vivo*, and validate its utility as a tool to access translating mRNAs from various defined neural populations in the midbrain and hypothalamus. A direct comparison of high throughput RNA sequencing results from layer 6 corticothalamic projection neurons revealed a high correlation between the viral TRAP (vTRAP) and bacTRAP approaches and demonstrated the ability of vTRAP to distinguish regional differences in gene expression within the same cell type. Taken together, these results establish utility and broad applicability of the vTRAP strategy for profiling cell types within or outside of the CNS in a Cre-dependent manner.

Title: Sequence specific radiolytic footprinting study of monomer, oligomeric and fibrillar Aβ42

Authors: *A. KLINGER[1], J. KISELAR[2], A. PARAVASTU[3], T. ROSENBERRY[4]; [1]Dechiperbio, Wyndmoor, PA; [2]Case Western Reserve Univ., Cleveland, IL; [3]Florida State Univ., Tallahassee, FL; [4]Mayo Clin., Jacksonville, FL

Abstract: Increasing evidence suggests that soluble aggregates of amyloid-β (Aβ) are the pathogenic species in Alzheimer's disease (AD). However, detailed structural information on these species remains scarce due to low levels of endogenous Aβ oligomers and uncertainties surrounding current *in vitro* model systems. Herein, we describe a hydroxyl radical footprinting (HRF) study of Aβ42 monomers, small aggregates, homogenous and stable oligomers, and fibrils. Specific side chain solvent accessibilities of individual residues in the aggregated and

fibril forms of Aβ42 are measured with respect to the same residues of Aβ42 in a fully exposed reference state. These data provide residue specific side chain solvent accessibility protection factors and are used in complement with biophysical characterizations and ss-NMR analyses of the same systems. Results are discussed in the context of proposed NMR models of Aβ oligomers with implications towards further development of therapeutic and diagnostic strategies.

Title: MojoSort™, a versatile nanoparticle for magnetic isolation of CX3CR1+ cells with high purity, yield, and preserved functionality

Authors: H. ZHANG[1], M. TAM[1], D. GOHEL[1], J. KOURY[1], T. OIDA[1], X. ZHAO[1], S. GARCIA MOJICA[1], X. YANG[1], *M. TAYLOR[2];

Abstract: Isolation of a defined population from a complex mixture of cells is a frequent technical challenge. Strategies have developed over recent decades, including gradient centrifugation, Fluorescent Activated Cell Sorting (FACS) and Magnetic Cell Isolation. Magnetic labeling is the most commonly used approach, as it is a fast, reliable and convenient method to obtain discrete populations with high purity and yield, and the cells are readily available for downstream applications. Here we present a new type of magnetic nanoparticle that can be used in most commercially available separation systems, including magnetic separation columns. To illustrate the speed, ease and utility of the system for obtaining fully functional CX3CR1+ cells, a major marker for glial cells, bone marrow precursors were isolated from C57Bl/6 mice using CX3CR1-conjugated MojoSort™ particles. Immunophenotype of the >10-

fold enriched cells was confirmed by flow cytometry. The CX3CR1+ cells were then differentiated towards a macrophage-like phenotype *in vitro*. After culture, LPS and CpG were used to activate the CX3CR1 derivative cells and the activated phenotype was compared to non-stimulated cells. Surface markers analyzed include CD80, CD86 and MHC II. The supernatant was collected and screened for the presence of 24 inflammatory cytokines, such as IFN-β, GM-CSF, IL-1, IL-12 and MIP. The isolated cells show a differential activation phenotype, as well as a defined cytokine profile, in accordance with the stimulation used when compared to non-stimulated cells. Thus, we establish the high quality performance of BioLegend's new low-cost magnetic cell separation system and its relevance for neuroscience research.

Title: Pre-sequencing quality control metrics predicting success of sequencing single-cell transcriptomes

Authors: *M. VAN DEN HURK[1,2], C. BARDY[2], J. ERWIN[2], B. P. F. RUTTEN[1], G. KENIS[1], H. W. M. STEINBUSCH[1], F. H. GAGE[2];
[1]Maastricht Univ., Maastricht, Netherlands; [2]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Single-cell sequencing has emerged as a powerful tool for the quantification and characterization of transcripts in individual cells, including neurons. Although several methods are available to assess the quality of RNA or cDNA starting material prior to sequencing, there have only been limited investigations into which quality control (QC) parameters predict the success of sequencing single-cell transcriptomes. By correlating various pre-sequencing QC metrics with actual HiSeq sequencing data of over a hundred single neurons, we define a set of quantitative variables that identify single-neuron cDNA preps yielding good sequencing success. Our data reveals that several quantitative metrics, obtained from cDNA fragment profiles (size distribution) and quantitative real-time PCR measurements of expression of housekeeping genes and RNA spike-in controls, represent relevant predictors of read mapping and detectability of

genes and transcripts. The results and suggestions presented here may prevent redundant sequencing of low-quality cDNA preps and improve the quality of sequencing data.

Title: Practical optimization of *in situ* hybridization procedure for the detection of microRNAs and mRNA expression in brain tissues

Authors: ***A. KASAI**, S. KAKIHARA, R. OKADA, K. HAZAMA, T. NAKAZAWA, K. NAGAYASU, A. HAYATA-TAKANO, N. SHINTANI, H. HASHIMOTO;
Osaka Univ., Suita, Japan

Abstract: MicroRNAs (miRNAs) are endogenous small noncoding RNA transcripts that individually fine-tune the expression of target genes. Recent evidence supports fundamental roles for miRNA dysregulation in brain diseases as well as brain development. Since understanding spatial-temporal expressions of miRNAs is important to examine miRNA function, a fast and effective miRNA *in situ* hybridization (ISH) protocol using locked nucleic acid (LNA) probes has been developed. However, detection of low-abundance miRNAs by ISH remains to considerably depend on each laboratory technique to obtain reproducible results particularly in heterogeneous brain tissues. Here, we aim to optimize the procedures for *in situ* detection of miR-34a which is specifically expressed in parvalbumin positive γ-aminobutyric acid neuron in the brain. First, we investigated the effect of probe accessibility on the ISH signal intensity and pattern. In thalamic reticular nucleus (TRN) which is a thin layer of parvalbumin positive neuron, the ISH signal intensity of miR-34a in fresh brain samples was stronger than that in fixed brain samples. Proteinase K treatment was dose-dependently enhanced the ISH signals in both fixed and fresh samples. Second, since stringent hybridization condition is also important for intensity and specificity of ISH signals, we examined the conditions for hybridization temperature and stringency wash to get miRNA ISH signals. Although the ISH signals were

hardly detected at 30°C below the Tm of the probe, the signals could be obtained at 37°C below the Tm. In addition, the signals were a high signal-to-noise ratio at 50% formamide concentration. Third, the specificity of the miRNA ISH signal under optimized procedures was confirmed by comparing ISH and TaqMan RT-PCR for a miR-34 family member, miR-34c. miR-34c signals at 37°C below the Tm were predominantly detected in choroidal plexus unlike in the case of miR-34a. In accord with the ISH signal pattern, TaqMan RT-PCR showed that miR-34c was abundantly expressed in brain region including choroidal plexus and miR-34a in TRN. These data suggest that ISH at 37°C below the Tm detects miRNAs reliably. Moreover, we examined if the optimized protocol could have broad versatility. All miRNA ISH signals we tested showed each own expression patterns. Finally, by combining with mRNA fluorescence ISH, we also identified the type of the miRNA-expressing cells. Thus, the present study provides a comprehensive solution for detecting *in vivo* localization of a wide variety of miRNAs and contributes to the understanding of miRNA function.

Title: Improved gene delivery to adult mouse spinal cord through the use of hybrid adeno-associated viral (aav) vectors

Authors: ***J. J. SIU**[1], C. WANG[2], L. CAO[2];
[1]Neurosci., [2]Mol. Virology, Immunology, and Mol. Genet., Ohio State Univ., Columbus, OH

Abstract: Gene therapy is characterized by the delivery of nucleic acids into cells to treat or modify disease. Viral vectors are often used as vehicles to deliver genes to target cells. Of the possible candidates, adeno-associated virus (AAV) is ideal for neurological disorders because of its safety profile & promising results in current clinical trials. One challenge in AAV gene therapy is effective transduction of large numbers of the appropriate cell type, which can be overcome by modulating the viral capsid. This is accomplished through DNA shuffling, or the

random assembly of capsid genes from various AAV serotypes to produce new chimeric variants. Previously, some of our novel hybrid AAV vectors (Rec2, Rec3, Rec4) demonstrated higher viral yield, gene expression, and transduction volumes compared to naturally occurring serotypes such as AAV9, when injected directly into brain. We therefore hypothesized that direct injection of these new vectors into spinal cord would result in similar observations. To test this, green fluorescent protein (GFP) was first cloned into vectors AAV9 and Rec2-4, all of which drive gene expression through the CAG (hybrid CMV-chicken beta-actin) promoter. Next, 2x10^9 viral particles of each AAV vector was injected unilaterally into the T9 vertebral level of spinal cord in 9-week-old mice. Mice were sacrificed at 3 weeks post-injection, and brain and spinal cord were collected to evaluate cellular tropism, gene expression, and transduction volume compared to AAV9 control. Through immunohistochemistry, we demonstrated that Rec3 and Rec4 were able to transduce a broader region of spinal cord compared to AAV9 while Rec2 seemed to display higher GFP transgene expression than AAV9. All Rec vectors were able to transduce NeuN+ neurons. Further analysis will characterize the tropism towards glia and the extent to which these hybrid vectors are superior to natural AAV. Future work with these vectors will explore other methods of viral delivery and the expression of neurotrophic factors to protect against neurodegenerative diseases affecting brain and/or spinal cord.

Title: Exposure to blue light alters gene expression in murine microglia

Authors: ***K. P. CHENG**[1], S. K. BRODNICK[1], J. WILLIAMS[1], J. J. WATTERS[2];
[1]Biomed. Engin., [2]Comparative Biol., Univ. of Wisconsin Madison, Madison, WI

Abstract: The advent of optogenetics along with the prevalence of fluorescent assisted studies have led to a dramatic increase in the exposure of blue light to living tissues *in vitro* and *in vivo*. However, the potential effects of blue light alone on non-transgenic, native cellular behavior has been little reported. Here we studied the effect of repetitive low-level blue light (450nm) exposure on primary murine microglial gene expression in both *in vitro* and *in vivo* models. All experiments were performed using the C57BL/6 mouse strain with *in vitro* experiments using primary microglia isolated from the postnatal day 4-7 pup brain, and *in vivo* experiments used

10- 11 week old adult male mice. Illumination with 450nm light was provided using either CREE XT-E Royal Blue LED's or a Sutter Lambda DG-4 with appropriate 450nm bandpass filters. Following blue light exposure, microglial gene expression was immediately assessed via qRT-PCR. We found that blue light altered basal microglial gene expression in both a gene- and dose- dependent manner. Blue light delivered in this manner had a potent anti-inflammatory effect on the microglial LPS-response *in vitro*. Preliminary data *in vivo* suggest that blue light similarly reduces inflammatory gene expression in isolated microglia. These results demonstrate that long-term optogenetic and fluorescence-based studies in living tissues may have previously unreported off-target cellular effects, and also suggest the possibility of using blue light as a therapeutic agent. (Supported by DARPA RCI N66001-12-C-4025 and R01 HL111598).

Title: A convenient real-time neuronal molecule tracking system using a novel bidirectional-expressing system

Authors: *Y. YANG[1], Y. GENG[1], J. CHU[2], M. Z. LIN[1];
[1]Pediatrics, Stanford Univ., Stanford, CA; [2]Shenzhen Inst. of Advanced Technology, Chinese Acad. of Sci., Shenzhen, China

Abstract: Dendritic spines and synapses are plastic and play critical roles in neuronal functions. The dynamics of synaptic molecules contribute to synaptic plasticity and have been typically studied by co-expressing a fluorescent protein(FP)-tagged protein of interest together with a single fluorescent protein in a different color to trace the fine structure of neurons. However, low co-transfection efficiency, fast decay in fluorescent signal intensity in transient transfections, and poor properties of available red fluorescent protens (RFPs) severely place burdens to these studies. In addition, tracking and analysis of punctuated, dynamic synaptic molecules are often hindered by heave labor, potential bias and inconsistency due to manual analysis. Here we report an optimized neuronal long-term expression system, which allows concurrent expression of the protein of interest and a new RFP, mCrimsonT, as the cell-tracing marker. This system uses a novel bidirectional expression plasmid where the FP-tagged protein of interest is encoded in the forward direction and mCrimsonT is encoded in the reverse direction. mCrimsonT is a newly

developed RFP featuring high brightness and photostability. More importantly, mCrimsonT does not form aggregations in neurons, serving as an ideal cell morphological marker. We also report a MATLAB script that enables automatic outlining of neuronal dendritic structures and quantification of fluorescent signals. With this fluorescent labeling system and Matlab scripts, we are able to automatically trace neuronal dendritic tree through live time-lapse recording and analysis of punctuated, dynamic signal changes of specific synaptic molecules with much improved efficiency.

Title: A single vector platform for high-level gene transduction of central neurons with Tet-Off adeno-associated virus

Authors: ***H. HIOKI**, J. SOHN, M. TAKAHASHI, S. OKAMOTO, T. KANEKO;
Kyoto Univ. Grad. Sch. of Med., Kyoto, Japan

Abstract: To achieve high-level transgene expression in neurons, we developed new single vector platform with adeno-associated virus (AAV). The platform, AAV SynTetOff, is mainly composed of two parts: 1) the regulator part expresses tetracycline-controlled transactivator (tTA) under the control of human synapsin I promoter (SYN; Hioki et al, 2007); and 2) the response part produces transgene under the control of Tet-Response Element composite promoter (TRE; Hioki et al, 2009). We first assessed the expression level of GFP *in vitro* with Neuro-2A cells. One week after the infection with AAV2/1 SynTetOff-GFP, SYN-GFP-pA, or CMV-GFP-pA, expression levels of GFP mRNA were examined by quantitative real-time reverse transcription PCR (qRT-PCR). The expression level with SynTetOff-GFP was 15.6- or 1.8-fold higher than with SYN-GFP-pA or CMV-GFP-pA, respectively. We also measured average intensity per pixel of GFP-native fluorescence (GFP-NF) in the infected cells. With SynTetOff-GFP, the intensity exhibited 14.5- or 1.8-fold increase as compared with SYN-GFP-pA or CMV-GFP-pA. We then injected the AAV2/1 vectors into the mouse neostriatum. One

week after the injection with SynTetOff-GFP, GFP-NF was clearly observed not only in the injection site but also in the projection targets such as globus pallidus and substantia nigra. On the other hand, GFP expression with SYN-GFP-pA and CMV-GFP-pA was very low so that the slight signals were detected only in the injection site. Actually, GFP-NF with SynTetOff-GFP was markedly higher than with SYN-GFP-pA or CMV-GFP-pA, 34.3- or 43.3-fold higher. In addition, GFP expression with CMV-GFP-pA was not neuron-specific (around 75.5%), whereas the expression with SynTetOff-GFP and SYN-GFP-pA was almost specific for neuronal cells. Furthermore, we added the palmitoylation site (pal) sequence, one of the plasma membrane-targeting signals, to the N-terminal of GFP, and injected AAV2/1 SynTetOff-palGFP into the mouse neostriatum. Neuronal processes of the infected neurons were more clearly visualized as compared with SynTetOff-GFP. These results indicate that newly developed single vector platform, AAV SynTetOff, is promising genetic tool for strong gene transduction and efficient labeling of neurons.

Title: Generation of human iN cell line

Authors: *S. LAU[1,2], N. AVALIANI[3], A. HEUER[2], M. KOKAIA[3], M. PARMAR[2]; [2]Developmental and Regenerative Neurobio., [3]Exptl. Epilepsy, [1]Lund Univ., Lund, Sweden

Abstract: Human fibroblast can be directly reprogrammed to induced neurons (iNs) using lineage specific transcription factors. However, only a limited number of iNs can be generated from each conversion. Because the resulting iNs are post-mitotic, the low conversion could limit their use in biomedical applications and regenerative medicine. In this study, we have designed a dual promoter system that expresses two reprogramming factors from the same vector. The resulting iNs exhibit functional properties of neurons *in vitro* and in slice cultures. The 2-factor iN cells survive and innervate the host brain after transplantation to the adult rat brain. We discovered that by changing the order of transcription factors in the constructs, conversion efficiency was greatly altered, suggesting that protein expression levels and stoichiometry has a great impact on reprogramming efficiency. By further modifying the dual promoter system we were able to generate fibroblasts that carried the construct and that could be stably expanded whilst not loosing their potential to be efficiently converted to neurons when conversion was initiated, allowing for expansion and cryo-preservation. The high conversion efficiency, in

combination with the possibility to passage and bank cells expressing the dual promoter construct, points to the possibility that human iNs can be used for large scale studies such as drug screening and disease modeling.

Title: Patient centric gene targets for silencing the Huntington's disease mutation in adult and juvenile HD

Authors: *P. DENG[1,2], K. FINK[2], A. KOMARLA[1,2], J. HALMAI[1], A. TORREST[2], J. GUTIERREZ[2], T. TEMPKIN[3], V. WHEELOCK[3], L. CARVAJAL-CARMONA[1], D. SEGAL[1], J. NOLTA[2];
[1]Genome Ctr., UC Davis, Davis, CA; [2]Stem Cell Program and Inst. for Regenerative Cures, [3]Dept. of Neurol., Univ. of California Davis Hlth. Systems, Sacramento, CA

Abstract: Huntington's disease (HD) is an autosomal dominant disorder characterized by an abnormally long CAG expansion. Although the gene causing HD has been well characterized in adults, the exact function of the wild-type and mutant proteins are still unknown. Wild-type huntingtin protein is essential for development, while mutant huntingtin accumulates in the cells of HD patients. Nuclear aggregates cause alterations in gene transcription resulting in cellular impairment including dysfunction in RNA synthesis, protein quality control, impaired mitochondrial activity, cellular inclusions, and activation of apoptotic pathways. While the mutant protein is toxic it normally takes multiple decades before the resulting cell death leads to overt symptomology and clinical manifestation of the disease. In the juvenile form of HD (jHD),

disease onset occurs before the age of 20 and in many cases prior to the age of 10 and the functional decline is more rapid. While this early onset and severe progression has been attributed to a larger CAG expansion, this correlation does not always hold true. Since its discovery in 1993, there has been little headway in producing therapeutics for the disorder. Our lab has shown preliminary data suggesting selective transcriptional repression of the mutant huntingtin allele by targeting SNPs solely present in the HD population. The identification of novel SNPs in the HD population has allowed a host of research groups to produce various methods to silence expression of the mutant huntingtin protein such as antisense oligonucleotides, siRNA treatments and DNA nucleases. SNPs for the adult HD population are well characterized; but little research has been conducted to characterize SNPs in jHD. This is a current deficit in the field as a whole as jHD individuals would likely benefit from early intervention due to the severity and early disease onset compared to adult HD. We have isolated novel regions of interest through Sanger sequencing the promoter and exon 1 of the mutant huntingtin allele in a jHD patient population. A combination of conventional molecular biology techniques and bioinformatic analysis of HD haplogroups have been used to identify unique allele-signatures for jHD. This analysis will provide a rich and robust data set for other groups, including our own, to continue developing potential gene silencing techniques for a currently underserved subpopulation in HD. Furthermore, comparison analysis between adult and jHD SNPs provides insight into the unique mutations present in both populations and may be further studied in order to better understand causes for disease onset beyond CAG length.

Abstract: Recent studies have indicated the involvement of microRNAs in the development of epilepsy phenotypes. For instance, mice deficient in microRNA-128 are prone to fatal seizures. Here, we describe the development of an *in vitro* assay to screen the functional impact of microRNAs on seizurogenic risk. We utilized multiwell microelectrode array (MEA) technology to record the electrophysiological development of dissociated neural networks *in vitro*. Specifically, excitability phenotypes, such as the synchronization of network activity, were evaluated in response to the down-regulation of microRNA-128. We used primary cortical neurons from wild-type post-natal day zero C57BL/6J mice and a lentivirus delivered microRNA sponge to target the mature microRNA-128. Sponges are competitive microRNA inhibitors which express tandem repeats that are partially complementary to the microRNA sequence. The non-invasive and label-free nature of the MEA allowed chronic measurements of network activity throughout culture development, and excitability was quantified through a combination of spike, burst, and synchrony metrics describing the organization of the network activity. Our data show that down regulation of microRNA-128 by inhibition with a sponge results in significantly increased neuronal activity throughout network development. These results are consistent with the previous observations that microRNA-128 deficiency promotes neuronal excitability and illustrate the utility of the MEA platform in evaluation of the role microRNAs play in the regulation of functional network phenotypes.

Title: L-to-D-amino acid isomerization of peptides in the nervous system

Authors: *H.-C. TAI, I. LIVNAT, E. T. JANSSON, S. S. RUBAKHIN, J. V. SWEEDLER; Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: The study of cell-to-cell signaling peptides contributes to the fundamental understanding of physiological processes and improves the effectiveness of pharmaceutical drugs. Neuropeptides undergo a variety of post-translational modifications (PTMs) that are often crucial for their signaling properties. Importantly, conversion of an L-amino acid to a D-amino acid in a neuropeptide can substantially alter the three dimensional structure and modify the

bioactivity and metabolism of the D-amino acid-containing peptide (DAACP). However, peptide isomerization is rarely characterized because this PTM is undetectable in current mass spectrometry-based peptidomics due to the lack of an associated mass shift. To uncover both the extent and functional role of peptide isomerization in the nervous system, we have developed a series of techniques that enable the identification of DAACPs from the neuropeptidome of *Aplysia* californica and other species. The first step in our multi-stage method is to assay endogenous neuropeptides using aminopeptidase M (APM), which selectively cleaves off L-amino acids but not D-amino acids. Resistance to digestion indicates the possibility of a D-amino acid, and peptides that degrade slowly on exposure to APM are considered candidate DAACPs. Subsequent confirmation is achieved by isolating candidate peptides with liquid chromatography and analyzing the chirality of their component amino acids. The presence of specific D-amino acids is determined through acid hydrolysis of the purified peptide, derivatization of its amino acids with Marfey's reagent for chiral separation, and analysis with a triple quadrupole mass spectrometer. We have previously reported the characterization and function of GdFFD in A. californica [Bai, J. Biol. Chem., 2013]; here we report a novel D-tyrosine-containing peptide, GdYFD, from the same achatin-like neuropeptide prohormone (ALNP). Furthermore, a third and longer peptide (amino acid sequence SYADSKDEESNAALDSFAED) from ALNP also appears to be a DAACP, suggesting that the isomerizing enzyme is capable of acting on a wide range of peptides varying from three to twenty amino acids long. While previously reported peptide isomerases in other species have been found to be somewhat flexible in the sequences they recognize, our results indicate that the isomerase in A. californica may be highly promiscuous in terms of peptide length as well as sequence. To advance understanding of this fascinating enzyme, an assay for detecting peptide isomerase activity is being developed using ALNP-expressing neurons and will complement the discovery of functional D-amino acid-containing neuropeptides.

Title: Neurosystematics and genealogy of neurons: Single-cell sequencing and computational approaches to reconstructing the natural classification of neural systems across species

Authors: *L. L. MOROZ[1,2,4], A. B. KOHN[3], C. BOSTWICK[2], E. DABE[2], G. WINTERS[2], Q. YANG[5], R. D. HAWKINS[5,8], K. KOKOT[9], N. WHELAN[9], K. HALANYCH[9], J. RUSSO[6], I. MOROZOVA[6], S. KALACHIKOV[6], J. JU[7,6];

Abstract: Neurons are different not only because they have different functions but also because they might have different genealogies. However, the enormous diversity of neurons both within the same nervous system and across species presents tremendous challenges for their unbiased classification. Here, we developed novel approaches and algorithms toward establishing the natural classification of neurons. Our research strategy is based upon (1) high-throughput single-cell RNA-seq and single-cell epigenomic analyses of entire neuronal circuits, and (2) implementation of stochastic approaches from information theory and phylogenomics to incorporate the inherent statistical uncertainty in the operation of the genome, as well as natural selection within complex systems. These approaches are less developed in neuroscience, mostly due to the lack of necessary comparative information from the majority of animal phyla. First, we performed single-cell transcriptome and methylome analyses of hundreds of individually identified neurons in the defensive and feeding circuits of *Aplysia* californica under control conditions and during neuroplasticity (e.g. capture of nascent RNAs during behavioral learning or transmitter applications). As a result, we reconstructed an initial classification of neurons within the same nervous system, with the surprising finding that some neuronal subtypes are more different compared to each other than to selected non-neuronal cells. Second, we expanded this approach to homologous neurons in other related molluscan species (gastropods and cephalopods), and screened various cell phenotypes in mammalian nervous systems as well as in selected basal metazoans (ctenophores, sponges, placozoans and cnidarians). The results suggest that different classes of neurons and synapses might have evolved more than once (convergent evolution) and allow us to reconstruct the genealogy of neurons, trace ancestral cell lineages, and establish the natural classification of neurons within neural circuits across the majority of animal phyla. The field of Neurosystematics is emerging. This might be an analog of the periodic table for neurons, with the predictive power to delineate novel neuronal phenotypes and fundamental constraints on the origins and parallel evolution of neural systems.

Title: Development of a novel tool for the assessment of health outcomes and sickness behavior in rodents

Authors: *E. B. ENGLER-CHIURAZZI[1,2], D. N. DOLL[2,3], A. E. KERR[2,3], B. L. UNDERWOOD[4], J. H. WIMSATT[4], J. W. SIMPKINS[2,2];
[1]Physiol. and Pharmacol., [2]Ctr. for Basic and Translational Stroke Res., [3]Ctr. for Neurosci., [4]Office of Lab. Animal Resources, West Virginia Univ., Morgantown, WV

Abstract: In preclinical experimental neuroscience research using rodent models, animal subjects are commonly administered pharmacological agents and/or undergo a diverse range of surgical and non-surgical procedures for the evaluation of impacts on cognitive, affective and locomotor behaviors. Many of these procedures/agents can have a negative impact on overall health and may induce sickness behaviors in treated animals. These sickness behaviors can include poor self-care, disrupted locomotion, altered sensitivity to pain, aphagia, adispia, etc. The presence of these sickness behaviors could have a profound impact on the functional outcomes of interest, possibly confounding the interpretation of behavioral results. Until recently, there was no standard scale for determining the presence of these health alterations among experimental subjects. Here, we describe a newly-developed, multi-dimensional scale for the assessment of health outcomes and sickness behaviors in rodents. This tool has the benefit of 1) detecting a wide range of health outcomes including self-care measures, respiratory rate, posture changes, hydration and nourishment status, locomotion and social interaction, and weight and temperature changes, 2) being rapid to administer (approximately one minute per subject), 3) being adaptable so that specific phenotypes observed following unique insults may be added to the scale at the user's discretion, 4) having high inter- and intra-rater reliability due to its simple scoring system, 5) being repeatable at multiple timepoints during the recovery period, and 6) involving limited animal handling given that most scale outcomes can be evaluated while the subject is in its home cage. We have optimized this tool in several rodent models of brain disease and insult, including lipopolysaccharide-induced inflammation and transient middle cerebral artery occlusion. Scores on this scale can range from 0-20, with lower score representing healthy animals, mid-range scores representing mild-moderate sickness, and higher scores representing severe sickness/poor

health. Use of this tool will aid in the identification and control of health states and behaviors that can impact performance on subsequent behavioral tests. As well, this tool can serve as a triage mechanism to rapidly and consistently identify experimental animals in need of veterinary attention and intervention.

Title: Strategy for achieving a complete cns transcriptome for *Aplysia*, a model system in learning and memory

Authors: *P. SHRESTHA[1], J. ORVIS[2], L. J. TALLON[2], A. MAHURKAR[2], C. M. FRASER[2], T. W. ABRAMS[3];
[2]Inst. of Genome Sci., [3]Pharmacol., [1]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The feasibility of molecular approaches to studying learning and memory in *Aplysia* californica was substantially enhanced by release of an RNAseq assembly from Broad Institute in 2012. This assembly was achieved using Illumina HiSeq reads with the Trinity assembler, developed collaboratively by Broad Institute and Hebrew University for de novo reconstruction of transcriptomes from large-volume RNAseq read data sets. Despite read sets of >50 million for the Broad Institute RNAseq assembly, analysis of specific predicted transcripts revealed that many were fragmented or missing substantial regions. Some neurobiologically important transcripts had only ~25% coverage in the assembled contigs, whereas other contigs were complete. The present project was initiated in an effort to improve the RNAseq assembly for *Aplysia* CNS. We focused first on improving quality of RNA preps and increasing total read numbers. With >10x increase in read numbers, the coverage of the assembled transcripts improved. However, some of the same specific gaps in the 2012 assembly remained, and fragmentation of transcripts persisted. The consistency of the gaps suggested RNA degradation in Illumina library preparation step; this was confirmed for specific transcripts by PCR screening of the original RNA prep. Comparing a range of times for the chemical shearing step revealed that briefer shearing reduced the incidence of very short fragments below the minimum length for Illumina sequencing, which in turn yielded more complete assemblies. Although the transcriptome assembly improved substantially, for some transcripts with near complete

coverage, fragmentation persisted. We are now exploring bioinformatic approaches to link remaining fragments. We have also used a statistical approach to improving orientation correction of contigs with strand-specific reads, for which a small percentage are found to be unreliable in each library. To produce a useful annotated transcriptome, ORFs were called using TransDecoder and predicted proteins were searched using a multiple tools. HMM3 searches were performed against a custom HMM collection that includes TIGRFams and PFam, then BlastP was conducted against SWISSPROT, as well as Human and Mouse genome builds. The annotated assembly and assembled contigs are available at: http://*aplysia*genetools.org/

Title: A novel method for cell specific labeling of the nascent proteome

Authors: *R. M. BARRETT[1], H.-W. LIU[1], R. H. GOODMAN[1], M. S. COHEN[2];
[1]Vollum Inst., [2]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Translational regulation is necessary for many biological processes, a fact highlighted by the large discrepancy between mRNA and protein abundance. Although genetic methods have been developed for monitoring cell-specific transcriptional regulation within heterogeneous tissues, no such methods exist for determining the translatome, which can be equally important for cellular identity and function. We describe here a novel method to label the nascent proteome with cell-type resolution in heterogeneous tissue. This method uses a chemical genetic strategy based on de-blocking of a click-tagged puromycin analogue that can be activated by expression of penicillin G acylase in genetically targeted cell populations. The puromycin analogue incorporates into nascent peptides, which can be coupled to an azide reporter via click chemistry. Using our method, we demonstrate cell-specific labeling and identification of newly-synthesized proteins in cells and tissues. This unique strategy can be applied to many tissues, including the brain, and will allow us to answer questions about neural functions that require time sensitive gene expression including learning, drug addiction, and circadian rhythms.

Title: UnipicK+ for efficient collection of single cells from cell cultures and microdissection of complex tissues with subsequent dispensing of acquired material

Authors: *S. L. KARSTEN, A. ZAVALA, Z. MA, L. C. KUDO;
NeuroInDx, Inc., Signal Hill, CA

Abstract: Today cell specific studies are indispensable for basic and translational research in neuroscience. Yet collecting single or individual cells directly from cell cultures for downstream single cell analysis or recultivation (e.g. clonal expansion) remain a challenge. Tissue heterogeneity also poses a difficulty in retrieving cell and region specific molecular information. Current instrumentation, such as fluorescence assisted cell sorting (FACS) and laser assisted acquisition such as laser capture microdissection (LCM), are costly, complicated and often methodologically limited. We have developed a versatile capillary-based vacuum-assisted cell and tissue acquisition instrument, UnipicK+ with which individual fluorescently labeled and/or morphologically distinct live cells can be acquired from adherent, suspended, and 3D cultures grown in standard cell culture dishes. The instrument is suitable for individual cell collection and region specific acquisition of cell clusters and subanatomical areas from 10 to 500 µm thick slices of complex heterogeneous tissues such as the brain - native, fresh frozen, or sucrose treated. The instrument may be integrated with a fluorescence compatible inverted microscope or used as a free standing instrument mounted over most inverted microscopes, providing flexibility in the laboratory. UnipicK+ demonstrates a wide range of cell and tissue acquisition parameters. It collects individual cells from adherent cell cultures in as small as 15nl volume, compatible with various downstream single cell analyses and Next generation Sequencing (NGS). Here, individual cells were collected based on morphology from human neuroblastoma SH-SY5Y, CHO, and 3T3 cell cultures, immediately dispensed into individual wells, and successfully recultured for clonal expansion, demonstrating the minimal effect the process has on cellular

viability. Further single Purkinje cells, individual motor neurons and subanatomical regions (e.g. CA1-3, dentate gyrus) were efficiently collected from rat and mouse brain tissue sections. Dissociation protocols for hard to dissect tissues have been developed as well. High quality RNA and proteins were isolated from all collected samples. UnipicK+'s compatibility with most inverted microscopes, low cost, ease of use, single cell resolution, and minimal impact on cell viability, make it is a unique and vital instrument for neuroscience research.

Title: Single-neuron lipidomics analysis of hippocampal granule cells

Authors: ***C. B. MERRILL**[1], A. ARMIROTTI[2], A. BASIT[2], Y. JIA[1], C. M. GALL[1], G. LYNCH[1], D. PIOMELLI[1];
[1]Anat. and Neurobio., Univ. of California-Irvine, Irvine, CA; [2]Inst. Italiano di Tecnologia, Genoa, Italy

Abstract: The human brain contains as many as 100 billion neurons. Shape, electrical properties and gene expression differentiate them into a large number of distinct types - possibly more than any other organ system. This cellular diversity underpins the brain's unique capacity to form complex networks that allow for the processing of huge amounts of sensory information coming from the external and internal environment. Moreover, electrical activity and chemical signals can cause profound long-lasting changes in the properties of individual neuronal types, which in turn influence brain network activity. Understanding the molecular basis for this diversity and its dynamics is a key goal of neuroscience. The application of reverse transcriptase-polymerase chain reaction (RT-PCR) to study gene expression in individual neurons (Lambolez *et al.*, 1992) was a critical step toward achieving this goal. The insights provided by this technique are invaluable, but only illuminate differences in the transcriptome. Post-transcriptional changes in the metabolome are beyond its reach. Lipids are key constituents of the neuronal metabolome. They control protein traffic, facilitate cell-cell recognition and give rise to hundreds of molecules that carry information both within and across brain cells. Understanding how lipids work is the primary objective of lipidomics (Piomelli *et al.*, 2007). Here, we combined single-cell patch clamp electrophysiology and high-resolution nano-liquid chromatography/ tandem mass spectroscopy (LC/MS/MS) to profile the lipidome of individual granule cells in the mouse

dentate gyrus. Granule cells are among the smallest (≈5 μm diameter) and most plastic neurons found in the mammalian brain. Individual granule cells were isolated from acutely dissected slices using whole-cell patch clamp and their lipidome was probed by nano-LC/MS/MS. Signals for multiple lipid classes involved in neuronal structure and function were distinguished from background noise and unambiguously identified. High-frequency stimulation of the medial perforant path, a major excitatory afferent to the granule cells, resulted in substantial and reproducible changes in the levels of several of these lipids. While still preliminary, the results suggest that single-neuron lipidomics is feasible, and can be used to unmask activity-dependent fluctuations in the lipid composition of small neurons in mammalian brains. Abstract: S-Nitrosylation, a redox-based protein post-translational modification, has been increasingly recognized as a key molecular mechanism for Nitric Oxide (NO) signaling. It plays an important role in physiological conditions and in diseases such as diabetes, asthma, heart failure, cancer, and neurodegenerative disorders. S-Nitrosylation of critical cysteine residues on specific proteins regulates their activities and has been demonstrated in protein misfolding, transcriptional regulation and aberrant enzymatic activation. Detection and quantification of

protein S-nitrosylation have been challenging tasks due to instability and low abundance of the modification. Many studies have used mass spectrometry (MS)-based methods with different thiol-reactive reagents to label and identify proteins with S-nitrosylated cysteine (SNO-Cys). Here, we present a novel iodoTMT switch assay (ISA) using an isobaric set of thiol-reactive iodoTMTsixplex reagents (126-131) to specifically detect and quantify protein S-nitrosylation. Irreversible labeling of SNO-Cys with the iodoTMTsixplex reagents enables immune-affinity detection of S-nitrosylated proteins, enrichment of iodoTMT-labeled peptides by anti-TMT resin, and importantly, unambiguous modification site-mapping and multiplex quantification by liquid chromatography−tandem MS. In this study, the ISA approach was applied to investigate protein S-nitrosylation in a cellular neuroinflammation model—endotoxin lipopolysaccharide (LPS)-stimulated murine BV-2 microglial cells. We further evaluated the effects of S-allyl cysteine (SAC), an active nutritional compound of aged garlic extract, on S-nitrosylation in LPS-stimulated BV-2 cells and revealed that SAC acts in antioxidant signaling and mitochondrial metabolic pathways. ISA proved to be an effective proteomic approach for quantitative analysis of S-nitrosylation in complex samples and will facilitate the elucidation of molecular mechanisms of NO signaling under physiological conditions and nitrosative stress in disease.

Title: Western blot optimization using BlotCycler, automated western blot processor

Authors: A. MARGULIS[1], D. P. CHIMENTO[2], A. ZAORSKI[2], *R. YUKHANANOV[1]; [1]Precision Biosystems, Mansfield, MA; [2]Rockland Immunochemicals, Inc., Limerick, PA

Abstract: Western blot assays provide information about the presence and levels of protein expression in cell and tissue. The immunodetection protocol consists of multiple steps including blocking of the nonspecific binding sites, incubation using primary and secondary antibodies and extensive washing between steps. The resulting complex is detected by fluorescence or using appropriate chromogenic or luminescent substrates, depending on the type of detection agent or enzyme conjugated to the secondary antibodies. Immunodetection of proteins is often performed manually and involves multiple steps that easily introduce bias and errors. We have compared the traditional manual western blotting and a novel type of automatic western blot by using BlotCycler™ processor developed by Precision Biosystems. Manual western blotting is a labor-

intensive, time-consuming process. The quality of results is dependent on multiple subjective and objective factors such as the qualification and technical skills of the personnel performing the assay and the accuracy of temporal and temperature control, especially during the immunodetection step. Blotcycler™, automated western blot processor, uses fluidic control system that allows to eliminate the variability associated with immunodetection and to achieve higher sensitivity using optimized washing procedure. In this study we have compare protein detection using different incubation and washing temperature and have shown that incubation and washing at 4°C yields using automated western blot procedure yields significantly higher signal that allows reproducible detection of low expression proteins.

Title: Top down proteomics enables quantitative analysis of mouse brain tissue proteoforms

Authors: ***P. THOMAS**[1], K. KIM[1], R. T. FELLERS[1], R. D. LEDUC[1], B. P. EARLY[1], S. S. RUBAKHIN[2], E. V. ROMANOVA[2], J. A. ZOMBECK[2], J. S. RHODES[2], J. V. SWEEDLER[2], N. L. KELLEHER[1];
[1]Northwestern Univ., Evanston, IL; [2]Univ. of Illinois, Urbana-Champaign, Urbana, IL

Abstract: Development of top-down proteomics technologies has facilitated brain proteome research. State-of-art high resolution mass spectrometry and bioinformatics data analysis enable us to simultaneously identify and quantify intact proteoforms. Here, we employ a quantitative Top Down proteomics approach in discovery mode to investigate the intact proteome of brain tissues for two strains of inbred mice, C57BL/6J and FVB/NJ. Whole mouse brain tissue was lysed and proteins below 30kDa were fractionated using Gel-Eluted Liquid FRaction Entrapment Electrophoresis (GELFrEE) technology. Global qualitative top down data analysis identified 983 unique gene products (710 for C57BL/6J and 546 for FVB/NJ) arising from 3,772 proteoforms (2,940 for C57BL/6J and 2,096 for FVB/NJ, respectively). A proteoform is defined as a single protein molecule arising from all combinatorial sources of variation (e.g. genetic variation,

alternatively spliced RNA, transcripts, and post-translational modifications). Comparative quantitative analysis between C57BL/6J and FVB/NJ revealed 422 confidently identified Quantitation Mass Targets (QMTs) showing expression differences ($\alpha<0.05$, see Figure Panel C) and 241 proteoforms found in only one strain. A similar analysis between two mice of the same strain showed no significant difference, indicating that the differences observed are real. Gene ontology (GO) analysis for differentially expressed proteoforms further clarified the dissimilarities in neurobiology between two inbred mouse strains. This study sets the stage for the comprehensive characterization of the mouse brain intact proteome < 30kDa and will soon be applied to the analysis of drug addiction in mouse brains.

Title: Single-neuron methylomes and transcriptomes: determining the epigenomic basis of neuronal identity

Authors: *E. C. DABE[1,2], R. S. SANFORD[1,2], A. B. KOHN[1], L. L. MOROZ[1,2];
[1]Univ. of Florida Whitney Lab., Saint Augustine, FL; [2]Neurosci., McKnight Brain Institute, Univ. of Florida, Gainesville, FL

Abstract: On the genomic level, neuronal identity is encoded by complex epigenetic mechanisms leading to coordinated expression of about 10,000 protein-coding genes per neuron. To address these mechanisms, we performed single-cell bisulfite sequencing from single identified neurons using *Aplysia californica* as an experimental model. Single-cell DNA methylation profiling was complemented by single-cell RNA-seq analysis. *Aplysia* have lower overall genome-wide methylation (0.75-1%) than humans (1-4%), but both have more CpG methylation in their gene bodies compared to promoter regions, suggesting a common role for DNA methylation in gene regulation across phyla. *Aplysia* also showed evidence of non-canonical CHG (.05-.1%) and CHH (.25-.5%) methylation. Genome-wide methylation percentages are consistent across neuronal phenotypes and peripheral tissues. Quantal-type analysis of all individual CpG sites in single polyploidy neurons, whole ganglia, and diploid non-neuronal tissue yielded similar methylation distribution regardless of sequencing coverage, suggesting that each copy of the genome in a polyploid neuron has the same methylation pattern like diploid cells from peripheral tissues. Specifically, we produced methylome profiles (n=3 per cell type) for two symmetrical serotonergic (5-HT) interneurons (Metacerebral cells) and two homologous cholinergic (ACh) motor neurons (LPL1 and R2) with an average sequencing depth of 25X coverage per single cell. We also made single-neuron transcriptomes (n=3 per cell type) that mapped to 75% or more of the 26,299 *Aplysia* gene models. We used these data sets to discern what transcription factor (TFs) could control neurotransmitter phenotypes and performed *in situ* hybridization to map their expression across the CNS. *Pitx*, which has been shown to be a regulator of 5-HT neuronal identity in planarians, is expressed in *Aplysia* serotonergic cells. We also correlated DNA methylation patterns with expression of TFs and 5-HT or ACh biosynthesis genes. Though methylation patterning for each gene was unique, we found that genes for 5-HT biosynthesis machinery had lower levels of CHG methylation in 5-HT neurons than in outgroup neurons. ACh synthesis and signaling genes had higher CpG gene body methylation in cholinergic neurons. Non-neuronal tissue (salivary gland) showed no transcript expression of neurotransmitter biosynthesis genes and had lower levels of both CpG and CHG methylation of respective genes compare to the identified neurons studied. Our study suggests that DNA methylation contributes to the maintenance of overall neuronal phenotypes, but additional epigenetic mechanisms might also be involved.

Ctr. for the Oceans and Human Health, City Univ. of Hong Kong Shenzhen Res. Inst., Shenzhen, China

Abstract: Ciguatera fish poisoning (CFP) remains one of the most challenging foodborne illness in humans caused by the consumption of ciguatoxin (CTX)-contaminated tropical fish. CFP has become a global health issue due to the increasing international trading of tropical fish species. CFP cases have been reported around the world not limited to the tropical regions and its incidence has been increasing in the past decades. CFP patients usually result in gastrointestinal and neurological disorders. Gastrointestinal disorders usually last for two weeks only after the onset of symptoms; however, severe neurological manifestations can persist for months to years in about 20% of patients. The chronic neurological effects of CTXs on motor function remain largely unknown. Our initial study indicated that the motor function was affected significantly after repeated exposure of pacific ciguatoxin-1 (P-CTX-1). Electroencephalography recordings suggested that P-CTX-1 exert a direct effect on motor cortex electrical activity in brain. In the present study, we aim to understand if reduction in brain activity after repeated exposure of P-CTX-1 correlates with the perturbation of the neurotransmitter expression profile of in the motor cortex. Sub-lethal doses of P-CTX-1 were administrated intraperitoneally in male adult C57BL/6 mice at day 0 and 3, and the motor cortexes of the exposed mice were harvested two hours after second administration. 48 neurotransmitters were quantified using liquid chromatography tandem-mass spectrometry, and normalized with the protein content of the brain tissue for multivariate analysis. Preliminary expression profile study revealed that several neurotransmitters were altered significantly in P-CTX-1 exposed mice. By combining with metabolic pathway analysis, the neurometabolomic profile will provide an insight into the

mechanistic action of P-CTX-1 on brain activity which accounts for the reduced electrical activity in motor cortex after P-CTX-1 exposure.

Title: Post-sampling changes in opioid peptide levels and the effect of tissue heat stabilization

Authors: ***M. SÖDERQUIST**[1], L. SEGERSTRÖM[2], M. BORÉN[1], I. NYLANDER[2]; [1]Denator AB, Uppsala, Sweden; [2]Uppsala Univ., Uppsala, Sweden

Abstract: Aim of Investigation: The present project aims to evaluate the use of conductive heat transfer for the preservation of sample composition in a routine radioimmunoassay protocol for measurement of opioid peptides in rat brain. This is done to investigate the effects of sampling and handling during the analytical process in order to evaluate how the analytical results are influenced. Methods: Different extraction procedures were tested on heat stabilized and non-stabilized tissue and the effect was evaluated on the levels of opioid peptides in rat hypothalamus (HT), striatum (Str), and cingulate cortex (Cg). Dynorphin A (Dyn A), Dynorphin B (Dyn B), Leu-enkephalin-Arg6 (Leu-Arg), and Met-enkephalin-Arg6Phe7 (MEAP) was analysed using radioimmuneassay (RIA). Results: Levels of Dyn A, Dyn B, and MEAP in HT were higher in stabilized tissue than in non-stabilized. Leu-Arg, a degradation product from the dynorphins, showed an opposite pattern. Stabilization before freezing resulted in higher Dyn A, Dyn B, and MEAP compared to samples which were stabilized in a frozen state. Conclusions: This work proves that samples enzymatically stabilized with heat can be analyzed using standard RIA protocols and keep the sample integrity. All of the peptide levels were stable two hours post-stabilization in room temperature, proving the instrument's application in the clinic. Extraction protocols without boiling and with non-denaturing buffers was made possible with heat stabilized samples extending the range of possible extraction buffers for extracting peptides from biological samples. Acknowledgments: Funding was provided from the Swedish Medical Research Council and ERAB

Title: Fractionation dependent improvements in proteome resolution in the mouse hippocampus by isoelectric focusing and mass spectrometry

Authors: *J. L. BUNDY, R. S. NOWAKOWSKI;
Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL

Abstract: Liquid-chromatography mass-spectrometry (LC-MS/MS) has become the method of choice to identify and quantify simultaneously hundreds of proteins from a single biological sample. Here, we show that from a typical brain region, such as mouse hippocampus, the number of proteins identified in an LC-MS/MS experiment can be increased from hundreds to thousands by fractionating the protein sample prior to the LC-MS/MS analysis. To achieve this improvement we exploited fractionation of complex samples upstream of LC-MS/MS by isoelectric focusing (IEF) which has been shown to improve proteome resolution by increasing the number of spectral counts. However, LC-MS/MS experiments can become impractically large when paired with methodologies such as IEF, which increase the number of necessary LC-MS/MS runs. To optimize both the benefits and drawbacks of IEF, an experiment was conducted in which the proteome of mouse hippocampal peptides was surveyed using IEF fractions varying in number and complexity. Protein extract from a single mouse hippocampus was digested and isoelectrically focused into 12 fractions. Aliquots of fractionated peptides were then pooled to make more complex samples containing six (6F), four (4F), or a single fraction (1F). The original unfractionated sample (UF), the pooled samples, and the 12 unpooled fractions (12F) were subjected to LC-MS/MS analysis. Samples consisting of multiple fractions (12F, 6F, and 4F) surveyed the hippocampal proteome with greater breadth (protein identifications), depth (spectral counts), and technical precision than samples consisting of a single LC-MS/MS sample (1F and UF). In 1F, the most complex LC-MS/MS sample, 745 proteins were identified. Fractionation of the hippocampal peptides resulted in additional protein identifications with 1761, 2601, and 3390 protein identifications in 4F, 6F, and 12F respectively. For proteins detected in all samples (740 proteins), the number of associated spectral counts per protein increased 2.66, 3.68, and 6.14 fold in 4F, 6F, and 12F relative to 1F. Finally, by using regression-interpolated synthetic datasets, quantitative precision and statistical power to discover differentially abundant proteins were found to be improved by sample fractionation. This investigation shows that isoelectrically focusing tryptic peptides prior to LC-MS/MS can increase the number of protein identifications over 4-fold, and the number of spectral counts over

6-fold. The rationale presented here can be generalized to other investigations of other complex samples, and can be used to alter experimental designs to meet specific experimental goals while minimizing cost and analysis time.

Title: The effect of elevated aSyn expression on the phosphoproteome in neuronal cells

Authors: *R. J. SCHUSTER[1], L. L. PARKER[3], J.-C. ROCHET[2];
[2]Medicinal Chem. and Mol. Pharmacol., [1]Purdue Univ., West Lafayette, IN; [3]Biochemistry, Mol. Biol. and Biophysics, Univ. of Minnesota, Minneapolis, MN

Abstract: Parkinson's disease (PD) is characterized by a loss of dopaminergic neurons in the substantia nigra and the formation of cytoplasmic inclusions called Lewy bodies. Lewy bodies are enriched with fibrillar forms of the presynaptic protein, alpha-synuclein (aSyn). aSyn contains four tyrosine residues that can be phosphorylated by various kinases. However, the impact of phosphorylation of these residues on the protein's propensity to aggregate and elicit neurotoxicity remains poorly understood. Evidence suggests that phosphorylation of alpha-synucleinaSyn tyrosine residues decreases with age in human brain, and this decrease is more pronounced in patients diagnosed with dementia with Lewy bodies. Here we carried out a study aimed at identifying tyrosine kinases that phosphorylate aSyn, thus regulating the protein's neurotoxicity, in a cellular model of PD. Mass spectrometric (MS) analysis of cell-permeable, kinase-specific biosensor peptides by multiple reaction monitoring (MRM) data acquisition was used to determine the effects of aSyn expression levels on the activation of tyrosine kinases in the SH-SY5Y dopaminergic neuronal cell line. SWATH-MS, a recently developed data acquisition method which combines the breadth of shotgun proteomic analysis and the depth of tandem mass spectrometric analysis, was employed to analyze the effects of aSyn expression on the proteome of SH-SY5Y cells, (including protein expression and post-translational modification profiles). We identified the specific tyrosine residues of the monomeric form of recombinant human alpha-synucleinaSyn phosphorylated by Abl, Lyn and Fyn kinases. Phosphorylation of the recombinant protein by Lyn and Fyn interfered with nitration of aSyn tyrosine residues and with aSyn oligomerization induced by incubating the protein with tetranitromethane. Current MS analysis is underway to determine the effect of increased aSyn

expression on the activity of Abl, Src family and Syk kinases using cell-permeable tyrosine kinase biosensors. These data advance our understanding of the role of aSyn post-translational modifications in PD pathogenesis and suggest modulation of these modifications could be a strategy to slow neurodegeneration in PD.

Abstract: Stroke is the fifth leading cause of death and a major cause of disability in the United States; ischemic stroke accounts for approximately 87 percent of all cases. Quantitative proteomic approach and advance bioinformatics tools have been implemented in translational ischemic stroke research to identify biological pathways, to understand cerebrovascular pathophysiology, and to develop novel therapeutics and diagnostics. New perspectives are needed to evaluate the complexity of ischemic stroke and the variability of outcomes. The purpose of the present study is to analyze possible factors and signaling events influencing different functional outcomes following injury by ischemic stroke. We used deuterium isobaric amine reactive tagging (DiART) sixplex reagents followed by liquid chromatography tandem mass spectrometry to globally investigate the differential levels of proteins in cortex, striatum and hippocampus affected by bilateral common carotid artery occlusion (BCCAo) for 30 min followed by a 3-day reperfusion in male C57Bl/6J mice. Results include measurement of sensorimotor deficits ranking either moderate or severe compared to sham surgery defined by the

rotarod test. Time of falling (s) is used to define the motor function: >80 is the sham group, between 80 and 20 is the moderate group, and <20 is the severe group. Our protocol detected 1828 proteins in cortex, 1806 in hippocampus, and 1716 in striatum in total. Among these, 44 proteins in cortex, 26 proteins in striatum, 42 proteins in hippocampus were differentially expressed, with more than 1.3-fold change, in moderate behavioral deficit group affected by BCCAo. Additionally, there were 91, 85 and 90 proteins with significant changes in level in cortex, striatum and hippocampus, respectively, in severe behavioral deficit group compared to sham group. By using Ingenuity Pathway Analysis, we found that some of the differentially expressed proteins, either in moderate or in severe group, play potential roles in inflammatory disease and response, mitochondrial dysfunction, Nrf2-mediated oxidative response, and neurodegeneration pathways. In addition, we demonstrated the role of NADPH oxidase and activation of the mitogen-activated protein kinase pathways associated with production of reactive oxygen species and signaling events in microglial cells after transient BCCAo in mice. To summarize, quantitative proteomic analysis identified proteins/pathways associated with oxidative and inflammatory responses correlated with neurobehavioral dysfunctions after ischemic stroke, and thus offer promising targets for therapeutic preventions and interventions.

Title: Sample preparation of brain tissue for extraction of β-amyloid and other neuronal markers

Authors: *S. GUTIERREZ, I. STRUG, J. L. SMITH, T. NADLER;
EMD Millipore, Danvers, MA

Abstract: The key to effective analysis of brain proteins starts with the disruption of the tissue in the appropriate buffer, which not only allows the complete extraction of proteins but is also compatible with the desired downstream analysis. While there are many protocols reported for the isolation and purification of neuronal biomarkers, most of these methods involve sequential extractions with aqueous buffers to remove the hydrophilic proteins followed by application of organic solvents to suspend the hydrophobic fraction. The isolation is often complemented by a delipidation step. The current protocols are lengthy, and usually fail to provide complete sample analysis. Here we present an alternative protocol for efficient solubilization of membrane-associated proteins like β-amyloid that results in three fractions each of which are fully

compatible with many downstream analyses like Western blotting, ELISA or mass spectrometry. During the extraction process, the total protein and lipid content was monitored by mid-infrared (MIR) spectrometry and by a fast immunodetection method. Each fraction was digested in a centrifugal ultrafiltration device (3 kDa) and analyzed by RP-UPLC-MS^{e} using Xevo G2-S mass spectrometer. The data from each was evaluated in regards to confidence of neuronal biomarkers detection, protein yield and number of identified proteins. The merits of analyzing multiple fractions over a single preparation will be elucidated.

Title: 4-Thiouracil tagging of RNA for transcriptional characterization of excitatory forebrain neurons

Authors: *D. F. ALZATE-CORREA[1,2], K. SAKAMOTO[3], K. KARELINA[1], K. F. HANSEN[1], K. HOYT[1,2], K. OBRIETAN[1];
[1]Neurosci., [2]Pharmacol., The Ohio State Univ., Columbus, OH; [3]Genet., Univ. of North Carolina, Chapel Hill, NC

Abstract: One major challenge when performing transcriptional profiling of Central Nervous System (CNS) tissue is that a typical sample represents a wide range of cell types, and thus, without the use of technically challenging cell-sorting techniques, the interpretation of the data can be problematic. To address this complication we developed a Uracil Phosphoribosyltransferase (UPRT) transgenic mouse line in which RNA can be tagged and isolated in a temporally- and cell-type specific manner. UPRT is a protozoan nucleotide salvage enzyme that synthesizes Uridine Monophosphate (UMP) from Uracil, which, can then be used for RNA transcription. Importantly, UPRT can also use the Uracil analog 4-Thiouracil (4-TU) for RNA synthesis (via 4-Thiouridine generation) producing a biosynthetic tagged RNA. 4-TU-

tagged RNA can be purified from non-tagged RNA by using a very well characterized reversible reaction that couples biotin to sulfhydryl (-SH) groups, followed by streptavidin-magnetic bead precipitation. Previously, 4-TU tagging has been used in cultured cells to monitor RNA production and decay, also UPRT-expressing transgenic flies and mice have been made and tagged RNA has been successfully isolated and profiled (Cleary, Meiering et al. 2005, Miller, Robinson et al. 2009, Gay, Miller et al. 2013). To generate our UPRT transgenic line, a UPRT construct provided by Dr. Chris Doe (University of Oregon) was cloned into a bidirectional Tet-regulated vector thus allowing for forebrain excitatory neuron-specific expression when our line was crossed with the αCaMKII-tTA line. Here we provide an overview of the mouse lines that were generated, the robust expression pattern of UPRT within excitatory neurons of the cortex, hippocampus and amygdala, and our initial set of experiments in which mice were exposed to 4-TU, and tagged RNA was effectively pulled down from forebrain tissues. We foresee this mouse line becoming a useful tool for the selective profiling of gene expression following a wide array of experimental conditions.

Title: Selective induction of alternate gene transcripts by cocaine treatment

Authors: ***M. A. ZYGMUNT**, J. RODRIGUEZ PARKITNA, S. GOLDA, M. PIECHOTA, J. FICEK, M. KOROSTYNSKI;
Inst. of Pharmacology, PAS, Kraków, Poland

Abstract: Impaired function of the brain's reward system is associated with several psychopathologies, including psychotic, affective and addictive disorders. It was observed that the pathological states correlate with long-term alterations in signaling in the mesolimbic system. Investigation of cellular mechanisms underlying the altered neuronal activity, gene expression in particular, may reveal molecular triggers for the development of the pathologies. Therefore, in this study we used next-generation sequencing (RNA-seq) to comprehensively map expression of cocaine-induced transcripts in the mouse striatum. Total RNA and small RNA sequencing was performed in samples collected 1h after acute cocaine treatment (25 mg/kg, i.p.). To identify transcripts responsive to psychostimulant treatment we used Tophat read-mapper and Cufflinks

algorithm for FPKM quantification. List of 35 expressed transcripts contained well-known activity-dependent genes e.g. Arc, Dusp1, Fosb as well as a set of novel transcripts e.g. Sik1, Dusp5, Bhlhe40 . Furthermore, in several cases we found that the induction is restricted to specific splicing variants or biotypes: alternative first exon (e.g. Stxbp1), alternative last exon (Hsph1), intron retention (Dnajb5), long non-coding RNA (Gm13889) and small RNA (Mir92b and Mir130a). The modules of transcriptional factors (e.g. SRF/CREB1 and E2F1/ETS1) that control inducible alternative transcription of genes in the striatum were identified using the seqinspector.cremag.org online tool. To compare cocaine-induced gene expression patterns between the subpopulations of striatal neurons we used fluorescence-activated cell sorting and genetically labeled dopamine receptor expressing cells. Further experiments will explore differences in activity-regulated gene expression in the D1 and D2 expressing medium spiny neurons of the striatum. Our results provide a comprehensive assessment of neuronal activity-induced gene expression at the level of individual transcriptional units.

Title: Involvement of long non-coding RNAs in cerebral changes associated with acute-liver failure

Authors: *V. R. SILVA[1], A. S. HAZELL[1,2];
[1]UNIVERSITY OF CAMPINAS, Campinas, Brazil; [2]Dept. of Med., UNIVERSITY OF MONTREAL, Montreal, QC, Canada

Abstract: Acute liver failure (ALF) leads to major pathological changes in brain that involve the development of brain edema due to profound astrocyte swelling and (Type A) hepatic encephalopathy. However, the underlying pathophysiology responsible for these effect remains unclear. Long non-coding RNAs (lncRNAs) are emerging as major regulators of cellular phenotypes. However their precise role in terms of the regulation of gene expression at the genomic level are only now beginning to be studied in detail. In order to gain new insight

regarding the involvement of lncRNAs in ALF, we utilized the established azoxymethane (AOM) model of this disorder to precipitate liver pathology. Groups of C57/BL6 mice (25-30 g) were treated with AOM (100 μg/g body weight, i.p.) and allowed to progress to the coma stage, at which time the mice were sacrificed and the frontal cortex dissected out. Cerebral tissue was then profiled at the genomic level for changes in the levels of lncRNAs. Our results show that the glutamatergic synapse, JAK-STAT pathway, NFkB, MAPK, Ras, and mTOR, are some of the major pathways targeted by this category of RNA species. Altered expression of these pathways may have significant consequences in terms of development of the RNA phenotype. Based on these findings, we conclude that lncRNAs participate in AOM- induced ALF and may play an important role in the pathophysiology of this often life-threatening illness. This study was supported by FAPESP (Brazil) and CIHR (Canada).

Title: The neurobehavioral phenotypes of the C57BL/6NJ substrain are not altered by genetic rescue of the Crb1^{rd8} retinal degeneration mutation

Authors: *S. J. SUKOFF RIZZO, G. WELLS, S. BURRILL, J. RYAN, L. C. ANDERSON, M. P. KREBS, P. M. NISHINA, M. V. WILES;
The Jackson Lab., Bar Harbor, ME

Abstract: The C57BL/6J (B6J) mouse and its C57BL/6N (B6N) substrain are inbred strains used for genetics and pharmacology studies, and their divergent phenotypic differences across behavioral, physiological, and biochemical measures are well established (Simon et al 2013). Aside from phenotypic differences, >10,000 putative and 279 confirmed variants have been reported between the substrains (Keane et al 2011, Simon et al 2013) including a mutation in the Crb1 gene, which is expressed in retina and brain (den Hollander et al 2002), and in the B6N substrain carries the *rd8* allele. This mutation results in retinal dysplasia, degeneration and related eye phenotypes (Chang et al 2002). While it has recently been reported that rescue of this mutation by TALEN-mediated homology-directed repair corrects the eye phenotypes (Low et al 2014), the effect on the divergent neurobehavioral phenotypes is unknown. In the present studies, C57BL/6NJ mice (WT) demonstrate the expected divergent behavioral phenotypes relative to B6J mice in the open field, rotarod, pre-pulse inhibition assay, electroconvulsive seizure threshold test, and pharmacological challenge with MK-801 or ethanol. Importantly, mice homozygous for the *rd8* correction (HOM) demonstrate behavioral phenotypes in these tests

identical to the WT non-corrected controls. We also confirm rescue of the dysplastic phenotype in HOM mice as determined by fundus imaging and optical coherence tomography. Despite genetic rescue, electroretinography and optokinetic reflex assays indicate identical visual performance of HOM, WT and B6J mice, suggesting that any functional effect of the *rd8* allele in the WT genetic background is below the limit of detection at the ages studied. Taken together, these data demonstrate that rescue of the *rd8* mutation in the C57BL/6NJ substrain does not alter the neurobehavioral phenotypes or ocular function and further suggest that the genetic underpinnings of the behavioral divergence of the B6N and B6J substrains are independent of the *Crb1*^{rd8} allele.

Abstract: Existing gene expression atlases of the developing human brain include either fine spatial resolution at few time points or more coarse sampling of structures across development, largely due to tissue limitations. Non-human primates make ideal model systems for studying human brain development due to their evolutionary proximity to humans, protracted development and maturation, and availability of multiple specimens from precisely specified ages. Here we present a high spatial and temporal resolution transcriptional map of the rhesus macaque brain to examine the genetic underpinnings of primate cortical development. Individual layers from several cortical areas (including V1) and associated subcortical structures (including dorsal lateral geniculate nucleus) were isolated by laser microdissection and profiled with DNA microarrays at ten time points across rhesus development. Six prenatal time points correspond to

ages of peak neurogenesis for different layers in V1, and four postnatal time points correspond to key phases of postnatal development: infancy, childhood, adolescence and early adulthood. We found extensive variation between cortical layers and across developmental stages, with dramatic rates of gene expression change in all assayed regions throughout prenatal and early postnatal development. These changes reflected the progressive generation and maturation of distinct cell types, which tended to either occur synchronously across regions or with an earlier onset in early-developed subcortical structures, with very few genes peaking at a single intermediate time point. Consistent with anatomical and birthdating studies, genetic signatures of neurogenesis and gliogenesis appeared later in V1 relative to prefrontal cortex. Strikingly, post-mitotic neuron expression patterns continued to change throughout development, well after their initial generation, such that only a few genes marking adult cortical layers were similarly patterned in perinatal cortex. Finally, we found that expression trajectories were significantly more conserved between rhesus and human than between mouse and human, supporting the value of rhesus as a model organism for studying the molecular basis of human cortical development. This dataset is publicly accessible as part of the NIH Blueprint NHP Atlas at www.blueprintnhpatlas.org.

Title: Modeling of inhibition of action potentials due to infrared laser heating

Authors: ***M. GANGULY**[1], K. M. SHAW[2], M. W. JENKINS[3], H. J. CHIEL[2], E. D. JANSEN[1]; [1]Vanderbilt Univ., Nashville, TN; [2]Dept. of Biol., [3]Dept. of Pediatrics, Case Western Reserve Univ., Cleveland, OH

Abstract: Elevated temperatures are known to inhibit nerve action potentials in myelinated and unmyelinated nerves. It has been shown that infrared lasers (1.87 μm) that heat the tissue due to water absorption can be used to block action potential propagation in *Aplysia* and in the rat

sciatic nerve. Optical nerve block was shown to be spatially precise, reversible and safe, and can be used to block action potential propagation in both sensory and motor neurons. However, questions remain about the underlying mechanisms. A comprehensive computational model simulating laser-induced conduction block will be helpful in deciphering the biophysical mechanisms responsible for infrared block and optimizing parameter space to deliver more efficient/safe block for a variety different tissues. Our novel approach combines an optical-thermal model of laser-induced thermal transients with NEURON to obtain a single comprehensive model to evaluate the effects of laser light on nerve signal propagation. The optical-thermal model simulates the spatio-temporal thermal transients induced by laser light by utilizing a Monte Carlo simulation for light distribution in tissue coupled to a finite difference heat transfer model. Conduction block in the nerve section as a result of these temperature transients was simulated using NEURON combined with Python. The simulation makes it possible to explore the effect of axon diameter, the longitudinal extent of the applied heat block, and the existence of myelination on inhibition threshold. Preliminary studies demonstrate that decreasing axon diameter lowers the radiant exposure threshold for block, suggesting that smaller diameter fibers may be selectively subject to inhibition prior to large diameter fibers. This finding implies that this technology could be used to selectively block pain conducting fibers in a new approach we have coined Photonic Analgesia by Inhibition of Nerves (PAIN). This model can be used in the future to explore the large parameter space in silica and optimize the effects of laser light on the induction or inhibition of neural signals in a controlled manner.

Title: Infrared inhibition of capsaicin evoked afferent potentials

Authors: ***J. FORD**[1], M. JENKINS[2], H. CHIEL[2], E. D. JANSEN[1];
[1]Vanderbilt Univ., Nashville, TN; [2]Case Western Reserve Univ., Cleveland, OH

Abstract: As of yet, the role of infrared neural stimulation (INS) in the activation or inhibition of afferent neural signals is unknown. Previous work with INS has shown the ability of infrared light to evoke contact-free, highly spatially selective neural activation. More recently, infrared

irradiation of neural tissue was shown to reliably inhibit neural conduction. Generally, either compound neural action potentials (CNAPs) or motor output are used as a measure of neural inhibition. In our lab, Duke et al. (Nature Scientific Reports, Sept. 2013) showed partial and total block in both the *Aplysia* buccal nerve and rat sciatic nerve using both CNAPs and motor unit recruitment as endpoints. While indicative of efferent signals, inhibition of motor output may be an inaccurate means by which to characterize sensory fiber inhibition, since the endpoint is motor neuron recruitment and muscle fiber activation. Furthermore, there is a lack of information demonstrating the ability of infrared light to block ascending sensory fibers. To view afferent specific signals, an *ex vivo* setup is preferable because it allows for more complete control of the system. Environmental parameters may be monitored, noise and spontaneous activity reduced, and drugs may be applied more precisely. Sensory information is mediated through small, unmyelinated neurons (C fibers). Capsaicin, a vanilloid, acts as an agonist for TRPV1 channels, found in C fibers. Application of small amounts of capsaicin (~0.1-1 uM) has been shown to preferentially excite C fibers in the rat sciatic nerve. We have created an *ex vivo* setup for C fiber specific chemical activation and optical inhibition. Adult male Sprague-Dawley rats will be used. Rats will be anesthetized with isoflurane inhalation and the sciatic nerves dissected out. Nerves will be maintained in a custom flow channel and superfused with oxygenated Krebs solution. CNAPs will be recorded using suction electrodes with silver wire leads. Capsaicin will be introduced into the solution to provide excitation of the C fibers, and conduction block will be attempted with optical irradiation. Identification of the ability to inhibit neural afferent signals is necessary to more fully characterize infrared modulation of neural conduction. The described *ex vivo* approach will provide a reliable, repeatable model that allows investigation into the parameter space and optimization of infrared conduction block, which may be adapted in future studies for more precise recording techniques if necessary. A greater understanding of the parameters necessary to inhibit afferent neurons will lead to better utilization of the advantages of infrared light for neural control.

Title: Optical inhibition for selective block of unmyelinated axonal subpopulations within nerves

Authors: *E. LOTHET[1], H. LU[2], Y. WANG[3], C. HORN[4], E. D. JANSEN[5], H. CHIEL[2], M. JENKINS[3];
[1]Biol., Case Western Reserve Univ., Lowell, MA; [2]Biol., [3]Pediatrics, Case Western Reserve Univ., Cleveland, OH; [4]Med. and Anesthesiol., Univ. of Pittsburgh, Pittsburgh, PA; [5]Biomed. Engin., Vanderbilt Univ., Nashville, TN

Abstract: Controlling sub-populations of unmyelinated axons within peripheral nerves would make it possible to treat a very wide variety of clinical syndromes. Within the last few years, implanted neural devices have been developed to control peripheral nerve activity (the new area of neuroceuticals). Another promising modality for control of neural activity that has recently been described has been infrared laser (IR) light. Previous studies have shown that brief pulses of IR can induce excitation of neurons. Recent studies have shown that IR can inhibit neurons with high spatial specificity. The inhibitory block is likely to be due to local temperature increases that may reduce the conductance of ion channels responsible for action potentials. We have modeled the response of unmyelinated fibers of different diameters (see Ganguly et al., this meeting) to the external application of changes in temperature. Axons of smaller diameter have lower thresholds for externally applied inhibitory influences than larger diameter axons. To test whether these modeling predictions were correct, we first studied large and small diameter individual identified axons in the marine mollusk *Aplysia* californica. Because axon size scales with soma diameter, by intracellularly controlling the activity of a large neuron (B3) and a small neuron (B43), we were able to simultaneously examine the effects of externally applied IR light to a single large and small diameter axon. We found that we could rapidly and repeatedly inhibit action potential propagation in the smaller axon before inhibiting the larger axon, and that this inhibition was also readily reversible. The functional physiology of the axons remained unchanged throughout many hours even after repeated exposure to the IR light, as action potential amplitudes and thresholds remained unchanged. To determine whether this phenomenon would also be observed in a vertebrate nerve, we applied laser light to the vagus nerve of the musk shrew. To understand the functional role of the vagus in the musk shrew, a novel preparation has been developed that makes it possible to examine activity of small sub-populations of axons in the vagus within a semi-intact preparation, during which respiration, blood pressure, EKG and body temperature can all be measured. We found that the application of IR light selectively blocked slow conducting fibers before blocking fast conducting fibers in the vagus. These results suggest that it may be possible to use IR light as a selective blocker of unmyelinated C fibers. In future studies, it may be possible to establish whether this could serve as a novel treatment for significant clinical syndromes such as chronic pain.

Title: Cortex-wide cellular-resolution imaging access in head-fixed behaving mice using chronically implanted glass cranial windows covering the entire dorsal cortical surface

Authors: *B. S. HUANG, S. VRONTOU, A. BELLAFARD, P. GOLSHANI;
Dept of Neurol., UCLA Sch. of Med., Los Angeles, CA

Abstract: *In vivo* two-photon calcium imaging in head-fixed behaving mice has enabled studies of real-time neural circuit dynamics at cellular resolution. However, one limitation of the current approach is the need to restrict imaging to a small pre-selected cortical region of interest. While this targeted approach has produced valuable insights into circuit mechanisms in more functionally circumscribed regions, it could be limiting for studies of higher-order cognitive functions, such as attention and decision-making, which may involve large-scale circuits spanning multiple regions across the cortex. To overcome this limitation, we have developed a novel cranial window preparation that provides long-term cellular-resolution optical access to the entire dorsal cortical surface of adult mice. Our new window prep entails a large craniotomy to remove the skull over an approximately 6 x 8 mm area, uncovering cortical surfaces extending from the anterior tip of frontal cortex all the way to visual cortex at the posterior end, and extending across both hemispheres. After the craniotomy, we implant a large custom-shaped glass coverslip window, which enables long-term optical access for repeated *in vivo* two-photon imaging. These chronically implanted cortex-spanning windows have been able to remain optically clear for over 3 months, with minimal bone or dural regrowth and no observed detrimental effects on the animals' health. We have implanted these windows in transgenic mice expressing GCaMP6 (the most sensitive genetically-encoded calcium indicators to-date) and have been able to image large-scale neuronal population activity from visual to parietal to frontal cortices, bilaterally, within single animals. This cortex-wide unrestricted imaging access has allowed us to measure and compare neural circuit dynamics among various cortical regions during resting state and behavioral engagement. To further extend the imaging access to cortical surfaces buried within the midline fissure, such as mPFC (medial prefrontal cortex) and ACC (anterior cingulate cortex), we have also incorporated right-angle microprisms into our new window prep. This microprism add-on is especially useful for studying circuit functions of frontal/prefrontal cortex. Overall, our new cortex-spanning window approach enables the unbiased sampling of neural circuit activity from multiple cortical regions without regard to predefined anatomical borders, opening the door to searches for critical cortical circuits mediating higher-order cognitive behaviors.

Title: *In vivo* patterned photo-stimulation and imaging in independent axial planes

Authors: M. S. KOH, *F. ANSELMI, A. BANERJEE, M. B. DAVIS, D. F. ALBEANU; Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Understanding the function of neural circuits requires monitoring large populations of neurons, while simultaneously perturbing specific circuit elements. Patterned illumination techniques (1) allow the generation of flexible spatial and temporal photo-stimulation profiles, which together with multiphoton imaging (2) and optogenetic manipulations (3, 4) provide an ideal framework towards achieving this goal. We describe here a platform combining one photon patterned photo-stimulation via a digital micro-mirror device (DMD) with two photon imaging (5). Since neural circuits are often arranged in three dimensions, we developed a simple method that allows decoupling of the imaging and the photo-stimulation planes. Briefly, the pulsed infrared laser beam for scanning two-photon imaging and a blue laser (488 nm) for photo-stimulation are coupled through the same objective. The blue light intensity is modulated by the DMD chip to form arbitrary spatial-temporal patterns on the brain surface. By introducing a movable holographic diffuser in a plane conjugated with the desired photo-stimulation plane in the sample, we decouple the photo-stimulation and the imaging planes, up to an axial shift of 500 μm. Additionally, this allows axial confinement of the photo-stimulation pattern. To target large populations of neurons, we set the photo-stimulation field to 1.5 x 1.2 mm2 with a lateral resolution of ~20 μm. Two fast shutters in front of the blue laser and the PMT are used in anti-phase to rapidly alternate between photo-stimulation and imaging (10 Hz). When this technique is applied to the olfactory bulb (OB), we are able to optogenetically photo-stimulate specific neural populations within individual glomeruli while simultaneously monitoring GCaMP3 & GCamP6f signals from populations of bulb interneurons, or output neurons (mitral and tufted cells). We use the two-photon imaging to obtain anatomical and functional information to target particular structures of interest. Within the OB, our strategy offers exciting possibilities for understanding broadcasting of signals by single glomeruli and their combinations, as well as information integration rules at the level of individual neurons during olfactory behaviors. Abstract: Modulating neural cell by light has received increasing attention due to its merits such as non-invasiveness, high spatial selectivity, and contact free method. Among light modulation techniques, we previously demonstrated gold nanoparticle mediated infrared neural stimulation (INS) which could evoke neural activation with safer and more enhanced manner compared to conventional INS. However, gold nanoparticles are easily washed out under the convective

media and it is hard to induce neuronal depolarization. In this research, we demonstrated cell targeted effective neural stimulation method using cell targeted gold nanoparticles. *In vitro* experiments were performed to verify that cell targeted gold nanoparticle are effective for optical neural stimulation. Pulsed infrared was irradiated and light evoked neural response were measured. The evoked neural responses were compared with light stimulation with and without cell targeted gold nanoparticles. When stimulating the neuron with cell targeted gold nanoparticles, stimulation threshold was lowered in the cell targeted gold nanoparticles suggesting that local heating of gold nanoparticles efficiently triggers neural activation. In summary, we successfully showed cell targeted gold nanoparticles could elicit neuron activation with low threshold.

Title: Micro-point photothermal stimulation for inhibition of single neuron activity

Authors: S. YOO, J.-H. PARK, *Y. NAM;
KAIST, Daejeon, Korea, Republic of

Abstract: Optical stimulation of nerves has great attracted attention due to their minimum invasiveness and high spatiotemporal resolution. Previously we demonstrated that gold nanorods (GNRs)-mediated photothermal stimulation could inhibit the electrical activity of neural networks, which was advantageous than current optical technique in terms of reduction of laser power consumption and improvement of the reliability. However inhibition ability of the photothermal stimulation at single cell resolution is still yet investigated. Here we demonstrated that GNRs-mediated photothermal stimulation can inhibit the activity of single neuron without thermal damage. Laser beam was focused into tens of microns in diameter for micro-point photothermal stimulation (μPops), and changes of network activities were simultaneously measured for mapping of functional connections. GNRs that can absorb the near-infrared laser (NIR, 785 nm) were synthesized by seed-mediated method. Surfaces of the GNRs were modified with polyethylene glycol (SH-PEG-NH2) that has a bifunctional group for covalent bonding to gold surfaces and providing the positive charge, respectively. The negatively charged radicals were introduced to MEA substrate by brief treatment of air plasma. And the GNRs were self-assembled on MEA substrate by electrostatic forces. Hippocampal neurons were cultured on the GNRs coated MEAs and the matured networks that showed the spontaneous firing were used as

a model network. NIR was focused to 20 μm in diameter by using a high- magnitude objective for single cell stimulation. Change of the neural activity during the optical stimulation was recorded and analyzed. The PEGylated GNRs were self-assembled and immobilized on the MEA substrate, which yielded the monolayered nanostructure. The concentration of the GNRs on MEA was controllable by changing the assembly time, and the nanostructure generated the heat during the NIR irradiation. Firing of single neuron was inhibited by the μPops, which showed the high reproducibility. The spontaneous activity of neural networks began to inhibit by 12.4 W/mm2 of power density, and most activities were completely inhibited by 32 W/mm2. And thermal threshold of the photothermal stimulation at single cell level was measured to 51 W/mm2. Furthermore it was demonstrated that inhibition of the single cell firing had influence on network activities, which was utilized for mapping of excitatory or inhibitory connections within the network. Together our approach could be a novel platform to explore the network functions and connections as well as treatment of brain disorders.

Title: ScanImage for closed-loop cellular resolution brain imaging and stimulation with two-photon laser scanning microscopy

Authors: N. CLACK, E. KANG, G. JAINDL, J. KING, J. ROCAMORA, B. KIMMEL, *V. IYER;
Vidrio Technologies, LLC, Arlington, VA

Abstract: ScanImage is widely used software (scanimage.org) for two-photon laser scanning microscopy (TPLSM), a powerful technique for cellular resolution imaging in the intact brain. TPLSM was recognized in 2015 by The Brain Prize for its transformative role in the ‘development, plasticity, and functional circuitry of the brain.’ In recent years, TPLSM has become increasingly used for comprehensive volumetric imaging of neural populations in awake animals, allowing fine-scale correlation of cellular activity to behavior. We present research towards extending ScanImage towards the next generation of experiments unraveling causal relations between neuronal activity and behavior. Three approaches are pursued towards this end of ‘closed loop’ TPLSM experiments. First, we have developed photostimulation controls designed to allow light-activation of targeted cells via TPLSM using optogenetics tools during

simultaneous high-speed resonant TPLSM imaging. Simultaneous photostimulation and imaging is achieved via parallel control of two independent scanner pathways and allows the study of direct causal links within living neural networks. Photoactivation of individual cells using TPLSM is shown to be feasible via very fast resonant raster scans across a cell body of interest, opening a sufficient number of light-activated channels to achieve cellular firing. Image correlation based alignment of the two scanner paths in software is shown, allowing precise targeting of photostimulation cells identified from an image acquired by the parallel imaging scanner pathway. Second, we present work towards the development of a parallel processing extensibility interface enabling custom analysis and control scripts to be developed for execution during live high-speed TPLSM imaging. Such an interface will allow experimenters to design and implement closed-loop experimental paradigms. For example, behavioral control signals could be linked to the live detection of cellular signaling, to perhaps achieve single neuron operant conditioning. Alternatively, control of targeted photostimulation could be programmably driven to linked to behavioral readouts. Third, we present work towards implementing such closed-loop experiments within a single frame (of < 30 ms) using similar analysis and control approaches implemented on commodity programmable hardware boards incorporated field-programmable gate arrays (FPGAs).

[1]Janelia Farm, Ashburn, VA; [2]HHMI Janelia Res. Campus, Ashburn, VA

Abstract: There are many applications for neurophysiology data acquisition, but often a user is forced to choose between a turn-key solution with limited flexibility and an open-ended solution that requires up-front programming before data can be acquired. Furthermore, performing coordinated optical and electrophysiological recordings can be a challenge. Here we present Wavesurfer (wavesurfer.janelia.org), the successor to the Ephus electrophysiology data acquisition package, which enables turn-key operation for basic electrophysiology, but also allows for extensive user customization. It is designed to integrate tightly with ScanImage, the well-known laser scanning microscopy software. Like ScanImage, Wavesurfer is implemented in Matlab, and allows the user to write custom analysis, visualization, and control scripts that extend its native capabilities. It works with any National Instruments X series data acquisition board and any patch-clamp or sharp electrode amplifier. Furthermore, it features tight integration with Heka and Axon patch-clamp amplifiers. Wavesurfer saves data in HDF5 format, an open standard for scientific data. It is open-source software, released under a permissive license.

Title: A novel wearable NIRS sensor module detects optical signal from every positions of head

Authors: *H. EDA[1], M. YAMAZAKI[2], K. SOETA[3], Y. OHTAKI[3], M. SAKURAI[3], T. YAMAUCHI[4], T. FUJITA[4];
[1]Grad. Sch. For GPI, Hamamatsu-Shi, Japan; [2]Div. of Sports and Hlth. Sci., Daito Bunka Univ., Higashimatsuyama-Shi, Japan; [3]ALPS ELECTRIC CO., LTD, Tokyo, Japan; [4]Genial Light.co., LTD, Hamamatsu, Japan

Abstract: Near infrared spectroscopy (NIRS) calculates hemoglobin parameters, such as changes in oxygenated hemoglobin (oxyHb) and deoxygenated hemoglobin (deoxyHb), using the near infrared lights around the 800 nm wavelength. We reported the portable NIRS system (Eda et.al., SfN2007) and the wearable NIRS system. The wearable NIRS system can capture

physiological information from everywhere in the body (Eda et.al., SfN2014). We have developed the system for health care at the first. For the brain science, we need to examine the brain measurement. The purpose of this study is to validate the wearable NIRS system for the brain science. NIRS sensor module (ALPS ELECTRIC CO., LTD, JAPAN) was newly developed for acquiring AC signals and DC signals separately for each wavelength. AC signals are used for measuring pulsation and DC signals are used for conventional NIRS. The sensor module has two light sources and one detector. Each light source has two wavelengths of near infrared LEDs. We attached the sensor module in the same positions each of the EEG 10-20 system, such as A2, C4, F4, F8, Fp2, O2, P4, T4, and T6. This time we attached the module on mastoid also. The sensor module was attached the head directly for 15 seconds. And we measured the optical signal to confirm the pulsation from each position. Both AC signals and DC signals were detected by the NIRS sensor module. The pulsation was detected at each position of A2, C4, F4, F8, Fp2, O2, P4, T4, T6, as AC signals. And we detected the pulsation at mastoid. There were difference of NIRS signals between the sensor's positions. Because the DC signals were also obtained precisely, we could acquire the hemoglobin parameters by applying the modified Lambert-Beer's Law used in NIRS calculation. The NIRS sensor module detected the optical signal from every part of the head even when the hair existed. Our sensor module showed the utility of the wearable NIRS system calculating the heart rate and hemoglobin parameters associated with bio-physical activities. And the NIRS sensor module also suggested a possibility of the brain imaging by using multi modules.

Title: Can wearable NIRS capture brain activities comparably to EEG?

Authors: *M. YAMAZAKI[1], H. EDA[2];
[1]Daito Bunka Univ., Saitama, Japan; [2]Grad. school for GPIHamamatsu, Hamamatsu, Japan

Abstract: Introduction Near infrared spectroscopy (NIRS) calculates hemoglobin parameters, such as change in oxygenated hemoglobin (oxyHb) and deoxygenated hemoglobin (deoxyHb), using the near infrared lights around the 800 nm wavelength. The NIRS has been used in brain science, phychology clinical field to evaluate the brain activities. We developed wearable NIRS sensor module and suggested that it can capture physiological information from everywhere in the body (Eda et.al., SfN2014). Purpose of this study is to validate the wearable NIRS as a new method of measuring the brain activities. Methods We conducted EEG and NIRS recording simultaneously. 1)EEG : We attached 19 scalp EEG electrodes on the head according to 10-20 system and recorded EEG data using Neurofax EEG-1200 (NihonKohden) for 3 sessions. The session consisted of both eyes open and close state for 20 seconds each. 2) NIRS : We put two wearable NIRS sensor modules on the frontal head region (between Fpz and Fz) and the occipital head region (between O1 and O2) and measured the hemoglobin parameters (oxyHb and deoxyHb). We compared the signals recorded by EEG and NIRS in both eyes opening state and closing state. Results Eye closing state : α activities were captured predominant in the occipital head region (O1 and O2) immediately after eyes closed. NIRS showed that oxyHb dynamically elevated and decreased deoxyHb 3-5 seconds after the appearance ofα activities in the occipital head region compared to the frontal head region. Eye opening state : EEG showed mixture of low amplitudeα and βactivities without predominant rhythmic activities. NIRS also showed no significant dynamic changes in both oxyHb and deoxyHb. Conclusion This study showed that the wearable NIRS module captured the dynamic oxyHb changes associate with the appearance of α activities. This result is concordant with fMRI studies which hemodynamic response (increased oxyHb and decreased deoxyHb) was shown when the brain activities increased. The wearable NIRS module suggests utility in the assessment of the brain activities as a new measuring tool. Title: Spike detection with biophysical models for GCaMP6 and other multivalent calcium indicator proteins

Authors: *D. S. GREENBERG[1], D. J. WALLACE[2], J. T. VOGELSTEIN[3], J. N. D. KERR[2]; [2]Dept. of Behavior and Brain Organization, [1]Res. Ctr. Caesar: A Max Planck Inst., Bonn, Germany; [3]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Two photon-imaging of pressure-injected fluorescent organic molecule calcium indicators can resolve single action potentials from neurons *in vivo*, but recording times are limited to a few hours. Genetically encoded indicators such as GCaMPs promise relatively noninvasive, long-term observation of neural activity. However, GCaMP fluorescence grows non-linearly with increasing numbers of action potentials, have slow kinetics across multiple binding states and show variable protein expression levels and transient shape across neurons. Consequently, previously developed algorithms for determining the action potential discharge pattern underlying the recorded fluorescence transients are substantially less accurate and reliable when they are applied to data acquired using GCaMPs. In order to detect action potentials despite the complex and variable relationship between spiking and fluorescence, we developed a mathematical framework for modeling calcium entry and extrusion, kinetics of transitions across multiple binding states, drifting baseline fluorescence, photon shot noise and variable indicator concentration across neurons. We used a sequential Monte Carlo algorithm with 100K particles to perform spike detection, microscope calibration, and estimation of indicator concentration from fluorescence data alone. In addition we have developed an efficient GPU-based parallel implementation to reduce processing time required for larger datasets. By using a biophysical modeling approach as opposed to "black-box" statistical methods, we were able to carefully control which aspects of our model were shared for all data (such as rate constants) and which could vary across neurons (such as indicator concentration). Importantly, we validated our approach with simultaneous optical and electrical recordings of mouse cortical L2/3 pyramidal neurons expressing GCaMP6s. In comparison to alternative methods, we show a significant increase in correct spike detection, combined with a large reduction in false positive detection rate. Our approach provides an accurate method for converting calcium transients measured from the latest generation of GCaMP indicators into the underlying train of action potentials, and has been designed to also accommodate future alterations to the indicators which result in differences in their binding kinetics.

Title: An algorithm for identification of structures from fluorescently labeled neuronal populations validated with simultaneous electrophysiological and 2-photon imaging recordings, *in vitro*

Authors: *K.-M. VOIT, D. J. WALLACE, J. N. D. KERR, D. S. GREENBERG;
Behavior and Brain Organization, Res. Ctr. Caesar: A Max Planck Inst., Bonn, Germany

Abstract: While protein-based calcium sensors such as GCaMPs can report neuronal activity longer and less invasively than their synthetic counterparts, they brightly label diverse, intricate and overlapping fluorescent structures, which makes precise isolation of the borders of single-neurons and single structured challenging. These indicators have very low fluorescence in the absence of action potentials. Consequently, small structures (eg. dendrites) from neighboring or nearby neurons which overlap with or lie in close apposition to a neuron of interest can be inadvertently included within that neurons assigned region-of-interest (ROI). Because these indicators also show very large increases in fluorescence following action potential firing, inclusion of even a single pixel from a neighboring structure can result in artifactual fluorescence increases larger than single action potential (AP) responses and with similar rise and decay times. These artifactual transients are frequently large enough to cause false positive errors in AP detection. To combat this problem, we have developed an algorithm to detect, separate and extract fluorescence signals from overlapping fluorescenct structures. Our method is based on non-negative matrix factorization (NMF), with a novel penalization term to enforce both temporal and spatial constraints on the detected signals. The time course of each structure's fluorescence is assumed to consist of low-frequency baseline drift added to sparse activity-associated increases. The number of fluorescence objects is assumed to be limited, both in the complete field of view and at any one pixel where they may overlap. An important aspect for validation of this approach was using simultaneous optical and electrical recordings from mouse L2/3 cortical pyramidal neurons expressing GCaMP6s. Firstly this allowed identification of artifactual signals not associated with the neuron of interest. Secondly, this allowed quantification of the validity of the automated segmentation for use with AP detection algorithms. We demonstrate improved AP-detection from automatically extracted signals compared to ROI-averaged fluorescence kinetics traces. The properties of the current generation of genetically encoded calcium indicators mean that imprecisely assigned ROIs can easily include structures from other labelled neurons which result in artifacts in the calculated kinetic traces. This segmentation approach minimizes errors caused by these indicator properties.

Title: DAQLab: A hierarchical data acquisition and task control software for imaging

Authors: A. NEGREAN, *H. MANSVELDER;
Neurosci. Campus Amsterdam, Amsterdam, Netherlands

Abstract: Complex experimentation typically encountered in the neurosciences requires the interaction of multiple instruments and software modules to acquire multidimensional data sets. Data and parameters can then be retrieved for analysis as (data, parameters) = {i = 0..l, j = 0..mi, k = 0..nj, ...} by specifying a value for each of the indices {i, j, k, ...} indexing the data set. In this picture, a change in the experimental design means: a) A change in the order of data indexing indices, b) Addition or removal of data indexing indices, as well as, c) A change of index boundaries {l, mi, nj, ...} and d) A change in the acquisition parameters. Ideally the acquisition software should easily adapt to new experimental conditions and manage multiple devices or software modules that sometimes may function in parallel and exchange data or hardware triggers. In the present work this was accomplished by developing a software framework structured around the concept of hierarchically interacting task controllers (TCs) that are modelled as extended state machines and mediate the interaction between hardware and software modules. In this manner, a change in the experimental design that can be formulated in terms of operations a-d) translates directly to operations on the task tree (TT) graph formed by the TCs: a) Reshuffle of TC nodes, b) Addition and removal of TCs, c) Change in the number of times a parent TC starts its child TCs, d) Change in the acquisition parameters - all adjustable from DAQLab GUI. In addition to this, DAQLab provides a convenient GUI for directing data and specifying hardware trigger relationships. Using this framework we developed a laser scanning and data acquisition software in C/LabWindows consisting of the following TC controlled modules: 1) National Instruments DAQmx hardware control, 2) Laser scanning, 3) XY- and Z-motorized stage, 4) Pockells cell modulator and 5) Data display and storage in HDF5 file format.

Title: Two-photon imaging of light-induced nociceptive processing *in vitro*

Authors: *H. C. JOHANNSSEN[1], H. U. ZEILHOFER[2];
[1]Inst. of Pharmacol. and Toxicology, Univ. of Zurich, Zurich, Switzerland; [2]Inst. of Pharmacol. and Toxicology and Inst. of Pharmaceut. Sci., Univ. of Zurich and Swiss Federal Inst. of Technol. (ETH) Zurich, Zurich, Switzerland

Abstract: The spinal cord dorsal horn is essential for the processing and relay of peripheral noxious information to several brain regions. In addition to physiological nociceptive encoding, adaptive changes to dorsal horn circuits are known to contribute to chronic pain development, including inflammatory and neuropathic pain conditions. Despite its fundamental significance in nociceptive processing, the spinal cord dorsal horn only recently became accessible for high-resolution optical monitoring of neuronal activity using two-photon imaging in living, anesthetized mice. Similarly, channelrhodopsin-based light activation has just been newly applied to control the activity of peripheral nociceptors. Here, we combine *in vivo* two-photon calcium imaging of primary nociceptors and dorsal horn neuronal circuits with light-activation of primary afferent fibers, which transmit noxious information from the skin to the central nervous system. To selectively activate nociceptive afferent pathways with light, we crossed mice expressing cre-recombinase in peripheral nociceptors (sns::cre mice) with cre-dependent ChRH2-eYFP reporter mice. In double-transgenic sns-ChRH2-eYFP mice, eYFP was detected in peripheral nerve fibers as well as in subpopulations of dorsal root ganglia (DRG) neurons, expressing the markers calcitonin gene-related peptide (CGRP) and Isolectin B4 (IB4), respectively. In sns-ChRH2-eYFP mice, we observed robust nocifensive behaviors triggered by brief (approx. 1s) hindpaw exposure to 473 nm laser light (approx. 15 mW/mm^2). In contrast to negative controls (n = 3), all double-transgenic mice (n = 7) showed paw withdrawal and licking immediately after light stimulation. Using transganglionic tracing with OGB1-dextran, we observed labeling of lumbar DRGs *in vivo* and light-stimulation of the hindpaw evoked calcium signals in OGB1-positive DRG neurons. In addition, we monitored nociceptive processing by second order neurons in the spinal cord of sns-ChRH2-eYFP mice previously injected intraspinally with AAV-GCamP6m. The optogenetic stimulation protocol evoked robust calcium signals in subsets of GCamP6m-expressing dorsal horn neurons *in vivo*. In summary, the approaches presented here allow us to selectively activate and visualize nociceptive signaling at various anatomical levels in living mice.

Title: 3D imaging of neurons *in vitro* using a variable focus fiber-coupled microscope

Authors: *B. OZBAY[1], J. T. LOSACCO[2], D. RESTREPO[2], R. CORMACK[3], J. T. GOPINATH[3], V. M. BRIGHT[4], R. WEIR[1], E. A. GIBSON[1];
[1]Bioengineering, [2]Cell & Developmental Biol., Univ. of Colorado Denver, Aurora, CO;
[3]Electrical, Computer and Energy Engin., [4]Mechanical Engin., Univ. of Colorado Boulder, Boulder, CO

Abstract: We have developed a chronically implantable fiber-coupled microscope (FCM) that incorporates an electrowetting variable focus lens to obtain real-time 3D functional images of neurons in a mouse brain. The device is coupled to a laser-scanning microscope through an optical fiber-bundle for lateral scanning with ~2 μm resolution. Axial scanning is accomplished by altering the focus of the electrowetting lens distal to the fiber-bundle and allows for a Z-scan range of ~150 μm. The FCM is manufactured through a 3D-printing process for rapid assembly, and allows for a variety of dimensions depending on the target brain region. The assembly includes a chronically implanted lightweight (< 0.5 g) adapter for the 0.5 mm diameter GRIN objective lens and an easily attachable FCM head for imaging. We have demonstrated the FCM by performing real-time 3D imaging of mitral/tufted cells in the olfactory bulb of a mouse expressing GCaMP6s, a calcium-sensitive fluorescent protein, over multiple sessions. Our FCM shows a robust and customizable implementation of a fast miniature 3D fluorescence imaging system for monitoring brain regions over the long term.

Title: Strategic positioning and characterization of the SH-SY5Y human neuroblastoma cell line

Authors: C. A. MANGOLD[1], M. M. SHIPLEY[1], T. J. HUANG[2], *M. L. SZPARA[1]; [1]Biochem. and Mol. Biol., [2]Engin. Sci. and Mechanics, Pennsylvania State Univ., University Park, PA

Abstract: Microfluidic devices are routinely used to study the details of molecular neurobiology, neurovirology, neuronal communication, and neuron growth *in vitro*. Integrating the use of polydimethylsiloxane (PDMS) chambers, substrate gradients, and orienting cues allows for strategic positioning of neurons and guidance of axons during development *in vitro*. Despite these advances, there remains a gap in our ability to precisely position individual cells with minimal stress and to guide synapse formation between adjacent neurons. Combining microfluidic chambers with standing surface acoustic waves (SSAWs) is a novel, gentle, and cost-effective method that enables positioning of single cells and monitoring of cell behavior and function. Cell flow can be directed through design of the microfluidic chamber, while positioning is achieved through variations in acoustic frequency. Additionally, the acoustic focusing platform can be miniaturized, making subsequent downstream analyses such as microscopy or high-throughput drug screening easier. We are adapting SSAW technology to strategically position individual human neurons. These neurons are derived from SH-SY5Y human neuroblastoma cells, a neuro-potent cell line that can be differentiated via an extended process of serum deprivation and introduction of neurotrophic factors. We first tested the ability of SH-SY5Y cells to develop into mature neurons at low density in PDMS microfluidic devices. This process requires culturing cells at low density for 7 days in a closed system with low media volume, which is beyond the typical time frame for neuronal culture in PDMS. Our results indicate we are able to culture SH-SY5Y cells for $\geq$ 7 days to maturity. We confirmed terminal differentiation via immunohistochemical localization of markers for neuronal maturity. Our preliminary data suggests that partially differentiated SH-SY5Y cells survive treatment with SSAW and are able to be positioned at specific acoustic nodes. Ongoing studies are aimed at optimization of PDMS devices, SSAW conditions, and neuronal connectivity. Successful adaptation of this method will provide researchers with a well-controlled platform to study neuron and/or neuroglial signaling, responses to infection, as well as the ability to execute high-throughput drug screening at the level of a single cell or small groups of cells.

Research to Prevent Blindness

Title: *In vivo* characterization of genetic expression of virus-transduced calcium indicators in retinal ganglion cells using a funduscope

Authors: *Y.-C. CHANG[1,2], S. T. WALSTON[1,2], R. H. CHOW[1,3], J. D. WEILAND[1,2,4]; [2]Biomed. Engin., [3]Physiol. & Biophysics, [4]Ophthalmology, [1]USC, Los Angeles, CA

Abstract: Genetically encoded calcium indicators (GECIs) have been widely used for observing neural activity, especially in vision research, because they enable repeated measurement of many cells in parallel at single-cell resolution. For example, some GECIs were developed to test and optimize stimulation strategies for epiretinal prostheses. Technically, the reporters can be delivered to cells via electroporation, biolistics, viral vector transduction, or generation of transgenic animal engineering. Of these methods, viral transduction provides the greatest cellular specificity in the retina. A suitable tool for monitoring GECI genetic expression *in vivo* following transduction is highly desirable. Compared with complex and expensive microscopic imaging, endoscopic fundus imaging is efficient and cost effective. Previous researchers had shown that endoscopes are capable of *in vivo* imaging of the fundus. Thus, we designed a custom endoscope-base fundus system, dividing the optical path into excitation and emission parts to facilitate fluorescence imaging of retina at single-cell resolution. We used a xenon lamp and a removable 469 nm excitation filter to generate illumination of 6-mW power for fluorescence excitation. Excitation light was coupled into the side port of a 3-mm-outer-diameter endoscope, the imaging endface of which was optically coupled by a drop of sterile saline added to the front of the lens of the mouse eye. Fluorescence emission was captured and transmitted via the fundoscope to a digital camera, with a 535-nm emission filter positioned in the optical path. To label the majority of RGCs in adult mouse retina, we designed AAV2-CAG vectors incorporating the GECI GCaMP6f. The virus was administered through intravitreal injection and the fluorescence images of the fundus were recorded every 4 days, starting at 7 days post injection. Representative fluorescence images show that the system clearly resolves individual RGCs and axons. In addition, analysis of RGC fluorescence intensity, normalized to background intensity, demonstrates a consistent rising trend from day 11 to 23 after viral injection, thus indicating a uniform increase of GCaMP6f expression in average. The normalization to background was also validated by parallel studies in which we imaged RGCs of transgenic mice expressing YFP in RGCs. The results prove that the fluorescence-endoscopy fundus system is a powerful and widely accessible tool for evaluating *in vivo* fluorescence reporter expression. Further comparison between *in vivo* and *in vitro* calcium imaging will be accomplished to determine the optimal timing for electrophysiological experiment.

Title: Mapping receptive fields of foveal ganglion cells in the living primate eye

Authors: *L. YIN, Q. YANG, J. ZHANG, D. R. WILLIAMS, W. H. MERIGAN;
Ctr. for Visual Sci., Univ. of Rochester, Rochester, NY

Abstract: The primate fovea dominates vision due to its magnified cortical representation and its exquisite acuity. However, remarkably little is known about the retinal circuitry supporting foveal vision because of the difficulty in recording from foveal ganglion cells (GCs) *in vivo* due to the blurring of stimuli by the optics of the eye and eye motion. To overcome those hurdles, we combine: (a) high-resolution adaptive-optics *in vivo* imaging, (b) real-time visual stimulus stabilization, and (c) optogenetics, to map the receptive fields of hundreds of macaque foveal GCs simultaneously at a spatial resolution of about 4 μm. We expressed the genetically encoded calcium indicator, G-CaMP6s, in foveal GCs by transfection with adeno-associated viral vector. Receptive fields (RFs) were measured using checkerboard stimuli of binary sequences at 100% contrast, refreshed at 0.5 Hz, matching the slow kinetics of GC calcium responses. For each responsive cell, we calculated temporal impulse response for each check by reverse-correlating check contrasts and fluorescence measurements from GC somas. To estimate the RF spatial profile, we calculated a weight for each check by averaging its temporal impulse response across time. The RF center was initially identified as the check having the highest weight. The temporal impulse response for this check was used as a template to decide whether adjacent checks should be included as part of the RF center or surround. Individual cells were typically responsive to only a single check, or two adjacent checks with unequal strength in the center, suggesting a RF only a few microns in diameter. A small fraction of cells were activated by three or more checks, indicating a RF center larger than that of midget cells. We observed a similar proportion of ON-center and OFF-center GCs. By correlating the spatial locations of RFs and somas of GCs, we

show that cell somas are distributed retinotopically, and the radial displacement from RF centers to cell somas matches known anatomy of the fovea. GCs on the temporal and nasal sides of the fovea form two distinct but adjacent clusters of RFs that do not cross the vertical meridian. In the future, we hope that by characterizing RF structures of foveal GCs, we may begin to identify other types of GCs in addition to the dominant midget types, and design specific visual stimuli to probe their visual functions. The ability to study foveal GCs in intact animals will eventually allow us to compare responses in retina to those in higher visual areas.

Authors: ***O. ASSAYAG**[1,2], R. CONTI[2], M. GUILLON[2], V. DE SARS[2], V. EMILIANI[2];
[1]Intelligent Imaging Innovations, Göttingen, Germany; [2]Neurophotonics Lab., Paris, France

Abstract: Stimulation of multiple cells through optogenetic tools inevitably suffers from the heterogeneity of the responses, mostly due to different expression levels of the light-gated channels. We have developed an algorithm for holographic multiple cell illumination that allows to independently adjust the light intensity on the targeted cell so that the currents elicited will have the same amplitude notwithstanding different levels of expression. The software is best suited for cell-filling type constructs where the fluorescence intensity is proportional to the density of channels. Fluorescence images are recorded and used to generate the holographic pattern with graded intensity so that more light can be directed onto dim cells with respect to

more fluorescent ones, thus achieving uniform excitation conditions. Experiments were done on cultured CHO cells expressing a p2A construct of YFP and ChR2 (cell-filling). Whole-cell voltage clamp experiments allowed us to verify the proportionality between YFP fluorescence and ChR2HR peak currents. We then characterized the behavior of the peak current as a function of the illumination power. We produced a simple model of the channel activation as a function of light power density which was in good agreement with the data. Based on this model, we derived the equations to implement in our home-made software to obtain equal stimulation on multiple cells with different expression levels. Paired recordings of CHO cells in the whole-cell voltage clamp configuration were performed to verify the software performance. We measured peak currents in conditions of equal patterned light stimulation and in condition of graded stimulation. In n=7 pairs (out of 9 tested) the ratio of peak currents was reliably brought to about 1 (ratio of equal stimulation peak currents ranged from 1.9 to 6.3 (avg =4±2); ratio upon graded stimulation varied from 0.8 to 1.4 (avg 1.1±0.2)). The other 2 pairs tested showed a bad initial correlation between the ratio of the peak currents and the ratio of fluorescence and were excluded from the statistics. This new method will permit uniform excitation of multiple cells independently on their relative expression levels, precisely tuning of the synchronicity of spike generation or photoactivation of caged compound with a specific concentration gradients

Title: Unraveling circuit mechanisms: linking circuits components to behavioral parameters through 3D holographic optogenetics

Authors: ***J. C. DONOVAN**[1,2], M. DAL MASCHIO[1], H. BAIER[1];
[1]Baier Dept., Max Planck Inst. of Neurobio., Planegg, Germany; [2]Neurosci. Grad. Program, UCSF, San Francisco, CA

Abstract: Understanding how components within a neural circuit interact to drive behavior is a challenging task. Progress will be made through highly targeted probing of how activity in small numbers of neurons drives network activation, from the perspective of the circuit function, and how these activity patterns lead to behavioral outcomes. To investigate these aspects we have developed a 3-dimensional light shaping system based on computer generated holography, which

can be used to optogenetically activate identified neurons in a spatially precise manner across a circuit of interest, while minimizing contamination in the network activity originating from off-target or broad photostimulation effects . For the study of the neuronal circuits, this activation protocol is combined with simultaneous functional imaging of the network and high-speed behavioral recording, to link the activity patterns induced in the network with the relevant parameters of the triggered behavior. We have taken advantage of this approach to distill a minimal subset of neurons in the zebrafish central nervous system whose activation is sufficient to engage a characteristic motor output and to record simultaneously the circuit activity supporting such a motor program. Assembling together information from induced activation patterns, neural activity, and behavior outcomes provides identification of critical driving elements of the circuit and their functional roles.

Title: Development of novel fast-response GCaMP6 sensors for monitoring neuronal action potential

Authors: N. HELASSA[1], B. PODOR[2], A. FINE[2], *K. TÖRÖK[1];
[1]SGUL, London, United Kingdom; [2]Dalhousie Univ., Halifax, NS, Canada

Abstract: Green Fluorescent-Calmodulin Proteins (GCaMPs) have been the reporters of choice for visualizing neuronal network activity *in vivo*. GCaMPs are based on a circularly permutated EGFP molecule (cpEGFP) flanked at the N and C termini by the smooth muscle myosin light chain kinase derived RS20 peptide and calmodulin (CaM), respectively. Upon Ca^{2+} binding, the formation of a tight complex between RS20 and CaM induces a fluorescence enhancement. However, the slow Ca^{2+}-response kinetics of the current GCaMPs does not make them optimal for monitoring action potentials (AP). To accelerate the Ca^{2+} response kinetics of GCaMP6f, we decreased the binding affinity of the Ca^{2+}.CaM.RS20 complex by point mutations in the EF-hands of CaM[1] (mutants EF-1 to EF-4) and in the RS20 target peptide sequence[2] (mutant RS-1). Newly engineered GCaMP6f proteins were characterised *in vitro* in terms of dynamic range,

Ca^{2+} affinity and kinetics at 37°C. Dissociation constants (K_d) for Ca^{2+} obtained from equilibrium Ca^{2+} binding were in the μM range (0.1-3.3 μM) with Hill coefficients from 1.7 to 4.2. The GCaMP6f RS-1 EF-3 mutant had half times ($t_{1/2}$) for Ca^{2+} rise and decay of 1.3 and 2.8 ms, respectively, compared to 10 ms and 63 ms for GCaMP6f. GCaMP6f RS-1 EF-4 had $t_{1/2}$ for Ca^{2+} rise and decay of 3.3 and 3.5 ms, respectively, 3- and 18-fold faster than the corresponding values for GCaMP6f. Fluorescence changes on Ca^{2+} association were highly cooperative and characterized by a rate limiting conformational change. *In vivo* Ca^{2+} responses associated with AP firing patterns were tested in cultured hippocampal slices by two-photon imaging at 28°C. The performance of GCaMP6f RS-1 EF-3 and GCaMP6f RS-1 EF-4 was compared with that of GCaMP6f. Ca^{2+} decay kinetics were determined by monitoring fluorescence changes evoked by 5 AP fired at a 100 Hz. $t_{1/2}$ values for GCaMP6f RS-1 EF-3 and GCaMP6f RS-1 EF-4 were 58 ms and 126 ms, respectively. With an up to 7-fold faster kinetics than GCaMP6f, GCaMP6f RS-1 EF-3 and GCaMP6f RS-1 EF-4 are promising tools for monitoring brain activity *in vivo*.

Abstract: Understanding how neurons integrate information from their inputs requires mapping the functional connections between two successive layers of a neural circuit. A method to systematically measure how the activity of one neuron will influence the next layer is still lacking. Here we have developed such a method by combining two photon computer generated holography and two photon calcium imaging, and tested it in the retina. The retina is an ideal system for studying information processing through different layers. The excitatory signals flow vertically from photoreceptors through the bipolar cells to the retinal ganglion cells, which send spikes down to the optic nerve to the brain. Here we focused on the information transmission between the bipolar and ganglion cell layers. We have designed an optical system combining two

photon computer generated holography stimulation of the bipolar cells and two photon calcium imaging of the ganglion cell layer. Using AAVs, we expressed Channelrhodopsin2 in ON bipolar cells of wild type mice and GCaMP6s in the ganglion cells. Single bipolar cells were stimulated with holographic spots, while imaging the responses of ganglion cells. Our method also allowed us to stimulate several cells simultaneously. Preliminary results showed that single bipolar cell stimulation can evoke unique activation patterns in the ganglion cell population. Our method paves the way to a comprehensive map of the functional connectivity between two layers, by reconstructing the projective field of each bipolar cell and the receptive field of each ganglion cell.

Abstract: Three-dimensional reconstruction capability and speed of image acquisition are two essential requirements in neuroscience to study the brain architecture and function *in vitro* and *in vivo*. Many efforts have been made to develop novel strategies and optical approaches that preserve the functional neuronal activity and allow for monitoring signal processing in 3D

networks. Structured illumination methods integrate 3D optical sectioning capabilities with widefield microscopy, generating configurations simple to construct, low-cost, versatile and enabling high acquisition speeds. In particular, the strategy of generating a speckle patterned illumination adopted in the HiLo method offers an optically robust and versatile approach to be implemented on a wide-field fluorescence microscope for three dimensional functional imaging in thick samples. In the present study, we use HiLo microscopy configured in a fast acquisition scheme to record calcium signals from living Zebrafish larva. This approach allows for monitoring calcium activity generated by specific neurons located at different depths, offering an affordable solution for monitoring at high acquisition rates the activity of large ensemble of neurons at subcellular resolution.

Title: Design and evaluation of an all-optical electrophysiology workstation integrating two-photon imaging, two-photon digital holographic photostimulation, and temporal focusing

Authors: *K. KILBORN[1], O. ASSAYAG[2];
[1]3i, Denver, CO; [2]3i, Göttingen, Germany

Abstract: Computer-generated holography (CGH) offers a novel and powerful means to deliver light in a spatially precise manner throughout a 3D volume of tissue for uncaging, optogenetic stimulation, and other photomanipulation applications. A particularly promising use of CGH is to enable “all-optical” electrophysiology where stimulating electrodes are replaced by 3D illumination patterns and recording electrodes are replaced by the expression of genetically-encoded activity reporters in the target neurons of interest. This combination enables significantly greater parallelism in both stimulation and recording, allowing one to investigate circuit-level connectivity, integration of many afferents, and elucidate neural algorithms in a way that is difficult with conventional methods at the circuit scale. Key design factors in such a system are the ability to selectively stimulate individual neurons in a volumetric field of excitation sufficiently large enough to encompass the circuit of interest, the ability to image neurons in the same (or potentially larger) volumetric field of view with sufficient signal-to-noise to detect single-cell responses, and the ability to synchronize stimulation and recording. By using a two-photon source with digital holography, it is possible to stimulate deeper in tissue and with greater axial confinement than with a one-photon source. The addition of temporal focusing

(TF) further improves axial confinement, particularly when the lateral extent of the region of illumination is large (on the order of one or multiple cell bodies). A system is presented which combines CGH and TF with two-photon resonant scanning and arbitrary 3D curve scanning to obtain a 500um x 500um x 500um volume of excitation and view with single-cell resolution. In order to achieve the maximum flexibility in configuring all-optical experiments, it is beneficial for the stimulation and acquisition to be tightly coordinated. The system presented provides such coordination, including facilities to automatically identify stimulation targets from imaging activity, using the image data to directly feed the stimulation patterns in a closed-loop fashion.

Title: Phase-based light shaping improves the spatial specificity of calcium and voltage fluorescence functional imaging

Authors: ***V. ZAMPINI**[1], D. TANESE[1], A. J. FOUST[1], E. PAPAGIAKOUMOU[1], M. CANEPARI[2], V. EMILIANI[1];
[1]Biomed. and Fundamental Sci. Fac. - CNRS, Paris Descartes Univ., Paris, France; [2]Lab. Interdisciplinaire de Physique, Univ. J. Fourier, St Martin d'Hères, France

Abstract: Calcium and voltage sensitive reporters have the potential to revolutionize our understanding of the neuronal electrical communications. Calcium and voltage changes can track neuronal activity simultaneously in neuronal compartments difficult to access with standard electrophysiological patch-clamp techniques. However, an efficient epifluorescence detection of rapid fluorescent transients in neighboring labeled structures is limited by contamination of out-of-focus and scattered light. To overcome this limitation, we used phase modulation approaches to distribute light excitation on user-defined regions. This method enables illumination of axons, dendrites and spines of interest to detect calcium and voltage fluorescence changes, without

exciting surrounding structures, thus achieving high spatial specificity while maximizing collected photon flux and signal-to-noise ratio. In CA1 hippocampal pyramidal neurons loaded with a low affinity calcium indicator (OGB488-5N, 1 mM), calcium fluorescent changes correlated with action potentials imaged by shaping light onto neighboring axons and dendrites. Neighboring axons and dendrites of neurons loaded with the voltage dye JPW3028 were also illuminated with shaped light. We observed different kinetics in dendritic back-propagating compared with axonal action potentials, differences not measured in the same structures illuminated with a large "pseudo-widefield" spot of the same excitation density. Shaped illumination reduced baseline fluorescence, increased fractional fluorescence transient amplitudes, and improved spatial discrimination compared to trials acquired with pseudo-widefield illumination of the same regions. In conjunction with the rapidly expanding toolbox of genetically encoded voltage and calcium reporters, light shaping can enable high signal to noise ratio and parallel detection of neural-evoked fluorescence transients from neighboring cells or subcellular compartments in regions with dense expression of genetically targeted fluorescent proteins.

Title: Three-dimensional simultaneous photoconversion of neuronal ensembles with single-cell resolution

Authors: O. HERNANDEZ[1], E. PAPAGIAKOUMOU[1], C. WYART[2,3,4,5], *V. EMILIANI[1]; [1]Neurophotonics Lab., CNRS-University Paris Descartes, Paris, France; [2]Inst. du Cerveau et de la Moelle Épinière (ICM), Paris, France; [3]INSERM, Paris, France; [4]CNRS, Paris, France; [5]UPMC, Paris, France

Abstract: Genetically encoded light-sensitive channels and reporters enable both neuronal activity optical control and read-out. Full exploitation of these optogenetics tools requires single-cell scale methods to pattern light into neural tissue. Computer Generated Holography can powerfully enhance optogenetics stimulation by efficiently shaping light onto multiple cellular targets. However, a linear proportionality between lateral shape area and axial extent degrades

axial precision for cases demanding extended lateral patterning i.e., to cover entire soma of multiple cells. To address this limitation, we previously combined computer generated holography with temporal focusing to stretch laser pulses outside of the focal plane, which combined with two-photon's nonlinear fluorescence dependence, axially confines fluorescence regardless of lateral extent. However, this configuration restricts nonlinear excitation to a single spatiotemporal focal plane, precluding simultaneous confinement of axially separated light patterns. Here, we report an optical system enabling remote axial displacement of temporally focused holographic patterns, as well as generation of multiple temporally focused holographic targets occupying separate axial planes. The capabilities of the system for axially confined multi-plane illumination are demonstrated by photoconverting, with single-cell resolution, tens of Kaede protein expressing neurons occupying separate axial planes in live zebrafish larvae.

Title: Optogenetic, calcium-sensing, and chemogenetic mouse models available from the JAX repository

Authors: *M. SASNER, S. F. ROCKWOOD, J. BECKWITH;
The Jackson Lab., Bar Harbor, ME

Abstract: The Jackson Laboratory (JAX) Repository distributes mouse lines with optogenetic and calcium-sensing technologies. Opsins are light-activated proteins that alter membrane potential in neurons, so that light stimulation allows control of neuronal activity. Several mouse models express improved/optimized opsins fused to fluorescent proteins, including channelrhodopsin expression directed by specific promoters, as well as Cre-dependent expression of archaerhodopsin, channelrhodopsin or halorhodopsin variants. Variants of GCaMP fluoresce in response to calcium binding, serving as an indication of neuronal activation. These include *Thy1*-promoter driven GCaMP3, GCaMP6f or GCaMP6s transgenic, Tet-dependent GCaMP6s transgenic, and Cre-dependent GCaMP3, GCaMP6f or GCaMP6s expressing mouse

lines. Several strains utilize both Cre-lox and Tet-On/-Off systems. Removal of a floxed-STOP allows Tet-dependent expression of channelrhodopsin (Chronos/EGFP), halorhodopsin (Jaws/EGFP), GCaMP6s, GCaMP6f or a voltage-sensitive FRET chromophore. This set features models created by the Allen Institute for Brain Science, the Genetically-Encoded Neuronal Indicator and Effector (GENIE) Project (Janelia/HHMI), Duke/MIT and others. Transgenic lines from the Cornell Heart Lung Blood Resource for Optogenetic Mouse Signaling (CHROMus) are designed for combinatorial crosses enabling the coexpression of sensors and effectors, or red and green calcium sensors (*e.g.*, RCaMP and GCaMP8) in interacting lineages. Designer receptors exclusively activated by designer drugs (DREADDs) are mutant G-protein coupled receptors activated by the pharmacologically-inert molecule clozapine-N-oxide. Several chemogenetic strains have Cre- or Tet-inducible expression of hM3Dq, hM4Di or rM3Ds. Search Repository holdings using the newly designed JAXMice webpage (*jaxmice.jax.org/query).* To donate mouse strains, use our online submission form *(jax.org/donate-a-mouse*). Abstract: Imaging neural activity using genetically-encoded calcium indicators (GECIs) is a widely used method for *in vivo* neurophysiology. GECIs allow tracking of activity in large populations of neurons, measurements from genetically-defined neuronal cell types, and imaging of small neuronal compartments. The most popular GECIs are based on GFP, and their emission spectra are therfore in the green range of the wavelength spectrum (green GECIs). Red GECIs could have advantages for *in vivo* imaging because of reduced absorption and scattering losses in intact tissue. However, so far the molecular properties of red GECIs are inferior to green GECIs

for *in vivo* imaging of activity. Here we present improved red GECIs, jRCaMP1 (based on mRuby) and jRGECO1 (based on mApple), with performance that is comparable to state-of-the-art green GECIs. We characterize the properties of the new red GECIs in cultured neurons and *in vivo*. We further compare the performance of a variety of red and green indicators for population imaging in the visual cortex *in vivo*. Finally, we discuss the limitations of jRCaMP1 and jRGECO1, and test their compatibility with other optical indicators and effectors.

Title: Multi-color genetically-encoded calcium indicators for fast-spiking neurons in *Drosophila*

Authors: ***Y. SUN**, D. HOD, J. P. HASSEMAN, G. TSEGAYE, G. HOLT, E. R. SCHREITER, A. NERN, M. REISER, K. SVOBODA, L. L. LOOGER, V. JAYARAMAN, D. S. KIM; Howard Hughes Med. Inst., HHMI Janelia, Ashburn, VA

Abstract: Genetically-encoded calcium indicators (GECIs) are preferred probes for optical neurophysiology in genetically modifiable model organisms. Current GECIs (e.g. GCaMP6) are optimized for action potential (AP) detection in the low firing rate range (1-50 Hz) and have high calcium affinities (low Kd). The high Hill coefficient of these indicators (2-3 for GCaMP6) narrows their linear range, and their slow decay kinetics limit their ability to track rapid changes in activity that are typical of several types of non-spiking and fast-spiking neurons found in *Drosophila* and other invertebrates. We are developing red and green GECIs for simultaneously monitoring the activity of intermingled populations of distinct classes of such neurons. We mutated GCaMP6 and the high-affinity red fluorescent sensors jRCaMP1 and jRGECO1, screened for useful low-affinity variants in *Drosophila* larval neuromuscular junction (NMJ), and identified GCaMP, RCaMP and RGECO variants with improved calcium detection. In the NMJ these indicators responded monotonically to spike rates from 1Hz to 160Hz, with improved linearity and faster kinetics compared to parent sensors. They enable reliable single trial imaging of neurons across a wide range of firing rates in behaving animals.

Title: Multisite two-photon three-dimensional random access *in vitro* calcium imaging

Authors: ***S. J. YANG**[1], W. ALLEN[2], I. V. KAUVAR[1], A. ANDALMAN[3], N. YOUNG[3], C. K. KIM[2], K. DEISSEROTH[3,4,5];
[1]Electrical Engin., Stanford, CA; [2]Neurosci. Program, [3]Bioengineering, [4]Psychiatry and Behavioral Sci., [5]Howard Hughes Med. Inst., Stanford Univ., Stanford, CA

Abstract: A major goal in neurophysiology is to record the activity of large ensembles of neurons simultaneously in awake, behaving animals. This problem is challenging for three dimensional volumes of neurons in scattering tissue. Current approaches to three-dimensional *in vivo* calcium imaging in scattering mammalian tissue utilize multi-photon single-point random access scanning techniques. However, such systems require acousto-optic scanners in order to sample the calcium sensor fast enough and inherently trade off the number of sites recorded against signal acquisition time per site, since each site is visited sequentially. Alternative approaches utilize spatial light modulators in an attempt to overcome this limitation by simultaneously illuminating all sites. However these simultaneous illumination techniques have been limited to ~100 sites in a less-scattering medium, and have not been demonstrated to work *in vivo* or to scale to large neuronal populations. Here we demonstrate multisite random access three-dimensional *in vivo* recording of neural activity in scattering tissue volumes using multifocal spatial-light-modulator-based two-photon illumination and coded detection using an sCMOS camera. Richardson-Lucy deconvolution allows for the reconstruction of cellular activity traces from coded images. We further scale the system by utilizing a regenerative amplifier modified to operate at 920 nm to overcome laser power limitations. The technique operates without fast scanners and is relatively easily implemented. We are able to sample calcium signals at 10 Hz from 106 locations through a cranial window over S1 barrel cortex in head-fixed mice (N=2) virally transduced with GCaMP6m (AAVdj-Camk2a-GCaMP6m)

undergoing whisker stimulation. This technique represents a promising approach to recording the activity of large neuronal populations in three dimensions in the cortex of awake, behaving animals; with further *in vivo* testing and optimization of single-cell spatial resolution, this approach may become a simpler alternative to fast single-point scanning approaches.

Title: Simultaneous 3-D optogenetics and volumetric imaging on neural circuits *in vitro*

Authors: W. YANG, L. CARILLO-REID, J.-E. K. MILLER, R. YUSTE, *D. S. PETERKA; Columbia Univ., New York, NY

Abstract: Optical recording and manipulation of *in vivo* neural circuits with cellular resolution could be important for understanding cortical function. Despite recent progress, simultaneous optogenetic activation with cellular precision has either been limited to 2-D planes, or a very small number of neurons, and rarely with simultaneous optical imaging. Here we demonstrate a novel paradigm for simultaneous 3D activation and imaging using a dual-laser two-photon microscope. The microscope utilizes a low repetition rate pulse-amplified fiber laser system and a spatial light modulator (SLM) to project 3-D holographic excitation patterns on the cortex of mice *in vivo* for targeted 3-D photoactivation. High speed volumetric imaging is simultaneously performed with a resonance scanner, and the imaging depth controlled by either an electrotunable lens or another SLM. This allows for remote focusing without moving the microscope objective. The system enables simultaneous activation of at least 50 cells simultaneously, using red-shifted opsins, such as C1V1 or ReaChR, while simultaneously

imaging GFP-based sensors such as GCaMP6. This all-optical 3D imaging and manipulation approach achieves simultaneous reading and writing of cortical activity, and should be a powerful tool for the study of neuronal circuits.

Abstract: Sensorimotor integration is by definition a closed-loop process, during which mechanosensory feedback modulates ongoing locomotor activity. Traditional “fictive preparations”, in which the spinal cord is isolated and/or the animal paralyzed, provides an “open-loop” access to spinal circuits deprived of muscle contraction and subsequent mechanosensory feedback. Here we developed a bioluminescent approach for monitoring the activity of motor or sensory neurons in the spinal cord during ongoing active locomotion. We estimated the global neural activity of genetically targeted populations of spinal neurons using the bioluminescent reporter GFP-aequorin during auditory-vestibular evoked escapes using a high-speed infrared camera in zebrafish larvae. The intensity of recruitment of spinal motoneurons during active escapes was associated with specific maneuvers: larger for escapes only, than escapes followed by a slow swim and then slow swims. In open-loop fictive locomotion, recruitment of spinal motoneurons was slower and the decay constant of their bioluminescence signal was longer compared to closed-loop active behaviors, suggesting that sensory feedback modulates the recruitment of spinal motoneurons. Using transgenic lines in which GFP-aequorin expression was restricted to different mechanosensory cell types, we showed which spinal sensory neurons were specifically recruited during active locomotion but not during fictive recordings. Using GCaMP-based calcium imaging, we confirmed that sensory cells were differentially recruited during active bending of the tail but not in paralyzed preparations during auditory-vestibular evoked escapes. Hence, we propose an intra-spinal closed-loop neural circuit including intraspinal sensory neurons, which would be mechanically

recruited and, in turn, would modulate the intensity and timing of motoneurons recruitment in the moving spinal cord. These results show a differential recruitment of motor and sensory spinal neurons during active compared to fictive locomotion using genetically targeted reporters emphasizing the importance of spinal sensorimotor integration during active locomotion.

Title: Single emitter light distribution in homogenous brain tissue for optogenetic applications

Authors: D. ANGELEY, *I. D. GALLAGER, D. ANDERSEN;
Behavioral Neurosci., Circuit Therapeut., Menlo Park, CA

Abstract: The actual distribution of visible light from a single fiber optic probe embedded in the brain has yet to be reported, although its knowledge is central to the accuracy of in-vivo optogenetic targeting, experimental planning and subsequent data analysis. Monte Carlo simulations of optical transport within tissue were performed using a 3-dimensional Henyey-Greenstein volume scatter model. Isotropic detection probes and light delivery fibers were deployed in-vivo by stereotaxic means into the Caudate Putamen (striatum) of rats and into homogeneous regions of ex-vivo fresh porcine brain for experimental validation. To measure light spread in-vivo, the isotropic detection probe was placed in the posterior region of the tissue and the light delivery fiber was inserted anteriorly at a set of predetermined x-y-z locations from distal to proximal. Laser wavelengths of 473, 588, and 635nm were used, as were a range of delivery fiber core diameters and numerical apertures. Measurements validated the modeling of optical transport. Importantly, peak fluence rates are located distal to the delivery fiber output and increase with wavelength. The distribution of light is predominantly spherical at distances from the fiber output greater than ~1mm. The fluence rate distribution is dependent upon the amount of scattering and absorption, and the wavelength used. Equivalent irradiance contours may be determined, and exposed tissue volumes calculated thereby. For example, a 200μm, 0.22NA fiber delivering 10mW of 473nm light into homogenous grey matter with 2% blood volume fraction creates exposure volumes of 15, 5, 0.3mm3 for irradiance thresholds of 0.4, 1, and 10mW/mm2 respectively. The distribution of light is predominantly spherical at distances that are “optically far” from the source (i.e. in the diffusion regime), after which incident directionality is lost. Furthermore, the fiber core diameter and numerical aperture have negligible impact upon the distribution. These findings may significantly influence results observed in

optogenetic behavioral testing and great consideration should be placed on the potential collateral (extracircuital) effects due to viral and light spread within the brain. Experimenters should therefore attempt to minimize the amount of light utilized within *in vivo* experimentation.

Title: Novel organic light emitting diodes for optogenetic experiments

Authors: ***A. SHAH**, A. SRIDHARAN, J. SMITH, J. CHRISTEN, J. MUTHUSWAMY; Neural Microsystems Laboratory,, Arizona State Univ., Tempe, AZ

Abstract: Optogenetics Current LED technologies are not readily scalable to high-throughput neural stimulation arrays due to power and interconnect constraints. In contrast, OLEDs offer distinct advantages such as monolithic fabrication, flexible substrate, power efficient multi-arraying, and orders of magnitude improvement in interconnect density. For the above reasons, OLEDs are a low cost and a high throughput technology. OLEDs reported here were fabricated at ASU's Flexible Display Center. We present *in vivo* results for blue OLEDs, and *in vitro* results for blue and green OLEDs. For *in vivo* testing, the light out of the flat OLED panel was collected into a collimating optical system and focused into the optical fiber. The optical fiber was then used for stimulating neurons in layer 5 of the motor cortex in transgenic mice expressing ChR2(B6.Cg-Tg(Thy1-ChR2/EYFP)9Gfng/J). EMGs evoked in response to electrical/optical stimulation were recorded from the contralateral vastus lateralis muscles. *In vitro* testing of the OLEDs was done in primary cortical neurons in culture transfected with blue light sensitive ChR2 and green light sensitive C1V1tt in separate cultures. The neurons were cultured on a microelectrode array for neuronal recordings. Statistically signicant ($p<0.01$) increase in neural activity was recorded in comparison to the baseline activity. Keywords - neuronal stimulation, activation, microelectrode arrays, light stimulation

Abstract: Optogenetic control of neural activity is a powerful strategy for causal investigation of neural circuitry. In order to simultaneously control and monitor neural activity in deep brain regions, it is mandatory to develop new light delivery/collection methods and technologies with high spatio-temporal resolution and low-invasiveness. Here we review emerging technologies and new strategies exploited for the experimental in-vivo probing of optogenetic activity for both open-loop and closed loop control of neural circuitry [Grosenick et al, Neuron 86, 106 (2015)]. Special emphasis is given to nanomachined tapered optical fibers, a successfully applied technology for in-vivo light multipoint-emission [Pisanello et al, Neuron 82, 1245 (2014)]. A focused ion beam is used to pattern multiple light windows on the tapered and gold coated section of the fiber to produce independently addressable light sources, slotted emission patterns and light collection windows. Selective and dynamic illumination of different brain regions along the taper have been demonstrated in the mammalian brain *in vivo* by coupling the fiber to a microelectrode array and performing simultaneous extracellular recording and stimulation at multiple sites in the mouse striatum and cerebral cortex with minimal invasiveness.

Title: Epidural optic fiber implant for spinal optogenetics

Authors: *R. P. BONIN[1], F. WANG[2], M. DESROCHERS-COUTURE[3], M.-E. BOULANGER[4], A. GASECKA[4], D. COTE[4], Y. DE KONINCK[2];

Abstract: Optogenetic tools enable the use of light to detect and control neuronal activity with remarkable temporal and cellular precision. Yet, the difficulty in delivering light to the spinal cord of awake, behaving animals has hampered the use of optogenetics in the study of spinal sensory processing. Accordingly, we have developed an epidural optic fiber implant that allows the delivery of light to the spinal cord dorsal horn and dorsal roots of sensory afferents. The epidural optic fiber was implanted in adult mice that expressed the light-activated inhibitory opsin ArchT in Nav1.8-expressing nociceptive afferents (Nav1.8-ArchT) and in wildtype C57Bl/6 mice. Amber light (592 nm) inhibited acute thermal nociception in the Nav1.8-ArchT mice, but did not affect nociception in C57Bl/6 mice. The acute delivery of blue light (488 nm) to the lumbar spinal cord of mice that selectively express channelrhodopsin (ChR2) in Nav1.8+ afferents (Nav1.8-ChR2) produced nocifensive behaviour, while repeated activation of Nav1.8+ afferents in these mice induced long-lasting mechanical hyperalgesia. Finally, inhibition of ArchT-expressing GABAergic interneurons in the lumbar spinal cord induced mechanical but not thermal hyperalgesia. Together, these results demonstrate the utility of our epidural optic fiber for the optogenetic modulation of both sensory afferents and intrinsic spinal cord neurons, permitting studies of activity-dependent nociceptive sensitization and the manipulation of sensory processing pathways within the spinal cord dorsal horn.

Title: Tapered fiber optical waveguide for homogeneous *in vivo* light delivery in extended brain structures

Authors: ***F. PISANELLO**[1], I. A. OLDENBURG[2], L. SILEO[1], M. S. EMARA[1,3], A. DELLA PATRIA[1], G. MANDELBAUM[2], M. PISANELLO[1,3], B. SPAGNOLO[1,3], B. L. SABATINI[2], M. DE VITTORIO[1,3];

Abstract: Although genetic techniques allow targeting well-defined neuronal sub-populations with light-sensitive proteins, most *in vivo* optogenetic experiments are limited by the use of

optical fibers with flat cleaved ends. With such devices light is emitted to a relatively small volume near the fiber facet. Moreover, light delivered into the brain undergoes to both tissue absorption and scattering [Yizar at al, Neuron 71, 9 (2011)], resulting in an exponential decrease of light intensity from the source and uneven illumination. Multipoint-emission tapered fibers [Pisanello et al, Neuron 82, 1245 (2014)] and other approaches [Grosenick et al, Neuron 86, 106 (2015)] can broaden the stimulated area; however, a viable strategy for homogenous illumination of extended brain structures has not yet been developed. Here we present a tapered fiber configuration that redefines the light delivery geometry in the living brain. The tapered fiber, having a very small taper angle (<3°), is designed to gradually and homogenously deliver light along a taper segment that can be tuned from a few hundreds of micrometers up to ~2mm. This is achieved by virtue of gradual loss of the total internal reflection condition along the taper, which acts as a spatial demultiplexer of the optical modes guided into the fiber. Moreover, the sub-micrometer tip (~500nm) allows for smooth insertion into the brain, greatly reducing the overall invasiveness compared to standard light delivery systems. To demonstrate the suitability of this approach for a more uniform illumination of extended brain structures, we have performed tests in the VGAT-ChR2 mouse line, with ChR2 expressed in all inhibitory interneurons. Tapered fibers were used to activate inhibitory neurons along the whole depth of motor cortex, while measuring the evoked effect on cortical neurons. Experiments on several animals show that the light emission geometry of the here-proposed tapered fiber permits sustained inhibition of neural activity at delivered powers 5-times smaller than the threshold recorded for standard flat-cleaved fibers. Moreover, by changing the input angle at the other end of the fiber [Pisanello et al, Neuron 82, 1245 (2014)], tapered fibers also allow the sub-sampling of the region of interest by illuminating only well-defined sub-portion of tissue within the total allowed emission length.

Title: A miniature wireless device for movement-triggered deep-brain optical stimulation in rats

Authors: *M. PASQUET, L. PETIT, D. ROBBE;
INMED, MARSEILLE, France

Abstract: Wirelessly controlled optogenetic stimulation systems are now currently available to perform in-vivo neuroscience research on freely behaving animals. Such devices allow performing deep brain stimulation while ensuring a better ethological experimental environment. The production of controlled movements in response to task-specific constraints is one of the fundamental outcomes of brain activity. The understanding of the neuronal basis of motor control would greatly benefit of techniques allowing to deliver selective perturbation of neuronal circuits at specific phases of movement production. In parallel to the stimulation devices evolution, wireless motion quantification devices are now commonly available. They brought unconstrained experimental possibilities and enable many applications in animal research. They are offering the possibility of quantifying, classifying or detecting efficiently all sorts of motion-related elements ranging from simple motion to complex animal behavioral sequences. Despite the interest of both technologies, an all integrated miniaturized headborne solution for performing real-time motion-triggered closed-loop deep-brain optical stimulation in unrestrained laboratory animals such as rats is still lacking. We are developing a miniature wireless device for performing motion-related closed-loop deep-brain optical stimulation on rats. We use a multi-axis movement sensor for motion quantification, a microcontroller performs real-time movement analysis and stimulation triggering, finally the optical deep-brain stimulation function relies on a fibered-LED implant. The motion sensing and computation assembly is coupled to the optical implant by a precisely machined device performing electrical and mechanical connections. The complete system can be worn on the head of a rat and controlled using a Bluetooth link. Both motion analysis and stimulation control are done by a single microcontroller which ensures real-time triggering of the stimulation. Overall, our system has the potential to offer an association between interactive motion sensing functions and deep-brain stimulation in a single device, headborne, and unleashed from many mechanical constraints. We believe that our system will enable all sorts of novel closed-loop motion based experiments on freely moving animals.

Title: LED-based neural probes for optogenetics

Authors: ***M. SCHWAERZLE**, F. POTHOF, O. PAUL, P. RUTHER;
Univ. of Freiburg, Freiburg, Germany

Abstract: This paper presents the design, fabrication as well as optical and thermal characterization of miniaturized optrodes with integrated light sources for optogenetic research. Light emitting diode (LED) chips are integrated in cylindrical polyimide (PI) based depth probes [1] or combined with miniaturized Si housings and optical fibers into MEMS-based miniaturized light sources [2,3]. The direct integration of bare LED chips into the neural systems reduces the overall system size and avoids mechanically stiff optical fibers interfacing with external light sources. This facilitates *in vivo* experiments with freely behaving animals. The all-electrical system control enables its integration into wireless headstages. The 40-mm-long depth probe comprises macroelectrodes as well as recording sites with a diameter of 30 µm. Bare LED chips are integrated within this cylindrical probe and electrically connected via a separate PI-based cable. The optical characterization revealed a radiant emittance of 1.03 mW/mm² measured through an aperture of 235 µm (driving current 45 mA; duty cycle 10 %). The thermal behavior is evaluated as a function of duty cycle using an infrared camera. The temperature increase at a duty cycle of 5 % is measured to be below 2.5 K when the depth probe is in contact with a brain phantom. The miniaturized, MEMS-based light sources enable a localized illumination at up to 3×3 independently controlled spots using individual LED chips (size 230×270 μm^2). They are integrated into micromachined Si housings ensuring mechanical stability and their precise alignment with respect to 5-mm-long optical fibers transmitting the light into the neural tissue. A highly flexible PI cable interfaces the LEDs electrically. With housings with volumes smaller than 2.2 mm³ and an optical output intensity of 2.1 mW/mm² at 10 mA and 30 % duty cycle, the 3×3 array is suitable for optogenetic applications [4]. As these devices are fixed on the skull, the temperature increase below 2.2 K is rated uncritical for chronic applications. **References** [1] F. Pothof, et al., *Proc. Abstract: Control of neural activity is a powerful approach to uncover a causal link between neural activity and behavior. Although optogenetics offers innovative approaches to achieve this in a cell-type-specific manner with millisecond precision, it is still challenging to activate cell populations at multiple depths *in vivo*. Here we present two types of microscale light-emitted diode (μLED) array for *in vivo* optogenetic stimulation: sapphire-based and silicon-based μLED arrays. Probes were designed to contain up to 96 μLEDs, which are independently controllable and emit at 450 nm wavelength with an irradiance of up to 2 W/mm^2. To minimize tissue damage, especially the silicon μLED probe has a compact design, with 100 μm width and 30 μm thickness. Thermal properties permit standard operation regimes with minimum temperature increase (<0.5 °C). We confirmed that μLED probes can achieve depth-dependent activation of mouse neocortical neurons *in vivo*. Our devices offer a new optogenetic toolbox to achieve parallel control of neural populations at multiple depths *in vivo*.

Abstract: Optogenetic tools are revolutionizing neuroscience. They make it possible to remotely stimulate or inhibit firing of genetically selected neurons and brain regions and thus define their roles in brain circuits and behavior. Since the flow of information through neural circuits depends on synapses, an important next technological step is to bring optogenetic control to the neurotransmitter receptors that underlie synaptic transmission. Our new approach of Optogenetic Pharmacology makes this possible. Here we show that we can confer light-sensitivity on selected isoforms of the GABAa receptors by genetically-engineering the receptors to couple with synthetic Photoswitchable Tethered Ligands (PTLs). We validate in both *ex vivo* preparations and *in vivo* recordings from mouse brain the stable and repeatable photo-control of GABAa receptor-mediated synaptic inhibition. In brain slices, we show that we can photo-antagonize postsynaptic GABAa receptor currents by up to 60%. *In vivo* recordings from visual cortex show that photoswitching GABAa receptors caused a two-fold change of interneuron spike activities in response to visual stimuli. This new technology allows optical control of inhibitory transmission in the living brain for studies of synaptic mechanisms, neural circuit mechanisms, and behavior.

Title: The rhodopsin-guanylyl cyclase of the aquatic fungus Blastocladiella emersonii enables fast optical control of cGMP signaling

Authors: *C. E. GEE[1], U. SCHEIB[2], K. STEHFEST[2], R. FUDIM[2], H. KOERSCHEN[3], P. HEGEMANN[2], T. G. OERTNER[4];
[1]Inst. For Synaptic Physiol., Hamburg, Germany; [2]Humboldt-Universität, Berlin, Germany; [3]Ctr. of Advanced European Studies and Res. (caesar), Bonn, Germany; [4]Ctr. for Mol. Neurobio. Hamburg (ZMNH), Hamburg, Germany

Abstract: Blastocladiomycota fungi form motile zoospores that are guided by sensory photoreceptors to optimal light conditions. Recently, a single rhodopsin coupled to a guanylyl

cyclase domain was discovered in the genome of several members of this family (1). Here we show by heterologous expression that a codon-humanized version of microbial rhodopsin of *Blastocladiella emersonii* is indeed a rhodopsin-guanylyl cyclase (RhGC). Upon light absorption, RhGC (D525) converts in 8 ms after a light flash into a blue-shifted signaling state P380 and recovers within 100 ms. RhGC was well expressed, well tolerated, and rapidly produced cGMP in response to light in *Xenopus* oocytes and mammalian neurons. Rat hippocampal CA1 neurons electroporated with RhGC and the cGMP activated rat cyclic nucleotide gated channel (CNG A2) had normal morphology and electrophysiological properties. The activation spectrum obtained from rat hippocampal CA1 neurons expressing RhGC together with the cGMP activated CNG A2 channel had a maximum at around 530 nm (green light). Cyclic GMP production was light dose-dependent, rapid and reproducible. The light dose required for half-maximal activation in neurons was 1.5 mW mm^{-2}, which is close to the published value for channelrhodopsin of 1.1 mW mm^{-2} (2). Currents activated rapidly (time to onset 120 ± 30 ms) and could be repeatedly and reproducibly activated by short light flashes at 0.2 Hz. In the absence of the CNG A2 channel, almost no endogenous current was activated in CA1 neurons expressing RhGC when illuminated at 530 nm with 19.2 mW mm^{-2} (currents less than -20 pA). Thus, RhGC is poised to become a versatile tool for optogenetic analysis of cGMP-dependent signaling in neurons. 1. Avelar, G. Abstract: The Cre/loxP recombination system enables to investigate systemic function of targeted genes, and has been adopted to examine a function of specific gene. For *in vivo* experiments, rats offers potential advantages of larger body size and progressed ability to accomplish more complex behavioral task over mice. Here we evaluated two new transgenic rat strains. One shows strong expression of tdTomato ubiquitously in its whole body (Flame rat) and other is conditional reporter rat line which has a gene of bistable channelrhodopsin (ChR) in the downstream of loxP-flanked STOP cassette. Flame rats; Previously we established a reporter line, NBPR-0734 from three BAC Tg rats, carrying tdTomato gene in the downstream of floxed STOP cassette. By microinjection of Cre-mRNA into fertilized eggs of this reporter rat, two lines that expresses tdTomato ubiquitously were newly established (flame rats). Flame rats were examined its expression of tdTomato in any tissues including brain, lung, liver, spleen and other main organs, and all those were brightly fluorescent positive. Flame rats can be used as an ideal source for tissue/cell transplantation and also beneficial in cell lineage trace studies. They have been successfully deposited in National Bio-Resource Project for the Rat in Japan (NBPR-0789 and -0790). Bistable ChR reporter rats; ChRFR(C167A) is a new bistable ChR (step-function opsin, SFO) which is activated by blue-cyan light and deactivated by yellow-orange light, and is suitable for enhancing the intrinsic activity of neurons at a minimal magnitude of irradiance (Hososhima et al., 2015). ChRFR(C167A)-Venus was evidenced to be expressed conditionally with Cre gene which is virally introduced. This reporter rat line would facilitate the neurophysiological and behavioral studies. All animal procedures were conducted in accordance with the guiding principles of Physiological Society of Japan and NIH. Reference: Hososhima S et al. Title: Using optical activation to redefine gain modulation in detailed biophysical neuron models

Authors: *S. JARVIS[1], K. NIKOLIC[2], S. R. SCHULTZ[3];
[1]Bioengineering, [2]Inst. of Biomed. Engin., [3]Ctr. for Neurotechnology, Imperial Col. London, London, United Kingdom

Abstract: One of the key mechanisms for sensory, motor and cognitive processing within the brain is gain modulation, in which the amplitude of a neuron's response changes while its selectivity remains unaffected. However, as synaptic locations are located throughout the dendritic arbor and dendritic integration is non-linear, it remains unclear how gain is modulated as a function of competing excitatory and inhibitory dendritic input. For this purpose, optogenetics is well-placed to answer this as not only are opsins expressed throughout the dendrites, but also due to the fine temporal and spatial precision that optogenetics offers. Using models of opsins in combination with abstract and biophysically detailed neuron models, we redefine a neuron's gain by co-expressing excitatory (ChR2) and inhibitory (NpHR) opsins throughout the dendritic membrane as well as the soma. By providing external driving input in the form of current injection or as multiple synaptic-like events at multiple locations to mimic inputs for both *in vitro* and *in vivo* scenarios, we find that dendritic morphology strongly indicates a neuron's capacity for gain modulation in abstract models and confirm this in detailed biophysical models of cortical pyramidal cells (PC) and hippocampal stellate cells. In PCs, simultaneous activation in both apical and basal dendrites are necessary for modulating gain. Finally, we evaluate the effects on partial and graded illumination to mimic physical effects of optically illuminating tissue and find that light absorption can decidedly reduce the gain modulation. Consequently, we are able to identify improved experimental illumination strategies that are not only tailored to neuronal morphology but also able to account for this phenomena in modifying the illumination protocol, thereby increasing the robustness of optogenetics for the fine manipulation of neural activity.

Title: Progress towards high throughput, *in vitro* cell-type identification using coupled electrophysiological and morphological properties

Authors: *G. HOLST[1], W. A. STOY[2], I. KOLB[2], L. LI[3], U. KNOBLICH[3], S. B. KODANDARAMAIAH[4], S. A. SORENSON[3], H. GILL[3], T. JARSKY[3], J. WATERS[3], A. C. SINGER[4], B. YANG[2], G. T. FRANZESI[4], E. S. BOYDEN[4], H. ZENG[3], C. R. FOREST[2]; [1]Mechanical Engin., [2]Georgia Inst. of Technol., Atlanta, GA; [3]Allen Inst. for Brain Sci., Seattle, WA; [4]MIT, Boston, MA

Abstract: There are a number of neuronal cell type classification schemes based on analysis of transcripts, protiens, elepctrophysiology, connectivity, and morphologly although generally these are used independently and lack a one-to-one correspondence between them. We will present progress towards establishing a cell type scheme for layer 5 cells in the mouse visual cortex using coupled *in vivo*, visually-evoked, whole-cell patch clamp electrophysiology and morphological reconstruction on the same cell. We anticipate there to be correlation between the detailed electrophysiological identity and the morphology and connectivity fingerprint that informs the specific functional role of each cell type in the larger network processing of the visual cortex. Similar results in layer 6 cells (Velez-Fort et. al. 2014) have increased our understanding of their exact role and the interactions, and we anticipate there to be similar insights for cells in layer 5. These coupled electrophysiological and morphological experiments are, however, often quite difficult to perform due to low yields and low throughput. Previously, we developed the "autopatcher," an automated *in vivo* patch clamp robot for automatic neuron detection and whole cell recording. Here, we also describe additional robotic tools that enable the first autonomous serial patch clamp recordings. The robot can perform up to 40 fully automated serial recording attempts and compensates for cell health and recording quality in real-time. These tools allow the robot to run unattended for the duration of experiment and include algorithms for automated break-in, amplifier compensation, access resistance monitoring and improvement, and automated electrical and visual stimulation. It also includes electrical and mechanical hardware for pipette storage, filling, wire threading, aligning in the craniotomy, and pneumatic control. The combination of the hardware and algorithms significantly reduces time between trials and eliminates common operator errors resulting in an overall increased throughput and unattended operation.

Title: Oscillatory modulation of action potential firing in hippocampal neurons of awake mice via periodic shunting inhibition

Authors: G. TALEI FRANZESI[1], *A. C. SINGER[1], S. B. KODANDARAMAIAH[1], E. WU[1], B. ARKHURST[1], C. R. FOREST[2], C. BORGERS[3], N. J. KOPELL[4], E. S. BOYDEN[1]; [1]McGovern Inst. and Media Lab, MIT, Cambridge, MA; [2]George W. Woodruff Sch. of Mechanical Engin., Georgia Inst. Of Technol., Atlanta, GA; [3]Tuft Univ., Medford, MA; [4]Boston Univ., Boston, MA

Abstract: Neuronal oscillations are postulated to be fundamental to how the brain encodes, processes, and transmits information, and different oscillations identify distinct network states. Despite striking behavioral and field potential differences between these distinct network states, the cellular mechanisms through which oscillatory dynamics modulate neural firing are difficult to assess in awake, behaving animals. In particular, although inhibition is believed to play a crucial role in mediating the effects of several kinds of oscillations on neural activity, GABAergic inhibition can both shunt neural inputs as well as directly hyperpolarize the neuronal membrane potential, and thus there could be multiple cellular mechanisms by which oscillatory neural activity impacts neuronal firing. To probe these cellular mechanisms we recorded intracellularly in awake, headfixed mice navigating a virtual reality maze, employing a modified autopatcher robot capable of whole cell patch clamp recording in awake mice. As a model region we chose the hippocampal CA1 field, focusing on theta (6-12Hz) and gamma (30-80 Hz) oscillations. We found that intracellular dynamics changed with different network states and oscillatory phases, but, perhaps surprisingly, the membrane voltage did not display rhythmic fluctuations that mimic the local field potential oscillations, consistent with inhibition serving a rhythmic shunting, rather than hyperpolarizing, role. We are currently testing this hypothesis by using somatic current injection via the patch pipette to assess the degree of shunting inhibition

present during various phases of the oscillations. We are also working to create computational models to probe these phenomena. These results may offer new insight into the cellular mechanisms through which oscillations achieve their impact on neural activity in awake, behaving animals.

Title: Automated two-photon guided patch-clamp electrophysiology *in vitro*

Authors: *H.-J. SUK[1], I. VAN WELIE[2], C. FOREST[6], E. BOYDEN[3,4,5];
[1]Hlth. Sci. and Technol., [3]Media Arts and Sci., [4]Biol. Engin., [5]Brain and Cognitive Sci., [2]MIT, Cambridge, MA; [6]Bioengineering, Georgia Inst. of Technol., Atlanta, GA

Abstract: Two-photon guided patch-clamp is a powerful tool for studying properties of identified cells *in vivo*. By combining two-photon laser scanning microscopy with whole cell patch-clamp recording, it uniquely enables accurate localization and analysis of individual neurons in the intact brain. However, the complicated and laborious procedures of this technique require much skill and experience, making it difficult to perform in a high-throughput fashion. To address this issue, we have developed a strategy for a robotic system that can automatically complete the tasks involved in two-photon guided patch-clamp recordings, from target cell detection, pipette trajectory calculation and navigation to pipette resistance measurement, pressure modulation and holding voltage control, all of which will be initiated via an easy-to-use user interface. To enable automated imaging and detection of fluorescently labeled cells *in vivo*, we have built a Matlab-based custom module that can be easily integrated into ScanImage, the open-source software commonly used by electrophysiologists for image-guided patch-clamp recordings. The custom module can also automatically locate the tip of a pipette filled with a fluorescent dye and determine the optimal trajectory for the placement of the tip onto the target cell. As the pipette is navigated into the brain tissue by a computer-controlled micromanipulator, the pressure level inside the pipette is sequentially adjusted using the automated pressure box previously developed by Kodandaramaiah et al (2012) to prevent pipette blockage and to

minimize background fluorescence. Meanwhile, our system monitors the pipette resistance and identifies a physical contact between the pipette tip and the cell membrane by detecting a distinct rise in resistance. At this point, a closed-loop pressure and holding voltage controller will be activated for the formation of a gigaohm seal and the whole-cell configuration. By testing our automated patch-clamp strategy on fluorescently labeled parvalbumin-positive interneurons in the mouse cortex, we will optimize the experimental parameters to achieve high robustness of our robotic system. Once fully developed, our system has the potential to become a useful tool for skilled electrophysiologists as well as for those new to the field, as it can eliminate several laborious manual procedures. Furthermore, our system will be highly scalable as the code and algorithms for all of the automated procedures may be extended to multi-cell patch-clamp recordings.

Title: Human iPSC-derived neurons stably expressing a GCaMP3 calcium sensor demonstrate robust (and temporal) HTS capabilities

Authors: ***G. C. LUERMAN**[1], R. KETTENHOFEN[2], A. EHLICH[2], T. PALM[2], H. BOHLEN[2]; [1]Axiogenesis Inc, Plymouth Meeting, PA; [2]Axiogenesis AG, Cologne, Germany

Abstract: Human induced pluripotent stem cell-derived neurons provide a powerful preclinical cellular tool for predicting/modeling pharmacological behavior, especially as it relates to ion channel modulation, neurotoxicity, and network activity. The combination of high-throughput fluorescence detection technology (Hamamatsu FDSS 7000EX) with extracellular and intracellular calcium and/or voltage sensors permits the acquisition of fast calcium and voltage (transient) events. We compared the effects of multiple ion channel and neurotransmitter modulators, as well as neurotoxic compounds on commercially available iPS-derived dopaminergic and peripheral neurons either stably expressing a GCaMP3 calcium sensor or loaded with a calcium-binding dye (fluo-4). Results from acute ion channel block were comparable between the two methods of detection. However, temporal effects from chronic applications of chemotherapeutics or neurotoxic drugs (e.g. Vinblastine) were only able to be detected with the GCaMP3 sensor. In addition to ease of use, reproducibility, and scalability, these results provide strong rationale for the use of integrated calcium sensor technology in high throughput neuronal safety/toxicity or drug development studies.

Title: Testing the role of SK channels in frequency tuning with a novel dynamic clamp system for sharp electrodes

Authors: *H. POLDER[1], J. PRESERN[2], J. LOOSER[1], J. BENDA[2];
[1]npi electronic GMBH, Tamm, Germany; [2]Inst. for Neurobio., Eberhard Karls Univ., Tuebingen, Germany

Abstract: The dynamic clamp is a powerful closed-loop technique for intracellular recordings that allows one to introduce artificial membrane conductances into neurons in a graded manner, without pharmacology or genetics. So far, the method was limited to low-resistance (patch) electrodes, which are not suitable for all the cell types. Injecting current trough high-resistance sharp electrodes requires usage of a current-clamp amplifier in discontinuous mode, with high-frequency switching between current injection and voltage measurement. Because of the Nyquist theorem the switching cycle of the amplifier needs to be more than twice of the frequency of the dynamic clamp software loop. This can be a major limitation because such high switching frequencies might be difficult to achieve. We slightly modified the SEC-05LX amplifier (npi electronic GmbH, Tamm, Germany) such that its switching cycle is triggered by the dynamic clamp loop, thus halving the required switching frequency. Controlled by the RELACS software (www.relacs.net) this allows for sampling rates of up to 50 kHz. Potassium currents not only shape the afterhyperpolarization following action potentials but also modify their signal processing properties. For example, pyramidal cells (PC) of the three segments of the electrosensory lateral line (ELL) lobe of weakly electric fish receive identical input, but the presence of SK-type potassium currents in the PCs of one of the segments shifts their sensitivity to higher frequencies. We used this dynamic clamp system to introduce SK type potassium currents into superficial PCs of the centromedial segment lacking this current. This shifted the frequency tuning of the cells towards higher frequencies as in PCs of the lateral segment that express SK currents.

Title: HumSilencer: A smart and simple Axon Digidata 1550 series feature for eliminating line-frequency noises

Authors: *K.-C. TANG, B. BLIZARD, K. SRIDHAR, W. DANILO, B. MAERTZ, M. YOUNGQUIST;
Mol. Devices, LLC., Sunnyvale, CA

Abstract: Electrical hum is the most common source of background noise in electrophysiology experiments. It is caused by the alternating current (AC) of the electrical mains delivered via power outlets. This background noise can obscure the biological signals of interest, making analysis difficult, if not impossible. Typical methods for mitigating this type of electrical noise can be time consuming and are only partially effective. In this study, we examined the noise elimination performance of the newly developed Axon™ Digidata® 1550 series Low-Noise Data Acquisition System plus HumSilencer™ Adaptive Noise Cancellation. We found that HumSilencer removed 50/60 Hz interference within 50 ms after it was enabled. If the 50/60 Hz noise pattern changed, the HumSilencer rapidly adapted and subtracted the new noise pattern within one second. In addition, it eliminated noise amplitudes at the digitizer's analog input of up to 20 V, peak-to-peak. We also examined if the HumSilencer algorithm distorts acquired biological signals. Our results showed that it did not distort evoked end-plate potential and action potential analyzed parameters, such as, peak amplitudes, time of peaks, half-widths, rise times, rise slopes, decay times, decay slopes, and several others. More importantly, the HumSilencer was able to distinguish between 50/60 Hz noise that was caused by background interference and 50/60 Hz frequencies within the biological signal and only removed the former. Together, this evidence shows that HumSilencer provides a smart and simple way for background interference elimination and ushers in a new level of ease and confidence in electrophysiology data acquisition. HumSilencer is not a filter and does not have a filtering effect on acquired biological signals; nor does the HumSilencer system cause signal distortion, such as frequency change, amplitude attenuation, phase shift, or DC voltage change.

Title: 3d data mapping and real-time experiment control and visualization in brain slices

Authors: ***M. E. MILLER**[1], M. A. NAVARRO[2], J. V. K. HIBBARD[2], T. W. NIVIN[2], A. A. PETERS[2], L. S. MILESCU[2];
[1]Life Sci., [2]Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: We have designed software that streamlines electrophysiology and imaging experiments in brain slices and enhances data collection and analysis. The experiment is interfaced with a 3D scene viewer, where the rig, the brain slice, and the recorded data are represented to scale. Within this viewer, the user can visualize a live image of the sample and 3D renderings of the recording electrodes, with real-time position feedback. Furthermore, the user can control the instruments and visualize their status in real-time, and can reload previously executed experiments and run simulations. Multiple types of experimental data can be integrated into a spatial and temporal map of the brain slice. These data can consist of low-magnification maps of the entire brain slice, for spatial context, and any other types of high-resolution structural and functional images, together with time-resolved electrical and optical signals. The entire data collection can be visualized within the 3D scene viewer. These ideas can be applied to any other types of experiments where high-resolution data are recorded within a larger sample, at different spatial and temporal coordinates.

Title: Volume effect of localized injection on PO2, single unit activity, and fMRI

Authors: ***D. P. AKSENOV**[1], K. RUTILA[2], L. LI[1], M. MILLER[1], R. LINSENMEIER[2], A. WYRWICZ[1];
[1]NorthShore Univ. HealthSystem, Evanston, IL; [2]Northwestern Univ., Evanston, IL

Abstract: The local injection of neurotransmitter agonists and antagonists to modulate functions of neurons is a widely-used technique that avoids many of the confounding effects of systemic drug injections, which affect the whole brain and can change input to the recorded area of interest. Localized drug delivery in the brain is typically accomplished via either iontophoresis, reverse microdialysis or microinjection under pressure. Compared to iontophoresis, localized microinjection allows the delivery of larger volumes which can affect a much larger area of interest, but is often accompanied by mechanical displacement of the tissue, known as “volume

effect" (VE). VE can cause changes in oxygen tension (PO2), single unit recordings, and fMRI signal. This study describes the changes in these signals associated with VE, as well as an approach for minimizing these effects. fMRI data, single unit recordings, and oxygen tension measurements were performed to characterize the signal changes resulting from the local injection of artificial cerebrospinal fluid (ACSF) in the whisker barrel cortex of the rabbit. fMRI experiments were performed on a 9.4T Bruker BioSpec imaging spectrometer. Imaging data were acquired from four consecutive slices using single-shot gradient-echo EPI pulse sequence (TR=2s and TE=11ms). The slices included the whisker cortex and whisker thalamus. Single unit activity was recorded from the whisker barrel cortex using gold-silver wires, attached to a chronically implanted microdrive. To record PO2 changes an oxygen sensitive electrode was polarized to −0.7 V with respect to a silver-chloride reference electrode, and the current was measured with a Keithley model 614 electrometer. Our results indicate that combining local microinjection with fMRI, single unit recording, and PO2 is a feasible approach, but the technical issues particular to each technique require careful consideration. The localized injection can produce significant intensity changes in MR images in addition to effects on electrophysiological recordings, such as changes in waveforms and magnitude of the spikes. The fMRI changes are localized to the vicinity of the injection needle, and diminish over time due to diffusion of the injected volume. VE also affects the PO2 signal in a volume-dependent manner, and the changes were found to be long-lasting. Experiments involving local injections therefore should carefully consider the impact of VE in their design. Our results indicate that a slow speed of injection, limited volume and sufficient post-injection waiting period can significantly mitigate the effects of VE.

Title: Nonapplication of neuroscience data to medical treatment

Authors: *G. S. WASSERMAN;
Purdue Univ., W Lafayette, IN

Abstract: My life's work involved intracellularly recording sensory responses in single photoreceptor cells in *Limulus,* the horseshoe crab. Twice this work led to possible treatments for behavioral disorders. The first involved the invention of cochlear implants. Around 1980, Dr. Richard T. Miyamoto of Indiana U. Medical School came to Purdue and told us that implants

restored hearing to the deaf but they could not understand speech. I asked him how the implants coded sound and learned that they did it the way that hi-fi audio systems do -- by stimulating auditory nerves of the deaf with faithful electrical *copies* of physical sounds. I then showed him my recordings of the way sensory receptors temporally *dispersed* them. He then sent cochlear implant patients to my laboratory where I acoustically inserted temporal dispersion and response compression into the signal path. The result was *immediate* and *useful* comprehension of spoken language. Within a year, the incorporation of such modifications into cochlear implants enabled *legions* of sufferers to converse easily. This achievement was recognized by the award of a US Patent (Sensory Prostheses: US 4611596 A) and other honors. Years later, my last trio of graduate students (Amanda Bolbecker, Jia Li, and Corrinne Lim) reversed the line of investigation and began to examine the efferent neural signals that the brain sends *to* neural receptors. They found profound temporal effects of such efference: Substance P *speeds* receptor responses while Octopamine *slows* them. It was obvious that such efference allows the brain to adjust the temporal properties of its inputs so that they are appropriate for whatever external situation engages an organism's attention. About that time, a new tool was invented by Erich Sutter. It is the multifocal electroretinogram (mfERG) and it makes it possible to record retinal activity from a contact lens electrode placed on the eye. My understanding is that *hundreds* of mfERG system have been produced and, with funding from the NIH, are in the hands of many scientists in various institutions. I have spent more than a decade trying to get just *one* of these investigators to determine if changes in the behavioral attention of a person fitted with an mfERG system changes the pattern of activity in that person's neurovisual responses to well controlled stimuli. If that were true, it would lead to *new* ways of understanding and treating attention disorders and thereby aiding *millions* of sufferers. Not *one* investigator has *reported* undertaking *any* such investigation. Clearly *something* has changed quite radically in the culture of science in recent times.

Title: Voltage-gated calcium channels regulate neural precursor cell migration in the directed current electric field

Authors: *A. STEIGER[1], H. ZHAO[2], Z. BINDA[2], H. YE[2];
[2]Biol., [1]Loyola Univ. Chicago, Chicago, IL

Abstract: Effective stem cell transplantation is dependent upon the cells' ability to restore function after migration, differentiation, and integration with the host's damaged tissue. Taking a bioengineering approach, recent studies have attempted to use an electric field to guide neural precursor cell (NPC) migration (termed electrotaxis) and differentiation. However, the mechanism of NPC electrotaxis is largely unknown. Previous studies have documented that direct current (DC) electric field can guide the undifferentiated NPCs towards cathode migration, but not the differentiated cells (Babona-Pilipos et al., 2011). We propose that the difference between undifferentiated and differentiated cell migration is largely mediated by newly-expressed ion channels on the differentiated cells, particularly the voltage-gated calcium channels (VGCCs), which allows for calcium influx when the membrane is depolarized in the DC electric field. Western Blot analysis suggested the presence of L-type VGCCs in the differentiated cell population, but not in the undifferentiated NPCs. Immunocytochemical staining indicated the presence of L-type VGCCs on the differentiated neurons, but not the undifferentiated cells. Pharmacological blockage of the L-type VGCCs in the differentiated cells promoted neuronal migration toward the cathode. Taken together, these data elucidate the crucial role of VGCCs in EF-guided migration, and provide a potential ionic target for the control of stem cell migration under EF guidance.

Title: An automated patch-clamp platform (CytoPatch™) for neuronal ligand- and voltage-gated ion channels pharmacology and recordings in cell lines and dissociated neurons

Authors: T. KNOTT[1], *S. FRECH[1], O. SCHEEL[1], J. EISFELD[1], B. AMUZESCU[1], S. WIERSCHKE[1], J. KUDOLO[1], K.-H. LIN[1], J. WOLFART[2];
[1]Cytocentrics Biosci. GmbH, Rostock, Germany; [2]Oscar Langendorff Inst. of Physiol., Univ. of Rostock, Rostock, Germany

Abstract: In recent years, automated patch clamp has been established as a standard tool for drug discovery and screening in recombinant cell lines. However, when using primary or freshly dissociated cells, the seal quality and low signal-to-noise ratio is of high importance. The CytoPatch™ is a high performance cellular electrophysiology platform using an innovative Cytocentering™ technology based on quartz pipette tips embedded in a silicon microfluidic chip. The chip includes orifices and channels that capture cells in suspension and convey them to the pipette tip, allowing higher quality and stability gigaseals, using physiological external and

internal solutions. The low-volume microfluidic circuitry (100 nL perfusion chamber volume) ensures successful captures with only 150 cells/seal in 0.1 μL, reduced compound consumption (perfusion flow rates < 10 μL/min), and permits very fast wash-in and wash-out speeds. The system features fast signal sampling frequencies (10/20/40/80 kHz) and works in voltage- and current-clamp mode, with automated capacitive transient cancellation and series resistance compensation. Perforated whole-cell configurations are achievable, as well as several types of patch configurations. To demonstrate the performance of the system and suitability for neuroscience-related experiments, we present several examples of recordings in ligand-gated and sensory transduction neuronal-specific ion channels: activation by glutamate in 10-ms applications of GluA2 AMPA receptors transiently transfected in HEK293 cells (rise time < 3.2 ms), mechanosensitive stimulation (140 mbar/50 ms) of Piezo1 and 2 channels in cultured Neuro2A cells and inhibition by ruthenium red (90 μM), pH 6.0-evoked inward current transients by activation of ASIC1a/1b channels in HEK293 cells. We also present voltage- and current-clamp recordings in primary sensory neurons freshly dissociated from rat dorsal root ganglia, as well as recordings at different temperatures in dissociated rat anterior hypothalamic neurons. These results demonstrate the feasibility of complex *in vitro* electrophysiology automated patch-clamp assays with applications for advanced neurophysiology, pathophysiology and pharmacology studies.

Title: Glycine-induced currents are insensitive to the glycine receptor α1 subunit-specific blocker, cyanotriphenylborate, in older circling mice

Authors: *J. PRADHAN, SR[1], S. AHN[2];
[1]Kathmandu Ctr. For Genomics and Res. Laborat, Kathmandu, Nepal; [2]Physiol., Dankook Univ., Cheonan, Korea, Republic of

Abstract: The pharmacologic characteristics of glycine receptors (GlyRs) in the lateral superior olive (LSO) of circling mice, animal model for inherited deafness, were investigated using a GlyR α1 subunit-specific receptor blocker (cyanotriphenylborate [CTB]). There was a

statistically significant age-dependent increase in the antagonistic effect of CTB in heterozygous (+/cir) mice. In postnatal (P)0-P3 heterozygous (+/cir) mice, glycine currents evoked by glycine puffs were reduced to 20.4 ± 2.6, 37.1 ± 3.1, and 63.9 ± 2.5% at 0.1, 1, and 10 μM CTB (n = 13) compared to controls, while the glycine currents were reduced to 22.3 ± 3.5, 52.9 ± 4.1, and 78.3 ± 3.5% at 0.1, 1, and 10 μM CTB (n = 7) in P8-P12 heterozygous (+/cir) mice. In contrast, the antagonistic effect of CTB was not strong and even less than that of younger animals in older homozygous (cir/cir) mice. In P0-P3 homozygous (cir/cir) mice, the extent of inhibition was 20.2 ± 3.7, 37.8 ± 4.3, and 66.8 ± 4.2% at 0.1, 1, and 10 μM CTB (n = 6) compared to controls, while the extent of inhibition was 18.7 ± 2.4, 28.1 ± 3.9, and 39.1 ± 8.2% (n = 6) in P8-P12 homozygous (cir/cir) mice. The age dependent decrease in the antagonistic effect of CTB indicates the abnormal development of the α1 subunit-containing GlyRs in homozygous (cir/cir) mice.

Title: Fluorescent nanodiamonds: a novel tool for detecting neuronal activity

Authors: *A. M. MONACO[1], J. MOTYLEWSKI[1], S. K. R. SINGAM[2], E. GOOVAERTS[2], M. GIUGLIANO[1,3,4];
[1]Dept. of Biomed. Sci., [2]Dept. of Physics, Univ. of Antwerp, Wilrijk - Antwerpen, Belgium; [3]Brain Mind Institute, Swiss Federal Inst. of Technol. Lausanne, Lausanne, Switzerland; [4]Dept. Computer Sci., Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Understanding the complex phenomena underlying specific brain functions has always been a challenge for neuroscientists. Recently, the new discoveries in the field of Nanotechnology provided researchers with novel tools that allow studying the brain on its own scale. One of the most fruitful results of this new interdisciplinary approach is the use of carbon-based nanomaterials as nanostructured substrates for cellular growth and regeneration, as labels for cellular imaging and as nanoscale electrodes. However, these applications find limitations in their spatial and temporal resolution, as well as in their invasive character, and this calls for the

development of non-invasive techniques, which allow localizing brain structures on the order of micrometres and measuring neural function on a temporal scale of few milliseconds. To overcome these limitations, we are exploiting the use of Nitrogen Vacancy Nanodiamonds (NV-NDs) to directly evaluate the local electromagnetic fields generated by neuronal activity by means of spin sensitive photon detection. These Nanodiamonds, in fact, are one of the most powerful sensors of magnetic field, thanks to the high sensitivity of the electron spin states of their Nitrogen Vacancy centres to light and to magnetic field. Here we present preliminary results on incubating NV-NDs with primary cortical neurons. Firstly, we evaluated viability of neurons when incubated with NV-NDs, finding that NV-NDs do not affect neuronal viability and morphology compared to conventional glass coverslips. We then studied, by means of DIC and fluorescence microscopy, the localization of these NV-NDs with respect to living neurons, in presence and in absence of a magnetic field, in order to vary the fluorescence of the NV centres. These encouraging preparatory results are fundamental for the forthcoming electrophysiological testing of contingent effects of NV-NDs on neuronal electrical activity and for optical quantum imaging, which will allow a contactless mapping of neuronal activity by monitoring weak electromagnetic field in neurons.

Title: Connectivity analysis of whole-network recordings obtained by a high-spatiotemporal-resolution microelectrode array

Authors: ***J. MUELLER**, D. J. BAKKUM, A. HIERLEMANN;
ETH Zurich, Basel, Switzerland

Abstract: To investigate the plasticity of ensembles of multiple neuronal cells over time requires means to quantify the strength of many synaptic connections. The traditional method to assess synaptic strength relies on paired patch-clamp recordings, which is difficult to do for many pairs at the same time. Instead, functional connectivity in a neuronal network has been inferred by analyzing the relative timing of extracellular action-potentials. Recently, various algorithms to infer such functional connectivity have been proposed. However, most of these algorithms can

only approximate connectivity because conventional microelectrode arrays drastically under-sample network activity. Here we utilize a recently developed high-density microelectrode array (MEA), based on complementary-metal-oxide semiconductor (CMOS) technology, to record from potentially every neuron in a small cultured network. The microelectrode array features 26,400 platinum microelectrodes (5×9 μm^2), arranged in a grid-like configuration of 3.8×2.1 mm^2 area at a center-to-center pitch of 17.5 μm. An array of switches and wires residing below the electrodes is used to connect a subset of these electrodes to 1024 low-noise readout channels (2.4 μV_{rms} noise in the action-potential signal band, 300 Hz - 10kHz) and 32 dual-mode voltage and current stimulation units, all residing at the periphery of the electrode array. The electrode-to-readout channel routing can be reconfigured within milliseconds to adapt the electrode selection to the neuronal culture under study and to scan neural activity on all electrodes. Signals are sampled at 20 kHz and 10-bit resolution through on-chip analog-to-digital converters. Low-density cultures of dissociated E18 rat cortical neurons were grown on top of the MEA. Experiments were started after 2 weeks of culturing. First, the entire array was electrically scanned to find neurons that exhibit spontaneous action potentials, and to identify all putative single cells in the culture. Once all cells have been identified, 1024 electrodes that captured electrical signals from neurons were selected in a second step to record activity over several hours. The large number of tightly packed microelectrodes, together with the low-noise recording amplifiers, enabled us to identify up to about a thousand single cells and to record their activity over days and weeks. By confining the growth of neurons to the electrode area, potentially every spike from every neuron and the connectivity throughout the whole network can be investigated.

Title: Neurophysiological investigation of spontaneous BOLD fluctuations in the orbitofrontal cortex and anterior temporal lobe

Authors: *M. J. SUTTERER[1], C. K. KOVACH[2], P. E. GANDER[2], M. A. HOWARD, III[2], M. W. VOSS[3];
[1]Dept. of Neurol., [2]Dept. of Neurosurg., [3]Dept. of Psychology, Univ. of Iowa, Iowa City, IA

Abstract: Resting-state functional connectivity (RSFC) in fMRI has been demonstrated to be a powerful tool for noninvasive brain mapping, showing particular utility in imaging clinical populations. Despite this, limitations of standard BOLD imaging apply, including issues of signal dropout in temporal and orbitofrontal cortex. Concerns about signal dropout in these areas have limited large scale efforts to characterize the connectivity properties of the human brain, with the properties of the orbitofrontal and anterior temporal lobes largely ignored. More focused studies of intrinsic brain networks have identified both the orbitofrontal cortex and the anterior temporal lobes as important nodes in the default mode network (DMN), and altered connectivity in these nodes of the DMN has been characterized as a feature of several neurological and psychiatric disorders. To better understand the neurophysiological properties of spontaneous BOLD fluctuations in these regions, we investigated the concordance of resting-state BOLD connectivity in the orbitofrontal and anterior temporal lobe with oscillations in high-gamma power in a series of patients who were implanted for intracranial electrocortiography (ECoG). Each patient was implanted with 100-256 surface grid and penetrating depth electrodes, including multiple contacts covering the orbitofrontal cortex, the anterior temporal lobe, amygdala, and hippocampus. All patients completed 12 minutes of resting-state fMRI imaging prior to electrode placement, and at least 10 minutes of resting-state ECoG recording. For each patient we generated spherical seed regions of interest corresponding to each electrode contact (registered to MNI space) and extracted for each contact the low-frequency ($0.008 < f < 0.08$) BOLD time-series, and the low-frequency ($0.01 < f < 0.1$) oscillation in high gamma (70-150 Hz) power. We organized the resultant BOLD and ECoG correlation matrices using the Infomap clustering algorithm, and examined the correlation between the ECoG and BOLD connectivity matrices. We observed significant correspondence ($p < 0.05$ under permutation test) between the correlation patterns of spontaneous BOLD fluctuations and low-frequency oscillations in high-gamma power in contacts in the orbitofrontal and anterior temporal lobe similar to that observed in other regions of the brain ($0.3 < r < 0.7$). This correspondence persists even after accounting for the linear distance between contacts. These data support the neurophysiological basis of fMRI-based resting state connectivity in the orbitofrontal cortex and anterior temporal lobe.

Title: Fast-scan cyclic voltammetric measurements of stimulation-induced dopamine release with chronically implanted carbon fibers in awake non-human primate

Authors: *H. N. SCHWERDT[1,2], H. SHIMAZU[2], K.-I. AMEMORI[2], S. HONG[2], J. C. SY[1], K. C. SPENCER[1,3], P. L. TIERNEY[2], Y. YANG[1], H. YERRAMREDDY[2], C. DAGDEVIREN[1], K. RAMADI[1], R. S. LANGER[1], M. J. CIMA[1,3], A. M. GRAYBIEL[2];

Abstract: Measurement of rapid changes in dopamine concentration via fast-scan cyclic voltammetry (FSCV) has transformed current understanding of neurotransmitter dynamics and their relation to neuronal electrical signaling events. These phenomena are intimately related to motor and neuropsychiatric disorders. Continuous and rapid sampling of neurochemicals may be used in the future as a diagnostic tool and also to improve therapeutic measures for Parkinson's disease and many other disorders. As a first step toward this goal, we used FSCV to measure striatal dopamine in an awake rhesus macaque from carbon fiber microelectrodes (CFMs) implanted in the caudate nucleus for over a month. Polyacrylonitrile-derived carbon fibers 7 μm in diameter and cut to exposed lengths of 100 - 250 μm were used as the electrochemical sensing interface. A triangular voltage waveform was applied at −0.4 V - 1.3 V at 400 V/s every 100 ms while recording current produced at the CFMs. Phasic dopamine release was evoked by targeted medial forebrain bundle (MFB) stimulation, as commonly used to assess sensitivity of CFMs to dopamine in rodents. MFB stimulation was generated at 60, 120, and 200 Hz, for 11 - 48 biphasic 1 ms pulses, and with amplitudes of 50 - 400 μA. Local striatal stimulation also produced dopamine signals as recorded by CFM tips 500 μm away. MFB stimulation was shown to reproducibly evoke dopamine release in both the caudate nucleus and putamen over a depth of ca. 0.9 mm through the MFB as measured across separate acute recording sessions spanning several days along with recordings 1 month post-implantation. The chemical selectivity of the measurements was evaluated via principle component regression as well as by chemical modulation (0.05 - 0.1 mg/kg intramuscular injections of the D2 receptor antagonist, raclopride). Only signals with signal-to-noise ratios > 7 and correlation coefficients (r) > 0.75 were considered to reflect changes in dopamine concentration. Raclopride induced up to 230% and 130% amplification of the peak stimulation-induced dopamine oxidation current from both the acutely implanted and month-long implanted CFMs, respectively. The frequency of endogenous (non-stimulation evoked) dopamine transients recorded by the CFMs was also compared before and after raclopride in both the acute and chronic settings. Collectively, these experiments demonstrate the robust measurement of rapid changes in dopamine from the striatum over prolonged periods in the non-human primate.

Title: Self-rolled-up 3D microtube arrays for enhanced control and guidance of hippocampal neurons in synthetic circuits

Authors: *O. V. CANGELLARIS[1], P. FROETER[2], X. LI[2], M. U. GILLETTE[3];
[1]Bioengineering, Univ. of Illinois, Urbana, IL; [2]Electrical and Computer Engineerinig, [3]Bioengineering, Cell and Developmental Biol., Univ. of Illinois, Urbana-Champaign, IL

Abstract: Directing neurons to form pre-determined circuits is a fundamental goal of neuroengineering with the intention of treating neurological disorders and neurodegenerative diseases. Until recently, only aggregate populations of neurons were able to be studied and characterized in culture. Through the use of a novel arrayed platform of strain-induced self-rolled-up 3D architectures, we are able to measure and provide new insights into mechanisms driving organization of neuronal architecture at the level of a single cell [1, 2]. The array elements, transparent microtubes (2.7-4.4 m diameter), are formed using an ultrathin silicon nitride (SiNx) film that attaches to transparent substrates under conditions that control the size, site, and pattern of the array. Furthermore, functionalization of this substrate with electrodes allows for local application of electric fields (EFs) to accomplish precise manipulation of the directionality and growth patterns of neurons. In order to establish a baseline for the alignment imposed by the topography of the non-powered (inert) microtubes, we cultured hippocampal neurons from post-natal day 1/2 Long Evans BluGill rats at low-density (~250 cells/mm^2) and developed a method for quantifying the degree of alignment. Compared to control substrates, the neurites were significantly more aligned toward the zero degree reference on the inert microtubes. We then studied neuron growth on powered microtubes to determine how the presence of EFs enhances alignment beyond that imposed by the topography. These interactions will inform future experiments for optimization of the stimulation parameters and platform

geometry in order to tune our control over neuron growth. Application of this technology will enhance our ability to construct intentional neural circuits through array design and manipulation of individual neurons, and can be adapted to address challenges in neural repair and neuroregeneration, such as reinnervation. Title: Target-specific modulation of descending prefrontal cortical inputs to the dorsal raphe nucleus by endocannabinoids

Authors: *S. D. GEDDES[1,2], S. ASSADZADA[1], D. LEMELIN[1,2], A. SOKOLOVSKI[1,3], R. BERGERON[3,1], S. HAJ-DAHMANE[4], J.-C. BEIQUE[1,2,5];

Abstract: The serotonin (5-HT) system has long been implicated in mood regulation. The coding features of 5-HT neurons *per se* are however complex and multifaceted and it has historically been difficult to capture them in a simple and unifying framework. At least part of this complexity likely arises from the sole nature of the synaptic network in which 5-HT neurons are embedded. Indeed, the dorsal raphe nucleus (DRN), where the majority of 5-HT neurons reside, receives strong innervation from a vast array of subcortical and cortical regions. It has further been historically difficult to study in isolation these descending inputs in order to identify with precision how they modulate the excitability of the DRN subnetwork. For instance, the medial prefrontal cortex (mPFC) sends long-range axons to the DRN but the basic processing features of this input to the DRN is still elusive. The details of this top-down control from the mPFC to the DRN are of particular interest, in part because of its role in stress processing and in mediating antidepressant-like effects. Here, using a combination of immunohistochemistry,

optogenetics and electrophysiological whole-cell recordings we dissect out the functional properties of the mPFC-DRN projections. We found that the mPFC inputs to the DRN: 1) are glutamatergic; 2) mono-synaptically activate both 5-HT neurons and local GABA neurons located primarily in the lateral wings of the DRN; 3) are permissive to strong feedforward inhibition; 4) are modulated by endocannabinoids. We further identify a target-specificity in the CB_1R-mediated neuromodulation of mPFC inputs to the DRN that results in a powerful gating of PFC information flow in the DRN by favoring the direct excitatory drive to 5-HT neurons at the expense of the feedforward inhibition. The precise elucidation of how information flow is dynamically regulated by neuromodulators in this mood-related network may lead to the development of informed pharmacological strategies for the treatment of affective disorders.

Title: Neck collar: A novel non-invasive system for restricting head and body movements in rats for behavioral task performance and simultaneous neuron activity recording

Authors: *Y. TATEYAMA, K. OYAMA, C. LO, T. IIJIMA, K.-I. TSUTSUI;
Div. Sys Neurosci, Tohoku Univ, Grad Sch. Life Sci., Sendai, Japan

Abstract: In behavioral neuroscience, it is necessary to restrain movement of the head and/or the body of the animals in order to reduce movements irrelevant to the behavioral task. In monkeys, fixation of the head has been a major technique in behavioral neurophysiology. On the other hand, in rodents, most behavioral experiments have been conducted under freely-moving condition. While there is an increasing importance of rodents as a model subject in modern systems neuroscience following recent advancements in molecular biological techniques, there is still a gap between data obtained from head-fixed monkeys and freely-moving rodents. In order to fill this gap, it is necessary to conduct behavioral physiological experiments in rodents under head-fixed condition. However, head-fixation requires surgical procedures to implant the head-fixation device onto the animal's skull, which essentially induce risks of intracranial infection, or necrosis and softening of the bone. Therefore, a head-fixation method that does not require the surgical procedure would be useful. In this study, we developed a novel "neck collar system" for restricting head and body movements during the performance of the behavioral task and simultaneous neuron activity recording. We trained rats to perform a delayed response task, in which rats were required to lick a spout toward the remembered visual cue or away from it after

a delay period with neck collar system. We also conducted single-unit recordings with implanted multi-wire electrode in the medial prefrontal cortex from two rats which were trained in the delayed pro-licking task. We successfully recorded the single-unit activity from the neck-restrained rats with low noise. These results suggest that this system can be used in a wide range of behavioral experiments, including electrophysiological recordings.

Title: Novel *in vitro* assay of embryonic stem cell-derived neural network properties

Authors: *J. R. GAMBLE, S. SAKIYAMA-ELBERT, D. L. BARBOUR;
Biomed. Engin., Washington Univ. In St Louis, Saint Louis, MO

Abstract: Recent stem cell transplantation therapies for spinal cord injury (SCI) have elicited encouraging though limited improvement in motor and sensory function using spinal cord neural progenitors and embryonic stem cells (ES). This recovery appears to be promoted through various mechanisms, including the creation of new spinal circuits 1) externally, between grafted neuronal populations and the endogenous host circuit, and 2) internally, within the transplant. Current assays of transplant efficacy in animal models of SCI include gross measures of electrophysiological input/output, as well as molecular quantifications of graft neurite outgrowth and synapse formation. Missing is any assessment of the functional connectivity within the graft network, owing to the insurmountable challenges making these measurements *in vivo*. This shortcoming poses a significant barrier to designing effective SCI therapies because functional interactions involving transplanted ES-derived neuronal populations will greatly affect the transmission of activity through the transplant. We have developed a novel high-throughput *in vitro* assay combining ES technology and microelectrode array (MEA) platforms to study functional connectivity of candidate neuronal populations directly for the first time. To induce transplant candidate populations enriched for Chx10-expressing V2a interneurons, which are excitatory and ipsilaterally projecting spinal cord neurons *in vivo*, mouse RW4 ESs were subjected to an appropriate 2-/4+ protocol *in vitro* prior to being dissociated and cultured on 60-channel MEAs. Recorded spike waveforms were sorted offline using thresholding, principal components analysis and k-means clustering. After two weeks in culture, neural network activity

revealed two regimes of activity: synchronized network bursting and spontaneous random firing. Different patterns of putative neuron-neuron connectivity, including monosynaptic and disynaptic connections, were inferred from spike-sorted activity using spike-time cross correlation histograms. The ability to monitor various types of synaptic connections simultaneously across a candidate transplant population has multiple implications: 1) the strength and category of connections can be monitored during manipulations such as electrical stimulation 2) the neurotransmitter(s) underlying these connections can be identified with the use of specific neurotransmitter antagonists and 3) network formation and remodeling can be monitored over extended time periods. These outcomes are essential for rationally improving transplantation therapies for SCI.

Abstract: Complex behaviors rely on coordinated firing of neurons in local networks which are dynamically regulated by neuromodulators such as dopamine. However, tools for simultaneous monitoring of neural assemblies and dopamine dynamics have not previously been developed due to difficulties in integrating electrophysiological and electrochemical hardware. We have engineered a measurement platform capable of tandem measurements of dopamine and neural activity. This platform consists of high-density electrode arrays for measurement of single-neuron activity and local-field potentials in conjunction with a separate carbon electrode for measurement of real-time dopamine release using fast-scan cyclic voltammetry. Electrochemical instrumentation was improved to allow a common reference to be utilized for both electrophysiological and electrochemical measurements resulting in a higher signal-to-noise ratio for all measurements. To prevent damage to sensitive instrumentation, current between the

implanted electrodes and the neural recording amplifier circuitry is interrupted during the application of the voltammetric waveform. *In vitro* testing was carried out in a porcine gelatin to mimic brain conductivity and 500 μV sine waves with various frequencies (10 - 3000 Hz) near the electrode array) to simulate neural oscillations. It was found that all frequencies tested were rapidly recovered following resumption of neural recordings in relation to the time between waveforms (200 ms).

Title: Isoflurane dose dependent functional connectivity in the rodent somatosensory cortex

Authors: ***M. NEZAFATI**[1], J. C. W. BILLINGS[2], W. PAN[1], S. D. KEILHOLZ[1]; [1]Biomed. Engin., Georgia Inst. of Technology/Emory Univ., Atlanta, GA; [2]Emory Univ., Atlanta, GA

Abstract: Resting state functional connectivity measurements are sensitive to network alternations caused by neurological and psychiatric disorders. Multimodal studies in animal models help us to understand the basis of these connectivity measurements so the alternations in humans can be interpreted and potentially used for diagnosis or treatment. Local field potential measurements provide a picture of brain function undistorted by hemodynamic filtering. Although utilizing anesthetic agents is inevitable to study the animal models, their effect on the functional connectivity of the brain networks is still unknown. We examined correlated LFP power as a function of sedation depth to characterize functional connectivity in a dose-dependent measure. Male Sprague Dawley rats weighing 200-210 g were acclimated to the operational environment for 10 days prior to the recording day using a custom restraining set up and time frame designed to reduce animal stress during data acquisition. To avoid pain, Lidocaine paste was applied to the sites of mechanical restraint and those exposed during surgery. The animal was anesthetized using 2% Isoflurane for electrode implantation. Interhemispheric connectivity measurement was performed using vertical implantation of Ag/AgCl microelectrodes at the bilateral sites of primary somatosensory of the forelimb. The anesthetic concentration was reduced by the factor of 0.3% every 45 minutes till it reached 0.5%. The data was collected every 10 minutes at the rate of 1000Hz for 420 seconds. The animals' physiological parameters were

monitored during the experiment no sign of struggle or stress was observed even at very low doses. The acquired data shows significant correlation among the bilateral regions of somatosensory cortex that increased in proportion to the concentration of anesthetic agent. These findings are in agreement with BOLD -LFP based measurements made by Pan et al [1] and shows that the change in correlation has a neural origin and is approximately linear even at very low doses. Title: Understanding frequency dependencies in transfer entropy estimates

Authors: *S. E. ROBINSON[1], A. J. MANDELL[2];
[1]MEG Core Group, NIH/NIMH, Bethesda, MD; [2]Psychiatry, Univ. of California San Diego Sch. of Med., La Jolla, CA

Abstract: We have applied a unique temporo-dynamic symbolic transfer entropy (tdSTE) analysis to a MEG recording of normal subject performing a working memory (n-back) task, in order to determine if directional information transfer is distributed uniformly across all frequencies. Data were acquired from a 275-channel instrument (CTF Systems, Inc.) at a sample rate of 1200 Hz in a bandpass of DC-300 Hz. A comb-notch filter removed 60 Hz and its harmonics. Data consisted of 18 blocks of 25-seconds duration, alternating among 0, 1, and 2-back tasks. Transfer entropy (TE) was estimated independently for each of the tasks for 5-50 Hz,

50-100 Hz, 100-150 Hz, 150-200 Hz, 200-250 Hz, 250-300 Hz, and 50-300 Hz. TE magnitudes were lowest for the 5-50 Hz bandpass, peaked at 150-200 Hz (375 mbits/sec), and then rose sharply at 250-300 Hz (see figure, for example). Rhythmic activity and oscillations reduce the TE estimates, explaining why the 5-50 Hz band had the smallest TE values. At the highest frequencies one would expect TE to be smallest due to the declining signal-to-noise ratio. However, the observed sharp rise in TE for the 250-300 Hz (as large as 1,100 mbits/sec) suggests that multi-unit activity rather than local field potentials dominate this frequency range. This was tested against empty MSR data to determine if this was due to instrumental noise. Differences in information transfer for each of the n-back tasks could be observed for all frequency ranges, including the 50-300 Hz bandpass. In conclusion, we caution that TE estimates should not be interpreted as measures of absolute connection strength.

Title: A millisecond short-latency reprogrammable silicon chip solution for the pre-processing of electrophysiological data: Towards a real-time closed-loop approach

Authors: L. S. MONDRAGON[1], N. OUARTI[2], *E. BURGUIERE[3];
[1]Brain and spine Inst. - UPMC – INSERM U1127 – Pitie-Salpetriere Hosp., PARIS, France;

Abstract: Closed-loop electrophysiology systems require to detect and respond to neural events within short and strict timing constraints of millisecond range. Currently, this approach has been mainly performed in processor-based systems with the major inconvenient that algorithms are executed under general purpose operating systems that are sensitive to dispatch latency variability. Thus, to improve the closed-loop system approach, there is a necessity to develop a platform that improves the throughput from neural data streams to signal processing within well-controlled short time limit. These new systems would open a wide possibility for accurate closed-loop experimentation and brain-computer interfaces. To address this question we used a field-programmable gate array (FPGA) to propose a modular design for automatic fast pre-processing, including artifact removal and action potential detection. Designs were carefully optimized by implementing low-memory algorithms to reduce time response below a millisecond range. Here, we present a design that has been tested using intra- and extra-cellular *in vivo* recordings, and synthetic data. This design has been validated with a set of performance indicators that confirm the feasibility of hardware implementation of this system. The benefit of this approach makes it suitable for time-critical tasks such as online closed-loop optogenetic interventions, as the artifact removal module avoid false positives in action potential detection within sub millisecond processing time. By taking advantage of FPGA parallelism and the short latency of this approach we discuss the possibility of adding other data processing modules. As an example, we will discuss the pertinence of an automatic pattern recognition standalone module to discover biomarkers related to behavioral events in a mouse model of obsessive compulsive disorders.

Title: Whole-brain, sub-second data collection with little cost using simultaneous multi-slice/multiband acquisition in task-evoked fMRI

Authors: *S. A. MCMAINS[1], R. M. HUTCHISON[1], R. W. MAIR[1,2];
[1]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA; [2]Dept of Radiology, Harvard Med. Sch., Athinoula A Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: Slice-accelerated EPI using multiband (MB) RF pulses that allow for simultaneous multi-slice (SMS) acquisition of BOLD contrast images can significantly enhance the temporal and spatial resolution of fMRI by acquiring up to 8 non-contiguous slices at the same time, thus enabling whole-brain sub-second TRs. Here we studied visual cortex response at a variety of MB accelerations and TR reductions to investigate whether there were any costs associated with parameters that allowed for whole-brain, sub-second data collection at 2mm resolution. 6 subjects were scanned (3.0T Siemens Tim Trio) with a 32-ch head coil while they performed a fixation task and blocks of flashing checkerboards were presented to alternating visual fields. BOLD scans were acquired at 3mm and 2mm isotropic resolutions, a max TR of 3s, and MB accelerations of 0 (conventional BOLD sequence), 1 (MB sequence, no acceleration), 4 and 8 (Siemens WIP 770A). Beta and t-statistics were extracted from regions localized with a separate scan in visual cortex. With a TR of 3s, there were 91 timepoints, while for TR= 1.25/0.75/0.7s, there were 184/307/328 timepoints. There were no significant differences in betas for any parameters, or in t-statistics for levels of MB when holding the TR constant. Shortening the TR increased t-statistics significantly. This advantage was reduced when temporal autocorrelations in the noise were modeled. An event-related study was also conducted for 2mm voxels to compare 3s TR (MB1) versus 750ms TR (MB8). Betas were larger for the MB8 scans, likely due to improved characterization of the hemodynamic response, even though stimulus onset was jittered to the TR. The results suggest that whole brain coverage with high spatial and temporal resolution can be achieved using SMS with little to no cost in terms of BOLD signal sensitivity, as measured by betas and t-statistics, even though time-series SNR decreased significantly at high MB factors.

Title: Point source networks: relationship between dynamics of cortical/sub-cortical neuron firing and regional cortical imaging in mouse cortex

Authors: *D. XIAO[1,2], M. P. VANNI[1], A. CHAN[1], A. C. CHEN[2], T. H. MURPHY[1];

Abstract: A more complete understanding of brain function will require measurement techniques which monitor large-scale neuronal activity across multiple brain areas and relate this to single neuron properties. We present a step towards achieving this aim: by simultaneous *in vivo* recording of cortical/subcortical single unit activity while wide-field cortical imaging during spontaneous activity. We use glass pipettes to record single unit activity in target sites, and use wide-field cortical imaging (GCaMP) to determine large-scale neuronal activity. By employing spike-triggered averaging we established temporal relations between single neuron firing and regional cortical calcium imaging. We apply the method in cortex and establish expected regional maps that are associated with spiking activity at single cortical points. Extension of the electrophysiological assessment to sub-cortical structures permits the relationships between these regions and maps of cortical activity to be determined. We find that unique wide-field regional cortical calcium imaging patterns are highly correlated with spiking activity from single neurons. Spike evoked maps should be useful for assessing the functional relationship between single neurons and wide-field activity in *in vivo* models of neurological disease.

Title: The use of thomas electrodes and traditional tetrodes in an *in vitro* reloadable hyperdrive

Authors: *M. KESLER, H. STEENLAND, K. LIN, B. L. MCNAUGHTON;
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Electrode technology for extracellular multi- and single- unit recording typically involves either rigid single wire electrodes which can penetrate both deep and superficial structures or nichrome tetrodes which have an excellent ability to isolate neurons for long periods of time but tend to lack structural rigidity. Thomas quartz-glass electrodes possess both structural rigidity and potential tetrode configurations to better isolate neurons from both superficial and deep cortical layers. While these electrodes have been on the market for some time, their use has limited due to their cost and inherent difficulties in their preparation. Moreover, there are no reports for the use of these electrodes in high-density hyperdrives. Here, we standardized a protocol for the use of Thomas single electrodes and tetrodes in high-density

Kloosterman-style hyperdrives. We find that quartz glass electrode material costs could be cut in half by simply tapering electrodes with fused/molten sodium hydroxide and beveling them with a grinder. We also show that sodium hydroxide is an excellent etchant to remove the insulation from the electrode so that electrical contact can be made. Furthermore, we present a flexible connection and new design for an electrode interface board to permit easy connection and disconnection from recording electronics. Flex connectors also permitted replacement of defective electrodes from a hyperdrive and subsequent replacement in an awake unrestrained rat, extending the life and quality of recordings. We also present data which show that single Thomas electrodes can penetrate rat dura matter and in some cases bone window for high quality recording of both superficial (i.e. cortex) layers and deep brain structures (e.g. ventral tegmental area and reuniens nucleus), with stability over multiple days. Furthermore, Thomas electrodes were also found to be ideal for reliably detecting high-amplitude positive spikes (HAPS) (as previously described by Gold et al., JNP, 2009 and Guld, Med. Elect. Bio. Engng. 1964) and so they offer insight into the identity of these rare cells.

Abstract: One of the main obstacle to decipher the information processing and the neural communication in the brain is the lack of any experimental technique which is able to measure

the spatio-temporal distribution of synaptic currents on individual neurons in freely behaving animals. Thus, we developed a new micro electric imaging technique, which is able to determine the currents flowing on single hippocampal, neocortical or thalamic neurons during action potentials based on the extracellular electric potentials recorded by micro electrode array. We have shown the differences of cell-type specific input current patterns preceding and causing the action potentials during different oscillatory states of hippocampus. The layers and subfields of the hippocampus have been identified based on the recorded electrical signals, by using our electroanatomy concept and latter verified by histology. The types of the extracellular recorded and clustered cells were determined based on their electrophysiological characteristics and their spatial tuning. Analyzing the temporal dynamics of the cell type specific micro-field potentials we have found, that the onset of the synaptic currents preceding the action potential was the shortest in the CA1 region: 8.9 and 11.4 ms for pyramidal and interneurons respectively). We have found longer onset times in the dentate gyrus (12.4 ms for granular cells and 16.7-31.2 ms for interneurons). Finally, the longest onset times were found in the CA3 pyramidal neurons (40 ms), while the onset times of the interneurons were shorter in this region (7.6-21 ms). As the dynamics of the total synaptic current is depending on the natural statistics of the synaptic activations, measuring the temporal aspects of net synaptic currents could lead to better understanding of the neural code, by refining our knowledge about the input-output transformation implemented by the neurons.

Title: The open ephys gui: Plugin-based software for high-channel-count electrophysiology

Authors: *A. CUEVAS LOPEZ[1], Y. A. PATEL[2], J. VOIGTS[3], J. H. SIEGLE[4];
[1]Dept. de Ingeniería Electrónica, Univ. Politècnica De València, Valencia, Spain; [2]Georgia Inst. of Technol., Atlanta, GA; [3]MIT, Cambridge, MA; [4]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Software for acquiring extracellular electrophysiology data should ideally be robust, scalable, and easy to extend. To meet these requirements, we have developed the Open Ephys GUI, an open-source graphical user interface for processing electrophysiology data based on a plugin architecture. Essential functions for electrophysiology experiments, from filtering to spike detection to visualization, are encapsulated within discrete modules, which can be compiled separately from the base application. The behavior of each module can be customized

independently, without the need to understand the entire code base. This makes it much easier for end users to tailor the software to the specific needs of their experiments. Our software was developed in C++ (based on the JUCE library), but plugins can be written in Python or Julia, a language with Matlab-like syntax. Although plugin-based applications are the standard in the audio recording industry, they have yet to catch on for extracellular electrophysiology. The advantages of such an architecture are most apparent when real-time signal processing is needed for the purpose of delivering closed-loop feedback. Closed-loop experiments have the potential to greatly enhance our understanding of neural function, but are not widely used due to the difficulty of implementing them with currently available tools. We hope that as more neuroscientists contribute general-purpose, reusable modules to the Open Ephys GUI, such experiments will become more commonplace as the barrier to entry is lowered.

Title: Analysis of channel cross-talk in microwire bundles: microwires go far enough from each other to record activity of different neurons

Authors: *L. N. VASILEVA, I. V. BONDAR;
Inst. of Higher Nervous Activity, Moscow, Russian Federation

Abstract: Single-unit extracellular recording continues to be a widely-used method to study brain activity over relatively short periods of time. Chronic recordings with implantable devices can reveal long-term changes in brain activity critical for complex behaviors. We make use of Ni-Cr microwire bundles to maintain high signal-to-noise ratio over time (Kruger et al., 2010) and record activity of the same single-units for up to one year (McMahon et al., 2014). In contrast to arrays with regularly spaced recording sites, each recording site on the microwire bundles has a unique trajectory while being inserted into the brain and the experimenter has no information regarding individual microwire positions. Despite this, statistical methods can assess relative distances between microelectrodes by assessing the similarity of observed activity between different channels. In this study we aimed to define channels recording the same neuronal activity by multidimensional scaling and cross-correlation analysis. Recordings were performed in hippocampus of 9 chronically-implanted rats and in one anesthetized rat. First, we assessed relative distance between microwires by multidimensional scaling. We calculated

correlation coefficients between local field potentials (0-500 Hz) of 100 ms length on different channels as a similarity measure. Then we applied the multidimensional scaling method to establish relative distances between microwires. Microwires turned out to gather into consistent clusters and the indicated positions remained highly stable regardless of which data segment was analyzed. Our second goal was to evaluate the probability of recording the activity of the same single unit on different microwires within the bundle. For that purpose cross-correlation analysis was used. Raw signal was band-pass filtered (500-10000 Hz) and action potentials were detected by crossing an amplitude threshold. We used principal component analysis for spike sorting (implemented on Spike2 software, Cambridge Electronic Design, UK). Finally, we assessed the cross-correlation between the activity of single-units on different channels. A prominent central peak in cross-correlation histograms suggested the same single unit was present on two of the channels. When compared to the remaining channels, only 6 % exhibited similarly correlated single-unit activity.

Title: Long-term isolation of same single unit activity: stability criteria and estimation of longevity

Authors: *I. V. BONDAR[1], L. N. VASILEVA[1], A. M. BADAKVA[2];
[1]Inst. of Higher Nervous Activity and Neurophysiol. RAS, Moscow, Russian Federation; [2]RF SRC-Institute of Biomed. Problems RAS, Moscow, Russian Federation

Abstract: Once started neuronal activity persists for the whole cell lifespan. Neuronal discharge magnitude can vary depending on the brain state: arousal, sensory information flow, administration of chemical substances etc. To establish main principles of brain function we need to track activity of single and multiple neurons over extended period of time. Currently, technical capabilities allow to place registration device in close proximity of the neuron and leave it there for long-term single-unit recording. More recently, possibility to observe activity of the same neuron for a long period of time met serious criticism, but recent publications provide a new point of view on the problem of stable neuronal recordings (McMahon et al., 2014). It is important to elaborate well-defined criteria for evaluation of stability of recorded activity

(Jackson & Fetz, 2007; Dickey et al., 2009; Fraser & Schwartz, 2012). Taking in account background discharge of neurons we made attempt to develop stability criteria for evaluation of neuronal activity. Two rhesus macaques were implanted with guide tubes over M1 under general anesthesia. Each microwire bundle contained 16 microwires (diameter 12 or 18 μm) insulated with polyimide. Microwire bundles were inserted into M1 through the guide tubes. Neurophysiological recordings were performed every 3-4 days. Spikes were detected by crossing an amplitude threshold in raw data with Spike 2 software (CED, UK). Correlation coefficients were calculated between average spike forms belonging to the same and different neurons. Stable recorded neurons showed high level correlation coefficients between average spike forms (over 0.98). Based only on the spike forms classification of stable recorded units yields ambiguous result. Additional comparison form of interspike interval histogram decreased misclassification probability considerably. Using proposed criterion we were able to identify 82 neurons that were recoded for more than one day. In a remarkable case activity of one neuron was observed for 94 days.

Title: Next generation of large-scale, semi-chronic micromanipulator systems for measuring neuronal activity in distributed neural circuits in behaving, non-human primates

Authors: *A. B. GOODELL, C. M. GRAY;
Gray Matter Res., Bozeman, MT

Abstract: In order to gain a greater understanding of the neural mechanisms that mediate cognitive function new approaches and technologies are needed to dramatically expand the ability to record and manipulate the activity of large numbers of neurons throughout widespread areas of the primate brain. To accomplish this objective, we have developed large-scale, semi-chronic recording instruments that permit the implantation of hundreds of independently movable microelectrodes in behaving non-human primates. These devices can be flexibly configured to enable the long-term measurement of neuronal activity from distributed circuits spanning the depth and breadth of the brain. The instruments are now in widespread use in laboratories in North America, Europe and Asia. Findings from these studies have revealed several weaknesses in our original designs. These include inconsistencies in the reliability of the

actuator mechanism, problems associated with fluid leakage into the devices, and limitations in the manufacturing of the devices. Here, we report results from new designs that eliminate or alleviate each of these potential problems. Electrode position is controlled by rotation of a fixed lead screw (125 μm/turn resolution) that advances or retracts a cylindrical shuttle to which the electrode is bonded. We have greatly improved the reliability of this design by constructing the shuttle to have a cross-sectional teardrop shape and by fabricating the actuator block with matching hole dimensions using 3D printing technology. We have also implemented a procedure to inject a calibrated amount of sterile silicone grease into the electrode guide holes on the bottom of the actuator block. Together these design changes have significantly improved the performance and reliability of the system. Future improvements will include 1) reduction of the inter-electrode spacing to permit higher density recording, 2) the incorporation of injection cannulae for intra-cerebral drug injection, 3) longer lead screws to permit access to the ventral surface of the brain, and 4) the incorporation of zero-insertion-force connectors to increase reliability and ease of connecting to the headstage amplifiers.

Title: Ultrasound-induced long term potentiation of the spontaneous neural activity recorded from hippocampal neurons cultured on multi-electrode arrays

Authors: ***S. HWANG**[1], H. JEONG[1], S. KIM[1], Y. LEE[1], T.-S. KIM[3], S. JUN[2,4]; [2]Dept. of Electronics Engin., [1]Ewha Womans Univ., Seoul, Korea, Republic of; [3]Kyung Hee Univ., Gyeonggi-do, Korea, Republic of; [4]3Department of Brain and Cognitive Sci., , Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Ultrasound is an emerging non-invasive neuromodulation approach due to its advantages of the noninvasiveness, high spatial selectivity and high penetrating power. In the past few years, several studies have been performed to examine the effect of ultrasonic

neuromodulation in an animal model. However, the underlying mechanisms have not been clarified yet. In the previous study, we reported that the low-intensity, low-frequency ultrasound (LILFU) increases the neuronal activity using cultured hippocampal neurons on microelectrode arrays with simultaneous calcium imaging. In the present study, we showed that ultrasound induced the long term potentiation (LTP) of spontaneous neural activity. Primary hippocampal neurons were dissociated from embryonic 17-day gestation Sprague Dawley rat hippocampi and seeded on microelectrode arrays at the density of 1500 cells/mm2. After DIV 14, LILFU was applied at the intervals of 20 min to the cultured neural networks and the individual spontaneous action potentials (APs) were recorded before, during and after ultrasound stimulation for 4 times and analyzed. Repeated ultrasound stimulation lead to the increase of the frequency of APs and the increased activity remained even after 20 min resting time in the absence of ultrasound stimulation. Additionally, in order to figure out the synaptic change after ultrasound application, immunocytochemistry was performed. This study indicates that ultrasound can induced the synaptic changes in order to treat various neurological diseases.

Title: Semi-automated high-frequency oscillation detection from tripolar concentric ring electrode electroencephalography

Authors: ***W. G. BESIO**[1], M. ABTAHI[2], I. E. MARTÍNEZ-JUÁREZ[3], J. N. GAITANIS[4]; [1]Electrical Computer and Biomed. Engin. Dept., Univ. of Rhode Island/Cremedical Corp., Kingston, RI; [2]Electrical Computer and Biomed. Engin. Dept., Univ. of Rhode Island, Kingston, RI; [3]Epilepsy Clin. and Clin. Epileptology Fellowship, Mexico's Natl. Inst. of Neurol. and Neurosurg. MVS, and Natl. Autonomous Univ. of Mexico, Mexico City, Mexico; [4]Pediatric Neurol., Tufts Med. Ctr., Boston, MA

Abstract: Epilepsy is one of the most frequent neurological diseases with an overall incidence between 0.5 and 1% [1]. Electroencephalography (EEG) records the electrical activity from large

groups of neurons in the brain. The EEG has excellent temporal resolution however, it typically has poor signal quality due to movement artifacts and muscle contractions. To overcome these problems with EEG, tripolar concentric ring electrodes (TCREs) have been developed by Besio [2]. Two bipolar differences of the potentials from the three closely spaced elements perform the tripolar Laplacian derivation first described in [2] as a weighted sum. It was shown that, compared with conventional EEG signals, tripolar EEG (tEEG) has nearly 4-fold (374%) the signal to noise ratio and less than a tenth (8.27%) the mutual information [2-3]. Further, there are reports that high-frequency oscillations (HFOs) can be attributed to epileptic brain tissue [1, 4] but are not consistently detected in scalp EEG. Methods: Our recording protocol was approved by the IRB committees and did not interfere with the clinical EEG recording and evaluation. The tEEG recordings, from eight patients having seizures, were performed concurrently with the clinical EEG with TCREs place just behind the EEG sensors. We used a modified version of the algorithm reported by [4] for detection of HFOs. We performed the Fourier transform to calculate the power spectrum over consecutive one second epochs using a Hamming window and summed the power for each frequency within the window. A threshold was set at the mean plus one standard deviation of the spectrum to determine where/when HFO activity was present. Results: We found that in all eight patients we were able to detect HFOs in the tEEG but none in the EEG. The semi-automatic detection worked well for all patients directing us where to look for HFOs. We were able to detect HFOs up to two-hours prior to the clinical seizures and up to 425 Hz all from the scalp surface. Conclusion: Using the threshold of the power spectrum lead to HFO detection in the tEEG for these eight patients. [1] Jacobs J, et al. Title: Miniature wireless and batteryless device for longitudinal recording and stimulating of bioelectric events in small animals

Authors: *K. L. SEBURN[1], R. BERCICH[2], Z. WANG[3], D. PEDERSON[3], H. MEI[2], P. P. IRAZOQUI[2];
[1]The Jackson Lab., Bar Harbor, ME; [2]Weldon Sch. of Biomed. Engin., [3]Electrical and Computer Engin., Purdue Univ., West Lafayette, IN

Abstract: Longitudinal collection of bioelectric data in small animals such as mice and rats is typically performed using tethered headstages or battery-powered implants which, despite offering some sophisticated features, still pose practical and experimental limitations to the testing environment and device lifespan. To overcome these obstacles a fully wireless (telemetry and power) miniature, chronically implantable recording and stimulating device has been developed that employs resonantly coupled filter energy transfer (RCFET) to provide system power. This device and its auxiliary hardware represent a comprehensive and non-proprietary solution for chronic collection and stimulation of bioelectric events. Once implanted the device is able to non-invasively and continuously record electrophysiological information and stimulate excitable tissue in conscious, untethered, freely behaving animals. The device is equipped with two differential recording channels and one stimulating channel. All device logic is mediated by an ARM® Cortex™ M0 microcontroller. Bidirectional communication between the device and a base station allows for adjustment of functional specifications such as sampling rate up to 25kS/s, ADC resolution, and stimulus parameters. Data is telemetered to the base station and then to a custom software application for real-time display and storage. The power needed to drive the microelectronics is continuously coupled between an external coil and a thin (0.13mm), flexible harvesting coil. With a total volume of less than 0.2cc and mass of 0.7g, it is smaller and lighter than any commercially available system with the same or fewer capabilities. To date, we have successfully recorded electromyograms (EMG) of voluntary evoked muscle activity from conscious, freely moving wild-type rats and mice for several consecutive days. We also recorded spontaneous fibrillations/fasciculations from a conscious mouse carrying a laminin α2 mutation that causes muscular dystrophy (MDC1A). This type of aberrant, spontaneous muscle activity is characteristic of this model, and it is an example of the type of data that is now accessible, but that has previously been technically difficult or impossible to obtain longitudinally from conscious animals. Additional data collection using other mouse models of neuromuscular disease is currently underway. Importantly, although the current emphasis is on EMG recording to facilitate longitudinal study of our neuromuscular disease models, the system is versatile such that with only minor modifications to the electrode configuration, it may find utility for other neurophysiological recordings.

Title: The path of least resistance: minimizing vascular damage from electrode array insertions

Authors: *W. J. JOHNSTON[1,2], N. GAUDREAULT[2,3], D. DENMAN[2], B. LONG[2], H. PENG[2], T. J. BLANCHE[2,3];

Abstract: Extracellular electrophysiological recordings are an essential tool for studying neural activity. However, the signal quality, number of isolatable single units, and stability over time can be extremely variable from one implantation to the next. One possible explanation for this variability is the extent of damage to the vasculature caused by the electrode, and the concomitant local hypoxia and inflammatory response. Targeting electrode insertions to avoid the microvasculature may thus improve recording reliability. Preserving the integrity of the blood-brain-barrier may also improve the outcome of chronic implants. Here, we study the disruption of blood vessels caused by planar silicon probes. We developed a detailed 3D neurovascular model in Vaa3d (http://vaa3d.org) based on high resolution *in vivo* 2-photon imaging of mouse cortical neurovasculature using fluorescently labeled dextrans, up to a depth of 600µm. Our preliminary results, based on manually estimating the fraction of cut vessels, indicated that damage at the insertion site and the surrounding neuropil increases supra-linearly with probe size. The smallest probes (25µm wide) induced uniform damage over all depths, whereas larger probes (>100µm) produced a conical zone of damage with greater vascular disruption in deeper layers. We used the model to expand on this result by simulating the insertion of electrodes of various sizes, tiling all possible locations and orientations within an image volume. These simulations allow us to estimate the damage from a “blind” insertion of arbitrary electrode size with respect to number, length, diameter and predominant orientation of vascular segments in the ~0.5mm3 volume of imaged tissue. Such maps can also be used for targeting actual probe insertions. We confirmed our model’s predictions by comparing reconstructions obtained before and after a real electrode insertion. Finally, we used our model to explore several potentially crucial predictors of damage, such as intersection of large feeder vessels that are important for regional circulation, and show that, with respect to these more specific metrics, larger electrodes may be successfully targeted to achieve an impact similar to that caused by a much smaller electrode inserted blindly. Results from this study demonstrate the value of developing smaller, high-density electrode arrays, and suggest that actively avoiding intracortical microvasculature may improve neural recording outcomes.

Title: A High-resolution flexible electrode manufacturing with a platform 3-d printing system

Authors: ***D. R. MERRILL**, T. J. PARK, C. F. SMITH, D. A. MCDONNALL, K. S. GUILLORY;
Ripple, Salt Lake City, UT

Abstract: We describe a flexible electrode manufacturing process based on robotic deposition of alternating layers of nonconductive polymers and polymers doped with electrically conductive particles forming the electrodes and interconnections. This process facilitates production of composite structures with feature sizes below 100 μm, and supports synthesis of the electrode array and encapsulation of integrated electronics at low cost. We have performed flexural testing on electrodes, demonstrating electrical and mechanical reliability for over 100 million flexions. As an initial application, we have developed a wireless recording system for short-term electrocorticographic (ECoG) monitoring. Reliable monitoring is necessary to guide accurate resection of cortical seizure foci in epilepsy patients who do not respond to drug therapies, but who are candidates for surgical treatment. State-of-the-art monitoring relies on percutaneous leads which may be a source of infection, and relatively stiff electrode arrays which may cause hemorrhaging and unacceptable foreign body response. The system described here comprises a wireless transcutaneous system using infrared data transmission which mitigates infection risk, and a manufacturing system for production of highly flexible electrode arrays which mitigates the foreign body response of traditional electrodes, together allowing the appropriate substantially larger epilepsy patient base to receive surgical treatment. Although the system design targets an underserved epilepsy population, the solutions offered by these technologies are also well-suited to providing a long-term brain-machine interface.

Title: Highly-flexible package and silk fibroin assisted needle penetration for 5-μm-diameter neuroprobe device

Authors: *D. TEO[1], H. SAWAHATA[1], S. YAMAGIWA[1], A. MORIYA[1], H. OI[2], Y. ANDO[2], R. NUMANO[3], M. ISHIDA[1,2], K. KOIDA[2], T. KAWANO[1];

Abstract: To achieve low invasive neuronal activity recordings, we have proposed a very fine (<10 μm in diameter) and high-density multi-electrode array fabricated by the selective vapor−liquid−solid (VLS) growth of silicon 'whisker' wires (Fujishiro et al., 2014). However, it is difficult to insert such out-of-plane needle-electrode into certain parts of the brain such as the subdural spaces and the inner sulcus due to the rigid, large silicon substrate (>5 mm × 8 mm). Here we newly developed a neural electrode device with the polyimide-based flexible printed circuit (FPC, 12.5 μm in thickness). The silicon whisker needle-electrode (3 μm in diameter, 160 μm in length) was fabricated on a low resistance 1mm×1mm silicon block which was assembled to a FPC package using electrically conductive epoxy. Electrical impedance was reduced (~100kΩ at 1 kHz) with the platinum black plating. Neuronal activity was recorded from the mouse's primary somasensory cortex (S1) to evaluate the recording capability of the FPC packaged needle-electrode. As a result, electrode was able to penetrate through the cerebral cortex by surface tension between the silicon block and cortical surfaces, without applying any external force. After the penetration, single unit activity and local field potential (LFP) signals were stably recorded for a long period (>80 minutes). Additionally, for future application such as device placement into subdural and inner sulcus spaces, the needle electrode was entirely covered with silk fibroin, which is soluble in water (cerebrospinal fluid). In the acute experiments, approximately 30 minutes after this device was placed on a wet surface of mouse cortex, the silk fibroin layer was dissolved and the needle-electrode successfully recorded the cortical activity (LFP) from the cortical tissue. These results suggest the feasibility of long-term recording of neuronal activity from subdural and inner sulcus spaces of large animals, including monkey. The silk fibroin remain solidify for minutes, allowing electrode to be effectively protected before being slid into the targeted cortical area. Furthermore, the high flexibility of the FPC is able to mitigate the vibration caused by throbbing or organism movement, therefore the electrode was able to be stably fixed to the brain tissue. If the single unit recording from the

cortical area in the narrow space can be achieved, this proposed device is expected to become a powerful tool to contribute significantly to neurophysiology.

Title: A neuroelectronic device based on nanocoax arrays

Authors: J. R. NAUGHTON[1], J. M. VARELA[2], J. N. LUNDBERG[2], T. J. CONNOLLY[3], M. J. BURNS[1], T. C. CHILES[3], J. P. CHRISTIANSON[2], *M. J. NAUGHTON[1];

Abstract: We report on the development of a nanocoax-based neuroelectronic array. A nanocoax consists of concentric conductor core, a dielectric annulus and an outer conductor shield. Computer simulations with this architecture indicate that a nanocoax array can pixelate local field potentials (LFPs) at a spatial pitch far smaller than bare wire sensors of equal size. Moreover, the shielded nature of the nanocoax provides improved signal-to-noise ratio at any pitch. We have developed fabrication techniques in which nanocoax arrays, consisting of individual coaxes as small as 300 nm diameter, can be deployed as multielectrode arrays for neural LFP recordings. First, we made extracellular LFP recordings from leech Hirudo medicinalis ganglion sacs. Biphasic waveforms with amplitude and duration akin to published leech action potentials were evident. Next, we cultured HEK293-Channelrhodopsin2 cells (HEK-ChR2) on 5×6 arrays of 2 um coaxes. Brief application of blue light (0 to 30 mW/mm^2) evoked negative LFPs with a linear optical dose-response relationship. Importantly, optically-evoked LFPs were only observed on nanocoax sensors found to be in direct contact with HEK-ChR2 as determined after recording with fluorescent microscopy. These results encourage future development of nanocoax electrode arrays for optogenetic neural recordings with high spatial and electronic resolution.

Title: Toward pan-retinal characterization of ganglion cells responses to finely controlled spatio-temporal light stimuli on 4096 CMOS-MEAs

Authors: *A. MACCIONE[1], S. DI MARCO[2], G. HILGEN[3], S. PIRMORADIAN[4], M. HENNIG[4], E. SERNAGOR[3], L. BERDONDINI[1];
[1]Inst. Italiano Di Tecnologia, Genova, Italy; [2]Univ. degli Studi dell'Aquila, Aquila, Italy; [3]Newcastle Univ., Newcastle, United Kingdom; [4]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Advances in the field of CMOS multielectrode array sensors [1] for extracellular recordings with sub-millisecond resolution of neuronal electrical activity allows scaling up the number of the simultaneously recorded single-units from few tens up to several thousands. This offers a novel opportunity to perform fine-grain yet large-scale analysis of brain circuits to investigate how they develop and to gather novel knowledge about information processing at the level of large neuronal populations. In particular we focused on recording from the retinal ganglion cell (RGC) layer in retinal wholemounts by taking advantage of CMOS-MEAs with 4096 electrodes (7.12 mm^2 active area, 42 μm electrode pitch) to investigate the effects of inner and outer lateral inhibition in mediating the responses of RGCs to light stimuli. In order to provide finely controlled spatio-temporal light stimuli, a visual stimulator based on a DLP custom system was integrated in the recording platform to focus and project light patterns on local or large retina areas at a 4 x 4 μm2 spatial resolution and with sub-millisecond temporal precision. Here, we present preliminary results on functional RGC classification at pan-retinal scale (hundreds to thousand well responding neurons). We first characterized the spatial frequency sensitivity of RGCs based on Fourier analysis computed on responses to moving bars at different spatial frequencies. We show how the receptive field properties and the spatial tuning are influenced by varying the extent of the stimulus projected onto the retina. We then quantified RGCs receptive fields using full field stimulation and linear models by reverse correlation. Although broadly distributed, response kinetics had a clear dorsoventral gradient: RGCs in more ventral locations responded more slowly, and receptive fields of Off cells were smaller in ventral than in dorsal locations. This potentially obscures the classification of cell types based on kinetic measures. In contrast, full field responses yielded more distinct groups of neurons with different response polarities and transient versus sustained activity. [1] L. Berdondini, A. Bosca, T. Nieus, and A. Title: Flexible electrodes and insertion machine for stable, minimally-invasive neural recording

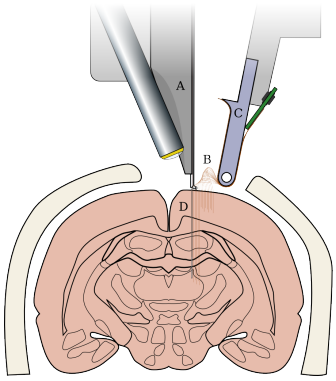
Authors: ***T. L. HANSON**[1], M. M. MAHARBIZ[2], P. N. SABES[1];
[1]Physiol., UCSF, San Francisco, CA; [2]Electrical Engin., Univ. of California, Berkeley, Berkeley, CA

Abstract: Current approaches to interfacing with the nervous system rely mainly on stiff electrode materials, which work remarkably well, but suffer degradation from chronic immune response due to mechanical impedance mismatch and blood-brain barrier disruption. Current technology also poses limits on recording depth, spacing, and location. In this project, we are working to ameliorate these issues through a system of very fine and flexible electrodes, a robotic system for manipulating and implanting these electrodes, and a means for integrating electrodes with neural processing chips. We have fabricated preliminary flexible 5μm x 16μm polymer electrodes, and have demonstrated their manual and automated insertion into an agarose tissue proxy, and both ex-vivo and in-vivo brains using etched and laser micro-welded 25μm and 13μm diameter tungsten needles. We have also fabricated and tested several inserter robots; the most recent design uses replaceable needle and electrode cartridges, the latter to which electrodes are mounted. Electrodes are lithographically fabricated in groups of 64, and include a peel-away backing, which holds the fine wires and keeps them from tangling until they are inserted, and provides a more robust means of handling and mounting the structures. To integrate these electrodes with neural processing chips, we have tested electroplated bond sites with aluminum wirebonding. We will describe the development and operation of the system, as well as preliminary functional tests in rats.



Not-to-scale schematic of the ``**sewing machine**'' method for inserting *fine and flexible* electrodes into the brain.
Inserter head, **A**, moves in three dimensions to individually pick flexible electrodes **B** from a replaceable, sterilizable cartridge **C**.
Electrodes are then inserted with a fine needle **D** into the brain.
The needle is retracted, leaving the electrode in place, and the inserter head moves to pick a new electrode.
Note electrodes and needle are enlarged to make them visible. In practice, it is not possible to manipulate either manually -- *a specialized machine is required*.

Title: Simultaneous *in vivo* single-unit recording and fast-scan cyclic voltammetry in the behaving rat

Authors: *A. G. HOWE, K. M. WASSUM, H. T. BLAIR;
UCLA, Dept. of Psychology, Los Angeles, CA

Abstract: In-vivo fast-scan cyclic voltammetry (FSCV) allows rapid sampling of electroactive neurochemical concentrations (e.g., dopamine) from targeted brain regions in behaving animals. Relationships between neuronal firing and dopamine function can be investigated by performing FSCV simultaneously with single-unit recording. Previous approaches to this have relied on fast switching between the two techniques, so that unit recordings were interleaved with FSCV voltage sweeps (Takmakov et al., 2011; PMC3160449); a disadvantage of this approach is that unit recordings are occluded during FSCV scans, resulting in loss of ~10% of the single unit spikes. Moreover, recording directly from the FSCV probe limits sampling of single units to the immediate vicinity of the FSCV probe, precluding analysis of neural population activity. Here we introduce a new approach with zero data loss and the ability to record hundreds of single units throughout the brain. Following conventional FSCV methodology, a custom-made voltammetric potentiostat was used to apply a triangular waveform (-0.4 to 1.3 V, 8.5 ms waveform width) to a carbon-fiber microelectrode implanted in the nucleus accumbens of a

behaving rat through a head-mounted voltammetric amplifier; 16 tetrodes simultaneously recorded units from nucleus accumbens, ventral tegmental area, and hippocampus. A highly regular voltage artifact generated by the FSCV scan was removed from unit recording signals via a 4-step offline analysis process, to yield full recovery of all single-unit waveforms originally occluded by the FSCV scanning artifact. These units were then classified using conventional spike-sorting techniques. Future work is targeted towards online artifact removal to achieve real-time single unit spike sorting simultaneously with FSCV dopamine recordings. This approach allows a circuit-level analysis of the relationship between ventral striatal dopamine concentration changes with striatal, ventral tegmental, and hippocampal neuronal activity.

Title: Long-term recordings with immobile silicon probes in the mouse cortex

Authors: ***M. OKUN**, M. CARANDINI, K. D. HARRIS;
UCL, London, United Kingdom

Abstract: One of the main experimental approaches in systems neuroscience involves extracellular chronic recording of population activity in awake behaving mammals, especially rodents. Chronic recordings have traditionally been performed with self-fabricated tetrodes, but in recent years the emphasis has shifted to silicon probes, and this trend will be further reinforced by the forthcoming new generation of high-density, high-count probes. There is a widespread belief that to use silicon probes in long-term chronic recording, one must attach them to microdrives. Microdrives allow one to advance the recording sites inside the brain. The common concern is that an immobile silicon probe rigidly affixed to the skull would introduce too much damage to the surrounding neural tissue, compromising the ability to observe high quality spiking activity. Here we report that, contrary to this opinion, it is possible to obtain high quality

recordings in both head-fixed and freely moving animals for at least several months following the implantation of immobile chronic probes into the mouse cortex. We implanted mice with a head plate and 16- or 32-channel Neuronexus CM-type probes, with tetrode and octrode organization of contacts. The probes were positioned in the deep layers of the primary visual cortex (V1). To assess the stability of well-isolated single units recorded with the probes we utilized the highly reproducible responses in mouse V1. We recorded responses to gratings across four consecutive days in mice head fixed in the same position relative to the screen showing the stimuli. Spike sorting was performed on all sessions together, using standard procedures, oblivious to any sensory response properties. Qualitatively, neurons' responses were similar to acute recordings performed in the lab and conserved across days. Quantitative analysis showed that PSTHs computed from half of the trials on one day predict 71% ± 25% (median and MAD) of the explainable variability in the PSTH from half of the trials on the next day (i.e., 100% is taken to be the level of PSTH variability explained by the other half of trials in the same recording session). Thus, although electrode drift cannot be completely eliminated, our results suggest that immobile silicon probes represent a straightforward and reliable technique to obtain stable, long-term population recordings in mice.

Title: Predicting current density induced by transcranial direct current stimulation (tDCS) in the human motor cortex using an optimized electrode configuration and high-resolution head models

Authors: ***M. E. RASMUSSEN**[1,2], P. LUU[1], E. ANDERSON[1], K. K. MORGAN[3,1], A. R. GUNN[1], D. M. TUCKER[3,1];
[1]Electrical Geodesics, Inc., Eugene, OR; [2]Human Physiol., [3]Psychology, Univ. of Oregon, Eugene, OR

Abstract: Transcranial direct current stimulation (tDCS) is emerging as a promising research and clinical tool to modulate excitability of the human cortex. Both noninvasive and inexpensive, tDCS utilizes weak electrical current (0.5-2mA) conventionally administered through patch electrodes positioned on the scalp over a target cortical region of interest. While anodal stimulation typically facilitates cortical excitability through neuronal membrane depolarization and cathodal stimulation typically inhibits through hyperpolarization, there exists a widespread inconsistency in efficacy and duration of neuromodulation effects. This unpredictability proves problematic for dosage considerations particularly in clinical applications. For example, the use

of tDCS for the suppression of epilepsy necessitates both focal and predictable current induction in order to provide maximal therapeutic benefits. In this study we utilized high-resolution head models, derived from MRI images, to characterize each individual's head tissues to predict the current density at the hand region of the primary motor cortex using 1) a standard M1-supraorbital patch electrode configuration and 2) a dense-array, target optimized electrode configuration and then compared the current density at the target region associated with each configuration. The results show that the M1-supraorbital patch electrode configuration often produced maximal current density at non-target locations and sometimes with the opposite current direction than intended. In contrast, the dense-array, target optimized electrode configuration produced maximal current density in at the target location and always with the intended current direction. The results suggest that variability of tDCS after-effects observed in previous research may be directly attributable to the variability in current density and direction associated with conventional M1-supraorbital patch electrode configuration, and that to reduce the variability dense-array, target optimized electrode configuration should be employed.

Title: Effect of shank spacing and probe sharpening on insertion force and dimpling depth in Matrix Array 3D probe implantation into the primate cortex

Authors: ***A. E. SNELLINGS**[1], M. FUKUSHIMA[2], J. JEON[1], R. J. VETTER[1], M. MISHKIN[2], R. C. SAUNDERS[2];
[1]NeuroNexus Technologies, Ann Arbor, MI; [2]Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: The Matrix ArrayTM is a 3-dimensional silicon-based microelectrode array that can be used to obtain high-density recordings from large populations of neurons in a volume of

tissue. The Matrix ArrayTM is comprised of multiple two-dimensional 32-channel probes that are stacked in a platform with a fixed amount of spacing, typically producing a 64-, 128- or 256-channel array. It is implanted with a variable-speed computer controlled insertion motor that allows for precise, low speed insertions. In this study we examine the so-called "pincushion" effect for 3D probe implants in a primate model. We measure the insertion force required to insert a Matrix ArrayTM, as well as the depth of dimpling prior to pial penetration, across several implantation speeds (0.1 mm/s, 0.3 mm/s, 0.5 mm/s, 1.5 mm/s, 4.5 mm/s, 6.0 mm/s, 8.0 mm/s). We tested three different inter-platform spacings (0.3 mm, 0.6 mm, 1.0 mm), two different inter-shank spacings (0.2 mm, 0.4 mm), and standard probe tips (e.g. chisel shaped) vs. sharpened tips (e.g. chisel shaped, tapered to a point) to fully characterize this design space. Initial results indicate that both spacing and probe sharpness are factors that influence the dependent variables. In the first comparison, which tested two-dimensional probes with shank spacing of 200 microns ("M4x8-2mm-100-200-704") across the seven insertion speeds, the standard-tipped array required 2.90 g ± 0.32 g of force to insert and produced a 2.3 mm ± 0.14 mm dimple prior to insertion while the sharpened array required only 1.91 g ± 0.12 g of insertion force and produced a 1.85 mm ± 0.13 mm dimple before insertion. Similarly, a three-dimensional 128-channel Matrix ArrayTM comprised of four two-dimensional probes with standard tips and 200 um shank spacing ("M4x8-2mm-100-200-704") with 300 μm platform spacing required 7.32 g ± 0.30 g of insertion force and produced a 3.6 mm ± 0.07 mm dimple (across insertion speeds 0.5 mm/s, 1.5 mm/s, 4.5 mm/s, 6.0 mm/s, 8.0 mm/s) while an array comprised of the same 32-channel probes but with sharpened tips and 600 μm platform spacing required only 3.27 ± 0.29 g of insertion force and produced a 1.80 ± 0.11 mm dimple. Testing in this study is on-going, and the final results will span the parameter space described above.

Title: Tunable microelectrode arrays for monitoring neurons in deep brain structures

Authors: ***S. PALANISWAMY**[1], A. SRIDHARAN[1], J. MUTHUSWAMY[1], M. BAKER[2], M. OKANDAN[2];

[1]Biomed. engineering, Arizona State Univ., Tempe, AZ; [2]Biomed. engineering, Sandia Natl. Labs, Albuquerque, NM

Abstract: We report here a scalable technology using micro scale actuators and movable microelectrodes for the unprecedented capability of seeking and recording/stimulating targeted single neurons in deep brain structures up to 10 mm deep (with 6 μm displacement resolution) in behaving or head-restrained animals. Using a combination of a unique micro bonding technique and a modified flip-chip process, we have now extended the repertoire of our previously reported movable microelectrode arrays to enable us to mate conventional stainless steel and Pt/Ir microelectrode arrays of desired lengths to steerable polysilicon shafts. We have tested scalable prototypes in rigorous bench top tests to assess electrical and mechanical stability under long-term implantation. The method allows a wide variety of electrode configurations to be realized such as a rectangular or circular array configuration or other arbitrary geometries optimal for specific regions of the brain with inter-electrode distance as low as 25 um. The autonomous moveable MEA is coupled with robotic tracking algorithms that operate in one of 3 phases - seek (to seek neurons of interest), optimize (fine positioning after identifying neuron of interest to maximize signal quality) or maintain (maintain the quality of neural recording over long periods of time). We will report results from *in vivo* experiments.

Abstract: Assessing neural dynamics in the sensorimotor cortex gives a valuable source of information to study motor control and its functional recovery from neurological deficits. Among various recording procedures, Electrocorticogram (ECoG) is considered to be appropriate to capture characteristic neural activities in sensorimotor cortex because ECoG provides more reliable measurements than penetrating electrodes into the cortex and ECoG carry rich information sufficient for decoding forelimb movements. In the current study, we aimed at investigating ECoG signals in common marmosets, which has been attracting much attention in the field of neuroscience as a primate model in both basic and clinical studies. However, for ECoG recordings in common marmosets, localization of the motor cortex is essential because there is no cortical landmark on their sensorimotor cortex. Here, the purpose of this study was to characterize neural activities of the motor and somatosensory cortices in marmosets, by using custom-made ECoG electrode arrays that can be used for both epidural cortical stimulation (ECS) and recording of cortical neural activity. In order for detailed motor cortex stimulation mapping, recording Electromyographic (EMG) activity was necessary to evaluate motor evoked potential (MEP) by ECS as well. In this study, at first, we developed methods for chronic implantation of ECoG electrode arrays and EMG wire electrodes, and then identified the motor and somatosensory maps in the cortex. We implemented EMG wire electrodes in 7 forelimb muscles and ECoG electrode arrays epidural in common marmosets (N=2). After the implantation, ECS was applied through ECoG electrode arrays and MEP of each forelimb muscle was recorded. Somatosensory evoked potentials induced by electrical stimulation of peripheral nerve were also recorded by the same electrode arrays. With ECS and neural recordings in the same electrodes, we obtained combined motor and somatosensory maps of the forelimb area in the cortex in the same individuals. These maps were consistent with the anatomical findings in previous studies. The current results suggest that our ECoG electrode arrays can reliably assess both MEP and somatosensory somatotopy with sufficient spatial resolution. Implantation of EMG and ECoG electrodes enabled both cortical stimulation and recording of cortical neural activity in high reproducibility, and also recording in awake. Moreover, the present method may enable activity-dependent cortical stimulation for inducing functional reorganization in the cortex.

Title: 4096 CMOS multielectrode arrays reveal lognormal firing patterns in hippocampal neuronal networks and allow to characterize early distribution changes induced by amyloid-beta toxicity

Authors: *H. AMIN, A. MACCIONE, L. BERDONDINI;
Fondazione Inst. Italiano Di Tecnologia (IIT), Genova, Italy

Abstract: Lognormal-like distributions of neuronal firing patterns in large populations have been recently reported for *in vivo* brain circuits and their role to the structural and functional properties of brain networks has been investigated (Mizuseki and Buzsáki 2013). By taking advantage from recently developed high density multielectrode arrays (MEAs) based on Complementary Metal Oxide Semiconductor (CMOS) technology, that enable simultaneous *in vitro* recordings from 4096 electrodes (Berdondini et al. 2005), we have recently demonstrated that lognormal-like firing patterns can be unveiled also from *in vitro* grown hippocampal neuronal networks and can be estimated already after 10 minutes of recording (Amin et al. 2015). On the other hand, a growing body of evidence suggests that soluble oligomers of amyloid-beta (Aβ1-42) are cytotoxic and their aggregates can inhibit many critical neuronal activities such as long-term potentiation (LTP) (Lambert et al. 1998), thus representing an hallmark of Alzheimer's disease (AD). Here, by analyzing changes (shifts) in the lognormal-like distributions of extracellular firing patterns recorded by 4096 CMOS-MEAs and quantified in a logarithmic histogram by means of Gaussian fit parameters, we have investigated the functional effects induced by oligomeric Aβ toxicity on the network activity of hippocampal neuronal cultures grown on-chip for 21 days *in vitro* (DIVs). Results show, in a nutshell, that firing patterns of untreated control cultures exhibit skewed distributions with non-significant inter-culture differences and tend, over development, to shift from the left to the right (i.e., toward higher firing rates). Always with very low variability, cultures treated with Aβ manifest over 26 hours a salient shift from the right to the left (i.e., toward low spiking frequencies) and loose a lognormal-like distribution after 19 hours. Overall, these results show that large-scale multielectrode array recordings combined with the analysis of the firing rates distribution within a network undergoing functional changes, provides a way to investigate the induced functional re-organization occurring at the cellular scale within the network. This suggests that this methodology might be a valuable approach to investigate neuronal networks beyond their characterization based on simple network-wide activity parameters (e.g. Mean Firing Rate and Mean Bursting Rate), and can find applications for studying neurodegeneration, for developing analytical tools for neuropharmacology, and for the development of computational neuronal network models.

Title: The Real-Time eXperiment Interface: a closed-loop data acquisition system with sub-millisecond latencies for electrophysiology

Authors: *A. GEORGE[1], Y. PATEL[2], F. ORTEGA[1], J. WHITE[3], D. CHRISTINI[1], A. DORVAL[4], R. BUTERA[5];
[1]Weill Cornell Med. Col., New York, NY; [2]Georgia Tech, Atlanta, GA; [3]Boston Univ., Boston, MA; [4]Univ. of Utah, Salt Lake City, UT; [5]Georgia Tech., Atlanta, GA

Abstract: To understand causal interactions between neural activity and function, both function and neural activity need to be monitored with timing precision at the sub-millisecond scale. This requires enabling of closed-loop, hard real-time technologies that are capable of controlling stimulation (optogenetic, electrical, thermal, etc) dependent upon some functional measure (behavior, motor action, etc) within a deterministic period. While monitoring neural activity at precise time scales is commonplace, there is an important unmet need in a cost-effective sub-millisecond closed-loop real-time framework capable of interacting with neural activity and function at the appropriate timescales. To enable investigation of neural activity and function at these time scales, we have developed the Real-Time eXperiment Interface (RTXI) - a versatile interface based off of real-time Linux that enables deterministic closed-loop monitoring, stimulation, and control of single-cell, network, animal, and human electrophysiology experiments. RTXI is a free and open source platform currently employed by over 65 labs around the world. At the base of RTXI are built-in modules such as a high-speed oscilloscope, signal generator, and common filters. The value of RTXI arises from it's plugin-based architecture, enabling community-developed modules that enable numerous options for customizing closed-loop control. Such an architecture enables resource sharing and maximizes reproducibility of experimental setups and results. Most recently, RTXI's user interface and underlying architecture have been rewritten to provide up to 32 16-bit I/O channels, with worst-case jitter less than 5 microseconds. Addtional information is available on our website (http://www.rtxi.org), and our code repository is open on GitHub (https://github.com/RTXI).

Title: Event-related potential correlates of mindfulness meditation aptitude

Authors: *R. M. ATCHLEY, D. KLEE, T. MEMMOTT, E. GOODRICH, B. OKEN; Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Background: Mindfulness meditation interventions produce some clinical benefit, but the neurophysiological mechanisms underlying these benefits and how they are acquired are poorly understood. This study assesses a physiological marker of meditation aptitude using EEG. Objectives: The primary objective was to measure changes in various event-related potentials across three groups: naïve, novice, and experienced meditators. Heart rate, eye blinks, respiration, galvanic skin response, salivary cortisol, and blood pressure were also assessed. Methods: Forty-three healthy adults (M age = 49 years) participated in the study. Participants completed a variety of cognitive tasks while EEG was recorded. These tasks included a target tone detection task and a breath counting task that also served as a meditation condition for those with meditation experience. Participants were instructed to respond to target tones with a button press in the first task (Tones), and then ignore the tones as they sounded in the background while breath counting. Statistical analyses focused on event-related potential responses to target tones. Results: Mixed 2x3 ANOVAs revealed a task effect for P3 amplitudes ($p < .001$). As expected, the P3 was attenuated during the breath counting task in comparison to the Tones task. When comparing meditators to non-meditators, there was a task by group interaction for P3 ($p = .035$) with a greater decrement in P3 amplitude in the meditators compared to non-meditators. Furthermore, both experienced meditators ($p = .003$) and novice meditators ($p = .004$) exhibited less task-related change in N2 in comparison to controls. Conclusions: Meditators had stronger P3 responses to target tones when they were instructed to attend to them, and a greater attenuation of P3 responses to the same tones when they were instructed to ignore them during the breath counting session. The results of this study provide initial steps in the identification of ERP markers of mindfulness meditation aptitude. This information has potential to improve mindfulness meditation interventions by allowing objective assessment of meditation quality.

Title: A novel micro-fabricated tetrode

Authors: *S. SHIN[1], J.-H. KIM[2], J. JEONG[1], J. PARK[1], T. GWON[1], S.-H. LEE[2], S. KIM[1]; [1]Dept. of Electrical and Computer Engin., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Biol. Sci., KAIST, Daejeon, Korea, Republic of

Abstract: For decades, microwire-based tetrodes have been widely and usefully used for *in vivo* -neural signal recording experiments. The advantage of microwire-based tetrodes among various neural electrode arrays is that its structure allows electrode sites to have easy access to nearby intact neurons. However, the fabrication process of the microwire-based tetrodes requires a mastery of manual skills and the resulting device tends to be unregulated. In this presentation, we suggest a polymer-based tetrode fabricated by micro-fabrication processes, so that, the dimensions in the device are well controlled and the devices are mass producible.
The suggested neural probes are made with liquid crystal polymer (LCP) and they have four contacts at the tip. The fabrication involves bonding multiple layer LCP films by thermal lamination and exposing electrode sites by laser micromachining. Among the LCP films, two LCP layers are used for covers and the others contain metal patterns to form the tip contacts. After thermally laminating the LCP films, the four tip contacts are made by cut-exposing the thickness of the electroplated metals. The four tip contacts have enough contact areas and electrochemical impedance to ensure good quality of neural signal recordings. ($1000\mu m^2$, 88.63 ± 49.34 kohm at 1kHz) To demonstrate recording capability of the fabricated polymer-based tetrodes, *in vivo* recording experiments were done. Spontaneous activity was successfully recorded from the primary visual cortex of the rodents using the LCP-based tetrode.
In summary, we present a polymer-based tetrode fabricated by micro-fabrication processes. The suggested LCP-based tetrodes can be exquisitely fabricated by micro-fabrication processes and laser micromachining. And its use has been proven by through *in vivo* neural signal recording tests.

Title: OvalDrive36: A chronically implantable microdrive system for brain-wide single-unit recording, optogenetic stimulation, and cyclic voltammetry in behaving rats

Authors: *H. T. BLAIR, IV[1], A. G. HOWE[1], R. M. DE GUZMAN[2];
[1]Dept Psychology, UCLA, Los Angeles, CA; [2]Univ. at Albany, Albany, NY

Abstract: OvalDrive36 (open-ephys.atlassian.net/wiki/display/OEW/OvalDrive36) is a chronically implantable microdrive system for rats that allows up to 36 individually movable probes to accurately target any desired combination of neural structures throughout the brain. The oval shape of the drive places almost the entire anteroposterior, mediolateral, and dorsoventral extent of the rat brain within range of the probes, and also permits simultaneous targeting of brain regions that are widely separated from each other by distances of up to 2 cm. The advancement path of each probe tip can be precisely specified by importing brain atlas diagrams into a computer-aided design (CAD) software template, which is then used to construct a targeting cone that is fabricated on a 3D printer. The CAD design process makes it easy to specify complex probe trajectories, including angled paths that avoid obstacles such as bone and blood vessels. The targeting cone is fitted onto a drive core that features a shuttle-in-groove design, which assures micrometer stability of each probe tip along the entire length of its 15 mm advancement path. Each of the 36 shuttle grooves can be fitted with different types of probe shuttles: 1) microwire shuttles that hold tetrodes or bipolar stimulating electrodes for neurophysiology, 2) optical fiber shuttles equipped with light shields and ferrule receptacles for plugging in light sources, 3) carbon nanofiber shuttles for fast-scan cyclic voltammetry (FSCV) studies, or 4) injector cannula shuttles for intracranial drug infusions. The drive core contains a large central payload space which can fully enclose a wireless telemetry transmitter, and also contains pedestals upon which up to four electrode interface connector boards can be mounted. These combined features make OvalDrive36 well suited for experiments employing convergent methods of electrophysiology, optogenetics, voltammetry, and neuropharmacology.

Title: Self–curling and –sticking flexible thin–film ECoG array device

Authors: *S. YAMAGIWA[1], H. SAWAHATA[1], M. ISHIDA[1,2], T. KAWANO[1];
[1]Toyohashi Univ. of Technol., Toyohashi-Shi, Aichi Pref., Japan; [2]Electronics-Inspired Interdisciplinary Res. Inst. (EIIRIS), Toyohashi Univ. of Technol., Toyohashi-Shi, Aichi Pref., Japan

Abstract: An array of ECoG electrodes, which enable electrical interface between electronics and human brain, potentially offers low-invasive ECoG−based brain-machine interface and epilepsy detection. However, thick and stiff substrate−based conventional ECoG devices are still problematic because it is difficult to sufficiently cover hemispherical shaped brain and sulci. A way to cover the brain with ECoG electrodes is the use of a sub-10-μm thick substrate with a great flexibility. Handling of such flexible thin-film device can be improved by using a stiff substrate of silk fibroin, which is a dissolvable material in brain [D. H. Kim et al, Nature materials, 9, 2010]. However, the silk fibroin is a foreign-body material in human brain. To overcome the issue of handling of flexible thin-film devices, here we propose an easy-to-use "self-actuating" flexible thin-film ECoG device. The device is based on a biocompatible parylene-N/-C sandwiched substrate with the self-curled property, but it is flatten out and stuck to brain surface once the substrate contacts with solution over the brain. To realize the curled parylene-film, herein we use the differences of linear expansion coefficient between the parylene-C (35 ppm) and the parylene-N (69 ppm). After calculations of mechanical properties of parylene-C/-N substrate and preliminary experiments, the parylene-C/-N film ECoG array device was fabricated. First of the device fabrication, a sacrificial layer of titanium was sputtered on a silicon substrate. After the first layer of parylene-C and thin parylene-N were deposited, platinum-electrodes and interconnections were formed by sputtering and etching. After the device metallization, an insulator of parylene-N was deposited. To enhance the sticking properties of the device, hydrophobic surface of the parylene-N was changed to hydrophilic property by oxygen plasma treatment. The parylene-N/-C was etched by oxygen plasma by using titanium hard-mask. Finally, the titanium layers were etched by ammonium solution to release the film device. The width, length, and thickness of the fabricated parylene-C/-N film ECoG

substrate were 1 cm, 5 cm and 5 μm respectively. Each ECoG electrode with the diameter of 1 mm exhibited the electrical impedance of 3 kΩ at 1 kHz in room temperature saline. *In vivo* experiments using a rat's brain demonstrated that the fabricated ECoG device stuck to the brain surface and detected evoked potentials from the visual cortex (V1) during the visual stimulation. These results indicated that the proposed self-actuating flexible thin-film ECoG device can be used in ECoG recordings.

Title: phy: a fast, next-generation spike sorting and data analysis framework for high-channel-count electrophysiology

Authors: ***M. L. D. HUNTER**, D. F. M. GOODMAN, S. N. KADIR, N. A. STEINMETZ, K. D. HARRIS, C. ROSSANT;
Univ. Col. London, London, United Kingdom

Abstract: The brain operates through the parallel activity of large sets of neurons. To understand brain function, it is thus essential to record the simultaneous activity of these populations. A leading method for large-scale neuronal recordings is extracellular electrophysiology with multi-site recording probes. Advances in microfabrication technology have recently enabled the production of electrodes with close to a thousand sites, allowing for recording of thousands of neurons simultaneously. In order to draw scientific conclusions from such data, the problem of "spike sorting" - grouping recorded action potentials into clusters putatively corresponding to individual neurons - must be solved. Traditional spike sorting methods scale poorly, if at all, to this new generation of electrodes. Not only are the error rates of traditional methods high, but they also typically require weeks or months of computation time, on servers with several hundred gigabytes of RAM, followed by multiple days of manual curation per experiment. To make spike sorting efficient in terms of both human and computer time therefore requires careful consideration of algorithms, data access patterns, caching, and underlying file storage structures

when writing code to perform scientific analyses. We developed “phy”: a new, fast open-source framework for extracellular electrophysiology data analysis. phy is based upon a previous set of tools (Klusta-Suite), but rewritten from the ground up in Python. It includes a customisable pipeline for spike sorting with inbuilt functions for efficient spike detection and automated clustering, and a fast GUI based on Vispy views for manual curation and arbitrary analyses. An improved ‘wizard’ guides a human operator through the manual curation process, greatly reducing the operator burden required by presenting choices in under 500ms. Many of the internal data structures of KlustaSuite have been changed, to reduce disk and memory usage and computation time by orders of magnitude for large electrodes. All the functions for accessing data are abstracted away, so it is easy to write and benchmark new algorithms, read different file formats, or access and modify any data with documented Python functions. We demonstrate the ease and speed of clustering an 128-channel dataset from new IMEC-manufactured electrodes, and run various sample common analysis functions as an example of the framework’s extensibility.

Title: A 512-channels, whole array readout, CMOS implantable probe for acute recordings from the brain

Authors: *L. BERDONDINI, G. ANGOTZI, M. MALERBA;
Inst. Italiano Ditecnologia, Genova, Italy

Abstract: Over the last 40 years, much progress has been made in the development of implantable neural recording probes based on MEMs and individual electrode wiring technologies. Current devices permit to record action potentials simultaneously from hundreds of neurons, but it is still unclear which technology will permit to step toward several thousands of single-neurons in the near future. An emerging approach is based on the adoption of CMOS technology to realize dense and large-scale multielectrode array (CMOS-MEA) probes [Berdondini et al., 2014]. CMOS-MEAs were extensively demonstrated in-vitro [Hierlemann et al.,2011] over the last decade and more recently also in-vivo [Lopez et al.,2014]. This allows to realize microelectronic micro-machined probes that permit to implement arrays of active electrode-pixels with local amplification and filtering circuits, as well as addressing and multiplexing circuits on the same substrate. The design of CMOS probes enabling whole array

recordings at sub-millisecond resolution from densely integrated microelectrodes on single shafts would potentially allow to literally image spiking activity and field potentials in multiple brain circuits at the same time, as demonstrated so far in-vitro on brain slices [4], cell cultures and retina whole mounts [Maccione et. al, 2014]. However, such CMOS-MEA probes must meet very demanding constraints in terms of sizes and power consumption imposed by their implantation into brain tissue. Making the shafts extremely small with smooth surfaces and rounded corners can minimize brain tissue damages at the time of insertion. Also, smart power-management circuit solutions and resource sharing approaches can effectively contribute in reducing power consumption much below the 40mW limit for a mouse brain. Here, we present a complete probe system based on a fully multiplexed CMOS neural probe that was designed for in-vivo acute recordings with a scalable circuit architecture. In particular, a first prototype of a single-shaft probe with 512 electrodes was realized in a standard CMOS 0.18µm technology and post-processed to structure the shaft with a wedge-like geometry of 30µm in thickness at the tip and 80µm at the base. Preliminary results on electrical, mechanical and implantation tests demonstrate the feasibility of realizing large-scale recording implantable probes.

Title: Large-scale multi-regional neural recordings reveal altered frontostriatal network dynamics following cocaine administration

Authors: *W. C. SMITH[1], L. CLAAR[2], M. ROSENBERG[2], V. CHANG[1], N. CHONG[1], S. SHAH[1], S. MASMANIDIS[2];
[2]Neurobio., [1]UCLA, Los Angeles, CA

Abstract: It is increasingly understood that drugs of abuse alter brain circuit function at the network scale. This places limitations on approaches that study the neurobiological basis of addiction in one brain region at a time. However, it remains unclear how network dynamics are altered between different regions at the resolution of single cells and spikes. We hypothesize that

cocaine administration reduces frontostriatal functional connectivity, in part due to the well-known effect of frontal cortex hypoactivity. To address this hypothesis we utilize novel 512 channel silicon microprobes to simultaneously record in two interconnected areas, the medial prefrontal cortex (mPFC) and nucleus accumbens core (NAcC), which are strongly implicated in mediating the addictive properties of cocaine. To study network activity and behavioral changes that accompany cocaine administration, we have established a conditioned odor preference test for head-restrained mice. When animals are tested with brief presentations of two odors after cocaine conditioning, they exhibit a conditioned response by dilating their pupils and running on a spherical treadmill preferentially after the cocaine-paired cue, but not a saline-paired cue. The microprobes enable recordings of around 100 single units per area, providing novel opportunities for studying how firing and local field potentials within and between the mPFC and NAcC are correlated during different behavioral states. We find that intra-cortical and intra-striatal interneuron firing patterns at rest become decorrelated after chronic drug administration, while putative projection neurons from both regions also decouple within their populations to a lesser extent. Encoding of the odor stimuli changes after drug exposure, whereby a significant proportion of neurons shifts from non-discriminating to odor discriminating. Prefrontal hypoactivity after drug treatment is observed in the form of lower baseline firing and altered burst firing patterns. Both pyramidal neurons and putative fast spiking interneurons burst less frequently compared to saline-injected controls. Interestingly, pyramidal cells shift to having more spikes per burst compared to controls, while cortical interneurons have fewer spikes per burst, suggesting a change in information processing intracortically. Future work will focus on solidifying these findings and attempting to rescue drug-conditioned behaviors by altering frontostriatal network synchrony.

Title: Novel electrical stimulation paradigm to reduce habituation of the nociceptive withdrawal reflex: preliminary results

Authors: C. B. LAURSEN[1], S. GERVASIO[1,2], O. K. ANDERSEN[1], K. HENNINGS[2], *E. G. SPAICH[1];
[1]Aalborg Univ., Aalborg, Denmark; [2]Nordic NeuroSTIM ApS, Aalborg, Denmark

Abstract: The lower limb nociceptive withdrawal reflex (NWR) can be elicited in humans by electrical stimulation of the sole of the foot. A stimulation train consisting of five 1ms-wide pulses delivered at a frequency of 200 Hz, repeated four times at a frequency of 15 Hz, has been used in reflex-based functional electrical therapy for gait rehabilitation in stroke patients. However, repetitive electrical stimulation can result in habituation leading to gradually lower reflex responses. Less habituation can be accomplished by varying the stimulation amplitude and frequency. The aim of this study was to identify a stimulation paradigm that induced the least amount of habituation of the NWR during walking. Three stimulation paradigms were tested: 1) Deterministic paradigm (fixed pulse width, 1 ms, and frequencies, 200 Hz inter-pulse, 15 Hz inter-train), 2) stochastic pulse width paradigm (random pulse width between 0.5-1.5ms), and 3) stochastic frequency paradigm (random inter-pulse frequency between 200-300hz and random inter-train frequency between 10-30hz). The NWR was evoked in healthy subjects (n=7) by stimulating the arch of the foot, every heel-off during 10 minutes of treadmill walking. The three different stimulation paradigms were tested in random order in three different days. To set the stimulation amplitude across experimental days, the same fixed factor (1-1.5) was used as an individual multiplier to the identified pain threshold. The reflex magnitude was assessed from the tibialis anterior muscle as the difference between the root mean square (RMS) of the electromyography (EMG) signal from 250-500 ms after stimulation onset and the RMS in the equivalent window in a control step (no stimulation). The reflex response was normalized to the mean amplitude of the rectified EMG of 30 control steps. To determine the degree of habituation during the course of the stimulation period, the average of the responses to the 10 first stimulations was compared to the average of the responses to the last 10 stimulations. The results showed that by using the deterministic paradigm, the reflex amplitude decreased from 1.32±0.64 (mean±SEM) to -0.10±0.10 after 10 minutes of walking (one-tailed paired t-test, $p<0.03$). For the stochastic pulse width paradigm, the reflex amplitude was 1.21±0.38 at the beginning of the walking period and 0.91±0.48 at the end (N.S.). For the stochastic frequency paradigm, the reflex amplitude was 1.08±0.66 at the beginning of the walking period and 0.25±0.23 at the end (N.S.). These preliminary results suggest that stochastic paradigms result in no significant degree of habituation after 10 minutes of walking.

Title: High-resolution artifact removal for single and multi-channel electrical stimulation of neural tissue

Authors: A. A. NORRIS[1], H. READ[2], K. DUTTA[3], *M. A. ESCABI[4];
[1]Biomed. Engin., [2]Psychology, [3]Univ. of Connecticut, Storrs, CT; [4]Univ. Connecticut, Storrs Manfld, CT

Abstract: Brain machine interfaces and prosthetic applications, such as cochlear and auditory midbrain implants, increasingly rely on stimulation of neural tissue and concurrent neural recordings to either asses function or provide neural feedback. In such applications passive inductive coupling of the stimulation array and the distant neural recording sites generate artifacts that can obscure neural activity making it difficult to interpret and quantify neural data. This is particularly true in high throughput applications, such as cochlear implants, were stimuli are delivered at a high rate (hundreds of pulses per second) so that the artifacts overlap the delayed neural activity and cannot be easily subtracted via windowing. Here we developed and test the performance of a high-resolution artifact removal algorithm that uses optimal linear filters to predict the stimulation artifacts followed by artifact subtraction. Multi-channel (16 channel neuronexus; 100 kOhms) stimulation arrays were placed in the inferior colliculus of rats along the tonotopic axis and neural recordings were performed concurrently in auditory and surrounding cortical fields of the rat. Biphasic current pulses (200 μsec pulse width) were delivered across the array in a pseudo random spatio-temporal sequence and neural signals were recorded from a cortical array (Neuronexus 4x4 tetrode; 2.5 MOhms). Depending on the stimulation current amplitude (10-50 μA) signal-to-noise ratios (signal=neural activity; noise=current artifact) prior to artifact removal varied approximately between 0 and -10 dB so that neural signals where obscured by the artifacts. For each cortical recording location, we used the multi-channel electrical stimulation signal (input) and the simultaneously recorded cortical signals (output) to estimate a multi-input single output Wiener filter to predict the stimulus artifacts. Predicted artifacts were then subtracted from the neural recordings and the residuals examined. Artifact prediction quality was estimated by cross-validation across multiple trials. Overall there was a substantial enhancement in the recording quality and isolation of the desired neural signals (e.g., isolated action potentials) with a signal-to-noise ratio improvement ranging between 30 and 50 dB.

Title: Low-frequency repetitive transcranial magnetic stimulation (rTMS) over parietal cortex in rhesus macaques alters neural activity and impairs numerical cognition

Authors: *C. B. DRUCKER[1,2], E. M. BRANNON[3,1], M. L. PLATT[2,1];
[1]Cognitive Neurosci., [2]Neurobio., [3]Psychology & Neurosci., Duke Univ., Durham, NC

Abstract: Repetitive transcranial magnetic stimulation (rTMS) is used widely for noninvasive neuromodulation in humans for research and treatment purposes. Despite the popularity of this technique, the precise neural mechanisms mediating observed cognitive and behavioral responses to TMS remain unknown. Here we directly probed the impact of rTMS on both neural activity and behavior in rhesus macaques (Macaca mulatta) using a custom coil that permits placement of an electrode within the brain at the site of stimulation. We first examined the impact of low-frequency (1 Hz) rTMS_a stimulation regime thought to suppress neuronal activity_to parietal cortex on the ability of monkeys to order numerical magnitudes and color hues. Stimulation was centered on the intraparietal sulcus, a cortical area strongly implicated in numerical processing and mathematics. Following application of real rTMS, compared with sham stimulation, to parietal cortex, performance on number trials deteriorated to a greater extent than on color trials. To determine the neurophysiological mechanisms underlying these effects, we recorded single- and multi-unit firing as well as local field potentials (LFPs) in parietal cortex prior to and following application of 1 Hz rTMS in both real and sham conditions. We found that single- and multi-unit firing rates decreased and delta band power in the LFP increased following real rTMS compared with sham stimulation. These results suggest that low-frequency rTMS impairs cognition and behavior by dampening neuronal firing while increasing low-frequency oscillatory activity.

Title: Peripheral Nerve Fiber Stimulation - Relevance of angle between electrode and nerve fiber

Authors: *K. S. FRAHM[1], K. HENNINGS[2], L. VERA-PORTOCARRERO[3], P. W. WACNIK[3], C. D. MØRCH[1];
[1]Aalborg Univ., Aalborg, Denmark; [2]Nordic NeuroSTIM Aps, Aalborg, Denmark;
[3]Neuromodulation Res., Medtronic Inc., Minneapolis, MN

Abstract: Introduction Peripheral nerve field stimulation (PNFS) is a novel technique for relieving pain. The method works by subcutaneously implanting a small electrode in the painful area. The electrical stimulation is believed to activate primarily Aβ fibers, which reduces the sensation of pain. When used in the lower back the electrodes are typically implanted either vertically or horizontally in the frontal plane. However, the general direction of the sensory nerves is rather diagonally downwards, originating at the spine. Previous studies have indicated that anodal blocking may block the propagation of an action potential along the nerve fiber. Thus, if anodal blocking occurs during PNFS it may limit the effectiveness of the method. Methods A mathematical model was developed to investigate the importance of the angle between the nerve fiber and stimulating electrode and potential anodal blocking. The model comprised two parts; first a finite element (FE) model was used to simulate the extracellular electrical field; second part, the nerve fiber activation using an active cable model. The FE model comprised of three layers, the skin, the subcutaneous fat and muscle. The stimulating electrode was simulated as a cylinder within the fat layer in a depth of 10mm. The diameter of the electrode was 1.3mm. The nerve fibers were simulated using cable models, with Wesselink membrane kinetics. The nerve fibers were simulated in three different depths; 15, 20 and 25mm below the skin surface and in various directions in relation to the stimulating electrode. Two types of nerve fibers were modeled; Aβ fibers had a diameter of 9μm and Aδ fibers had a diameter of 5μm. Results The results showed that the threshold of the nerve fibers was lowest when the stimulating electrode and nerve fibers were parallel. In contrast the threshold was highest when the nerve fiber and electrode were perpendicular. As the distance between stimulating electrode and nerve fibers decreased so did the activation threshold. Aβ fibers had lower thresholds than Aδ fibers. The lowest Aβ threshold was 0.563V and the lowest Aδ threshold was 0.75V. Most Aβ fibers had thresholds within the therapeutic range of PNFS (<10V), but only Aδ fibers located close to the electrode could be activated. The simulations found no evidence that anodal blocking could occur during PNFS. Conclusion As the results indicated the importance of the placement of the electrode in relation to the targeted nerve fibers, it may therefore be highly relevant to take the overall nerve fiber direction into account when implanting the electrode. This indicates that each PNFS setup should be adapted to each individual patient.

Title: Localized neuron stimulation with organic electrochemical transistors on delaminating depth probes

Authors: *A. KASZAS[1,2], A. WILLIAMSON[1,2], M. FERRO[3], P. LELEUX[4], E. ISMAILOVA[3], T. DOUBLET[1,2], P. P. QUILICHINI[1,2], J. RIVNAY[3], G. KATONA[5], B. RÓZSA[5,6], G. MALLIARAS[3], C. BERNARD[1,2];

Abstract: Stimulating individual neurons in a minimally invasive manner is a requirement for future brain-machine interfaces. Here we report on organic electrochemical transistors (OECTs), which outperform conventional electrodes for stimulating individual neurons. We recently

demonstrated the use of organic electrochemical transistors (OECTs) as high-quality recording devices for *in vivo* applications. However, it is important not only to record but also to stimulate large numbers of neurons. Here we present a minimally invasive and biocompatible device that consists of a channel made of a conducting polymer (PEDOT:PSS) placed in direct contact with an electrolyte. While traditional electrolyte-gated field-effect transistors contain a physical barrier separating ionic charges in the electrolyte from electronic charges in the channel, OECTs use ion transport directly across the electrolyte/channel interface to modulate the doping state of the conducting polymer. The lack of a physical barrier at the interface with the electrolyte creates the opportunity to use the conducting polymer channel as a current source for electrical stimulation, rendering the transistor a bidirectional neural interfacing device. To lessen tissue damage and inflammatory responses caused by the probe, we utilized OECTs implanted on a flexible Parylene-C film that detaches from the rigid shuttle after implantation to reduce the mechanical forces between the probe and the neural tissue. The electrical characteristics of the transistors before and after delamination remain identical when implanted in freely moving rats, and glial scarring was less prominent than for the implanted silicon probe even after 1 month of implantation. The ability of OECTs to deliver stimulation currents was characterized in saline, then in complete extracted hippocampus preparations. An OECT depth probe was implanted in the pyramidal layer to activate Schaffer collaterals, while the responses were followed by 3D two-photon imaging after bolus injection of SR-101 and OGB1-AM. Following stimulation, the devices could be returned to recording mode with no degradation in transistor performance. These results could provide the basis for the application of OECTs in a variety of research and clinical settings as a novel, high performance and minimally invasive transducer for *in vivo* electrophysiology.

Title: Desynchronization prior to seizures is a common feature of electrographic signals in acute and chronic seizure models in rodent and human temporal lobe epilepsy

Authors: *M. T. SALAM[1,2], R. GENOV[3], T. VALIANTE[4,1], J. L. P. VELAZQUEZ[5,6], L. ZHANG[2];
[1]Toronto Western Hosp., Toronto, ON, Canada; [2]Med., [3]Electrical and Computer Engin., [4]Surgery, [5]Paediatrics, Univ. of Toronto, Toronto, ON, Canada; [6]The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Objective: Electrographic seizures are commonly associated with various synchronization states, from higher to lower than normal synchrony. In this study, we have investigated the dynamic changes of synchronization states and focused on the detection of synchrony changes in the preictal period before the discharge or clinical manifestation of the ictus. Methods: We have investigated the dynamic changes of synchronization states in acute and chronic models of rodent of post-ischemic, cobalt-induced, 4-Aminopyridine (4AP) induced, kindle, and kainic acid (KA) induced EEG discharges, and as well in instances of human temporal lobe epilepsy. Our preictal detection technique relies on the monitoring of the fluctuations in phase synchronization, and detects an upcoming electrographic seizure upon a decrease in synchronization (or, equivalently, an increase in the fluctuations in phase difference) as early as a few seconds to a few minutes before the behavioural and electrographic seizure onset. In an acute (4AP) and a chronic (KA) models, responsive electrical stimulation (150 μA, pulse width 100 μs, frequency 5 Hz, and duration 5 sec) was triggered on the response of decrease in synchronization in order to disrupt the seizure formation. Results: The overall detection performance has been evaluated using EEG discharges from 25 rodents in the five different models (five in each model) and ten patients. The average detection sensitivity and specificity are 86% and 82%, respectively; with ~0.57 false alarms per hour. The mean early detection time is 30 seconds before seizure onset. The responsive stimulation reduced seizure frequency by a 90% in 10 rats, with 83% of the animals rendered seizure-free. Significance: Abnormal synchrony patterns are common features in epilepsy and other neurological and psychiatric syndromes; thus, this type of feedback stimulation paradigm could be a novel therapeutic modality for various neurological and psychiatric disorders.

Title: Non invasive brain stimulation techniques for improving cognitive functions in healthy individuals

Authors: *G. B. PATRUDU;
Andhra Med. Col. & King George Hosp., Visakhapatnam, India

Abstract: There is an increasing interest in developing novel noninvasive techniques for improving cognitive functions in healthy individuals. Non invasive brain stimulation methods that can have a positive impact on cognitive functions in healthy individuals are TMS (Transcranial magnetic stimulation) , tDCS (Transcranial direct current stimulation), tACS (Transcranial alternating current stimulation) , tRNS (Transcranial random noise stimulation), VNS (Vagal nerve stimulation) and TNS (Trigeminal nerve stimulation) .TMS was shown to improve speed and accuracy in a variety of tasks involving perceptual, motor, executive processing and memory in healthy individuals(Luber & Lisanby, 2014) . Higher frequency repetitive TMS (5-20Hz) can increase cortical excitability (Pascual-Leone et al., 1994; Chen et al., 1997). tDCS is shown to enhance performance across a range of cognitive tasks(Elmasry etal., 2015). It can boost cortical excitability (Boggio et al., 2006, 2007)and improve memory in healthy people(Bennabi etal 2014). There are limited number of studies on the effect tACS on cognitive functions in healthy subjects. tACS in the theta range can improve cognition and in the Alpha range can improve motor performance (Antal & Paulus, 2013).Theta synchronization by tACS significantly improves visual memory-matching reaction times (Polanía etal., 2012), performance on tests of fluid intelligence(Pahor & Jaušovec, 2014), working memory storage and processing functions (Jaušovec etal., 2014). tACS in the alpha range attenuates visual motion adaptation (Kar & Krekelberg , 2014). Santarnecchi etal.,(2013) found that stimulation in the gamma range can improve fluid intelligence. tRNS studies, showed that it positively modulates cortical excitability and improves motor learning in healthy subjects(Terney et al., 2008).It was shown to Improve Neuroplasticity in Perceptual Learning (Fertonani et al., 2011; Cappelletti etal.,2013; Snowball, 2013) and can induce long-term enhancement of cognitive and brain functions (Snowball, 2013; Cappelletti etal., 2013) .Vagal nerve stimulation in healthy individuals showed improvements in cognitive functions like memory (Jacobs, 2015) & response selection during action cascading processes (Steenbergen etal., 2015) .Even though,there are no studies on the effect of TNS on cognitive functions in healthy subjects, drawing from the results of a recent study on the effect of TNS on ADHD patients showing improvements in executive functions, incongruent reaction time and performance on computerized attention network task(McGough etal.,2015) , it has the potential to improve cognitive functions in healthy subjects.

Title: Engineering mechanoreceptor Piezo1 for fast magneto-genetic neuromodulation

Authors: *G. DURET[1], D. B. MURPHY[2,1], S. POLALI[2,1], E. ANDERSON[3], B. W. AVANTS[1], J. T. ROBINSON[1,3];
[1]Electrical and Computer Engin., [2]Applied Physics, [3]Bioengineering, Rice Univ., Houston, TX

Abstract: Fast remote stimulation of specific neuronal populations would help reveal how the activity of neural circuits deep within the brain affects the behavior of freely moving animals. One method to remotely stimulate these deep brain neurons is to convert magnetic fields that weakly interact with tissues into a force that can activate genetically encoded ion channels. Recent demonstrations of this approach have used paramagnetic nanoparticles to convert an RF magnetic field into heat that in turn activates thermally gated TRPV1 channels. While this approach is an effective and innovative method for remote neuromodulation, magneto-thermal neuromodulation is difficult to control with millisecond timing. Here we report our efforts to develop a temporally precise magneto-genetic neuromodulation method based on converting magnetic fields to a mechanical force that can activate the mechanoreceptor Piezo1. Specifically we have inserted affinity tags in extracellular domains of the cation-selective Piezo1 channel to which we can attach functionalized superparamagnetic nanoparticles. We have identified several binding sites on the Piezo1 protein that are accessible to magnetic nanoparticles and where the protein tag does not disrupt the gating mechanism. We have also demonstrated a high-binding affinity between functionalized superparamagnetic nanoparticles and several tagged variants of Piezo1. Additionally, we have found based on calculations and experiments in HEK293s that a DC magnetic field of only a few hundred mTesla (generated by a permanent magnet or an electromagnetic coil) creates enough force between the nanoparticles to activate Piezo1 and depolarize transfected cells. Ongoing work aims to use this magneto-mechanic ion-channel activation to stimulate action potentials in neurons.

Title: Dissolution of platinum electrodes during electrical stimulation of neural tissue

Authors: D. KUMSA[1,2], D. BARDOT[2], *P. TAKMAKOV[1];
[1]CDRH-OSEL-DBCMS, FDA, Silver Spring, MD; [2]Med. Device Innovation Consortium, St. Louis Park, MN

Abstract: Neuromodulation therapy is designed based on a risk-benefit analysis. One of the risks associated with this therapy is damage to tissue due to high electric current. Current boundaries for safety of electrical stimulation are evaluated based on charge per phase and charge density per phase. One of the possible damaging mechanisms which can be traced to electrochemical processes occurring at the electrode-tissue interface is the formation of soluble platinum salts. In this work, dissolution of platinum electrodes is studied *in vitro* using therapeutic stimulation protocols. Effects of parameters such as current amplitude and duration of stimulation have been investigated. The results show a significant increase in the dissolution of Pt when charge injection levels are exceeded past the currently used boundary of 85 $\mu C/cm^2$ for a 0.00785 cm^2 electrode. Longitudinal data show that Pt dissolution does not plateau, but keeps increasing up to 5 hours. Previous studies showed that stimulation above 85 $\mu C/cm^2$ causes tissue damage. It was also observed that Pt dissolution also significantly increases above this value. Possibility of causation between the two might suggest that minimization of Pt dissolution during electrical stimulation can mitigate tissue damage. The preliminary data quantify platinum dissolution and its correlation to existing electrical stimulation criteria. Future work will assess effects of duration of stimulation, presence of proteins in solution, pulse width, change of polarity of leading pulse, stimulation frequency and absence or presence of oxygen on platinum dissolution.

Title: Neurostimulation strategy for urinary stress incontinence

Authors: *X. HUANG[1,2], G. E. LOEB[1,2], L. LIAO[3,4];
[1]Biomed. Engin., USC, Los Angeles, CA; [2]Gen. Stim Inc., Los angeles, CA; [3]Dept. of Urology, China Rehabil. Res. Ctr., Beijing, China; [4]Dept. of Urology, Capital Med. Univ., Beijing, China

Abstract: The majority of patients with stress incontinence have weakness of the external urethral sphincter muscle (EUS) with hypotrophic changes. Kegel exercises are highly effective to treat urinary stress incontinence when done properly and conscientiously. Unfortunately, many patients lack the compliance to obtain full benefit. Electrically stimulated exercise should be able to provide the same effect as voluntary exercise, but previous attempts to use transcutaneous stimulation produced unpleasant sensations from activation of cutaneous nerves. An injectable and wireless microstimulator that can be implanted percutaneously into the pelvic floor muscles should be able to generate strong contractions of the EUS without producing unpleasant sensations or requiring voluntary effort. The pelvic floor muscles are innervated by myelinated motor axons in branches of the deep perineal nerves from the pudendal nerves on each side. In order to investigate the neuromusclar anatomy, percutaneous needle electrodes were used to locate electrical stimulation sites that recruited the EUS as measured by intra-urethral pressure catheter in two female and two male subjects and by recording intramuscular M-waves in two additional female subjects. Perceptual and pressure thresholds were generally concurrent in the range of 0.2-1mA at 0.2ms cathodal stimulation at ~4-5cm depth in female subjects. Unpleasant sensation were reported only in patients with urethral catheters or with high strength stimulations above 7 mA, which may relate to perception of a strong EUS contraction. The precise location of the stimulation electrode had little effect on the ability to achieve strong and widespread muscle contractions in the pelvic floor. Simultaneous bilateral stimulation at levels above unilateral thresholds produced no obvious change in pressure or subjective sensations. The strong EUS activation with unilateral stimulation is consistent with previous studies mapping bilateral spread of M-waves associated with single unit activation. It suggests that a single-channel percutaneous implant can be used to produce clinically effective muscle exercise. Stimulus charge will probably be well below 1uC (5mA x 0.2ms), which should be easily achieved with low voltage circuits (<5V).

Title: Temporally precise control of single-neuron spiking by juxtacellular nanostimulation

Authors: *M. C. STUTTGEN[1,2], L. J. P. NONKES[3,2], H. R. A. P. GEIS[2], P. H. TIESINGA[4], A. R. HOUWELING[2];

Abstract: The temporal patterning of neuronal spike trains affects sensations and activity-dependent neuronal plasticity. Elucidation of the underlying mechanisms requires imposing spike trains with precisely defined patterns, but this has been challenging due to the limitations of existing stimulation techniques. Here we present a new nanostimulation method providing control over the action potential output of individual cortical neurons. Spike induction is realized through the juxtacellular application of short-duration fluctuating currents, allowing for the sub-millisecond precise and reproducible generation of arbitrary patterns of action potentials at all physiologically relevant firing frequencies, including minute-long spike trains recorded in freely moving animals. We systematically compared our method to whole-cell current injection as well as optogenetic stimulation and found that while all three methods achieve high temporal precision, the nanostimulation method presented here is the most easily applied and can be readily performed in awake behaving animals. This new technique promises to be a powerful tool for systematic experimental investigations into the temporal elements of neural codes as well as the mechanisms underlying a wide variety of activity-dependent cellular processes.

Title: Artificial synapse chip: a nanopore array for local chemical modulation of neuronal activity

Authors: *P. D. JONES[1], M. STELZLE[2];
[1]NMI Natural and Med. Sci. Inst. At the, Reutlingen, Germany; [2]NMI Natural and Med. Sci. Inst. at the Univ. of Tuebingen, Reutlingen, Germany

Abstract: We have developed a novel microelectrode array (MEA) with integrated nanofluidics for local chemical modulation and electrophysiological recording of neuronal activity. Neurotransmitters or modulators can be released from single nanopores with high spatial precision. Integration with a network of microfluidic channels enables individual control of each nanopore. This will allow targeting of local populations within neural cultures or tissue slice preparations. Compatibility with standard microelectrode array technology will facilitate simultaneous chemical stimulation and electrophysiological recordings of neural response. State-of-the-art chemical stimulation relies on challenging micropipette-based methods which have remained conceptually unchanged for decades. Using modern microfabrication methods, we have produced a chemical stimulation device, analogous to the advance from single microelectrodes to the microelectrode arrays now widely used in neuroscience research. Microfluidic channels as small as 10 μm were produced by photolithography (SU-8, Microchem Corp., USA; ADEX, DJ DevCorp, USA) on standard MEAs (MCS Multi Channel Systems GmbH, Germany). Nanopores were fabricated by focused ion beam milling in silicon nitride membranes (Silson Ltd, England), which were bonded to the microfluidics by a dry bonding method. Microfluidic channels control fluidic delivery to each nanopore. Chemical release from single nanopores has been confirmed by fluorescence microscopy. Nanopores with diameters below 100 nm enable finer control in comparison to previous chemical release arrays, which have used micropores larger than 1 μm. Our method can be extended to exploit novel nanofluidic effects such as hydrophobic gating, which would prevent leakage by diffusion. This technology will open the possibility for chemical stimulation at a scale previously reserved for advanced electrode arrays, and is a necessary step towards realization of biomimetic neurotransmitter-based neuroprosthetics. We will present the results of proof-of-concept experiments, which will chemically stimulate neurons and measure their electrophysiological response. This technique will be broadly applicable for investigations of localized release of compounds which could include neurotransmitters, drugs, or other pharmacological agents. The adaptation of biological preparations established on normal MEAs, and the implementation of this device in other neuroscience laboratories will be facilitated by its foundation on standard MEA technology.

Title: Prolonged depressor response induced by transient deep peroneal nerve fasicular stimulation in a hypertensive animal model

Authors: ***A. KANNEGANTI**[1], M. MIZUNO[2], R. DOWNEY[2], M. WIJESUNDHARA[4], S. SMITH[2], M. I. ROMERO-ORTEGA[1,3];
[1]Bioengineering, Univ. of Texas At Dallas, Richardson, TX; [2]Departments of Hlth. Care Sci. and Intrnl. Med. and, [3]Departments of Surgery, Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [4]Univ. of Texas at Arlington Res. Inst., Fortworth, TX

Abstract: Hypertension affects approximately 70 million American adults, and an estimated half of these cases are not satisfactorily controlled by medication. Uncontrolled hypertension can greatly increase a patient's risk for stroke and myocardial infarction. Pharmacological interventions dominate the treatment options for hypertension, with seven in every 10 patients taking prescription medication despite the diverse side effects and resistivity after prolonged use. Other treatment options, such as transcutaneous or direct electrical stimulation of particular nerves, namely vagus, carotid sinus, and renal sympathetic, have resulted in mixed results among different patient groups. The targeted visceral nerves regulate diverse autonomic functions which may explain the mixed results and the potential side effects due to non-specific targeting. Alternatively, animal studies based on Electroacupuncture (EA), have been shown to attenuate the blood pressure in a hypertensive rat model by enhancing NO/NOS (Nitric oxide/oxide synthase) activity. Direct stimulation of the nerve which underlies a given acupuncture point has been shown to mimic EA efficacy. In this study, we evaluate blood pressure regulation in a spontaneously hypertensive rat (SHR) model via electrical stimulation of the somatic deep peroneal nerve fascicles (corresponding to ST36 acupoint), using a novel Microchannel based Multi-Electrode Array (μCEA). Constant current biphasic pulse stimulation (100μA pulses at 2 Hz for 5 seconds) of the ventral deep peroneal nerve fascicle (vDPN) in SHR rats elicited a significant decrease in mean arterial pressure (MAP) from 177.95 ± 49.20 mmHg, to normotensive levels (152.8 ± 47.8 mmHg; $p \leq 0.05$), as measured from the carotid artery. MAP levels returned to baseline levels within 5-10 minutes post-stimulation. Control WKY (normotensive) rats did not show any changes in MAP (142.6 ± 34.6) during or after electrical stimulation. We are currently investigating whether vDPN stimulation can elicit a prolonged

MAP drop. Preliminary results show that transient (5 minute) electrical stimulation at the motor threshold level results in a significant decrease in MAP from 186.01 ± 29.21 mmHg to 150.04 ± 28.4 mmHg ($p \leq 0.01$) and was sustained up to 3 hours post stimulation. The stimulation currents and duration used for existing somatic neuromodulation based therapies usually range between 2-4 times threshold and require 1 hour of continuous stimulation. Herein we report for the first time, an effective alternative for prolonged hypertension regulation via somatic nerve fascicular neuromodulation with only 5 minutes of stimulation at motor threshold currents.

Title: Comparing ultrasound neuromodulation and ultrasound stimulation in rat motor cortex

Authors: *D. W. GULICK[1], T. LI[2], B. C. TOWE[1], J. A. KLEIM[1];
[1]BME, Arizona State Univ., Tempe, AZ; [2]Neurol., Renmin Hosp., Wuhan, China

Abstract: Ultrasound is known to stimulate motor responses in small animals, and modulate brain activity in large animals and humans. It shows potential for noninvasive neuromodulation more focal than TMS or tDCS. However, the mechanism is unknown and there are unexpected limitations. In rats, ultrasound can evoke movement of hindlimbs and tail but not forelimbs. This experiment sought to clarify the effect of ultrasound on rat motor cortex by testing for modulation effects on electrically-evoked movements. A novel 16-channel epidural cortical stimulation array was implanted. The rat was stimulated under anesthesia, with accelerometers on the contralateral forelimb and hindlimb. Some electrical stimuli were preceded by ultrasound pulses (200 kHz, 60 W/cm^2 SPPA, 300 ms, pulsed at 1 kHz, 50% duty). Responses with vs. without ultrasound were compared. In an analysis for short-term modulation effects, neither limb showed a significant difference (9 trials). This may be due to the 100 ms delay between the end of the ultrasound pulse and the electrical stimulus. There was a significant long-term suppression (over several seconds to minutes) on both forelimb and hindlimb (10% and 13% decrease). In addition to modulating the electrically-evoked response, some ultrasound pulses directly evoked hindlimb movements. This response only occurred when ultrasound pulses were spaced more than ~3 seconds apart. During the refractory period when ultrasound could not evoke movement, the response to electrical stimulation was unaltered. This suggests that ultrasound stimulation has a mechanism separate from that of electrical stimulation.

Title: Efficient stimulation of hypoglossal nerve using cuff electrode

Authors: ***J. SEO**[1], J. PARK[1], H. KIM[2], S. HONG[2], W. LEE[2], J. AHN[2], S. JO[2], S.-H. AHN[1], C. KIM[1], J.-W. KIM[2], S. KIM[1];
[1]Electrical and Computer Engin., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Dept. of Otorhinolaryngology, Seoul Natl. Univ. Col. of Med., Bundang, Korea, Republic of

Abstract: In this study, we have evaluated threshold current level for stimulating hypoglossal nerve. A two-channel cuff electrode was designed with polyimide which has biocompatible and flexible characteristics. One of hypoglossal nerves of a rabbit was enclosed by the electrode, which was tightened up with suturing. Subsequently, the electrode was percutaneously connected to a pulse generator which generates a sequence of train-of-pulse with the output current level ranging from 14.4 to 1.84mA. Embletta x100 was used to measure an electromyography and the upper airway movement of the rabbit while stimulated was recorded using C-arm fluoroscopy. The minimum required current level for stimulating the hypoglossal nerve was 41.0with duration 0.376 and rate 0.635. The measured threshold is significantly lower than the previously reported value, several mili-amperes. C-arm fluoroscopy observed that the upper airway had been enlarged when the rabbit was stimulated with the level described above.
While the stimulation with 53.2 current evoked an intense response of the muscle, 41.0 current induced a slight response. The slight muscle response can be applied to treating obstructive sleep apnea during the sleep, since the response is small enough not to interrupt the sleep.
In summary, we have demonstrated that the threshold current level for stimulating the hypoglossal nerve with the cuff electrode is 41.0, which is far less than several mili-amperes described in previous researches. Furthermore, there was the difference in response between 41.0 and 53.2; the former induced slighter muscle response than the latter, which can be used to

stimulate hypoglossal nerve without interrupting the sleep in case of treating obstructive sleep apnea.

Title: Sub-second recording of dopamine release in the nucleus accumbens of awake head-fixed mice by fast-scan cyclic voltammetry

Authors: *C. DA CUNHA[1], A. GÓMEZ-A[1], C. D. BLAHA[2];
[1]Univ. Federal do Parana, Curitiba, Brazil; [2]Dept. of Psychology, The Univ. of Memphis, Memphis, TN

Abstract: In this study we established a new protocol to monitor dopamine (DA) release in the brain of awake head-fixed mice by fast scan cyclic voltammetry (FSCV). This protocol was adapted from a previous protocol established for electrophysiology studies in head-fixed mice (J Neurosci Methods 178:75-79, 2009) and uses the Wireless Instantaneous Neurotransmitter Concentration Sensor (WINCS, Mayo Clinic, USA) system for FSCV recordings of DA at carbon-fiber microelectrodes (J Neurosurg 111:701-711, 2009). Adult male Swiss mice were anesthetized with ketamine-xylazine and mounted in a stereotaxic frame. Two circular openings of 2 mm diameter were drilled above the nucleus accumbens (NAc) and the ventral tegmental area (VTA) in the left frontal and in the parietal bones, respectively. Cylindrical plastic recording chambers (3 mm diameter and 7 mm height) were fitted over the bone around the openings and filled with an antibiotic gel. An Ag/AgCl wire reference electrode was inserted into a smaller hole drilled in the right parietal bone. A V-shaped stainless steel headpost was placed over the skull in the space left between the two chambers and all pieces were fixed to the bone with super glue and dental cement. One or 3 days after surgery the head of the mouse was fixed by the headpost to a frame. This frame supported stereotaxic arms used to lower the recording and stimulation electrodes into the NAc and VTA, respectively. Triangular waveform potentials of -0.4 to +1.0 V versus Ag/AgCl were applied to the recording electrode every 100 ms and

oxidation and reduction currents were recorded. Spontaneous transient increases of DA oxidation current were observed (nearly 6 transients/min). Peaks of DA release were also evoked by electric stimulation of the VTA. Background subtracted voltammograms typical of DA were observed, with an oxidation peak at nearly +0.7 V. When the animals were recorded 24 h after surgery, DA concentration increased nearly 0.3 μM upon stimulation of the VTA. Significantly lower evoked peaks (nearly 0.2 μM) were registered when the animals were recorded 3 days after surgery. Habituation to the head-fixed procedure by handling and maintaining the animals head-fixed for 15 min per day in the 2 days interval between surgery and recording session did not alter the frequency and the magnitude of the DA peaks compared to non-habituated animals. This study showed that this head-fixed mouse preparation can be used for FSCV recordings of DA at carbon-fiber microelectrodes and that the best data can be obtained when measures are performed 1 day after surgery.

Title: Extracellular stimulation of rat VTA neurons with sinusoidal waveforms

Authors: *Y. A. CHO[1], Y. LEE[2], J. JANG[2], S. KIM[2], Y. LEE[3], J. LEE[2], S. JUN[2];
[1]Electronics Engin., Ewha Womans Univ., Seoul-City, Korea, Republic of; [2]Dept. of Electronics Engin., [3]Electronics Engin., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Rectangular waveform of electrical current or voltage is conventionally employed for most of neuroprosthetic systems. It was also reported that electrical sinusoidal waveform can be used for stimulating neurons instead of the square wave pulses. Sinusoidal stimulation has the advantage that the stimulation artifact can be effectively removed to identify the evoked neural activity during stimulation. Furthermore, recent studies showed that a large amount of charge injection can cause both electrode corrosion and tissue damage during electrical stimulation with rectangular waveforms. However, most previous studies have been limited in computational simulations or *in vitro* experiments. In this study, we demonstrated that sinusoidal electrical

stimulation on ventral tegmental area (VTA) effectively evoked the neural activities in nucleus accumbens (NAc) by removing the stimulation artifact via a simple bandpass filtering including the corresponding frequency. The VTA region was electrically stimulated with a tungsten stimulating electrode (254 μm diameter), and the neural activities of the nucleus accumbens (NAc) was simultaneously recorded in anesthetized rats. Local field potentials (LFPs) was investigated to show the difference of power discharged between two different stimuli with sinusoidal and rectangular waveforms. As a result, the sinusoidal wave stimulation is expected as an alternative of square wave pulse. In addition, tissue damage was evaluated using immunohistological analysis through long-term stimulation.

Title: Non-invasive brain stimulation using focused magnetic field produced by magnetic shielding

Authors: ***M. C. CHERRY**[1], Q. MENG[1], E. HONG[2], F.-S. CHOA[1];
[1]Univ. of Maryland Baltimore County, Baltimore, MD; [2]Psychiatry, MPRC, Univ. of Maryland Sch. of Med. and Maryland Psychiatric Res. Ctr., Baltimore, MD

Abstract: Transcranial magnetic stimulation, as one of the most popular brain and nerve stimulation methods, is now widely applied in diagnosis and treatment for many diseases, such as neuropathic pain, treatment-resistant major depressive disorder, and loss of function caused by stroke. Current commercial TMS stimulators are not capable of producing a focused magnetic field beam, particularly when target is located deep and away from the TMS source. The so called deep modulation tools, like e.g. H-coil, are usually spread global modulation tools which cannot target to a specific location in deep brain. In traditional magnetic field focusing methods, a piece of thin magnetic material rod or bar with high relative permeability is used to absorb the magnetic field, making it possible to restrict the magnetic field within a narrow space and realize field concentration. Using a high permeability waveguide would require a rod or bar to sit in between the TMS coil and the targeted treatment site and make it impossible to perform non-invasive stimulation. In this work, we used arrays of copper rings to distort the magnetic field and achieve focusing. The superposition of eddy current induced a field opposing the original magnetic field and produced a final concentrated field distribution. In this work, the stimulator was made of a part of a transformer. It has two poles, aligned in north-and-south arrangement.

The magnetic field was shielded by up to 4 different copper ring arrays. A field probe, reported in previous SfN meeting, was used for field recording at different locations. It was found that when using the shield and under the best condition with a design of 4 layers of ring arrays, the magnetic field spot size was reduced from 2cm down to 0.5cm. The measured results show that with appropriate usage of shielding effect we can distort the field and achieve magnetic focusing. This will be very useful for future targeted noninvasive stimulation applications.

Title: Gender and high definition transcranial stimulation

Authors: ***M. J. RUSSELL**;
Aaken Res. Inst., Davis, CA

Abstract: Knowledge of what electrical current tissues are receiving is a critical factor in transcranial brain stimulation. Previously we have shown that the 10-20 system or other positioning schemes allow for a great deal of variation in the current received by the brain and do not account for gender differences in cranial bone density. In this report we use MRI tissue resistivity modeling to compare two methods of transcranial electrical stimulation 1) high density electrode positioning and 2) and traditional non-cephalic referencing. Method A combination of MRIs (T1, T2, proton density, and diffusion tensor) was recorded from 14 subjects and then

combined for each individual to obtain models of tissue resistivity. After the models were formed virtual electrodes were placed on each to represent high density and non-cephalic referencing. The amount of current received within a 1 cm sphere placed inside the brain directly under the anodal electrode at a C3 scalp location was estimated for each condition and subject. In the high density stimulation condition 1 anode (+) was modeled with 4 cathode (-) electrodes 1 cm apart on the scalp of the MRI model. In the non-cephalic condition a single electrode was placed at the identical anodal scalp location and non-cephalic cathode electrodes were placed on the subject's trunk below the neck. Comparisons were then made for input current levels of 0.5 mA, 1mA, and 2mA. Result The results were strikingly different between conditions (P>.001) and between genders (P>.03) for the current entering the brain. Women received less current than men in the high definition condition (P>.03). The mean values for the high definition condition were exceptionally low with some individuals receiving less than 1 μA even with the high 2mA input condition. Many of the subjects in the high density condition received less than 1 μA/cm2. Conclusions The cranial bone is a high resistance tissue that prevents most of the electrical energy from entering the brain in the high definition condition when the electrodes are close together. Because female cranial bone is denser then male bone the effect is larger in women. A non-cephalic placement is more consistent for both genders and provides a much higher current density to the brain. Placebo effects should be considered when subjects are receiving less than 3 μA/cm2.

Title: Neural interfacing hardware for closed-loop stimulation with on-line stimulation artifact removal

Authors: ***A. E. MENDRELA**[1], V. NAGARAJ[2], M. P. FLYNN[1], T. I. NETOFF[3], E. YOON[1]; [1]Electrical Engin. and Computer Sci., Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Neurosci., [3]Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Closed-loop control of neural stimulation is a growing discipline in the treatment of neurological and neurodegenerative disorders such as epilepsy or Parkinson's disease. For example, closed-loop control can be used to deliver electrical stimulation when at particular phases of a pathological neural oscillation or during a seizure. Implantable systems incorporating such algorithms determine precise stimulus timing based on features from neural activity. However, the recorded signal following a pulse is corrupted by large stimulation artifacts on recording electrodes, masking underlying neural activity and hindering the performance of the closed-loop algorithm. Furthermore, to enable post-processing stimulation artifact removal, the gain of the amplifier must be reduced so that the stimulus does not saturate the amplifier. Previous studies suggest a variety of post-processing artifact removal algorithms based on large data set analysis but lacking real-time capability necessary for treatment, or limitations on electrode orientation and stimulation characteristics to suppress interference at the recording site. Currently, there are no generalized stimulation artifact removal algorithms for real-time closed-loop neural recording and stimulation that do not constrain electrode configuration or stimulation characteristics. In order to tackle this problem, we have designed and fabricated a neural interfacing integrated circuit for ECoG and LFP signals with a novel adaptive stimulation artifact removal algorithm in real time. The algorithm utilizes an adaptive FIR filter which learns the artifact waveform using a stochastic gradient descent LMS algorithm. The fit stimulation artifact is then subtracted from the recorded signal at the preamplifier to remove the artifact and prevent amplifier saturation. The algorithm learns the artifact waveform within a few stimulation pulses, and can dynamically adapt to changing artifacts over time. To validate the system's feasibility, we have tested the interface circuit in an epileptic rat model. Seizures were induced following injection of 4-aminopyradine unilaterally into the CA3 region of the hippocampus. A recording electrode was placed in the CA1 region of the hippocampus ipsilaterally to the injection region. Stimulation was applied to the ventral hippocampal commissure (VHC) which innervates the CA3 regions bilaterally. We compared neural recordings while stimulating, with and without stimulus artifact removal, during a seizure episode. Our results indicate a large reduction in spectral power and time-domain artifact-related voltage spikes when artifact removal was achieved.

Title: TMS waveforms and variability in response to an inhibitory TBS protocol

Authors: *D. AUSTIN, C. VAN DER BURGHT, M. CIOCCA, J. RATNER, R. HANNAH, J. ROTHWELL;
Sobell Dept. of Movement Disorders and Motor Neurosci., Inst. of Neurol., London, United Kingdom

Abstract: Background Continuous theta-burst stimulation (cTBS, Huang et al, 2005: Neuron 45(2)) can induce temporary changes in synaptic plasticity of motor cortical neurons in a LTD-like manner. Conventionally, cTBS is applied with biphasic stimulus pulses. Since different directions of monophasic pulse are known to activate separate populations of cortical interneurons, we asked two questions. First, does cTBS using monophasic stimulus pulses applied in the antero-posterior (AP) direction have different effects than TBS applied with posterior-anterior (PA) directions. Second, does cTBS have different effects on test responses evoked by different directions of monophasic stimulation? Experiments 14 healthy volunteers received monophasic cTBS using either AP or PA stimulus pulses to the first dorsal interosseous (FDI) representation of motor cortex. Corticospinal excitability was assessed before and after cTBS via amplitude of MEPs evoked by PA monophasic TMS pulses. A two way ANOVA revealed a significant TIME (pre/post) X DIRECTION (AP or PA) interaction ($F = 2.8$, $P = 0.017$) that was due to the fact that MEPs evoked with monophasic PA pulses were suppressed more by AP cTBS than PA. In a second experiment, 20 healthy volunteers received a "spaced" version of cTBS that has been claimed to be more effective than a single session of cTBS (Goldsworthy et al, 2012: Eur J Neurosci 35(1)) using AP monophasic TMS pulses. Corticospinal excitability was assessed before and after spaced cTBS by measuring the amplitude of MEPs evoked in FDI by PA and AP test pulses. Two way ANOVA of log transformed MEP amplitudes revealed a significant TIME (pre/post) X DIRECTION (AP or PA) interaction ($F = 9.4$; $p= 0.006$) due to the fact that monophasic AP cTBS produced more effective suppression of MEPs evoked by AP than by PA test pulses. For PA test pulses there was a significant correlation ($p=0.028$, $r = .490$) between the variability of an individual's baseline MEPs and the suppressive effect of cTBS. An ongoing experiment is comparing the effectiveness and reliability of AP and PA monophasic spaced cTBS on MEPs evoked by PA and AP test pulses. Discussion cTBS of motor cortex using monophasic AP pulses leads to larger effects on corticospinal excitability than PA-cTBS. The effects are more evident when excitability is tested with AP rather than PA pulses. We suggest that repetitive TMS of motor cortex does not condition all circuits by the same amount. Depending on the direction of stimulation, some circuits can be conditioned while others are relatively unaffected. This could contribute to some of the inter-individual variability that is typical of brain stimulation paradigms.

Abstract: Since the advent of optogenetics, there has been ever-growing interest in applying this technology to the control of neural activity. However, factors such as variable opsin expression, differential distribution of light, and spontaneous neural states make robust control of neural activity intractable with open loop stimulation. To overcome these limitations, we have engineered a system for closed-loop control of neural activity which combines single-unit thalamic recording and optogenetic stimulation through real-time interfacing in the rat vibrissa system in-vivo. Beyond allowing the experimenter to overcome unknown factors in the response of an opsin to light, closed loop control allows for decoupling of causally related variables such as firing rate and temporal precision. Previously, we demonstrated successful control of firing rate in single neurons in the ventral posteromedial nucleus of the thalamus (VPm) of the anesthetized rat using PI control. The controller operates on the error between the instantaneous firing rate and a target rate; the resulting control signal is used to modulate the intensity of light (470 nm, LED) conducted to VPM via optic fiber, thereby stimulating opsin-expressing cells in VPm. We have demonstrated the ability to follow target firing rates precisely, decoupling the magnitude of the firing rate from the statistics of the firing in the VPm. Furthermore, we can extend this framework to address the control of more complicated, dynamic firing rate trajectories. Closed loop control of firing rate to follow dynamic trajectories would enable precise characterization of sensory encoding in different neural contexts, such as oscillatory activity. To this end, we have tuned and characterized our system's ability to achieve sinusoidal trajectories. In assessing the capabilities of the original system outside the realm of static trajectories, we first carried out a system identification of the controller experimentally using step inputs, discrete sinusoids, and white noise as targets for the system. We found that the experimental system was limited by the transformation of the firing rate signal from a discrete representation of spikes to a continuous estimate of instantaneous firing rate. To systematically explore controller parameters in an environment that is not limited by experimental recording time, we developed a simulated model of the closed loop controller interacting with a single

neuron. Consistent with the experimental results, a sensitivity analysis of the simulated system parameters implicates the firing rate transformation as a critical parameter affecting the ability to follow arbitrary waveforms.

Title: Neurotransmitter monitoring via boron-doped diamond electrode-based voltammetry during human deep brain stimulation in essential tremor

Authors: ***S. PAEK**[1], P. MIN[2,3], J. TOMSHINE[2,4], C. BLAHA[2], D. JANG[5], M. MARSH[2], M. SETTELL[2], E. NICOLAI[2], C. KIMBLE[4], S.-Y. CHANG[2], K. BENNET[2,4], K. Engin., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Introduction: Although it is becoming more evident that neurotransmitter dynamics contribute to therapeutic deep brain stimulation (DBS) mechanism, technologies for human neurotransmitter monitoring still face significant limitations. Previously, we reported acute intraoperative human recordings of neurotransmitter dynamics during DBS using carbon fiber microelectrodes (CFM) together with the Mayo-developed wireless instantaneous neurotransmitter concentration sensor (WINCS) system. One problem with CFM electrodes is their poor durability for long-term neurochemical recording. To overcome this limitation, we developed a durable synthetic diamond-based electrode that is capable of measuring neurotransmitters for longer time periods than a CFM. Here, we demonstrate the use of diamond-based FSCV recording in human essential tremor patients undergoing DBS neurosurgery. Method: Patients undergoing frame-based stereotactic DBS neurosurgery for tremor were recruited to undergo paired pulse voltammetry (PPV) recordings during DBS electrode implantation. Boron-doped diamond microelectrodes were placed 2 mm anterior or posterior to the trajectory of the DBS electrodes, which were placed in the ventralis intermedius nucleus of the thalamus. PPV was applied at 5 Hz (200 ms between two binary pulse sweeps), 400 V/s sweep rate with respect to a reference electrode, from -0.4 V to 1.5 V back to -0.4 V. This study was approved by the Mayo Clinic Institutional Review Board. Results: The detection of

adenosine-like signature was evident both when the recording electrode was advanced and during implantation of the DBS electrode. However, without PPV, the extracellular environmental changes, including pH shift, obscured neurochemical detection. No complications occurred due to boron-doped diamond electrodes and PPV recording in any patients. Conclusion: These results demonstrate that boron-doped diamond microelectrodes in conjunction with PPV can be safely and effectively used for differentiating complex analytes in the human brain and support the potential of wireless PPV monitoring to investigate long-term DBS mechanism of action.

Title: A novel approach to rapidly and effectively perturb the rotation of the eye

Authors: M. O. BOHLEN[1], *L. L. CHEN[2];
[1]Program in Neurosci., [2]Otolalryngol & Commu Sci; Ophthalmol; Neurobiol & Anatom Sci., Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Despite recent excitement on the research of extraocular proprioception, validated approaches for studying this sensory signal remain limited. This is because the proprioceptive signal occurs during natural, visually guided eye movements, and the signal inevitably interleaves other visuomotor signals such as corollary discharge and vision. Therefore, separating extraocular proprioception from other sensory-motor signals remains a fundamental challenge. In the present study, we present a non-invasive methodology for probing extraocular proprioception independent of other sensorimotor processing during eye movements. We attached a rare earth magnet to a model eye ball and placed an electromagnet > 10 mm away from the robotic eye. The model eye was real-time controlled to rotate horizontally about a vertical axis. With this approach, we demonstrated that the electromagnet was able to perturb the rotation of the eyes by circumventing the constraints found with conventional approaches like manually tugging the eye ball by a suction lens. The electromagnet could increase or decrease angular displacements and velocities of the model eye. The comparison of the model eye's angular velocities under the presence or absence of electromagnet activation revealed that the

rotation could be rapidly altered within 2 ms of electromagnet activation. In addition, the angular displacement of the model eye was correlated linearly with the relative distance of the electromagnet from the model eye, suggesting that this perturbation can be remotely and safely applied to subjects. The results indicate that the electromagnet serves as an effective means to externally perturbing the rotation of the eyes, making it affordable to separating extraocular proprioception from other visuomotor signals.

Title: Generating neuron membrane action potentials using optimal input current stimuli in the medicinal leech

Authors: *D. A. MILLER[1], M. ELLINGER[1], J. JELLIES[2], A. C. FERGUSON[1], C. L. LINN[2], M. E. KOELLING[3];

Abstract: A “Reduced Energy Input Stimulus Discovery Method” [1] finds input current stimuli which enable a conductance-based neuron model to track a reference membrane voltage. The technique features an adjustable balance between tracking error and input current stimulus energy reduction. Higher-energy input current stimuli are traditional pulses of constant value, while reduced energy optimal input stimuli have varying values within the stimulation time window. Simulations confirm that variable currents with significantly reduced energies provide excellent tracking of neuron membrane voltages such as those produced with constant valued input currents [1, 2]. This project builds on an initial feasibility study [3] and demonstrates that key features of this method can be employed at a traditional electrophysiology rig. Optimal input current stimuli are computed using conductance-based models with parameters selected to match dynamics of different types of medicinal leech (*Hirudo verbana*) neurons. These optimal current stimuli provide a range of tracking performance; some emphasize reproducing action potentials (at the expense of a higher energy current), while others emphasize energy reduction (sometimes at the expense of action potential timing or generation). The stimuli are used to stimulate leech

neurons using standard sharp electrode electrophysiology techniques. Results for different sensory neuron types show that optimal input current stimuli having significantly reduced energy levels are able to evoke action potentials that closely resemble neuronal responses to non-optimal higher-energy current stimuli. **References** [1] M. Title: The dose response relationship between single pulse TMS intensity and neuronal activity in cerebral cortex of alert macaques

Authors: *E. M. GRIGSBY[1,6], M. V. SMITH[1], M. J. KOVAL[2], Z.-D. DENG[2,3], M. L. PLATT[4,5], A. V. PETERCHEV[1,2,3], W. M. GRILL[1], M. A. SOMMER[1,4,5];

Abstract: Transcranial magnetic stimulation (TMS) is a safe, non-invasive method of brain stimulation that induces an electric field in the brain. It has proven to be a valuable tool for cognitive research and clinical practice, despite the fact that little is known about its influence on neuronal activity. We designed a custom TMS coil to produce focal stimulation at the site of neuronal recordings *in vivo*, in combination with amplifier circuits to reduce TMS voltage and current artifacts (Mueller et al. 2014). The methodology permits recordings of neural activity starting a few ms after a TMS pulse. Here we characterize the dose response of single neurons to

single pulse TMS across stimulation intensities in rhesus macaque cerebral cortex (primary motor cortex and frontal eye field, n=3 monkeys). Using a MagStim Rapid2 base unit, we delivered TMS pulses from 10% to 90% of maximum intensity in 10% increments and compared normal TMS ("Stim") to a condition in which instrument currents were reversed to evoke TMS sound and peripheral stimulation but negligible electric field at the recording site ("Sham"). Our hypothesis was that significant, electric-field induced changes in activity occur at and above motor threshold (approx. 60% intensity in our monkeys). We found, first, that responses of individual neurons were heterogeneous, with diverse patterns of TMS-induced excitation and inhibition observed. Second, at the population level, all levels of Sham and <60% levels of Stim TMS caused a burst of activity around 30 ms latency. Third, for Stim TMS at >= 60% intensity, the population response shifted to a distinctly different pattern consisting of short-latency (10 ms) activation followed by long latency inhibition, the duration of which averaged ~100 ms but lengthened slightly with intensity. We conclude that the neuronal activity dose-response relationship to single pulse TMS is non-linear, stepping up near the motor threshold point in support of our hypothesis. At the same time, the Sham and low intensity Stim activations revealed significant effects potentially attributable to sensory afferent responses (e.g. auditory). In summary, single pulse TMS causes a short-latency, excitation-inhibition pattern of neuronal activity in accordance with a non-linear, stepwise dose-response curve that matches motor threshold.
